CHAPTER

ONE

GETTING STARTED WITH QUANTUMATK

This page contains the resources that will help you get started with QuantumATK as a new user.

1.1 Installation Guide

Version: X-2025.06

This guide describes how to install and configure QuantumATK on Windows and Linux. Note that you can skip some of the points if they do not apply in your case. We will describe the conditions for that in each section.

Note: Site information such as Site ID will be asked and checked by the installer, so it should be at hand when starting the process. You can find your site ID at the top of your license file or by contacting your site admininistrator.

If you experience any problems during the installation, first search the User Forum to see if a solution is posted there. If not, please file a case on the SolvNetPlus website (see below) or contact Synopsys QuantumATK support (quantumatk-support@synopsys.com).

QuantumATK can be expected to run out-of-the-box on Windows and Linux platforms (Windows 10+11 and all recent Linux distributions). In some cases, on Linux, there are a few libraries that may need to be installed, but this can always be done post-installation. Future support for platforms is outlined in the Synopsys Compute Platforms Roadmap

1.1.1 Access to SolvNet

The very first thing is to ensure that you have access to SolvNet, which is Synopsys software portal. Go to the SolvNetPlus website and create an account if you do not have one already. Note the following for account creation:

- During the registration process you will need to provide your Synopsys Site ID. If you do not know your site ID, obtain it from your site administrator or from your sales representative.
- You must provide your professional email address. GMail, Yahoo, and other general emails will not be approved.
- Account activation can take up to 48 hours to be processed. If you have not received a confirmation email after this period, please contact securelogin@synopsys.com for assistance.

When you have successfully logged in, please proceed to the next step.

1.1.2 Access to a License Server

You now need to ensure that you have access to a license server. If there is already a license server running at your site, you may skip the section on installation of a license server. If you do not have access, you need to install a license server yourself to use the license. Proceed to either the guide for Windows or Linux, depending on the OS of the machine where you wish to install the license server.

•license_server_linux

•license_server_windows

Note: **For Network or Nodelocked Licenses**: Purchased licenses are issued as Network licenses. That means that a central server will handle the license, and any computer which can connect over the network to the server can check out a license and run the software. Evaluation licenses are nodelocked. The software is then constrained to running on a particular computer only.

1.1.3 Linux only: Download and use Synopsys Installer

In order to install EST images on your Linux system, a working installation of **Synopsys Installer** is required. The main reference should be Synopsys official documentation, here we summarize the most common steps:

•In the official documentation linked above, find the link to the EFT directory and download the latest version of **Synopsys Installer**.

•Inside the folder you will find a file named *SynopsysInstaller_vX.X.run* (where *X.X* is the version), execute it in a terminal with `./SynopsysInstaller_vX.X.run`.

–The process will ask for the desired installation path and will quickly install **Synopsys Installer** at that location.

•Execute **Synopsys Installer**:

–If the *text-based interface* is sufficient, the installation is completed. **Synopsys Installer** executable is located at `<installation_path>/installer` and can be executed in a terminal.

–If the *graphical interface* is desired, execute `<installation_path>/installer -gui` and make sure a window is shown. If there appears any error related to a missing `libXss.so.1` library (possible on a minimal RHEL/CentOS 7.3 installation), proceed to install the *libXScrnSaver* package (for RHEL/CentOS 7.3 this direct download can be used: libXScrnSaver-1.2.2-6.1.el7.x86_64.rpm).

The text-based and graphical interface will provide the same information and ask the same questions. There is also a *batch mode* (or *unattended mode*) available, to install EST images from a command line with limited human interaction. This mode can be useful when automating the installation on several machines and/or several products at the same time. For more information, see below the paragraph *Batch Install on Linux*.

Note: The EST image files should not be renamed, otherwise **Synopsys Installer** will not recognize them as valid product files. Therefore, the original name of the installation file downloaded from SolvNet should always be preserved.

1.1.4 Downloading, Installing and Configuring QuantumATK

You are now ready to install QuantumATK. First step is downloading the QuantumATK installation file.

Downloading QuantumATK

•Log on to SolvNet

•From the SolvNet front page click Downloads or point directly to https://solvnet.synopsys.com/DownloadCenter

•Under **My Product Releases** choose the QuantumATK package assigned to your Site, i.e. a name of the form *QuantumATK xxxxxx*

•Choose the latest product version from the list of available versions. i.e. the X-2025.06 version.

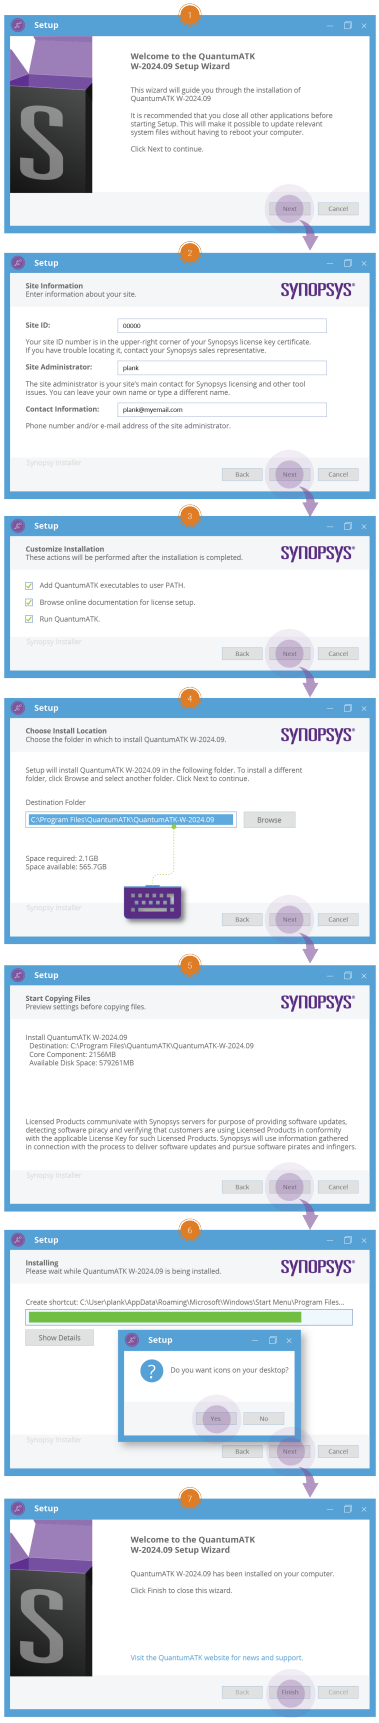
•After reading the legal page, Click on Yes I agree to the above terms.

•Click the Download button next to the QuantumATK installation file corresponding to your operating system.

Installing QuantumATK

Windows

The installation file downloaded from SolvNet is a standalone executable. Right-click and choose *Run as administrator*, as QuantumATK must be installed with *Administrator* rights. Follow the step-by-step instructions to read and approve the license agreement, choose the installation directory, etc. From the final page of the installer you can open QuantumATK, and/or the license configuration tool.



1
Setup
Welcome to the QuantumATK W-2024.09 Setup Wizard
This wizard will guide you through the installation of QuantumATK W-2024.09
It is recommended that you close all other applications before starting Setup. This will make it possible to update relevant system files without having to reboot your computer.
Click Next to continue.

Linux

The installation file downloaded from SolvNet is an EST image, with file extension `.spf`. A working installation of **Synopsys Installer** is needed, in order to install an EST image. If you do not have that available, jump to section *Linux only: Download and use Synopsys Installer* for additional instructions on this.

You can run the **Synopsys Installer** in text mode with the `installer` command, or in graphical mode with the `installer -gui` command. The installer will guide you through the installation process by asking for the site information (site ID, administrator and contact), the location of the EST image (the `.spf` file cited above), the installation path and possibly additional options.

Note: On machines without a dedicated GPU and vendor-provided drivers, which might be the case for **Linux** and **Virtual Machines**, some users experience issues with the 3D graphics. For these machines, we recommend choosing Software rendering when installing and upgrading to a higher quality graphics setting after installation, if possible.

Silent Install on Windows

A silent install will not allow any of the customization steps of a graphical install apart from the choice of installation path. Open a CMD shell with administrator rights, it is important to use a CMD shell because the next step might fail in a PowerShell shell. Inside the shell run the following command:

```
.\path\to\QuantumATK-installer.exe /S /LICENSE="I accept"
```

The above command will install QuantumATK in the default location, you can choose a custom location with an additional command line option: `/D=C:\path to\custom\location`. Note that this must be the last option on the command line and must not contain any quotes.

Batch Install on Linux

The main reference should again be Synopsys official documentation, but we summarize here the most common steps. In order to use the batch installer, a configuration file is needed. An initial template can be generated running the following command from the folder containing the EST image:

```
batch_installer -list -o <template_name>
```

Where `<template_name>` is the desired name for the configuration file and `batch_installer` is an executable shipped as part of **Synopsys Installer**. The command above generates a template configuration file that can be customized. The post-install arguments values can be modified as needed, since the default values are aimed at the interactive installation process. Once the configuration file is ready, the batch install can be started with the command:

```
installer -batch_installer -config <template_name>
```

If the command complains about a missing `-target` argument, it can be provided followed by the chosen installation path.

Here is an example of how the generated configuration file will look.

```
SourceDir: /synopsys/downloads
SiteID: 000
SiteAdmin: admin
SiteContact: admin@your_company.com
```

(continues on next page)

(continued from previous page)

```
PRODUCTS: quantumatk
RELEASES: X-2025.06

quantumatk, X-2025.06 {
  DESCRIPTION: Synopsys QuantumATK
  TARGETDIR: /home/user/synopsys
  POSTARGVALUE: softwareRendering (no)
  POSTARGVALUE: addToPath(yes)
  POSTARGVALUE: openLicenseDoc(no)
  POSTARGVALUE: runProgramAfterInstall(no)
}
```

Note: The batch installer will keep track of previous installations in a hidden folder at `<installation_path>/.installer`. If there is a warning about an existing installation, but the actual QuantumATK installation folder no longer exists, try removing this hidden folder and execute the batch installer again.

Configuring the QuantumATK License

If no valid license is detected when starting QuantumATK, then a step-by-step wizard will pop up and guide you through the license setup process. To connect to the license server, choose the corresponding option and enter the IP address or hostname of the license server. You only need to change the port number if the server is using a different port than the default 27020.

Version: W-2024.09
Path: 172.16.254.1
Port: 27020
Expires: 31-12-2025
Cancel
Back
Next

Note: If configuration is not successful you may want to verify the firewall of your machine or the one of the license server are not blocking port 27020 or whichever other port is used by the license server.

It is also possible to configure the license using environment variables on all platforms, though we recommend to configure the license system via the QuantumATK tool when possible. Using environment variables is the only option on machines without any access to graphics, for example in some Linux-based clusters. The license configuration can be controlled by the environment variable `SNPSLMD_LICENSE_FILE`. Example for a Unix environment: `export SNPSLMD_LICENSE_FILE="27020@mylicenseserver.edu"`

1.1.5 System Requirements

For additional information about the technical characteristics of the system or platform that you want to install the software on, see the technical_hardware section.

1.1.6 Using QuantumATK from the command line

Starting from QuantumATK X-2025.06, the installer will not add the QuantumATK executables to the system PATH on Linux and Windows.

The effect is that the newly installed QuantumATK executables are not available from the command line by default. You can still run QuantumATK from the command line by using the full path to the executable, e.g. `<installation_path>/bin/quantumatk` or `<installation_path>/bin/atkpython`. You can also opt to manually add `<installation_path>/bin` to the system path after the installation. For example, on Linux using the Bash shell, one can add `export PATH=<installation_path>/bin:$PATH` to the `~/.bashrc` file.

You can also use the QuantumATK environment script (`activate_env`) to prepare your command line environment. Users accustomed to Python virtual environments will find this approach familiar. More on the QuantumATK environment script can be found in the *Command Line Usage with QATK Shell Environments* section.

1.1.7 Troubleshooting

Slow Startup on Windows

If you experience slow startup of QuantumATK on Windows, the antivirus software on your system might be the reason. In particular when the application is started for the first time after a reboot of the system, starting QuantumATK might take a few minutes, because the antivirus software scans all files loaded by the program. The easiest way to address this issue is to add the QuantumATK installation directory to the list of directories that are excluded from real-time scanning by the antivirus software. Talk with your system administrator and consider the security implications before proceeding with any changes in antivirus configuration.

If you are using Windows Defender, you can add the QuantumATK installation directory to the exclusion list by following these steps:

1. Open the Windows Security app by clicking on the Start menu and typing Windows Security.
2. Click on Virus & threat protection.
3. Scroll down and click on Manage settings under the Virus & threat protection settings section.
4. Scroll down to the Exclusions section and click on Add or remove exclusions.
5. Click on Add an exclusion and select Folder.

6. Navigate to the QuantumATK installation directory (e.g., `C:\Program Files\QuantumATK\QuantumATK-<VERSION>`) and select it.
7. Click on Select Folder to add the exclusion.
8. Restart the system and start QuantumATK to see if the startup time has improved.

If you are using a different antivirus software, please refer to the documentation of that software for instructions on how to add an exclusion for a directory.

If you are experiencing slowness in relation to your project folder, you can also try adding the project folder to the exclusion list of your antivirus software. Alternatively, if you are using Windows Defender, you can use the above steps but add a Process type exclusion for the entire QuantumATK installation folder instead of a Folder type exclusion. This will make sure that all files opened by QuantumATK binaries at runtime are excluded from real-time scanning.

libGL.so: Cannot Open Shared Object File

The error message:

```
OSError: libGL.so: cannot open shared object file: No such file or directory
```

may appear on Linux systems when you try to launch QuantumATK for the first time.

To solve it, create a new link:

```
$ sudo ln -s /usr/lib/libGL.so.1.2 <quantumatk_installation_path>/lib/libGL.so
```

If you have a 64-bit Linux, use */usr/lib64* instead.

However, first check that you actually have *libGL.so.1.2* in */usr/lib* or */usr/lib64*. It might be called *libGL.so.1* or something else instead, or located in another directory, depending on the video drivers. You can use:

```
$ locate libGL
```

to find the correct file to link to. On some systems we have seen that the same link needs to be created for *libGLU.so* as well. Note that in this case, the error message may still complain about *libGL.so*!

Up to date details can be found in technical_hardware.

libGLU.so.1: Cannot Open Shared Object File

The error message:

```
ImportError: libGLU.so.1: cannot open shared object file: No such file or directory
```

may appear on Linux systems when you try to launch QuantumATK for the first time. To solve it, install the related OpenGL utility library:

- on Ubuntu the package name is *libglu1-mesa*
- on openSuSe the package name is *libGLU1*
- on CentOS/RHEL/AlmaLinux/Fedora the package name is *mesa-libGLU*

Could Not Find or Load the Qt Platform Plugin xcb

If you get the following message when trying to run QuantumATK on certain Linux platforms

```
This application failed to start because it could not find or load the Qt platform␣
↪plugin "xcb".
```

then you might need to install some additional xcb libraries. In order to find out what is missing exactly, one can add some debug output:

```
QT_DEBUG_PLUGINS=3 /path/to/installation/bin/quantumatk
```

This error may also prevent you from starting QuantumATK. In this case, especially if you double-clicked the Desktop icon, no error message is shown, but the text above can be found in the crashlog.txt file, which will be created in your user profile (aka home) directory at `<user_profile_dir>/.quantumatk/crashlogs`.

Read more in technical_hardware.

ATKError: Exceeded Maximum Number of Self-Consistent Iterations

As the error says, the calculation did not converge within the specified maximum number of iterations. If it looks like it is anyway about to converge, you can increase the maximum number of steps and rerun it, although you can save a lot of time by restarting the calculation, as described in the *Manual*.

Failure to Initialize

QuantumATK and atkpython may not be able to run on security-hardened systems. In particular, you should, after discussion with your system administrator, check for the following:

- Verify that the Security Enhanced Linux status is set to Disabled by invoking the utility program *getenforce*, generally available in your Linux distribution package system. You can disable Security Enhanced Linux by running *setenforce 0*
- Verify that resource usage limits are sufficiently high by issuing the command *ulimit -a*.
- Verify your hard disk quota limits with the program *quota*.
- Verify your firewall configuration for rules that may prevent your system to connect to the license server.

ImportError: No Module Named

If you are using the Job Manager to run a script which imports other scripts they must reside in the same folder as the main script or in another directory that is part of the Python path. The paths included by default in the Python path can be printed in a terminal with the command *atkpython -c import sys; print(sys.path)*. If ATKPython or QuantumATK are executed from a shortcut, the run location specified in the shortcut is usually included in the Python path as well. Thus, either move the script to be imported to a relevant folder from where it can be imported, or include the directory where the script resides explicitly in the Python path by inserting something like this in your script:

```
import sys
sys.path.append("c:/my files/scripts")
```

A simple solution is otherwise to run the script from the command line instead; as long as the script to be imported resides in the same directory as you are running from, it will work fine.

Pulay Mixing Inversion Failed. Using Only Last Step

This is an indication of a problem with the geometry of the system. Perhaps atoms are too close to each other. Check the configuration carefully!

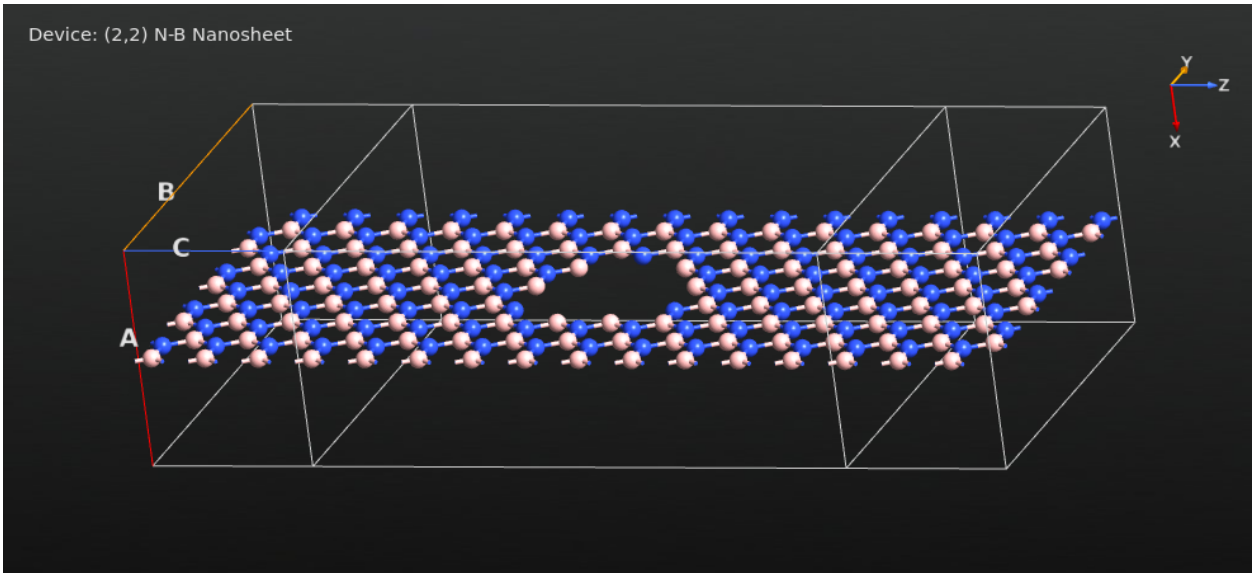
Why are so many k-points needed in the transport direction in a device calculation?

QuantumATK users often ask us why so many k-points are needed in the transport direction in a device calculation. Here is an example from the Forum:

For a calculation of a system like (metallic electrode)-(molecule)-(metallic electrode) with a molecule along the Z axis, some literature references mention k-point parameters like 1x1x100 or 3x3x100 for the Brillouin zone integration. It is surprising, because in a pure interface system like a self-assembled monolayer, reasonable k-point parameters are like 8x8x1. Can you explain this difference?

This is a rather subtle point, so we here address it carefully.

Note: The transport direction is always C || Z, and the X/Y plane is spanned by the A/B lattice vectors. Thus C and Z can be used interchangeably to denote the transport direction.



The key point of the NEGF transport model in **QuantumATK** is that the boundary conditions are not periodic in the C direction. Instead, open boundary conditions are used, in order to apply a voltage across the structure, so that one can compute the electron current under finite bias.

Since the system has no periodicity in C, one should therefore not need more than one **k**-point in this direction. And this is indeed the case - there is no **k**-point sampling used in the device calculation. This is reflected in the specification of the **k**-point sampling for the transmission calculation and other transport analysis quantities: The option for Brillouin zone integration is simply (k_A, k_B).

We do, however, need **k**-point sampling in all directions for the electrodes! These are still assumed to be periodic in C, and the electronic states of the electrodes are obtained from a standard bulk calculation, with **k**-points in all directions. But that still does not fully explain the unusual **k**-point sampling needed for device calculations, because for the typical electrode sizes used, it would appear to be sufficient to use 5 or 12 k_C-points - not 100.

Assume for a moment that you have an ideal system, i.e. the electrodes are identical to the central region. Let H_L, H_{CR}, and H_R be the Hamiltonians of the left electrode, central region, and right electrode, respectively. H_L and

H_R are calculated under periodic boundary conditions, while H_{CR} is evaluated with open boundary conditions using self-energies obtained from H_L and H_R. Now, clearly you will only get perfect transmission in this system if $H_L = H_R = H_{CR}$. To obtain this, the same **k**-point sampling should be used in the A and B directions in the electrodes and in the open boundary condition calculation for the central region. This point is quite trivial, and must always be obeyed in a calculation. The actual number of k_A, k_B points required is a matter of balancing performance vs. accuracy, just like for any other calculation.

In the C-direction, however, the self-energy calculation effectively corresponds to an infinite number of **k**-points, and you will need a lot of k_C-points in the electrode calculation to match the electronic structures of the electrodes and the central region. The primary quantity that needs to be closely matched is the Fermi level. A difference here will lead to slow or bad SCF convergence, and in the worst case inaccurate results due to artificial scattering introduced by the Fermi level mismatch. Such scattering cannot really be distinguished from actual scattering in a complicated system, but it is noticeable in a perfect system. The **QuantumATK** default value for the k-point density of 150 Å is usually on the safe side. But it is relatively inexpensive since these **k**-points are only used in the electrode calculation, which is the smaller and faster part of the full computation.

Note: The short message: Stick to the default value along the C direction, and you should usually be safe.

ATKError: St9bad_alloc

This error usually mean that the calculation went out of memory. Try reducing the number of MPI processes and use threading instead. Otherwise, calculation accuracy or system size have to be reduced.

Runtime Terminates an Application

The full error message is:

```
This application has requested the Runtime to terminate it in an unusual way.
Please contact the application's support team for more information.
```

and although it can, in principle, mean many different things, most likely the calculation has requested more memory than is available on the computer.

Killed by Signal 9

When running in parallel, sometimes you may see an error like:

```
rank 1 in job 34  n7_3767
caused collective abort of all ranks
exit status of rank 1: killed by signal 9
```

In most situations this is a case of out of memory. Be careful not to run too many MPI processes on the same node. Sometimes threading can help to reduce memory usage and still parallelize on the available cores.

Not Enough Space to Allocate vblock

This likely means that the calculation went out-of-memory error. Try again with fewer MPI processes and with some threading instead. Otherwise, reduce the calculation accuracy or the system size.

Cant Allocate Memory for Array

As the error message says, the calculation has used all the available memory on the computer. Reduce the number of MPI processes and use threading instead. Otherwise, you have to reduce the calculation accuracy or the system size.

ATKError: Bad Allocation

This message likely means that the calculation has run out of memory. Be careful not to run too many MPI processes on the same node. Sometimes threading can help to reduce memory usage and still parallelize on the available cores.

ATKError: Inverse(DZMatrix const&) : Could Not LU Factorize!

In the majority of cases this error occurs when something is wrong with the geometry, e.g. two atoms sit on top of each other (or are too close), or outside the unit cell (at equivalent positions, perhaps). Check your geometry carefully!

Cannot Run QuantumATK P-2019.03

If you receive the license error below or in general have any issue starting with QuantumATK P-2019.03 please verify the following:

- You must use the Synopsys Common Licensing (SCL) software, version 2018.06 or later.
- You must have the license key files issued later than December 10, 2018.

You can retrieve both SCL installers and license key from the SolvNet portal

License errors:

```
FlexNet Licensing checkout error: SIGN= keyword required but missing from the license␣
↪certificate.
This is probably because the license is older than the application
You need to obtain a SIGN= version of this license from your vendor
```

For more information please visit the License Installation Guide.

Network or Nodelocked Licenses

Purchased licenses are issued as **Network** licenses. That means that a central server will handle the license, and any computer which can connect over the network to the server can check out a license and run the software.

Evaluation licenses are **nodelocked**. The software is then constrained to running on a particular computer only.

License for QuantumATK Parallel Run

You do not need any special license to take advantage of OpenMP threading on multicore computers. To run QuantumATK in parallel using MPI, on a cluster or a single machine, you need so-called DP licenses. The number of DP licenses determines how many MPI processes can be used for QuantumATK parallelization. For more information on running QuantumATK in parallel, see the *Parallel Guide*.

Basic License Troubleshooting

If you have a very general license problem, here are some tips that might lead to actually generating one of those error messages, or solve the issue in a simple way. It will also be much easier for us to help you troubleshoot the license problem if you go through these steps first and let us know the result.

Automated License Setup

The easiest way to manage the license configuration is to use Virtual NanoLab (VNL), which has a built-in tool both for setting up the license environment and for changing it. This tool will either pop up when you start VNL and no license can be found, or you can start it from the Help menu. For more information, see the detailed guide here. If you to inspect the license setup in more detail, look in the file licenses.licconf, located in the directory .quantumwise, inside your home directory. This directory also holds any nodelocked or demo license you have, in the licenses subdirectory.

Manual License Setup

In some cases, for instance on a cluster, it is not possible or convenient to use VNL to configure the license. In this case, the easiest option is to use environment variables, as discussed here. To see how the license environment is currently set up, you can run the following commands in a terminal on Linux, or on Windows in Cygwin or similar:

```
echo $QUANTUM_LICENSE_PATH
echo $QUANTUM_AUTOMATIC_SERVER_DISCOVERY
```

or on Windows (in a regular Windows cmd terminal):

```
echo %QUANTUM_LICENSE_PATH%
echo %QUANTUM_AUTOMATIC_SERVER_DISCOVERY%
```

If you think that the license variables are set correctly, you can check what licenses are available on the system by using (on Windows or Linux):

```
lmxendutil -licstat
```

This will report where QuantumATK looks for licenses and what it found, and is particularly useful for checking **floating licenses** (when you are using a license server).

Some Further Particular Tips

If you have a **standalone license** file, check that this file is readable by the current user, by using the following command:

```
cat $QUANTUM_LICENSE_PATH     (Linux/Cygwin)
type %QUANTUM_LICENSE_PATH%   (Windows cmd)
```

If this doesnt produce the expected output (which is, that it prints out the contents of the license file), try

```
ls -l $QUANTUM_LICENSE_PATH    (Linux/Cygwin)
dir %QUANTUM_LICENSE_PATH%     (Windows cmd)
```

This will show if the license file actually exists in the specified location. If it does, but you cant see its contents - check the permissions of the file, maybe only root/Administrator can read it? A lot of useful information about the license setup can be found in the Installation Guide and the LM-X End-User Guide.

Advanced License Troubleshooting

When troubleshooting license problems, a very convenient tool is to define the environment variable **QUANTUM_EXTENDEDLOG=license.log**, then start QuantumATK, and afterwards inspect the file license.log which will contain a detailed account of all license-related system settings, and very importantly how LM-X/ATK tried to locate a license (file or server) and whether or not it was successful. For example, on **Linux** (or Windows/Cygwin), open a terminal and type (this syntax is for bash, see Notes below for tcsh)

```
QUANTUM_EXTENDEDLOG=license.log atkpython nothing.py
```

The file nothing.py need not exist, its just a placeholder for this test. Now, if you get a message saying

```
can't open file 'nothing.py': [Errno 2] No such file or directory
```

your license is actually working properly. However, if you see

```
License Error: (Internal: 719 Feature: ATKPython)
(Err: 9) Feature not found
```

you need to check license.log for more information. Make sure to provide this file to QuantumWise support when asking for help about license issues. On Windows, the corresponding approach would be to press WinKey+R and type cmd (or use the Start Menu), and then in the terminal window which opens type

```
set QUANTUM_EXTENDEDLOG=license.log
atkpython nothing.py
```

Note: The file license.log will be created in the current directory, so make a note of where that is, so you can locate the file afterwards. The test above only checks that atkpython can be started, and for that you only need the feature ATKPython in the license file. If you can launch atkpython and/or VNL without problems, but have license troubles when running a particular calculation, try running the calculation again with the environment variable set globally (in your login file .bashrc on Linux, or via the Control Panel on Windows). Note that on Linux, you cannot use this approach if you start VNL from the Desktop icon, unless you first log out and back in again. Its easier to run vnl from a terminal window for the test purpose. If your shell is csh/tcsh, the syntax is

```
env QUANTUM_LICENSE_FILE=license.log atkpython nothing.py
```

Maintenance, Updates and Support

As a customer of QuantumWise, you have access to support via email (and some other benefits, like participation in user meetings etc) provided that you hold an active maintenance contract.

Note: Always state your customer ID when communicating with support staff, so that we can identify your affiliation.

- For **annual licenses**, the maintenance period normally coincides with the validity of the license itself, unless otherwise specified.
- For **perpetual licenses**, the maintenance period is specified separately on your contract/invoice. When it expires, the contract can be prolonged for continued access to support, as well as upgrades.

Updates and Upgrades

If you hold a perpetual license, you can always update QuantumATK if a new minor version is released (typically bug fixes) free of charge, even if your maintenance period has expired. Minor versions are for instance 2016.1 and 2016.2, which are updates to 2016.0.

When a new major version of QuantumATK is released, you may upgrade free of charge if the new version is already included in your contract. You can check your license file or invoice to find out which version you may upgrade to; if the license file contains a feature label 17.0 you can upgrade to version 2017 and all updates (2017.1, etc) to it.

If you have an older version in your contract, you can purchase an upgrade as part of the maintenance (for perpetual licenses) or by prolonging your annual license.

License and QuantumATK Upgrading

Whether or not you can upgrade for free to a newer version of QuantumATK depends on which version is included in your license file, and correspondingly in your contract. Either check your latest invoice, or start QuantumATK and open Help>About, where the highest support version is written out as e.g. 17.0, in which case you are able to upgrade to version 2017 (if it says 16.0 or 16.5 or anything else with 16, your maximum version is 2016, and so on).

You can also inspect the license file (its just a text file). The highest supported version is written in the file, on the VENDOR line, for instance as

```
VENDOR=QUANTUM VERSION=17.0 END=2017-08-14 SHARE=VIRTUAL|TERMINALSERVER
```

If the new version is supported by your license, you can just download and install it. If your license does not support the new version, please contact us for upgrade options

Updating the License File

If you receive an updated **standalone license** file, for instance a prolonged demo/trial license, you dont need to reinstall the software. All you need to do is run the **license configuration tool** provided with QuantumATK, as described in detail in the Installation Guide. If you are running a **license server** and receive a new license file, the location of the license file should be obvious from the way the server is started. In this case, just replace the license file and restart the license server.

License Server Cannot Be Started

If the license server refuses to start on Linux, check the output of

```
ldd lmx-serv-quantum
```

If you see something like

```
./lmx-serv-quantum: /lib64/tls/libc.so.6: version 'GLIBC_2.4' not found (required by ./
↪lmx-serv-quantum)
libpthread.so.0 => /lib64/tls/libpthread.so.0 (0x0000003ca4700000)
libm.so.6 => /lib64/tls/libm.so.6 (0x0000003ca3f00000)
libc.so.6 => /lib64/tls/libc.so.6 (0x0000003ca3c00000)
/lib64/ld-linux-x86-64.so.2 (0x0000003ca3800000)
```

it means that this machine can not be used to run the license server, since it requires GLIC 2.4 or newer, and this machine uses GLIBC 2.3 (or lower).

SSH License Server Access

Normally ATK will locate active license servers automatically, as long as you are on the same network segment and there are no firewalls between your computer and the server. If there are firewalls which cant be opened for whatever reason, or you wish to access the license server remotely, e.g. from home or while traveling, a very convenient possibility is to set up an SSH tunnel to the license server. To make this work, you need:

•An SSH client. On Linux you will have this for sure, on Windows you can consider using Cygwin with OpenSSH, PuTTy, or another 3rd party SSH application. Below you will find instructions for different options.

•The hostname or IP address of the license server - ask your system administrator if you are unsure.

•An account on a machine which is able to connect to the license server, and to which you can login over SSH. This may be the license server itself, but it can really be any machine which can run ATK using the license server (like a cluster headnode, your office desktop, etc).

Below we will denote

•the hostname of the license server as LICSERV

•the machine you SSH into, which can run QuantumATK, as HOST

•your username on this machine as USER

All these should of course be replaced with the actual hostnames (e.g. server2.uni.edu) or IP number, and username.

Note: Make sure you verify first that HOST can indeed use the license server, else it may be hard to troubleshoot problems further on.

Step 1: Open the SSH Tunnel

Linux / Windows with Cygwin Open a terminal window and type

```
ssh -vvv -N -L 6200:LICSERV:6200 USER@HOST
```

Lots of information will be printed to the screen. After you have provided your password, the license tunnel should be open - proceed to step 2. The process will run in the foreground, it will be waiting for active connections. You will not, however, get a prompt on the remote host (due to the option -N). You need to keep this window open as long as you want the license tunnel to work.

Windows with PuTTY

1.Download and install PuTTY from here. The easiest option is to choose the Windows installer (putty-0.62-installer.exe, or a newer version if available).

2.Start PuTTY (if you cant find a Start Menu entry for it, its in C:Program Files (x86)PuTTYPUTTY.EXE).

3.Under Host Name, enter **HOST**. Replace HOST by the actual IP address or hostname of the computer you have an account on.

4.Then, in the *Category* tree in the left-hand panel, click the + next to SSH to expand the options. Go to Tunnels. - Make sure **Local** is selected. - Source port: **6200** - Destination: **LICSERV:6200** (replace LICSERV by actual license server hostname) - Click **Add**.

5.Do not click Open yet! Instead, go back to the first page (scroll up in the Category tree to find Session). Enter a name for the session, for instance License Tunnel and click Save.

6.Now click **Open** to initiate the connection. After you have provided your username and password, the license tunnel should be open - proceed to step 2.

Note: Under Connection>Data you can set your username so you dont have to type it in each time. Dont forget to Save the session profile. Next time you want to open the license tunnel: - Start PuTTY - Select the License Tunnel session and click Load - Then click Open You can also load this profile directly by providing the command line argument -load License Tunnel to putty.exe.

Step 2: Client License Environment Configuration

1. Start the QuantumATK license configuration (as described in the Installation Guide); the easiest way is to open a new terminal and type **atk_license_config**, or on Windows press **WinKey+R** and type **atk_license_config**.
2. Click the Next and OK buttons until you get to the page with license options
3. Select to use a **Floating license**, click Next, and on the next page set the server to **localhost** (the port number will be automatically added, do not enter it).
4. Complete the configuration utility to save the changes by clicking Next>Next>Finish.
5. Proceed to step 3 to test the license tunnel.

   Once you are able to connect to the license server directly again (say, when you return from your travel), you must rerun this configuration utility to change the configuration back to the original state, which most likely is Floating but with the server setting left empty, for autoconfiguration.

   If you are familiar with environment variables, you can also just type in the terminal

```
export QUANTUM_LICENSE_PATH=6200@localhost
```

   In this case the setting only applies to the current session (to this terminal), but it saves you from reconfiguring the license environment when you have direct access to the license server again. You must of course start both vnl and atkpython from this terminal to have access to the license.

Step 3: Testing

To test that the license configuration works, try to run (in a terminal):

```
atkpython nothing.py
```

If the license checkout is **successful**, there will be an error message like

```
can't open file 'nothing.py': [Errno 2] No such file or directory
```

Thats ok - the file does indeed not exist, but the point was to check whether QuantumATK manages to find the license or not, and this message only appears if it could.

If the license checkout in unsuccessful, you will instead see a license error message

```
License Error: (Internal: 719 Feature: ATKPython)
(Err: 9) Feature not found
```

In this case, first make sure - again - that the HOST computer can run QuantumATK and that there are licenses available, and then try to look for messages in the SSH window; the -vv verbosity option will print lots of debug messages that will be helpful for troubleshooting.

Even in the successful case, you may want to check the SSH messages, especially in case you notice that it takes a rather long time before the message about nothing.py appears. This may indicate that instead of actually using the license tunnel, QuantumATK is using the 2 week built-in trial license. In the truly successful case, you should see a message of the following form in the SSH window:

```
debug1: Connection to port 6200 forwarding to multiserver port 6200 requested.
debug1: channel 2: new [direct-tcpip]
debug1: channel 2: free: direct-tcpip: listening port 6200 for multiserver port 6200,␣
↪connect from ::1 port 50269, nchannels 3
```

Note: The license tunnel is only open as long as the SSH process is running. If the network connection times out, or you put the computer to sleep or reboot, you just run the same command again. - It is possible to put the license tunnel into the background by adding the -f option. This saves you from having an extra terminal open for this process, but its also harder to restart the tunnel if the network connection is broken, since you must first kill the initial process, since it binds port 6200. Thus we recommend keeping the tunnel running in the foreground unless you are very experienced with SSH tunnels.

If you have a HAL (high-availability license) solution with 3 redundant license servers, you need some special considerations. You need to set up a tunnel to the first two HAL servers (the 3rd one cannot be used to check out a license from anyway), on separate local ports (for instance 6200 and 6201), and then set the environment variable manually, in .bashrc (Linux/Cygwin) or via the Control Panel (Windows) as follows:

```
QUANTUM_LICENSE_PATH=6200@localhost;6201@localhost    (on Windows)
QUANTUM_LICENSE_PATH=6200@localhost:6201@localhost    (on Linux)
SmallBestOriginalRemove
```

Restricting Access to a License Server

By using a configuration file, it is possible to restrict access to the license features to certain computers, users, etc. The access is controlled using ALLOW and DENY statements, a bit like in a .htaccess file. The rules work a bit differently, however, so below we will present some simple examples to make it clearer.

The essential logic of the access restrictions is:

- You can ALLOW or DENY access to the license features all, or a single, or multiple specified users, IP numbers, hosts.
- The rules can apply to all license features, or only some specific ones.
- The rules are evaluated in the order they appear in the configuration file. The first matching rule is applied - the following rules are generally ignored.
- If no rule matches, the default is to ALLOW.

Point 4 is very important, because it means that if you wish to restrict access to the license in any way, you must explicitly ALLOW those with access and then DENY all others. So, in order to only allow computers in the IP number range 192.168.0.0 to 192.168.0.255 access to the license, you will need to use the statements

```
ALLOW_IPADDR_ALL = 192.168.0.*
DENY_IPADDR_ALL = *
```

Another typical option is to only allow a particular user to access the license. You can then use

```
ALLOW_USER_ALL = niceguy1 niceguy2
DENY_USER_ALL = *
```

Point 3 is also crucial - if we reverse the ALLOW/DENY statements in the two examples above, nobody will have access to the license server because everybody will match the DENY rule and thus be rejected. You only want the DENY rule to apply to those not matching the ALLOW rule!

There are multiple options for the ALLOW/DENY statements - for more details please see the extensive examples inside the configuration file **lmx-serv.cfg** which resides in the same directory as the license server binary. For example, you may just want to block a particular user, then its enough to use

```
DENY_USER_ALL = badguy
```

In this case all other users will be allowed by virtual of Point 4 above. To use the configuration file the license server must be started with the option **-c lmx-serv.cfg**.

Note: In general you should always use this option, and make sure to change the server password in the file from the default value.

1.2 Introductory Tutorials

Introductory tutorials below will help you get started and enable you to set up and analyze your first calculations using the **QuantumATK NanoLab graphical user interface**.

1.2.1 Geometry Optimization

Version: X-2025.06

In this tutorial, you will learn how to use QuantumATK NanoLab GUI to

- Find and use structures from the NanoLab Internal Database.
- Setup a basic geometry optimization simulation for SiO_2 (quartz) using Density Functional Theory (DFT).
- Inspect the optimized geometry.

All the workflow, input and output files can be found in the **Example Project - X-2025.06 → SiO2-quartz-geom-opt folder.**

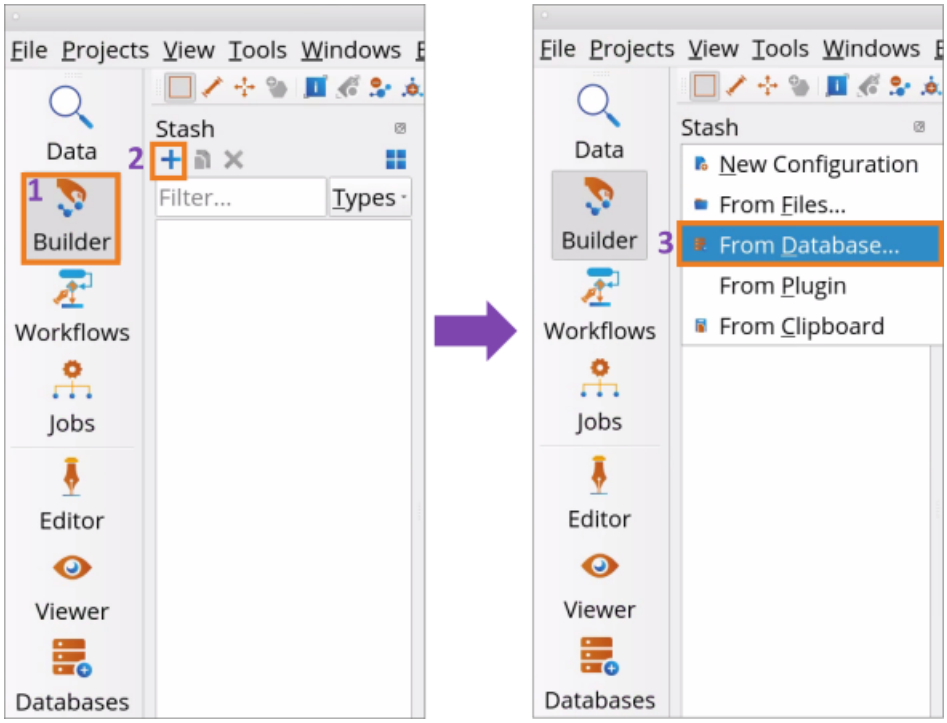
Prerequisites

- Video Introduction to QuantumATK NanoLab GUI
- Video tutorial on the Workflow Builder tool
- Video tutorial on the Job tool

Importing Structures from the NanoLab Database

To import a SiO_2 (quartz) structure from the NanoLabs Internal Database, follow the step-by-step protocol described below.

1. In the **Builder** *Stash* (1), click on the *Add* button (2) and choose *From Database* (3) to open NanoLabs *Crystal Database*.



2. Use the *Search* bar (1) to find SiO_2 (quartz) structure (2) and click on the *Add* button (3) to add the structure to the **Builder** *Stash*.

Tip: Internal NanoLab structure library contains several hundred basic molecule, crystal, fullerene, zeolite, monomer and 2D material structures. If you cannot find there a structure of your interest, click on **Databases tool** to use NanoLabs interface to query online databases such as Crystallography Online Database and Materials Project.

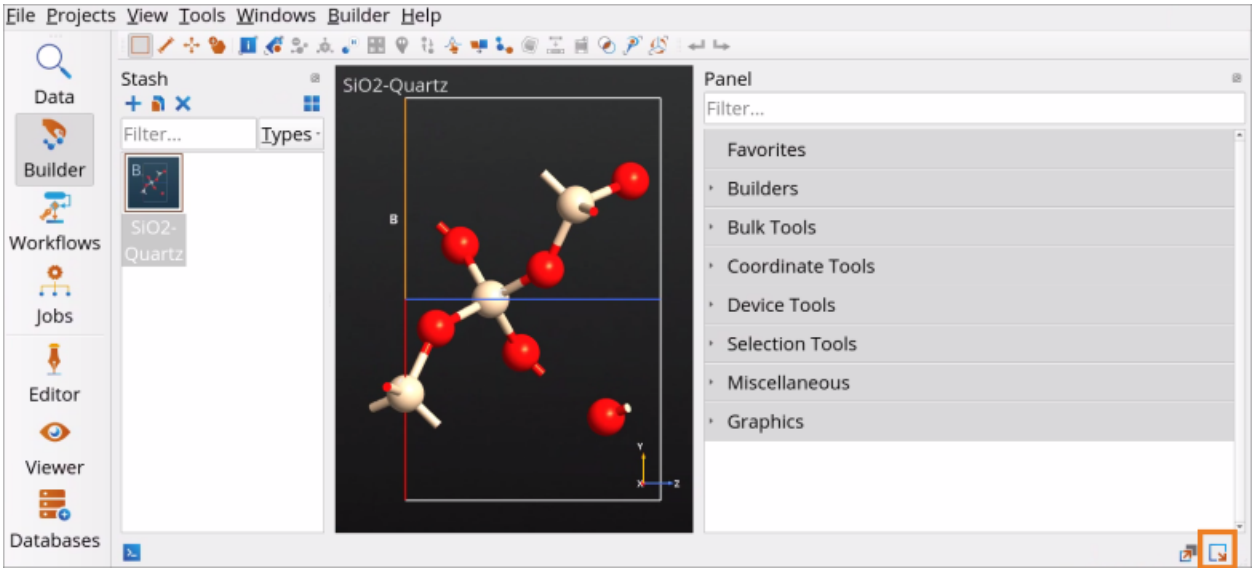
Setting up Geometry Optimization Workflow

To create a workflow for *OptimizeGeometry* calculations in the **Workflow Builder**, follow the step-by-step protocol described below. Here, we will use DFT with *LCAOCalculator* basis sets and a hybrid HSE06 DFT functional, as it is optimized for bulk semiconductor and insulator materials.

1. In the **Builder**, use the *Send content to other tools* button to send the imported SiO_2 (quartz) structure to the **Workflow Builder**.



2. Go to the *Block Catalog* → *QuantumATK* tab → *Calculators* category on the right hand panel and drag-and-drop the *SetLCAOCalculator* block to the middle *Workflow Area* → *Build* tab.

3. Double-click on the *SetLCAOCalculator* block and edit the *Main* tab:

- Change the *Exchange Correlation Family* from the default *GGA* to *Hybrid* with a predefined default *HSE06 (HybridGGA.HSE06)* functional (functional can be changed under the *LCAO Basis Set* tab).
- Change the numerical accuracy paremeter *Broadening* from 1000 K to 300 K (recommended for semiconductor materials).

Tip:

1. *SetLCAOCalculator* block sets medium k-point sampling, medium basis set and 125 Ha density mesh cutoff (system-dependent) by default, typically providing good accuracy results with modest computational resources. It is recommended though to check the convergence of your results with these parameters.

2. *SetLCAOCalculator* block uses a default *Fermi-Dirac Occupation Method* with 1000 K *Broadening*, which generally works reasonably well across various systems. Another setting may be more appropriate for your system, and you can adjust these settings according to the recommendations in *Occupation Methods* for semiconductor, insulator, metal, and molecule systems.

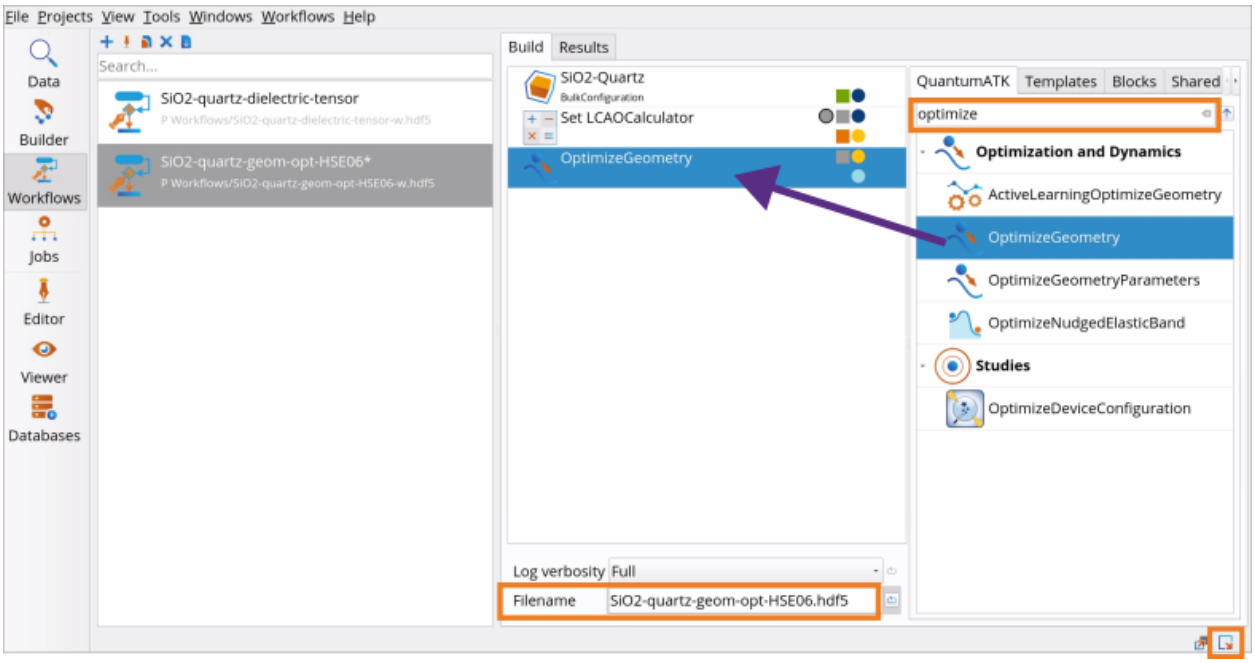
3. For slabs, surfaces and interfaces (modelled as slabs), it is recommended to set *FFT2D* Poisson Solver (*Dirichlet/Neumann*) in the out-of-plane (C) direction instead of the default *FFT* (*Periodic*) in the *SetLCAOCalculator* block, *Poisson Solver/Solver Type* section. For neutral molecules, stick to the default *FFT* Poisson solver, whereas for charged molecules, set the *Multigrid/Multipole* Poisson Solver. Read these technical notes on *Poisson solvers* to learn more.

4. Go to the *Block Catalog* → *QuantumATK* tab → *Optimization and Dynamics* category on the right hand panel and drag-and-drop the *OptimizeGeometry* block to the middle *Workflow Area* → *Build* tab.



5. Double-click on the *OptimizeGeometry* block and change from *Constrain Bravais Lattice* to *Constrain space group*.

6. Change the *Workflow* name in the *Workflow Stash* and *Filename* as needed (e.g., `SiO2-geom-opt-HSE06.hdf5`).

7. Click on the *Send content to other tools* button and choose *Jobs as a script* to send the workflow to the **Jobs** tool in order to submit this job on a local machine or a remote cluster. It is recommended to parallelize over both MPI processes and threads in DFT simulations. Read the technical notes on *Parallelization of QuantumATK calculations* to learn more.

8. This also generates a Python script `SiO2-geom-opt-HSE06.py`, based on this workflow. It can be opened and edited with the **Editor** tool and then sent to the **Jobs** tool.

Tip:

1. *Constrain space group* relaxes atom positions, unit cell volume and shape and preserves crystal symmetry during the geometry optimization, whereas the default *Constrain Bravais Lattice* allows to relax to a different crystal symmetry. *Constrain Bravais lattice* can also be used when optimizing the geometry of alloys, amorphous materials or crystals with defects with a preserved Bravais lattice type.

2. Unit cell volume and shape can be constrained by unchecking the box *Optimize cell* in the *OptimizeGeometry* block, thus allowing for local relaxation of atoms only.

3. When doing geometry optimization of a bare surface, or, e.g., surface covered by molecules, it is possible to *Add constraints* on selected (tagged) atoms or monolayers in the *OptimizeGeometry* block to, e.g., fix the bottom substrate layer.

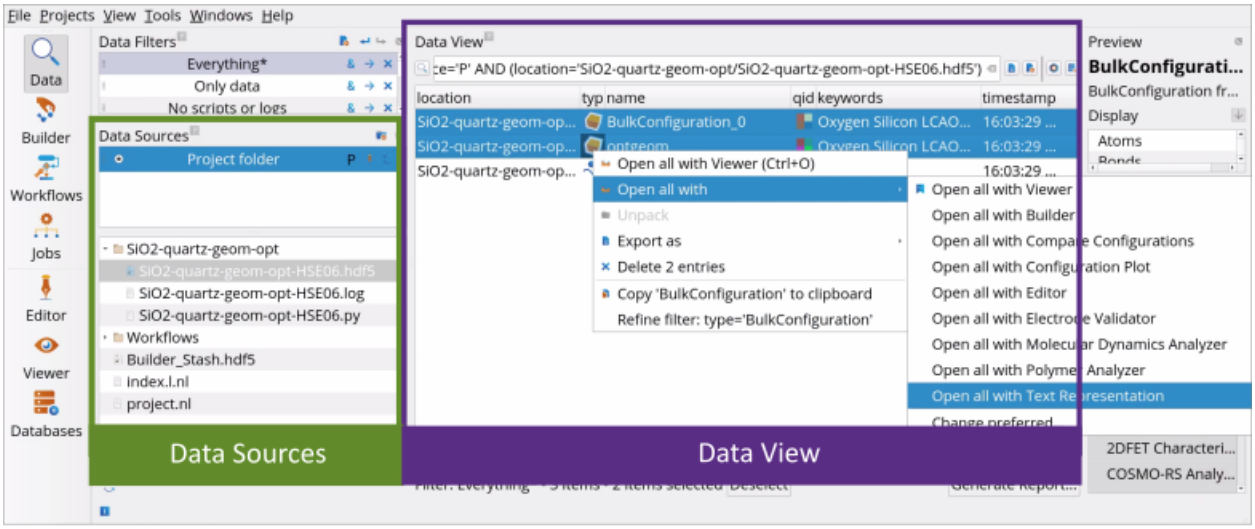
4. In case of calculating *PhononBandstructure*, *VibrationalMode*, *DielectricTensor* (or other properties that require *DynamicalMatrix* calculations), it is recommended to pre-optimize structure with a tighter force (e.g., 0.001) and stress (e.g., 0.01) tolerances than default.

Analyzing Results

Once the calculation has finished, we are ready to analyze the results.

1. Go to the **Data View** tool.

2. In the *Data Sources* select the file `SiO2-geom-opt-HSE06.hdf5` and then in the *Data View* window select both, *BulkConfiguration_0* (initial geometry) and *optgeom* (optimized geometry), followed by the right-click to *Open All with Text Representation*.



3. Inspect and compare lattice constants of initial and optimized geometries in text representation. The optimized lattice constants of SiO_2 (quartz) , a=4.908 Å and c= 5.409 Å, with the hybrid HSE06 functional are in a good agreement with experimental results a=4.913 Å and c=5.405 Å[1].

beta = 90.000000 deg
gamma = 120.000000 deg

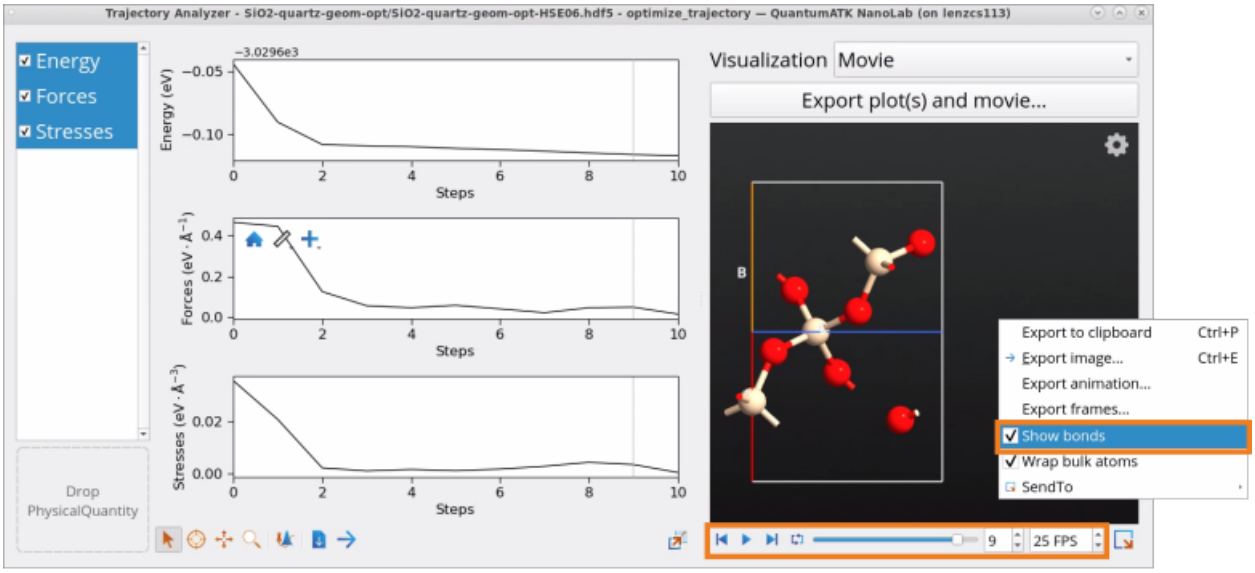
4. Right-click on the *optimize_trajectory* object in the *Data View* window and open it with the *Movie Tool* to investigate the convergence of energy, forces and stresses throughout the simulation. It took 10 steps to converge energy, forces and stresses to the default force and stress tolerance values.

5. Right-click on the structure in the *Movie tool* to check the box *Show bonds* and use the *Play* button to see the evolution of structure throughout the geometry optimization simulation.



6. Right-click on the the optimized geometry *optgeom* in *Data View* and choose to *Open with Builder*. The optimized geometry will be automatically saved in the **Builder** *Stash*, so you could use it for other simulations, such as *Band Structure, Projected Density of States and Effective Mass Calculations*, *Optical Property Calculations*, etc.

Note: Note that lattice parameters optimized with the default, computationally-cheaper GGA PBE functional instead, a=4.966 Å and c=5.466 Å, deviate by ~1% from the measured values, compared to ~0.1% when optimized with the more sophisticated hybrid HSE06 functional used in this tutorial example for SiO_2 (quartz).

In the next tutorial on *Band Structure, Projected Density of States and Effective Mass Calculations* you will learn how to set up and analyze band structure, projected density of states and effective mass calculations for the optimized structures of SiO_2 (quartz) and Si.

References

1.2.2 Band Structure, Projected Density of States and Effective Mass Calculations

Version: X-2025.06

In this tutorial, you will learn how to use the QuantumATK NanoLab GUI to

- Set-up band structure, projected density of states (PDOS) and effective mass calculations for bulk Si and SiO_2 (quartz) using Density Functional Theory (DFT).
- Analyze obtained results.

All the workflow, input and output files can be found in the **Example Project - X-2025.06** → **SiO2-quartz-bandstructure-pdos** and **Si-bandstructure-effective-masses folders.**

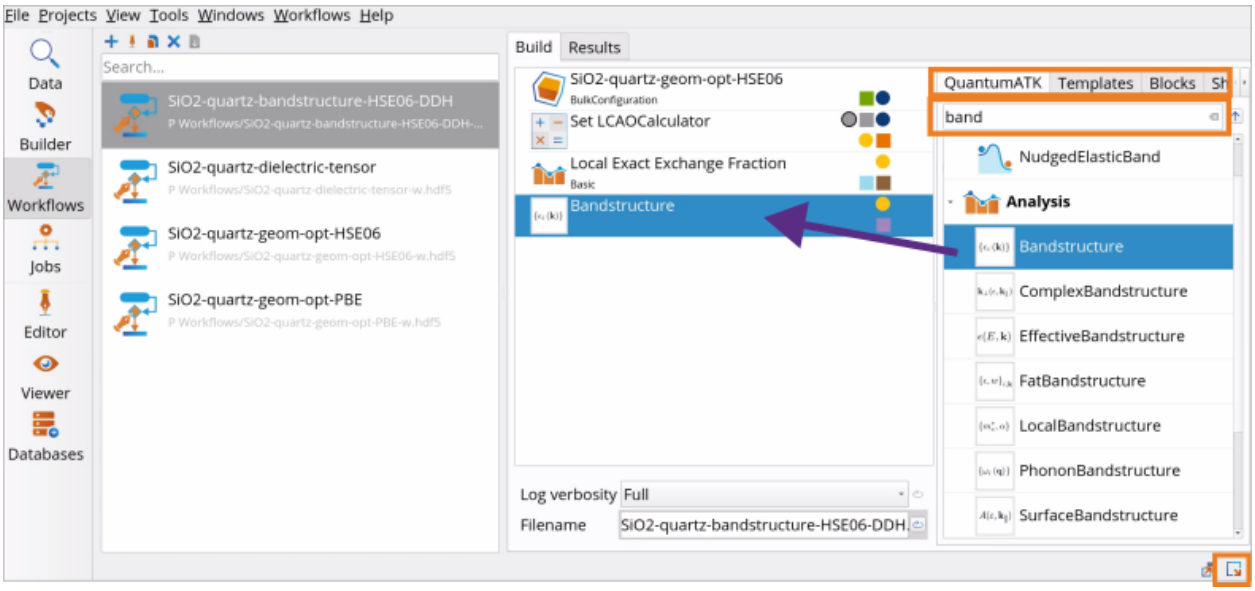
Prerequisites

- Video Introduction to QuantumATK NanoLab GUI
- Video tutorial on the Workflow Builder tool
- Video tutorial on the Job tool
- Tutorial *Geometry Optimization*

Setting up Band Structure Calculation Workflow

To create a workflow for *Bandstructure* and *ProjectedDensityOfStates* calculations in the **Workflow Builder**, follow the step-by-step protocol described below. Here, you will use DFT with *LCAOCalculator* basis sets. For the DFT functionals, choose a hybrid HSE06 DFT functional for bulk Si (exact exchange fraction of 0.25 optimized for Si) and a dielectric dependent hybrid HSE06-DDH functional (*DDHCustomExchangeCorrelation*) for SiO_2 (quartz) to find an improved material specific exact exchange fraction for more accurate band structure and band gap.

1. Follow the *Geometry Optimization* tutorial to optimize the structure of bulk Si and SiO_2 (quartz).
2. In the **Builder**, click on the *Send content to other tools* button to send the optimized structures from the **Builder** Stash to the **Workflow Builder**.
3. Go to the *Block Catalog* → *QuantumATK* tab → *Calculators* and *Analysis* categories on the right hand panel and drag-and-drop the *SetLCAOCalculator* and *Bandstructure* blocks, respectively, to the middle *Workflow Area* → *Build* tab.
4. For SiO_2 (quartz) case, add a *LocalExactExchangeFraction* block from the *Block Catalog* → *QuantumATK* tab → *Analysis* category. It will return the calculated improved material specific exact exchange fraction for SiO_2 (quartz).
5. Double-click on the *SetLCAOCalculator* block and make the following changes:



•In the *LCAO Basis Set* tab of the *SetLCAOCalculator* block, change the *Exchange Correlation Family* from the default *GGA* to *Hybrid* with predefined *HSEO6 (HybridGGA.HSE06)* functional for Si and *HSE06DDH (Hybrid.GGA.HSEO6DDH)* for SiO_2 (quartz).

•In the *Numerical Accuracy* tab of the *SetLCAOCalculator* block, change the numerical accuracy paremeter *Broadening* from 1000 K to 300 K (recommended for semiconductor materials).

Tip:

1. *SetLCAOCalculator* block sets medium k-point sampling, medium basis set and 125 Ha density mesh cutoff (system-dependent) by default, typically providing good accuracy results with modest computational resources. It is recommended though to check the convergence of your results with these parameters.

2. *SetLCAOCalculator* block uses a default *Fermi-Dirac Occupation Method* with 1000 K *Broadening*, which generally works reasonably well across various systems. Another setting may be more appropriate for your system, and you can adjust these settings according to the recommendations in *Occupation Methods* for semiconductor, insulator, metal, and molecule systems.

3. For slabs, surfaces and interfaces (modelled as slabs), it is recommended to set *FFT2D* Poisson Solver (*Dirichlet/Neumann*) in the out-of-plane (C) direction instead of the default *FFT* (*Periodic*) in the *SetLCAOCalculator* block, *Poisson Solver* section. For neutral molecules, stick to the default *FFT* Poisson solver, whereas for charged molecules, set the *Multigrid/Multipole* Poisson Solver. Read these technical notes on *Poisson solvers* to learn more.

---

6. Double-click on the *Bandstructure* block. Here, the Brillouin zone route is automatically detected, and there is an option to modify it. There is also a possibility to increase the number of points per segment for more fine sampling of bandstructure. Stick to the default settings.

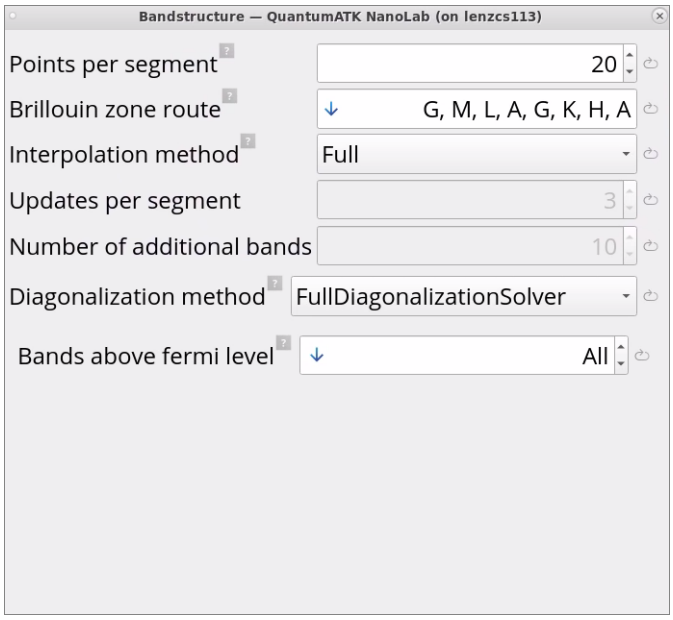
Advanced options



1. When calculating band structure of very large systems (> 1000 atoms), there is an option to choose *IterativeDiagonalizationSolver* instead of *FullDiagonalizationSolver* in the *Bandstructure* block to speed-up simulations, in particular with Semi-Empirical Thigh-Binding models for more than order of magnitude faster calculations.

2. Perform *LocalBandstructure* calculations to get insights into the local properties of the band structure such as effective masses and band unparabolicity for specified k-point, bands and directions.

3. When setting up bandtructure calculations for low symmetry crystal or systems with atomic disorder (e.g., alloys), one needs to define k-routes in the Brillouin zone in a script *input.py*. For example, for SiGe alloy specify inequivalent X and L points, resulting in degeneracy lifting, i.e., alloy broadening of bands.

```
# ------------------------------------------------------------
# Bandstructure
# ------------------------------------------------------------
def mysym():
    return {
            "G"   : numpy.array((0., 0., 0.)),
            "X1"  : numpy.array((1./2., 0., 0.)),
            "X2"  : numpy.array((0., 1./2., 0.)),
            "X3"  : numpy.array((0., 0., 1./2.)),
            "L1"  : numpy.array((1./2., 1./2., 1./2.)),
            "L2"  : numpy.array((-1./2., 1./2., 1./2.)),
            "L3"  : numpy.array((1./2., -1./2., 1./2.)),
            "L4"  : numpy.array((1./2., 1./2., -1./2.)),
        }

    points_per_segment=400,
    bands_above_fermi_level=All
    )

nlsave('SiGe_bandstructure.hdf5', bandstructure)
```

7. Change the *Workflow* name in the *Workflow Stash* and *Filename* as needed (e.g., `SiO2-quartz-bandstructure-HSE06-DDH.hdf5`).

8. Click on the *Send content to other tools* button and choose *Jobs as a script* to send the workflow to the **Jobs** tool in order to submit this job on a local machine or a remote cluster. It is recommended to parallelize over both MPI processes and threads in DFT simulations. Read the technical notes on *Parallelization of QuantumATK calculations* to learn more.

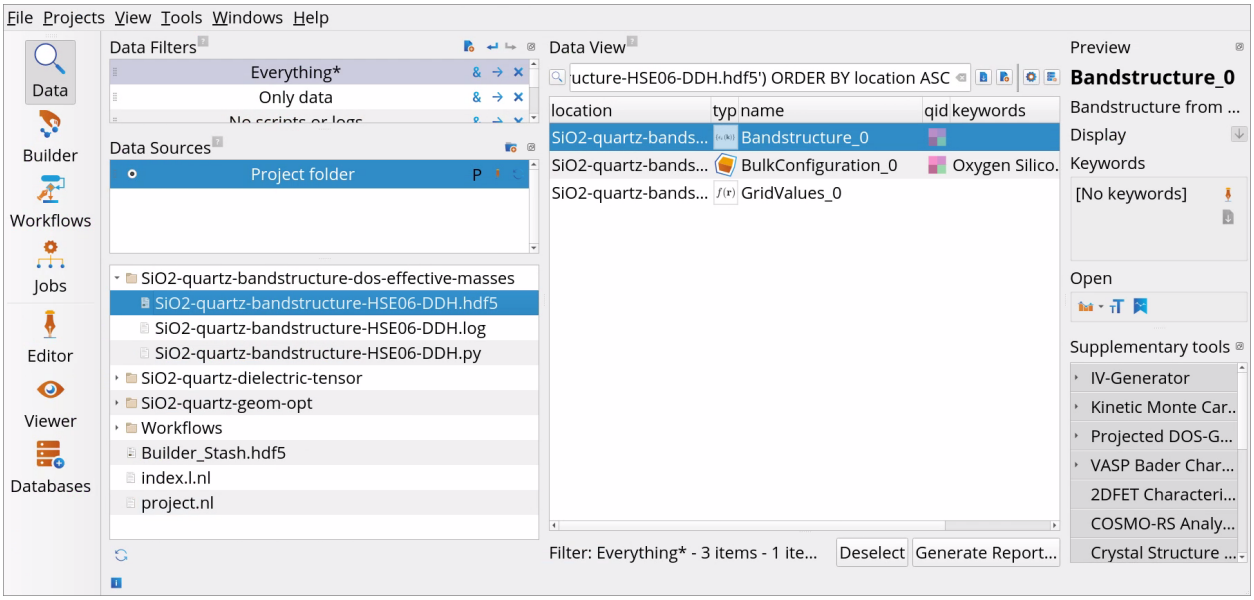
9. This also generates a Python script `SiO2-quartz-bandstructure-HSE06-DDH.py`, based on this workflow. It can be opened and edited with the **Editor** tool and then sent to the **Jobs** tool.

Analyzing Band Structure Results

Once the calculation has finished, we are ready to analyze the results.

1. Go to the **Data View** tool.

2. In the *Data Sources* select the file `SiO2-quartz-bandstructure-HSE06-DDH.hdf5` and then in the *Data View* window double-click on the *Bandstructure_0* object to open it with the *Bandstructure Analyzer*.



3. Examine *Direct band gap*, *Indirect band gap*, *Valence band edge* and *Conducion band edge* reported in the *Bandstructure Analyzer*.

4. Zoom into the band structure using *Zoom* and *Plot editor* tools and use measuring tools (right-click to *Add measurement*) to measure direct and indirect bandgaps yourself.

5. Double-click on *GridValues_0* object in *Data View* to open it with the *Grid 1D Projection Analyzer*. Examine the automatically calculated exact exchange parameter in HSE06-DDH, which is 0.4 for SiO_2 (quartz) - quite different from the pre-set 0.25 exact exchange parameter in the HSE06 functional.

1. Calculated indirect band gap of SiO_2 (quartz) 9.62 eV with the HSE06-DDH functional is in a good agreement with experimental (9.65 eV)[1] and many-body GW method (9.68 eV)[2] results. Indirect band gap obtained with HSE06 is 8.39 eV.

2. When simulating interfaces between different materials, choose *HSE06LocalDDH* for the predefined functional in the *SetLCAOCalculator* block, which automatically calculates material specific exact exchange fractions for each material in the interface.

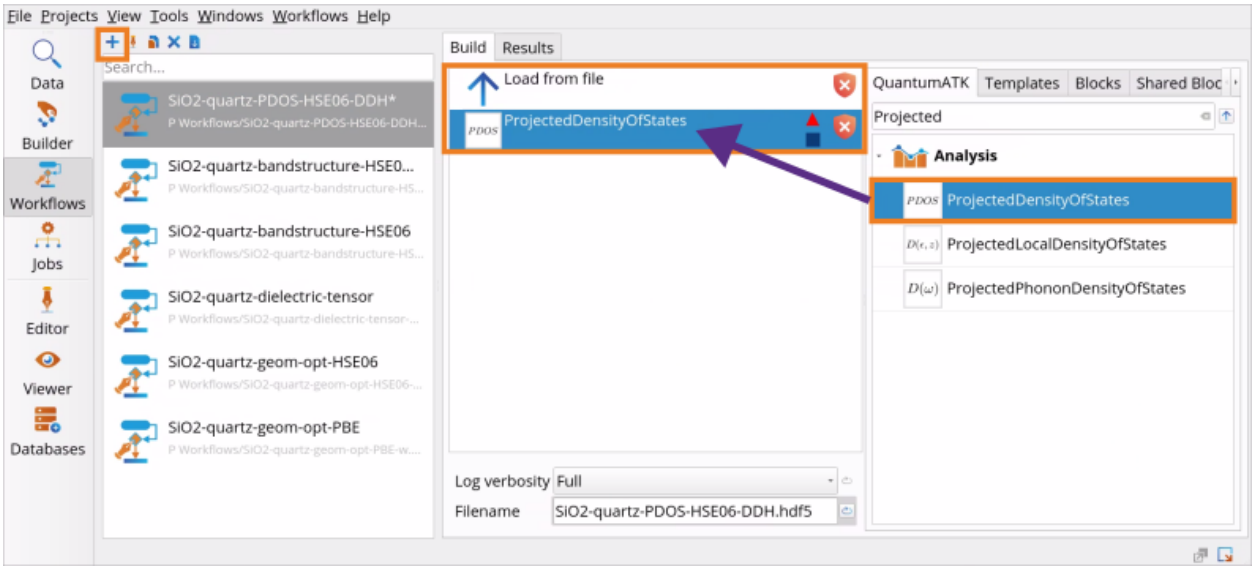
Restarting to Obtain Projected Density of States

In QuantumATK it is easy to restart from a previous simulation and calculate additional properties, for example, projected density of states, without re-doing the SCF convergence part. Follow this step-by-step protocol to set up additional projected density of state calculations.

1. Go back to the **Workflow Builder** and click on the the *Add* button to add a new workflow.

2. Change the *Workflow* name and *Filename* as needed (e.g., `SiO2-quartz-PDOS-HSE06-DDH.hdf5`).

3. Go to the *Block Catalog* → *QuantumATK* tab → *Algorithm* and *Analysis* categories on the right hand panel and drag-and-drop the *Load from file* and *ProjectedDensityOfStates* blocks, respectively, to the middle *Workflow Area* → *Build* tab.

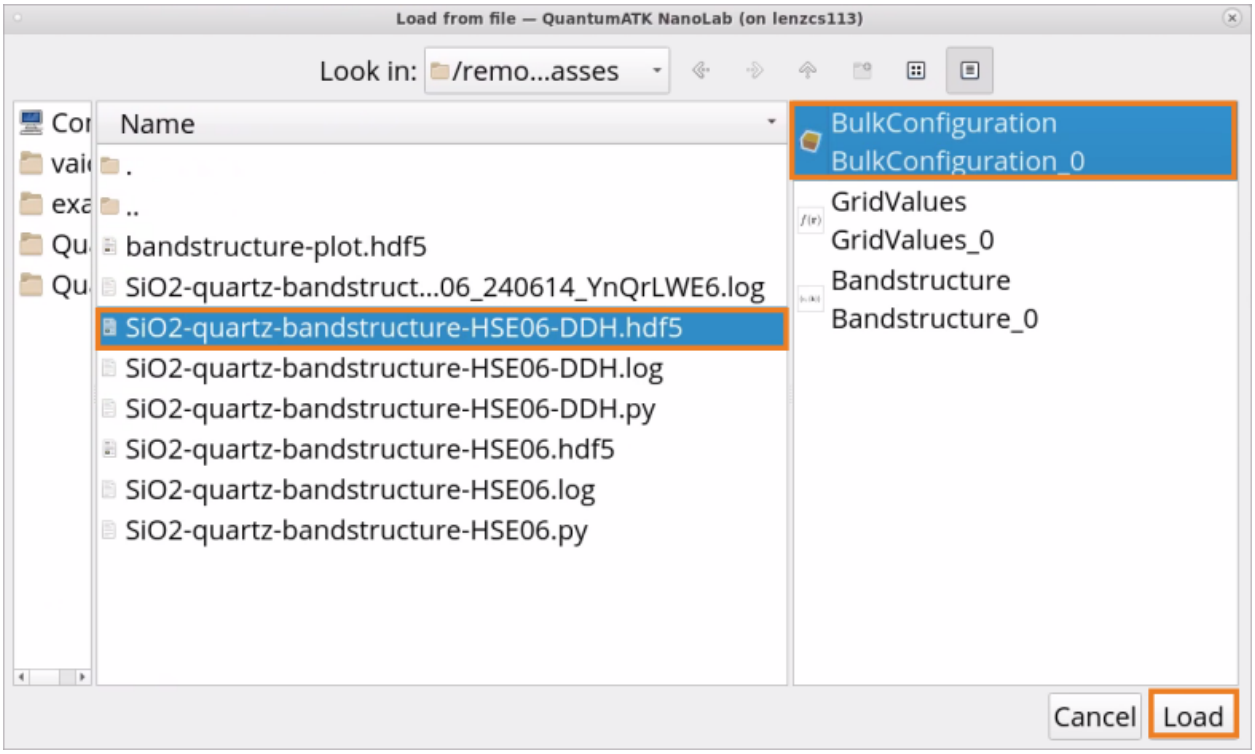


4. Double-click on the *Load from file* block to choose from which file to restart the calculation:

- Click on *Load from file*.
- Choose to restart from file `SiO2-quartz-bandstructure-HSE06-DDH.hdf5` → *BulkConfiguration*.
- Click *Load*.

[1] K.ăL. Milton, T.ăR. Durrant, T.ăCobos Freire, and A.ăL. Shluger. Difference in Structure and Electronic Properties of Oxygen Vacancies in -Quartz and -Cristobalite Phases of SiO2. *Materials*, 16(4):1382, 2023. doi:10.3390/ma16041382.

[2] T.ăMarkussen, R.ăFaber, P.ăA. Khomyakov, B.ăVerstichel, and A.ăBlom. Band Alignment in GAA Nanosheet Structures from Density Dependent Hybrid Functional and Many-Body GW Methods. *SISPAD*, 2024.



5.Double-click on the *ProjectedDensityOfSates* block and make the following edits:

- Define an *Energy range*: default -5 eV œ +5 eV is good for Si, but it should be increased for SiO_2 (quartz) to -15 eV œ +10 eV as it has a much larger band gap than Si.
- Choose *Projections* on *Elements and Shells* from various options, such as *Spin*, *Sites*, *Sites and Shells*, *Sites and Orbitals*, *Elements*, *Elements and Shells*, *Elements and Orbitals*.

Tip: Choose *Projections* on *Sites* to get local density of states / band diagram across interfaces, stacks or inhomogeneous systems in general.

6.Click on the *Send content to other tools* button and choose *Jobs as a script* to send the workflow to the **Jobs** tool in order to submit this job on a local machine or a remote cluster.

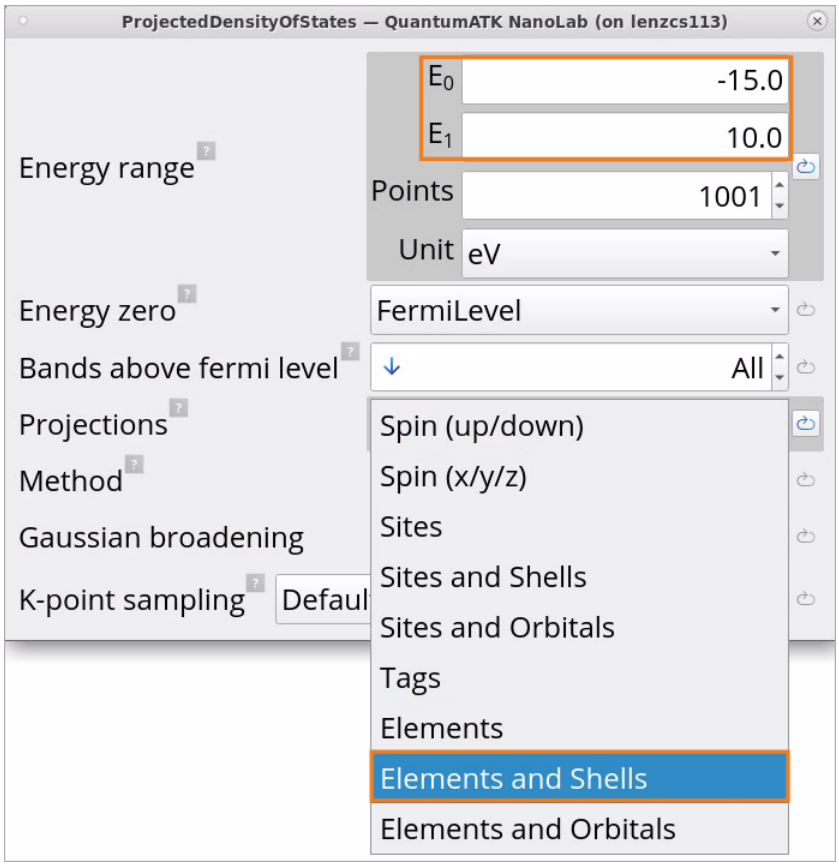
Analyzing Projected Density of State Results

Once the calculation has finished, we are ready to analyze the results.

1.Go to the **Data View** tool.

2.In the *Data Sources*, select the file `SiO2-quartz-PDOS-HSE06-DDH.hdf5` and then double-click on the *ProjectedDensityOfStates_0* object in the *Data View* window to open it with the *Projected DOS Analyzer*.

3.Use *Projected DOS Analyzer* to visualize and analyze Projected DOS on elements and shells in SiO_2 (quartz). As shown in the image below, valence bands are dominated by O *p* shell (l=1), whereas conduction bands are dominated by Si *p* shell (l=1).



4.Combine band structure and projected density of states plots for additional insights:

•Drag-and-drop handle from the *Projected DOS Analyzer* to the *Bandstructure Analyzer* plot to combine the two plots.

•Choose combination type: *Flipped and side-by-side with shared y axis*.

•Click *Merge*.

Calculation of Effective Masses

Lets see how to estimate effective mass of electrons in bulk Si from the band structure calculated with the hybrid HSE06 functional. The *EffectiveMass* of holes and electrons can be estimated by fitting a parabola to the minimum/maximum of the conduction/valence bands.

1.Go to the **Data View** tool.

2.In the *Data Sources*, select the file `Si-bandstructure-HSE06.hdf5` and then double-click on the *Bandstructure_0* in the *Data View* window to open it with the *Bandstructure Analyzer*.

3.Find the lowest conduction band of Si and determine the minima. As shown in the image below, the minimum is located at k-point (0.425, 0, 0.425) with 0.585 eV energy, where 0.425 is 85% of the distance to the first Brillouin zone boundary at X=(1/2,0,1/2). At this point, the energy isosurfaces are ellipsoids, thus you get different values for the effective mass depending on if you look in the longitudinal (along) or transverse (perpendicular to) directions.

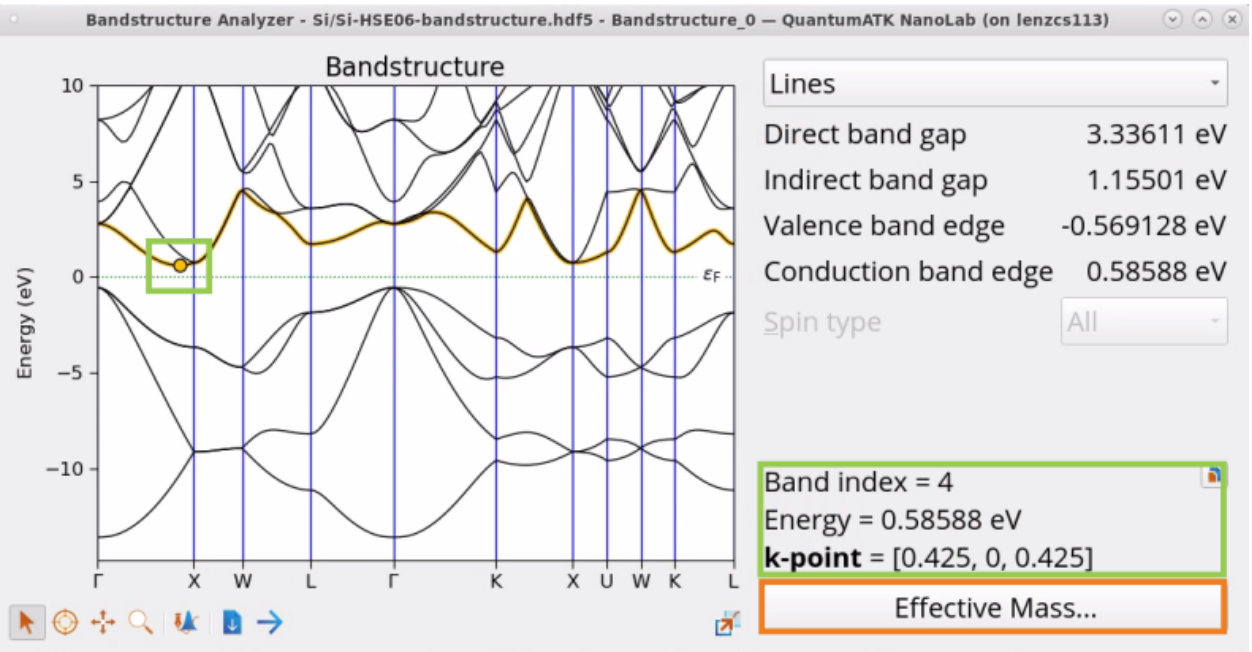
4. Click on the *Effective Mass* widget to open the *Effective Mass* block and set up an effective mass calculation at this conduction band minima k-point (0.425, 0, 0.425).



5. In the *Effective Mass* block, the parameters such as band index and k-point coordinates corresponding to the clicked point will be automatically set. Manually change the *Direction* to *Fractional* and set a=1, b=0, c=1, corresponding to the longitudinal direction.

6. Click on the *Send content to other tools* button to add this calculation as a block to the *Workflow* located in the *Workflow Area* → *Build* tab.

7. The workflow already has a *Load BulkConfiguration* block, which restarts the calculation from the former band structure calculation on Si: file `Si-bandstructure-HSE06.hdf5`.

8. Right-click on the *Effective Mass* block in the *Workflow Area* → *Build* tab and choose to *Duplicate* the block.

9. In the duplicated *Effective Mass* block, change *Direction* to a=1, b=1, c=0, corresponding to one of the transverse directions.

10. Optionally right-click on *Effective Mass* blocks and choose to rename the blocks to *Effective Mass: 101* and *Effective Mass: 110*, respectively.

11. Click on the *Send content to other tools* button and choose *Jobs as a script* to send the workflow to the **Jobs** tool in order to submit this job on a local machine or a remote cluster.

12. Once the calculation is finished, in the *Data Sources*, select the file `Si-effective-masses-HSE06.hdf5` and then double-click on the *EffectiveMass_0* and *EffectiveMass_1* objects in the *Data View* window to open them with the *Effective Mass Analyzer*.

13. Here, the effective mass corresponding to the specified band and direction is reported. From the two *EffectiveMass* objects you will obtain:

- Longitudinal effective mass, [1,0,1] direction, $m^* = 0.85\, m_e$.

•Transverse effective mass, [1,1,0] direction, $m^* = 0.186\, m_e$.

14. With these values we can now compute the density of states mass m^*_{DOS} and effective mass for conductivity m^*_C:

$$m^*_C = 3/(1/m^*_L + 2/m^*_T)$$
$$m^*_{DOS} = 6^{2/3}(m^*_L(m^*_T)^2)^{1/3}.$$

We get $m^*_{DOS} = 1.02$ and $m^*_C = 0.25$, very close indeed to the reference values 1.08 and 0.26 (see https://www.colorado.edu/ecee/sites/default/files/attached-files/sd_constants_sheet.pdf). Thus DFT actually does reproduce the effective mass of the electrons in the Δ valley very well.

References

1.2.3 Optical Property Calculations

Version: X-2025.06

In this tutorial, you will learn how to use QuantumATK NanoLab GUI to

•Set-up optical property simulations of dielectric constant, refractive index, IR spectra, absorption spectra, etc. for SiO_2 (quartz) using Density Functional Theory (DFT).

•Analyze obtained results.

All the workflow, input and output files can be found in the **Example Project - X-2025.06 → SiO2-quartz-dielectric-tensor folder.**

Prerequisites

•Video Introduction to QuantumATK NanoLab GUI

•Video tutorial on the Workflow Builder tool

•Video tutorial on the Job tool

•Tutorial *Geometry Optimization*

•Tutorial *Band Structure, Projected Density of States and Effective Mass Calculations*

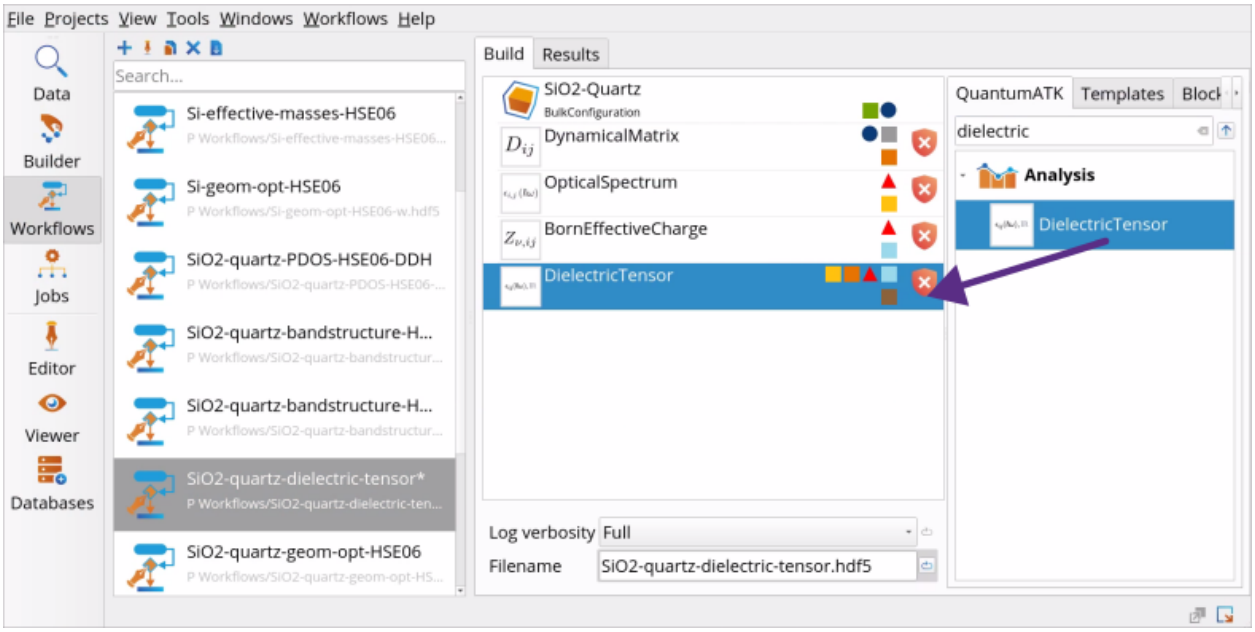
Setting up an Optical Property Calculation Workflow

QuantumATK can calculate many different optical properties from the *DielectricTensor*, including both electronic and ionic contributions, such as dielectric constant, refractive index, reflectivity, extinction coefficient, optical absorption coefficient, IR spectra, susceptibility. Follow the step-by-step protocol described below to set up these simulations for SiO_2 (quartz) in the **Workflow Builder**.

1. Follow the tutorial *Geometry Optimization* to import the structure of bulk SiO_2 (quartz) from NanoLabs *Crystal Database* to the **Workflow Builder**.

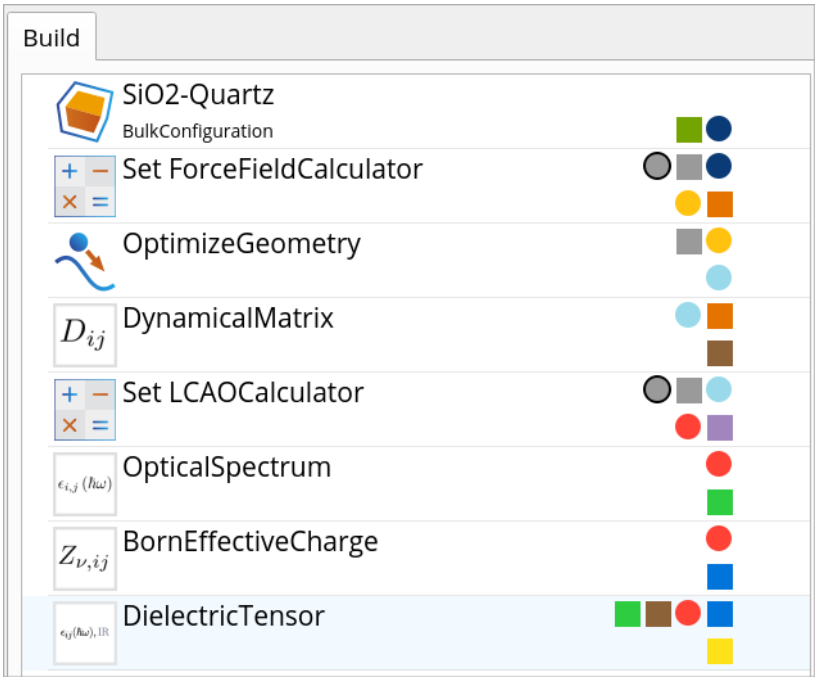
2. Go to the *Block Catalog* → *QuantumATK* tab → *Analysis* category on the right hand panel and drag-and-drop the *DielectricTensor* block to the middle *Workflow Area* → *Build* tab.

3. **Workflow Builder** automatically adds-in the *Optical Spectrum* block (for the electronic part of the dielectric tensor), and then *Dynamical Matrix* and *Born Effective Charge* blocks (for the ionic part of the dielectric tensor) to the workflow. You see the warning signs, because the calculators are not yet specified for these blocks (see the next steps).

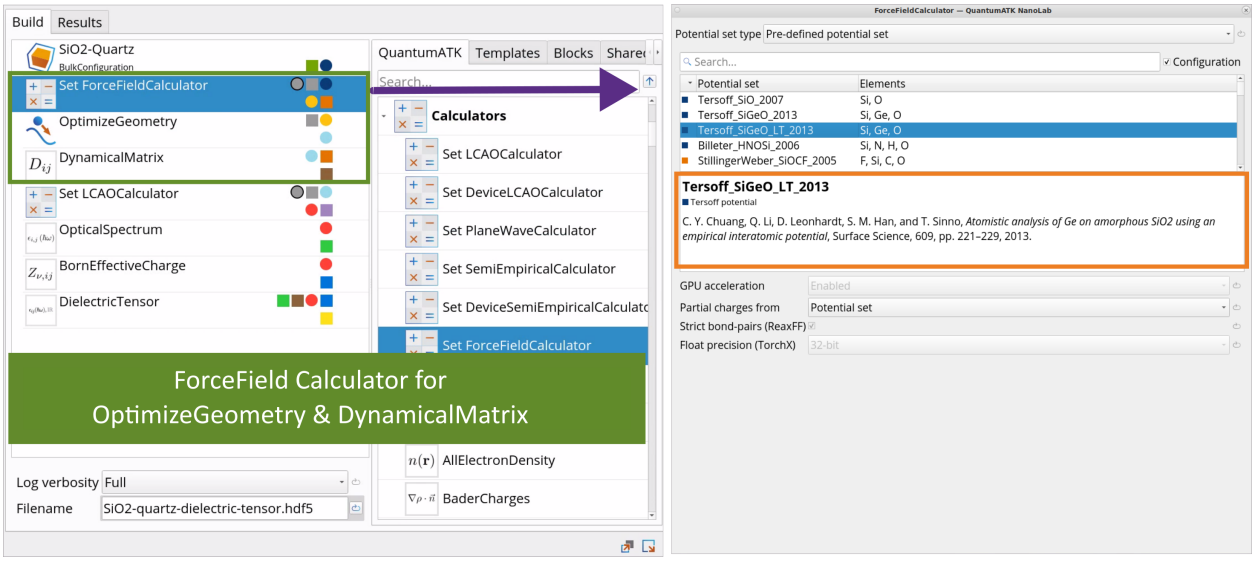


4. Go to the *Block Catalog* → *QuantumATK* tab → *Calculators* and *Optimization and Dynamics* categories on the right hand panel and drag-and-drop the *SetForceFieldCalculator* and *OptimizeGeometry* blocks, respectively, to the middle *Workflow Area* → *Build* tab, above the *DynamicalMatrix* block.

5. Go to the *Block Catalog* → *QuantumATK* tab → *Calculators* category and drag-and-drop the *SetLCAOCalculator* block to the middle *Workflow Area* → *Build* tab, below the *DynamicalMatrix* block, to define the DFT *LCAOCalculator* that will be used for *OpticalSpectrum* and *BornEffectiveCharge* simulations. The full workflow for optical property calculations is shown below.



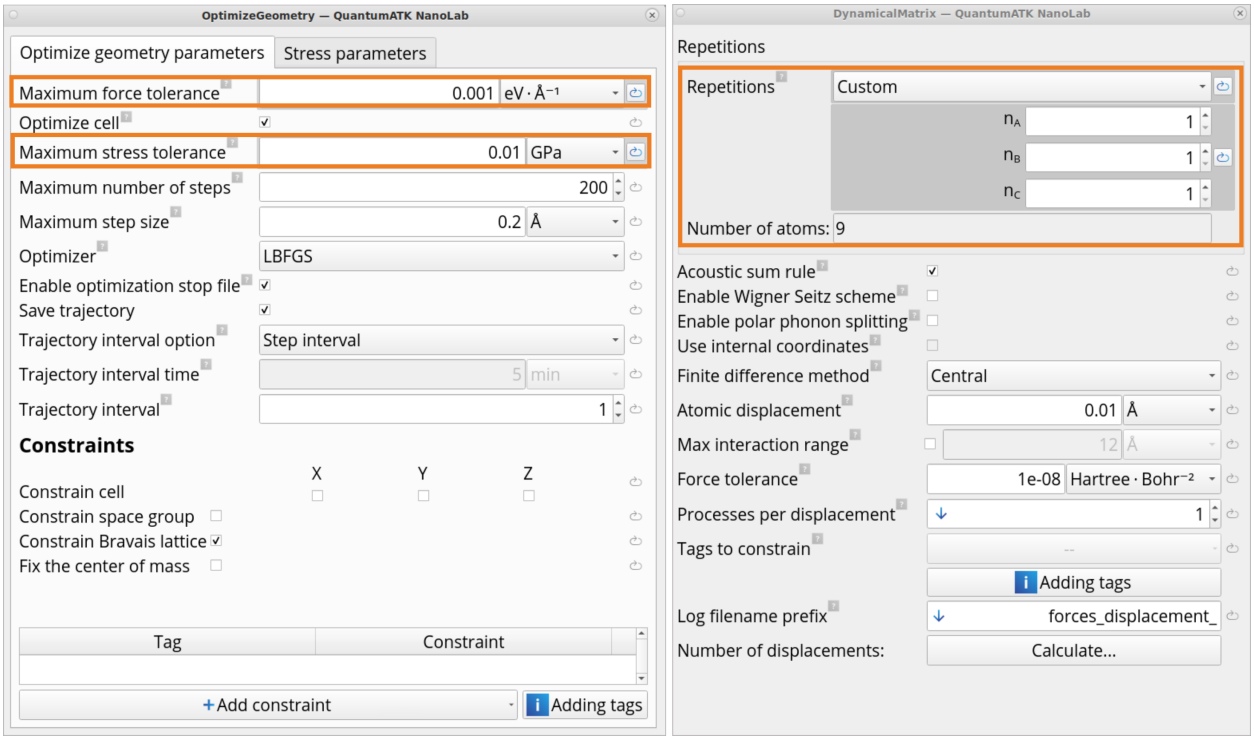
6. Double-click on the *SetForceFieldCalculator* block and choose a *Tersoff_SiGeO_LT_2013* Force Field for *OptimizeGeometry* and *DynamicalMatrix* calculations. It is important to use the same calculator for both geometry optimization and dynamical matrix simulations.



7. Double-click on the *OptimizeGeometry* block and set a tighter than default force (*0.001*) and stress (*0.01*) tolerances, as it is important to have a very well converged geometry for the subsequent dynamical matrix simulations.

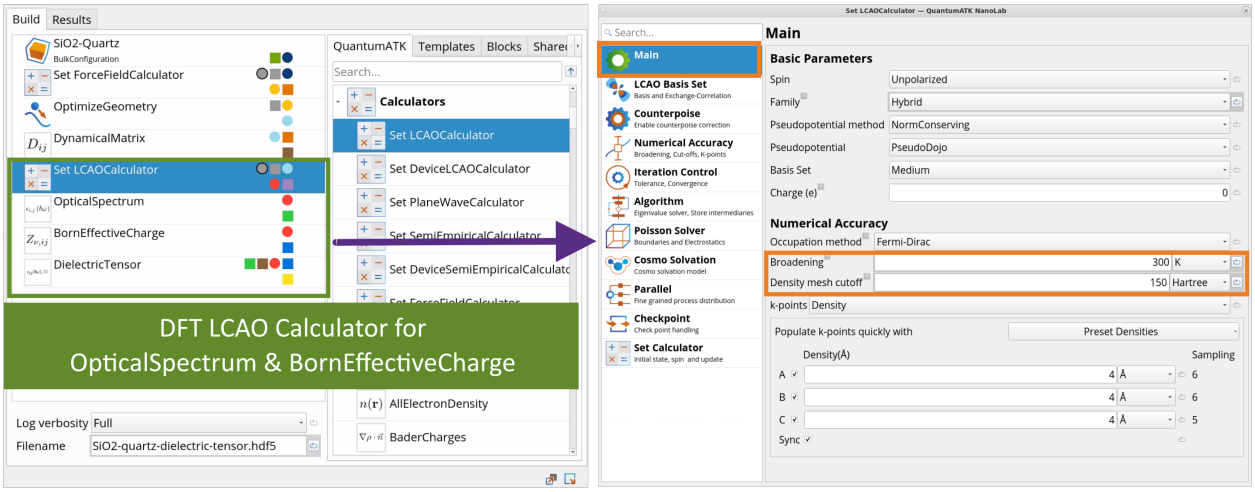
8. Double-click on the *DynamicalMatrix* block and change the *Repetitions* to *Custom*: *1, 1, 1*, as you need to include vibrations only at the point and do not need a repeated super cell. This makes the calculation computationally much

cheaper (and manageable with DFT if it is chosen instead of Force Fields) as now you need to calculate displacements for 9 atoms instead of 2205 atoms in the default 7 x 7 x 5 repetition.



9.Double-click on the *SetLCAOCalculator* block and make the following edits:

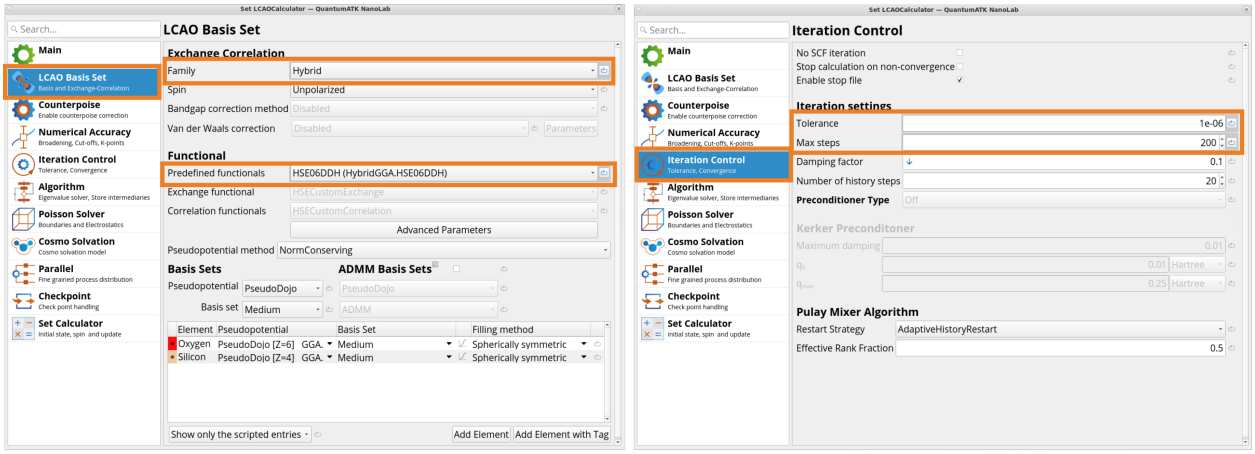
•Under the *Main* tab, increase the *Density Mesh Cutoff* from the default *125 Ha* to *150 Ha* as this is necessary for obtaining accurate and converged Born effective charges and thus optical properties, in particular the dielectric constants ionic part. Change the numerical accuracy parameter *Broadening* from *1000 K* to *300 K* (recommended for semiconductor materials).



•Under the *LCAO Basis Set* tab, change the *Exchange Correlation Family* from the default *GGA* to *Hybrid* and for the *Predefined functional* choose *HSE06DDH (Hybrid.GGA.HSEO6DDH)*. Here, we will use a dielectric dependent

hybrid functional HSE06-DDH (*DDHCustomExchangeCorrelation*) as it provides accurate electronic structure for SiO_2 (quartz), as shown in the Tutorial *Band Structure, Projected Density of States and Effective Mass Calculations*, which is important for optical properties.

- Under the *Iteration Control* tab, set a tighter than default SCF convergence tolerance (*1e-06* vs. *1e-04*), which is also crucial for calculating accurate and converged Born effective charges. In addition, increase the *Max steps* for SCF from the default *100* to *200* so the SCF cycle converges even if it needs more steps due to the tighter tolerance.



Tip:

1. *SetLCAOCalculator* block sets medium k-point sampling and medium basis set by default, typically providing good accuracy results with modest computational resources. It is recommended to check the convergence of your results with these parameters.

2. *SetLCAOCalculator* block uses a default *Fermi-Dirac Occupation Method* with 1000 K *Broadening*, which generally works reasonably well across various systems. Another setting may be more appropriate for your system, and you can adjust these settings according to the recommendations in *Occupation Methods* for semiconductor, insulator, metal, and molecule systems.

10. In the *OpticalSpectrum* block, change the following settings to calculate *OpticalSpectrum* accurately:

- Change the default number of *Bands below/above Fermi level* to arbitrary *1000* (as the default *4* is too few for SiO_2 (quartz)).

- For the *Transition matrix operator* method, select the *VelocityOperator* (which is also the default method for the DFT-LCAO calculator with Norm Conserving PPs), as it gives a more accurate optical spectrum compared to the *MomentumOperator* method.

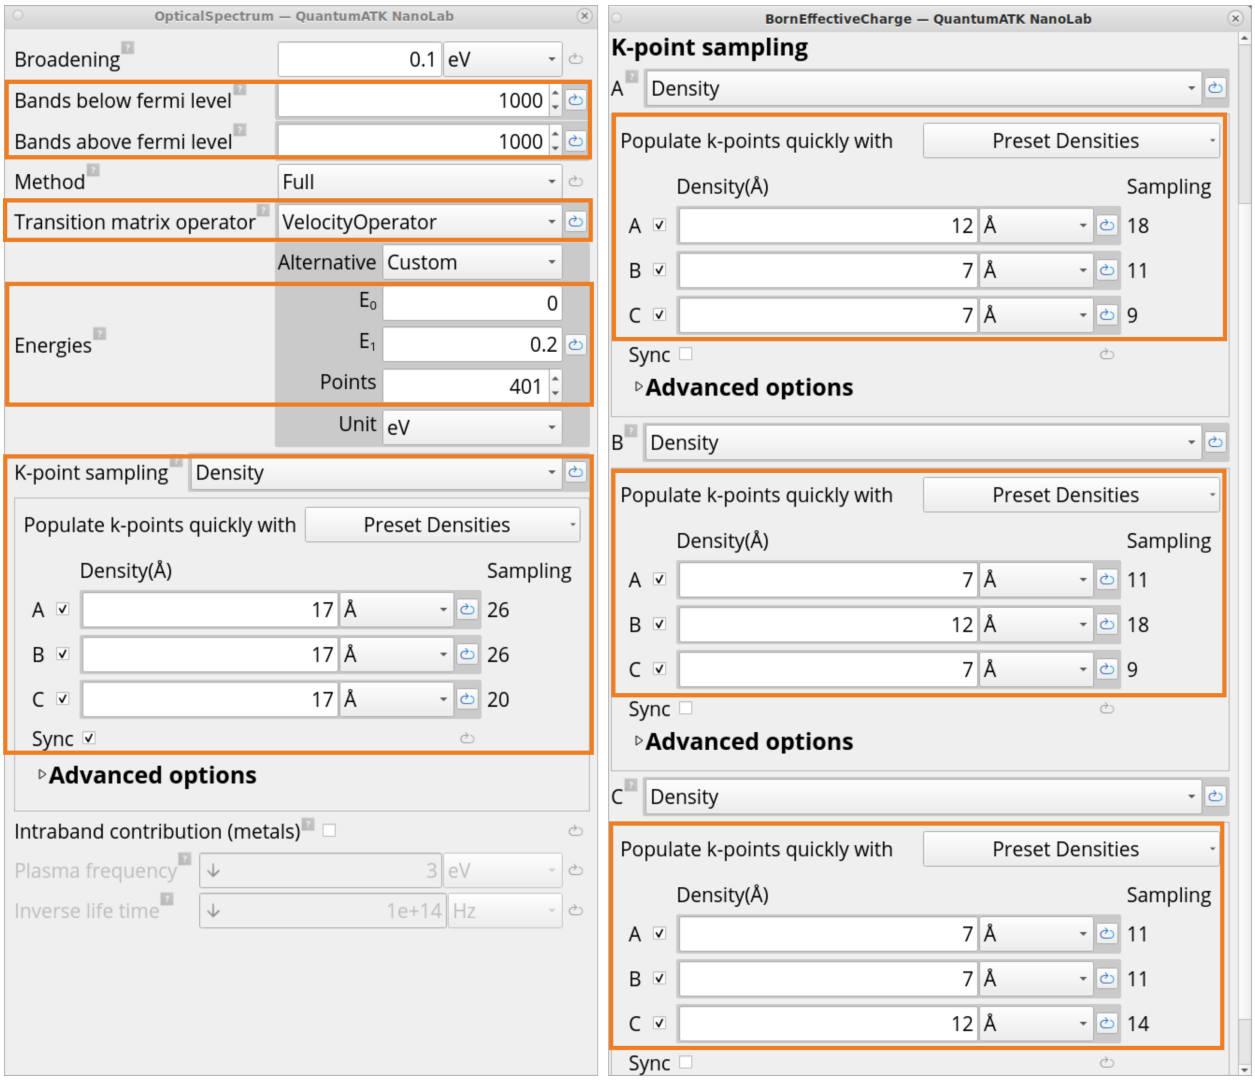
- Select the energy range *0 – 0.2 eV* and change to *401* points for finer sampling. This will ensure a high-resolution IR spectrum, which typically features many narrow and closely spaced peaks corresponding to different vibrational modes.

- For the *k-point sampling*, choose *Density* and click on *Preset Densities* to increase the k-point density from *medium* to *higher*, i.e., *17Å x 17Å x 17Å*. It is important to have a large k-point sampling for properties that depend on the conduction band minimum, for example, dielectric constant and electron transport properties.

Tip:

- When calculating absorption spectra, it is recommended to select a wider energy range and use default (more coarse) sampling. This is because an absorption spectrum typically covers a broader range of wavelengths and can include various types of transitions, often resulting in broader peaks compared to those in IR spectra.

11. In the *BornEffectiveCharge* block, for the *k-point sampling*, choose *Density* and click on *Preset Densities* to increase the k-point density from *medium* to *high*, i.e., A: *12Å x 7Å x 7Å*, B: *7Å x 12Å x 7Å*, C: *7Å x 7Å x 12Å*.



12. The *DielectricTensor* block has no adjustable paramaters. It takes in calculated *DynamicalMatrix*, *OpticalSpectrum* and *BornEffectiveCharges* in previous steps to compute the *DielectricTensor*.

13. Change the *Workflow* name in the the *Workflow Stash* and *Filename* as needed (e.g., `SiO2-quartz-dielectric-tensor.hdf5`).

14. Click on the *Send content to other tools* button and choose *Jobs as a script* to send the workflow to the **Jobs** tool to submit this job on a local machine or a remote cluster.

15. This also generates a Python script `SiO2-quartz-dielectric-tensor.py`, based on this workflow. It can be opened and edited with the **Editor** tool and then sent to the **Jobs** tool.

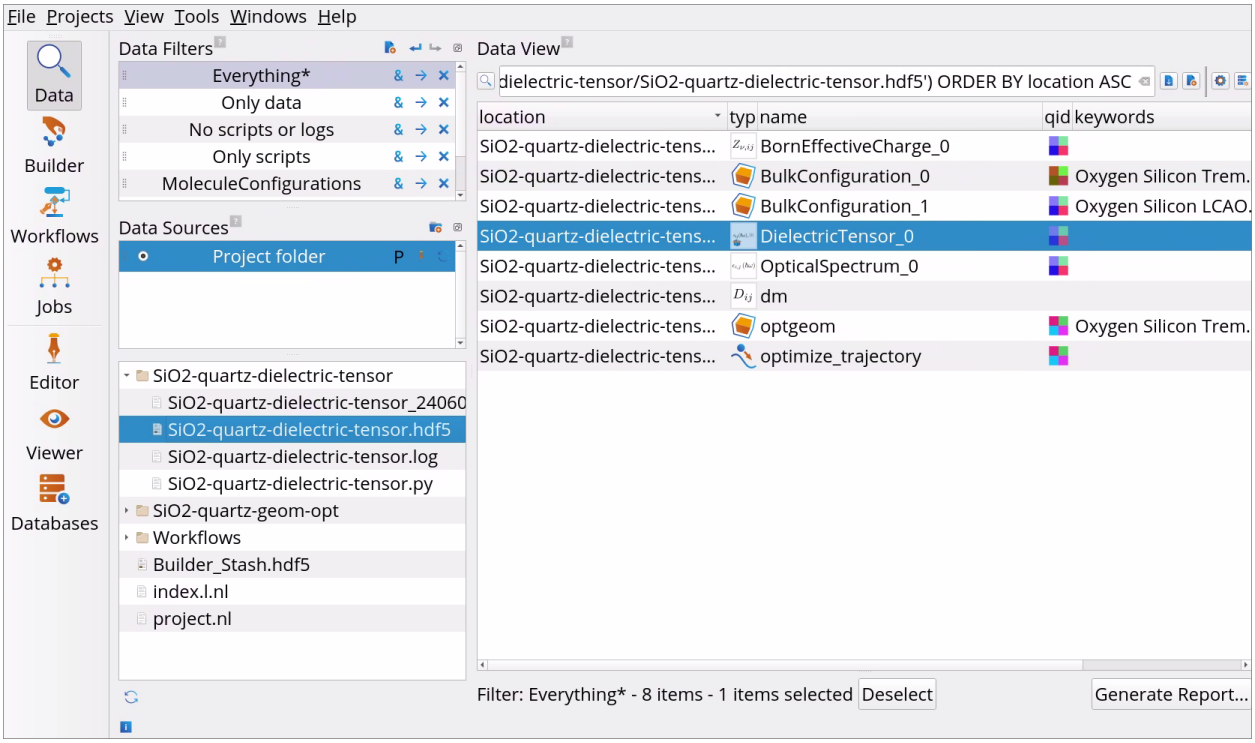
Note:

1. *DynamicalMatrix*, the second derivative of the energy, corresponding to the first derivative of the forces, is an object used to calculate many properties related to dynamics of the material lattice, e.g., *DielectricTensor*, *PhononBandstructure*, *Mobility*, *RamanSpectrum*, *DeformationPotential*.
2. The *BornEffectiveCharge* tensor is defined as the derivative of the polarization with respect to the atomic coordinate and is used for *DielectricTensor* calculation.

Analyzing Results

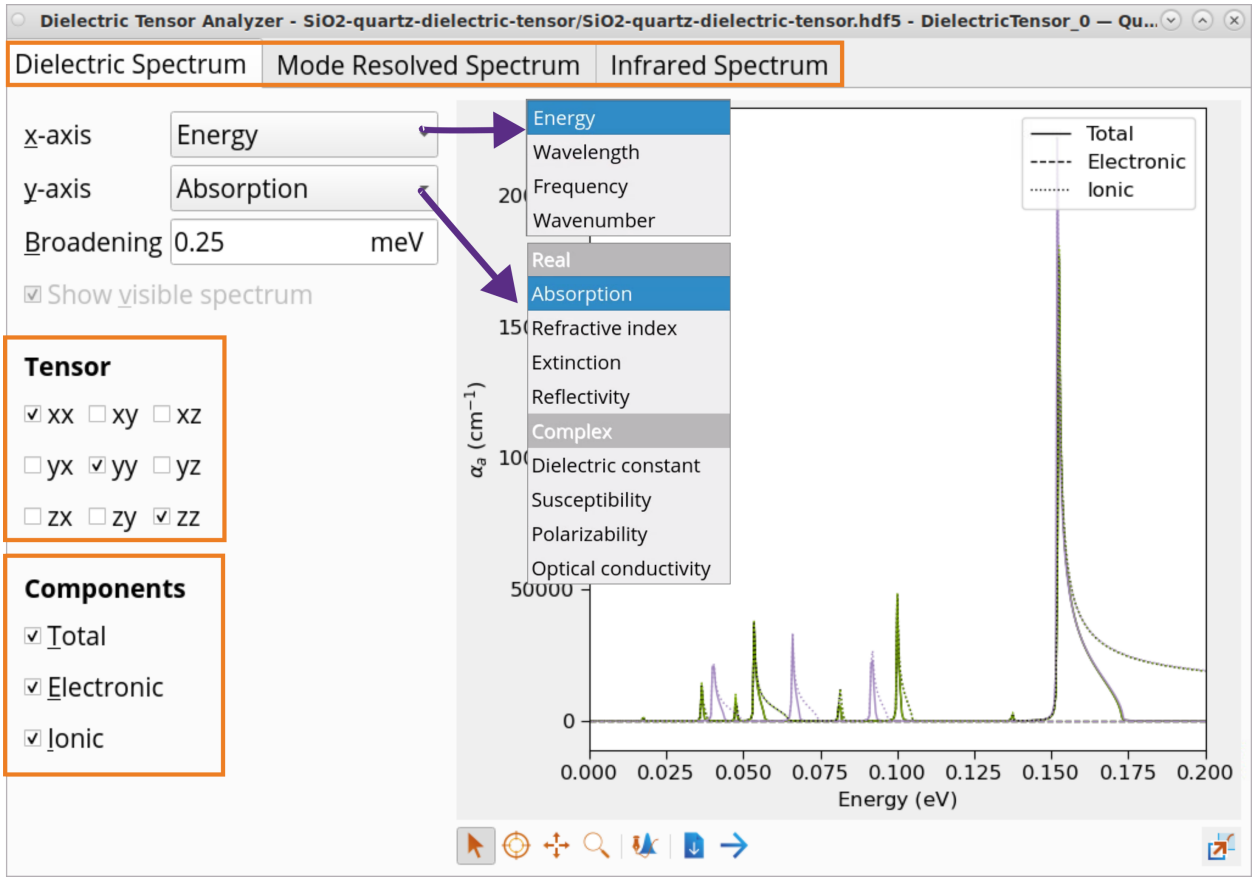
Once the calculation has finished, we are ready to analyze the results.

1. Go to the **Data View** tool.
2. In the *Data Sources*, select the file `SiO2-quartz-dielectric-tensor.hdf5` and then double-click on the *DielectricTensor_0* object in the *Data View* window to open it with the *Dielectric Tensor Analyzer*.



Tip:

1. The *Dielectric Tensor Analyzer* can plot a range of optical properties. In the *Dielectric Spectrum* panel, click on *y-axis* to see the list: *Absorption*, *Refractive index*, *Extinction*, *Reflectivity*, *Dielectric constant*, *Suscpetibility*, *Polarizability*, *Optical conductivity* as a function of *Energy*, *Wavelength*, *Frequency* or *Wavenumber* (x-axis).
2. Plot *Mode resolved spectrum* and *Infrared Spectrum*.
3. Plot differet tensor components (xx, yy, zz) and total, electronic and ionic contributions to the optical properties.



3.To plot and analyze the dielectric constant:

•Select the *Dielectric constant* (y-axis) as a function of *Energy* (x-axis).

•Click on the x axis and then on the *Plot editor* button.

•Adjust the *Lower limit* and *Upper limit* to x and y axes to zoom into the $Re[]$ at E = 0 eV to determine the static dielectric constant, $_0$. For the x axis, select a range from 0 to 2.5e-05, and for the y axis, select a range from 0 to 10.

•Use the *Inspect* tool to examine dielectric constant values for SiO_2 (quartz):

–total: $_{0_{xx/yy}}$ = 3.72 and $_{0_{zz}}$ = 3.92

–electronic contribution: $_{el_{xx/yy/zz}}$ = 2.11

–ionic contribution: $_{ion_{xx/yy}}$ = 1.61 and $_{ion_{zz}}$ = 1.81

Note:

1.Ionic contribution to the SiO_2 (quartz) static dielectric constant is significant and cannot be neglected.

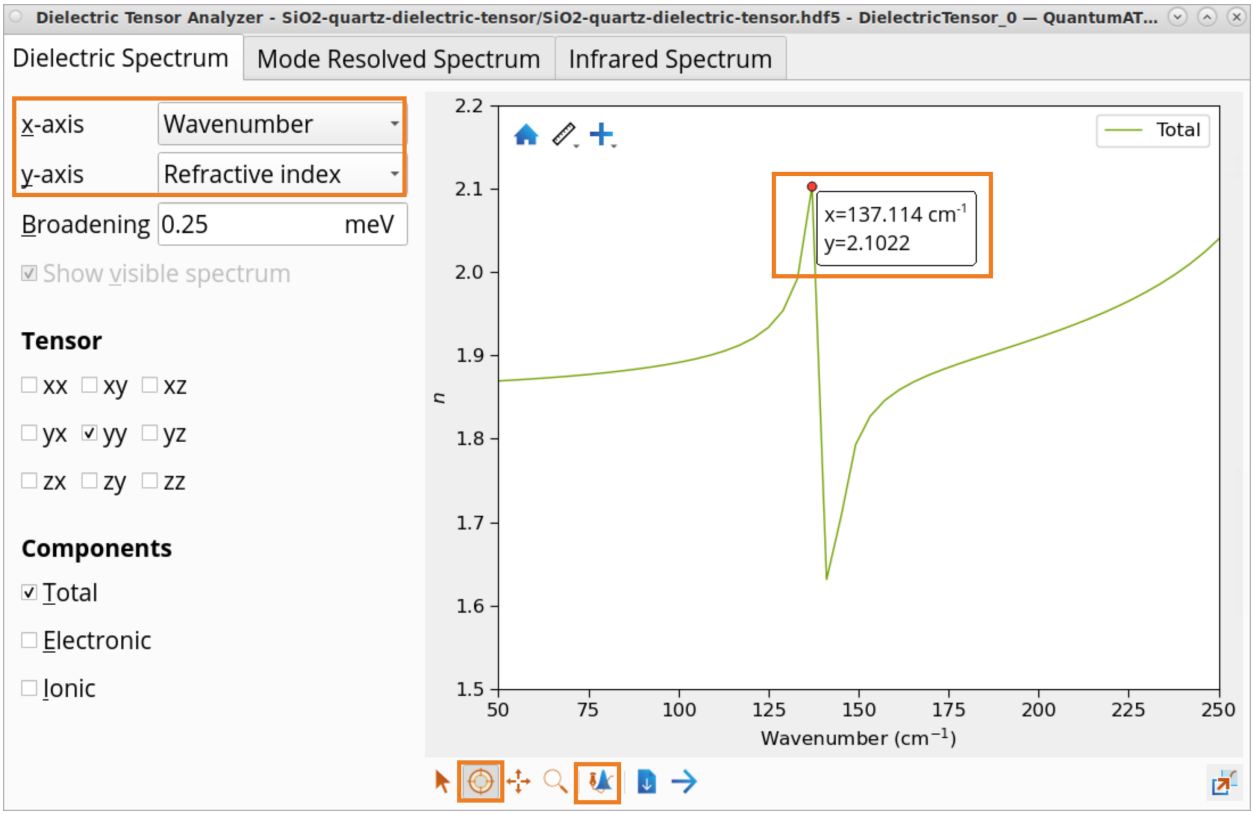
2.The calculated dielectric constant, $_0$, and symmetry break are in a reasonably good agreement with the experimental results at a room temperature: $_0$ = 4.43 and $_0$ = 4.64, in the directions perpendicular to and along the trigonal axis, respectively[1].

4.To plot and analyze refractive index:

•Select the *Refractive index* (y-axis) as a function of *Wavenumber* (x-axis).

•Click on the *Plot editor* to zoom in on the refractive index n at around 50-250 cm^{-1}.

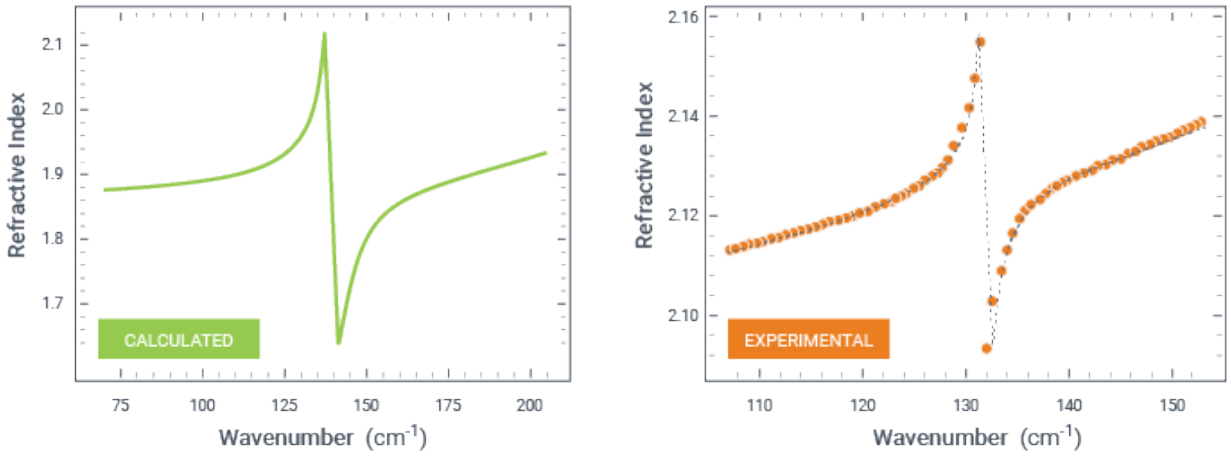
•Use the *Inspect* tool to examine refractive index values at the peaks: e.g., $n_{yy}(137cm^{-1})$ = 2.10 and $n_{yy}(141cm^{-1})$ = 1.63.



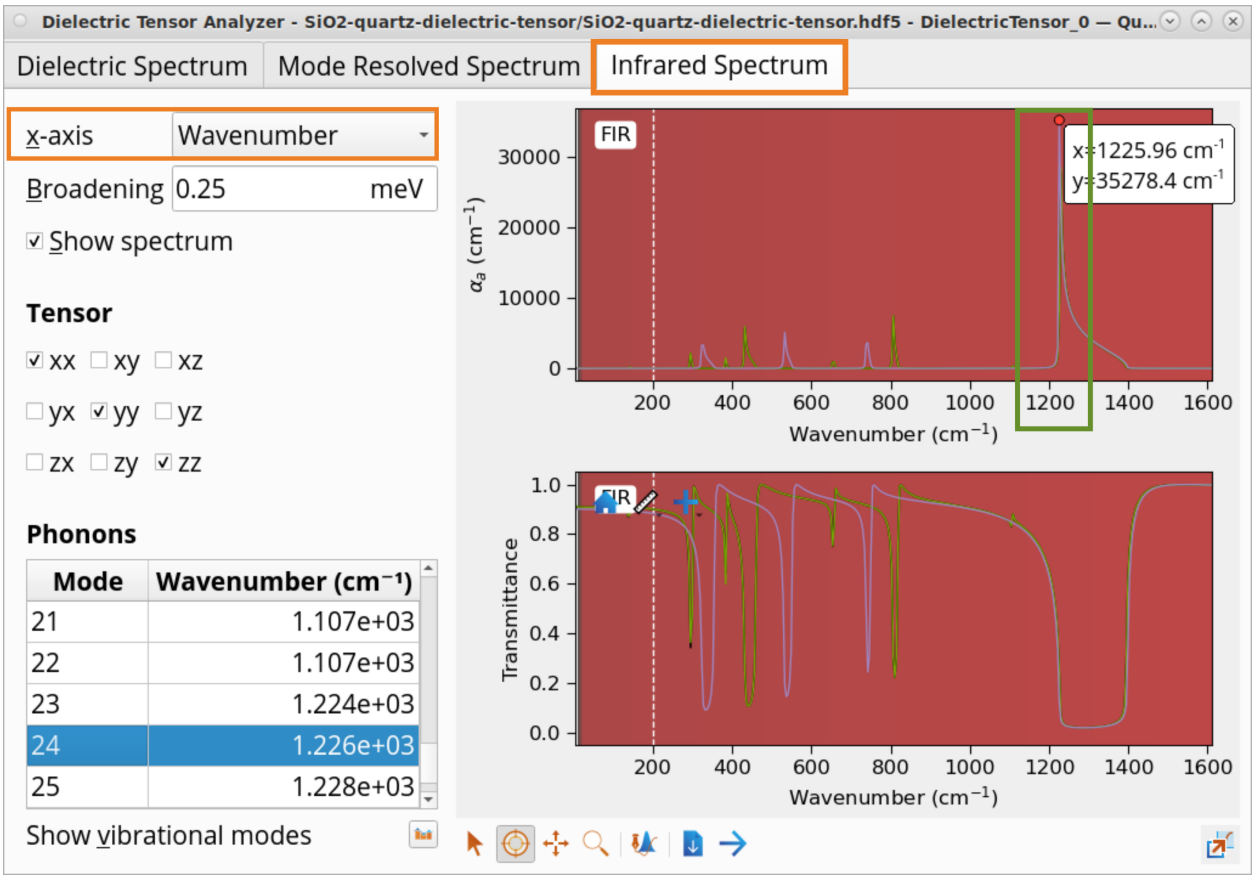
Note: The simulated refractive index at 0 K is in a qualitative agreement with the experimental results at 10 K[2] as shown in the Figure below.

[1] F.ăGervais and B.ăPiriou. Temperature Dependence of Transverse and Longitudinal Optic Modes in the and Phases of Quartz. *Physical Review B*, 11(10):3944–3950, 1975. doi:10.1103/PhysRevB.11.3944.

[2] C.ăL. Davies, J.ăB. Patel, C.ăQ. Xia, L.ăM. Herz, and M.ăB. Johnston. Temperature-Dependent Refractive Index of Quartz at Terahertz Frequencies. *Journal of Infrared, Millimeter, and Terahertz Waves*, 39:1236–1248, 2018. doi:10.1007/s10762-018-0538-7.



5.Click on the *Infrared Spectrum* tab to examine the calculated IR spectrum.



•The highest peak in the IR spectrum at ~1226 cm^{-1} corresponds well to the experimentally measured IR peak at ~1100-1200 cm^{-1} for powder SiO_2 (quartz). See https://webbook.nist.gov/cgi/cbook.cgi?ID=C14808607&Contrib=IARPA-IR-S&Type=IR-SPEC&Index=0#IR-SPEC).

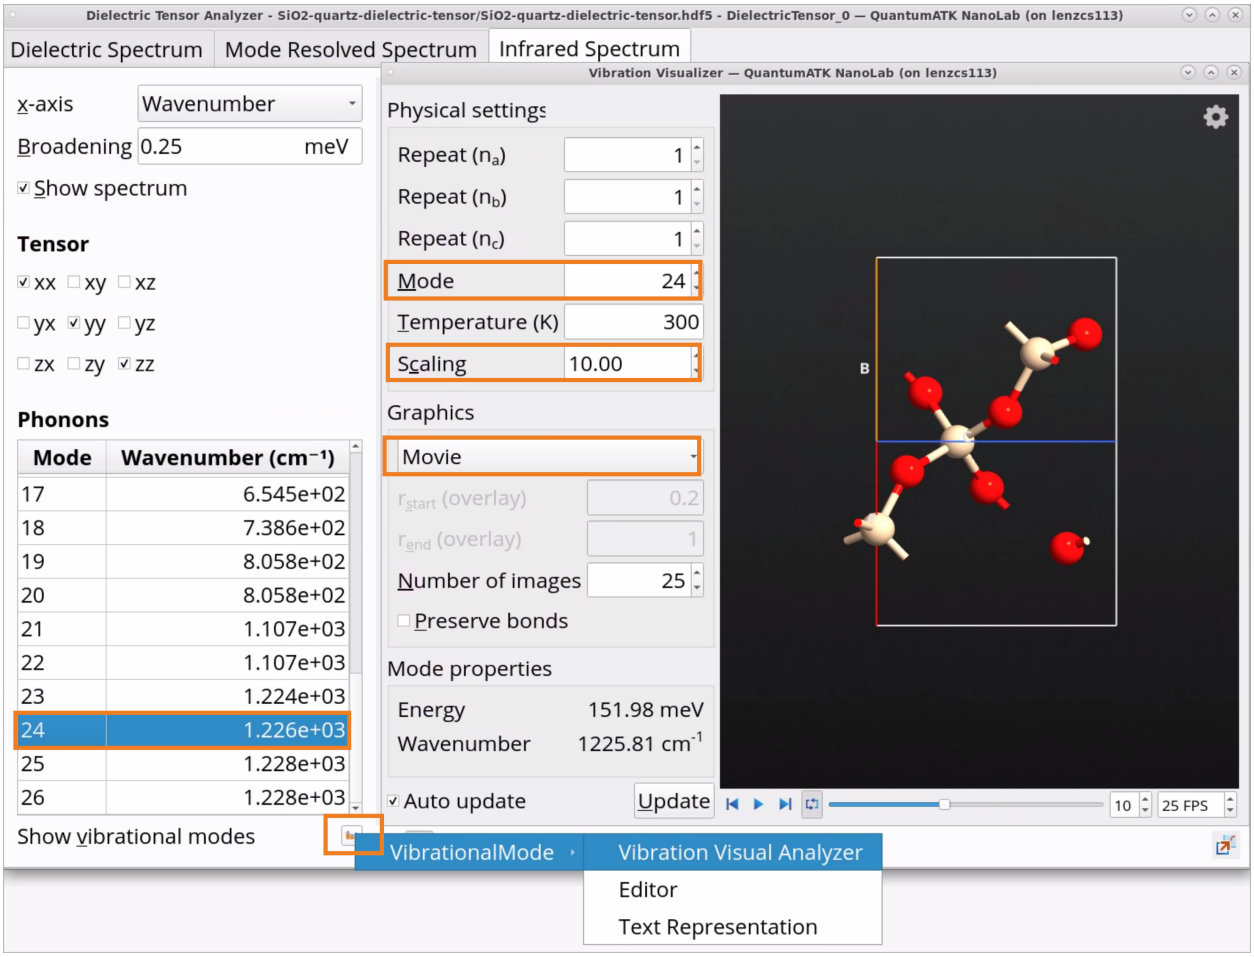
Note: Due to the temperature effects and random crystal orientations in the powder, the experimentally measured IR peak is broader than the calculated one for the single crystal direction at 0K.

6.Click on the *Show vibrational modes* icon and choose *Vibration Visual Analyzer* to visualize chosen vibrational modes.

•In the *Vibration Analyzer*, choose a vibrational mode, e.g., *24*.

•Set *Scaling* to *10*.

•Under *Graphics*, choose *Movie* to see the actual vibration for mode 24 at 1226 cm^{-1} corresponding to the highest peak in the IR spectrum.



Outlook

1. If you wish to explore optical properties further, QuantumATK has additional optical analyses like *RamanSpectrum*, *SecondHarmonicsGenerationSusceptibility*, and *ElectroOpticalTensor*.
2. For polar materials, it is possible to apply polar-phonon (LO-TO) splitting to the vibrational modes beyond the workflow presented here. This effect can be included by adding the optical properties and Born effective charge to the dynamical matrix analysis, and doing so will increase the LO mode vibrational frequency (observable in Raman spectroscopy for instance).

1.2.4 Molecular Dynamics Simulations for Generating Amorphous Structures

Version: X-2025.06

In this tutorial, you will learn how to use QuantumATK NanoLab GUI to

- Prepare an initial structure for amorphous SiO_2 using *Amorphous Prebuilder* based on *Packmol*.
- Set-up Molecular Dynamics (MD) melt-quench and subsequent MD equilibration simulations to generate a final equilibrated amorphous SiO_2 structure using classical Force Fields.
- Analyze obtained results, such as radial and angular distribution functions, RDF and ADF, to verify the quality of the generated amorphous SiO_2 structure.
- Set-up a geometry optimization simulation for amorphous SiO_2 in order to obtain a 0 K structure, representing the most stable configuration. This optimized structure can serve as a reference state for further calculations of electronic properties, phonons and other thermodynamic properties.

All the workflow, input and output files can be found in the **Example Project - X-2025.06 → Am-SiO2-MD folder.**

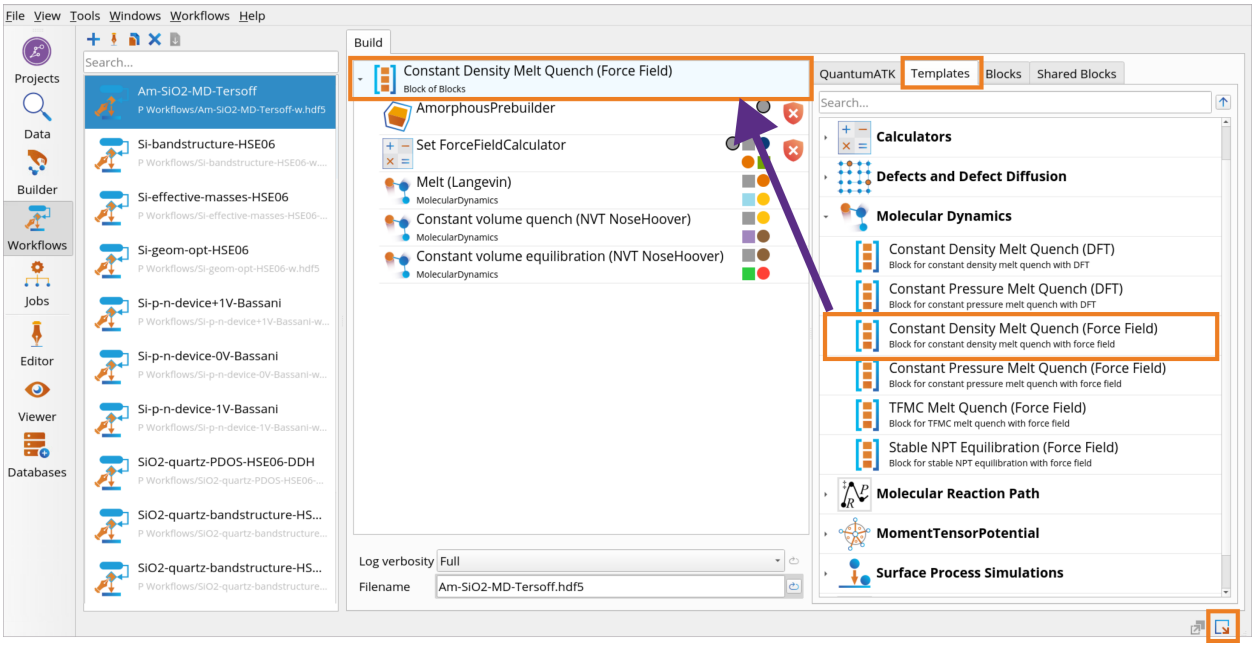
Prerequisites

- Video Introduction to QuantumATK NanoLab GUI
- Video tutorial on the Workflow Builder tool
- Video tutorial on the Job tool
- Tutorial *Geometry Optimization*

Setting-Up Molecular Dynamics Simulations

To create a workflow for generating an initial amorphous structure, performing *MolecularDynamics* melt-quench and equilibration simulations in the **Workflow Builder**, follow the step-by-step protocol described below. Here, we will use a classical Force Field *Tersoff_SiO_2007*.

1. Go to the *Block Catalog → Templates* tab → *Molecular Dynamics* category on the right hand panel and drag-and-drop the *Constant Density Melt Quench (Force Field)* template to the middle *Workflow Area → Build* tab. You see the warning signs, because the Force Field calculator and the initial amorphous structure are not yet specified for these blocks (see the next steps).



2.Click on the *AmorphousPrebuilder* block to set up a generation of an initial amorphous structure from selected elements on-the-fly. It will use *Packmol* to randomly pack atoms into a bulk configuration given a list of elements stoichiometry and material density.

•Click on *Add row* button.

•In the opened *Periodic Table* window, click on *Si* to add it to the *AmorphousPrebuilder*.

•Repeat the steps to add *O* to the *AmorphousPrebuilder*.

•Set *Stoichiometry 1* to *Si* and *2* to *O*.

•Set *Size multiplier* to *100* to generate an initial amorphous cell with 100 Si and 200 O atoms.

•For *Density option*, choose *By atomic mass* and specify *2.2* gcm^{-3} *Mass density* for the amorphous SiO_2 structure. This will automatically determine the *Lattice constant* of *16.55* $\AA$.

•The generated initial amorphous structure will automatically be passed into the 2nd part of the simulation workflow, which includes melt-quench and equilibration MD simulations.

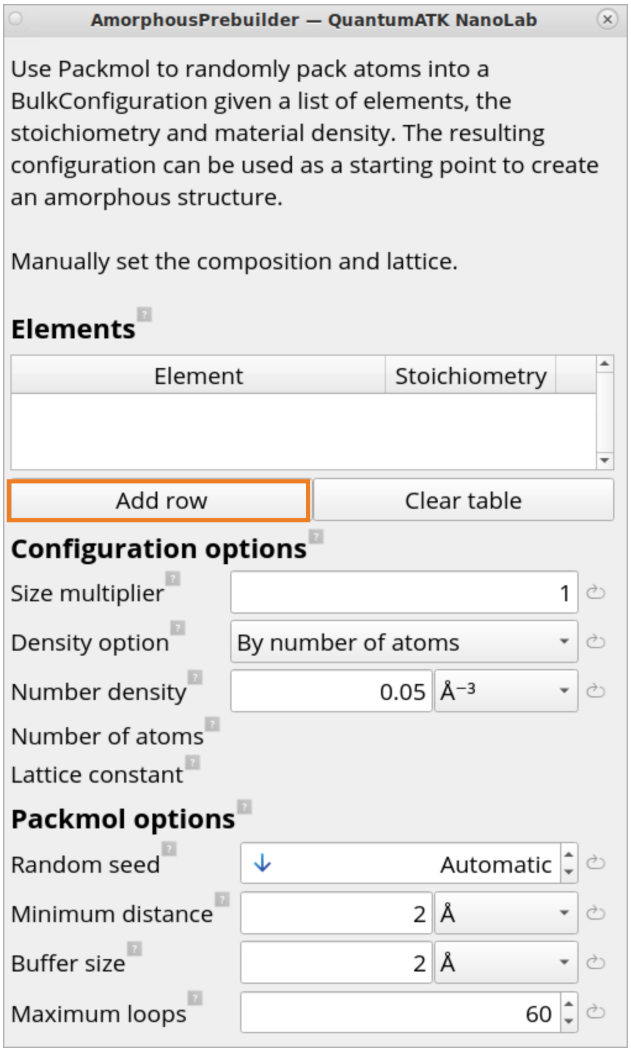
3.Click on the *Set ForceFieldCalculator* block and choose *Tersoff_SiO_2007* Classical Force Field.

Tip:

•For systems for which there is no conventional Force Field available or the quality is not good, we recommend to use Machine Learned Force Fields (ML FFs). Consider:

1.Using pre-trained custom Moment Tensor Potentials (MTPs) for a specific target system and application or pre-trained universal MACE or M3GNet Neural Network (NN) potentials. The list of available ML FFs can be found in the *SetMachineLearnedForceFieldCalculator* block.

2.Training and employing custom Moment Tensor Potentials (MTPs) for a specific target system and application. Learn about the MTP training here: https://docs.quantumatk.com/tutorials/mtp-training-c-am-TiSi/mtp-training-c-am-TiSi.html.



AmorphousPrebuilder — QuantumATK NanoLab
Use Packmol to randomly pack atoms into a BulkConfiguration given a list of elements, the stoichiometry and material density. The resulting configuration can be used as a starting point to create an amorphous structure.

3. Training new or finetuning existing MACE NN potentials. Learn about training MACE potentials here: https://docs.quantumatk.com/tutorials/mace-training-c-am-TiSi/mace-training-c-am-TiSi.html.

4. Click on the *Melt (Langevin)* block, which contains settings for the Langevin type MD simulations at high (i.e., *5000 K*) temperature to melt the structure. In this example, you will run *30 000* MD steps with a time step of *1 fs*, resulting in a total MD melt simulation time of 30 ps. Use the settings set by the template.

5. Click on the *Constant volume quench (NVT NoseHoover)* block, which contains settings for the NVT Nose Hoover type MD simulations to quench the structure from *5000 K* to *600 K* using *-88* Kps^{-1} *Heating rate* within 50 ps (*50 000* MD steps with a time step of *1 fs*). Use the settings set by the template.

6. Click on the *Constant volume equilibration (NVT NoseHoover)* block, which defines settings for the NVT Nose Hoover type MD equilibration simulations. In this example, you will equilibrate the system for 100 ps at *600 K* in order to reach a stable state where systems temperature and energy are stable, thus allowing us to obtain meaningful RDF and ADF values.

Tip:

1. In the *Molecular Dynamics* block, one can choose between various Molecular Dynamics methods: *NVE Velocity Verlet*, *NVT Berendsen*, *NVT Bussi Donadio Parrinello*, *NVT Nose Hoover*, *Langevin*, *NPT Berendsen*, *NPT Bernetti Bussi*, *NPT Martyna Tobias Klein*, *Non Equilibrium Momentum Echange* and *Stress Strain*. Read these technical notes on *Molecular Dynamics* to learn more.

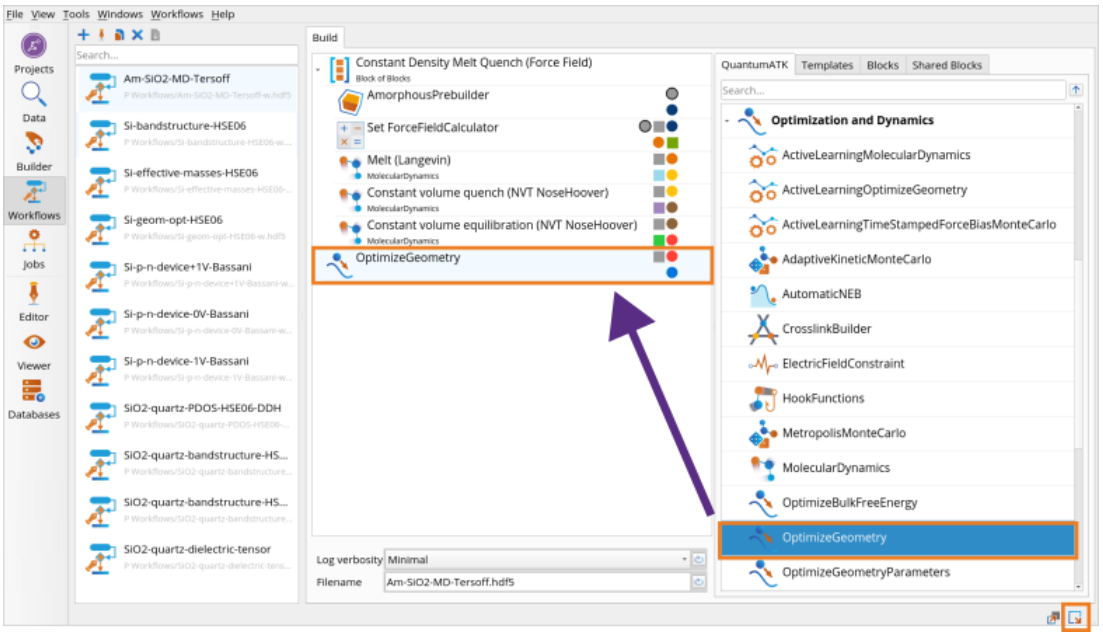
2.In the *Molecular Dynamics* block, it is possible to edit a variety of MD parameters, such as a number of steps, time step, reservoir temperature, heating rate, target temperature, friction, velocity initialization type and temperature.

7.Go to the *Block Catalog* → *QuantumATK* tab → *Optimization and Dynamics* category on the right hand panel and drag-and-drop the *OptimizeGeometry* block to the middle *Workflow Area* → *Build* tab.



8.Click on the *OptimizeGeometry* block to set the *OptimizeGeometry* to obtain the 0K structure of amorphous SiO_2 using the same *Tersoff_SiO_2007* Classical Force Field.

- Set a tighter than default *Force tolerance* (*0.001* eV^{-1}).
- Increase *Maximum number of steps* to *2000*, as many more optimization steps are needed when performing a geometry optimization with classical Force Fields.
- Constrain cell in *x*, *y* and *z* directions and un-click *Constrain Bravais lattice*.

Note:

- Note, that when calculating electronic properties, it is important to perform a prior geometry optimization with DFT to get accurate electronic properties. In such a case, drag-and-drop the *SetLCAOCalculator* and additional *OptimizeGeometry* blocks to the workflow to set up the simulation.

9.Change the *Workflow* name in the *Workflow Stash* and *Filename* as needed (e.g., `Am-SiO2-MD-Tersoff.hdf5`).

10.Click on the *Send content to other tools* button and choose *Jobs as a script* to send the workflow to the **Jobs** tool in order to submit this job on a local machine or a remote cluster. It is recommended to use threading for Force Field simulations.

11.This also generates a Python script `Am-SiO2-MD-Tersoff.py`, based on this workflow. It can be opened and edited with the **Editor** tool and then sent to the **Jobs** tool.

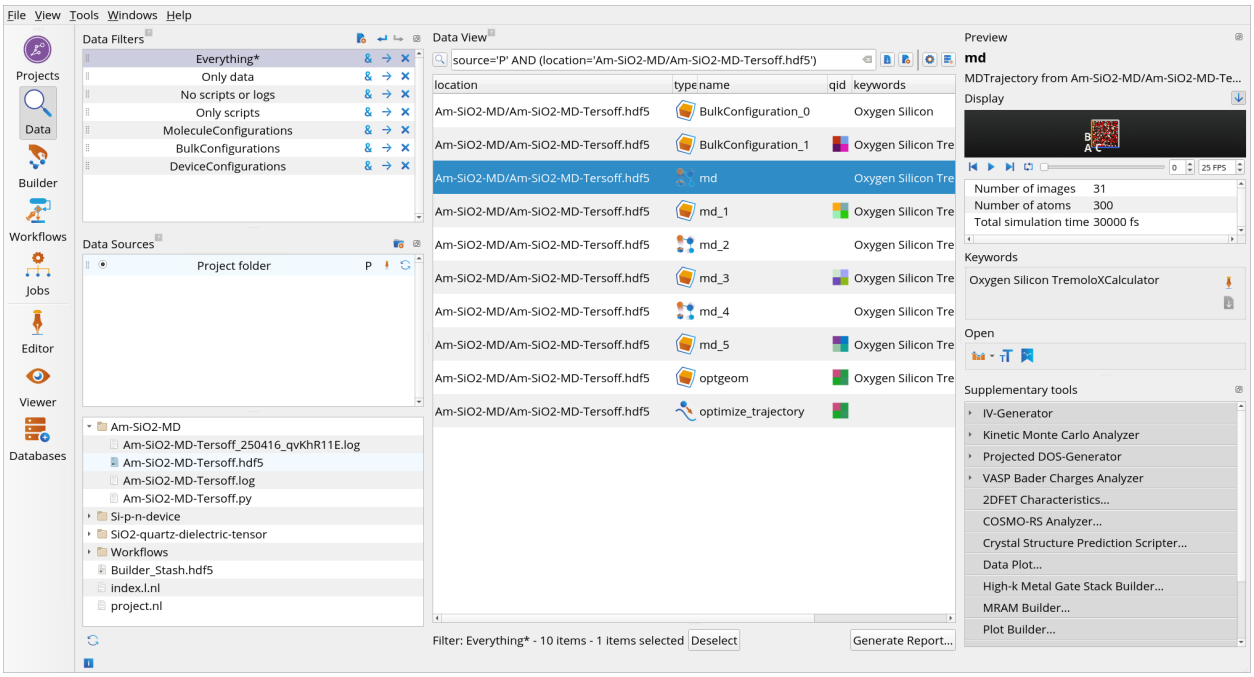
Analyzing Molecular Dynamics Simulations

Once the calculation has finished, we are ready to analyze the results.

1. Go to the **Data View** tool.

2. In the *Data Sources*, select the file `Am-SiO2-MD-Tersoff.hdf5` and then in the *Data View* window double-click on the *md* object from the melt Langevin MD to open it with the *Movie Tool*.



3. Use the *Movie Tool* to investigate the temperature as well as the kinetic, potential and total energies, pressure, density and volume of the system as a function of simulation time, 30 ps in this case. You will observe the temperature oscillating around the set temperature (5000 K).

4. Simultaneously, an animation of the motion of the atoms is displayed. Right-click on the structure in the *Movie tool* to check the box *Show bonds* and use the *Play* button to see the evolution of structure throughout the MD simulation.

5. Come back to the *Data View* window and double-click on the *md_2* object from the quench NVT Nose Hoover MD to open it with the *Movie Tool*.

6. Use the *Movie Tool* to investigate the temperature as well as the kinetic, potential and total energies, pressure, density and volume of the system as a function of simulation time, 50 ps in this case. The temperature is gradually reduced from 5000 K to ~ 600 K as set in the workflow.

7. Come back to the *Data View* window and double-click on the *md_4* object from the NVT Nose Hoover type MD equilibration simulations to open it with the *Movie Tool*. The temperature fluctuates around the set value of 600 K, and the energies also fluctuate around their equilibrium values, indicating that the system is stable. This allows us to obtain meaningful RDF and ADF values from this trajectory.

8. Come back to the *Data View* window and right-click on the *md_4* object from the NVT Nose Hoover type MD equilibration simulations to open it with the *Molecular Dynamics Analyzer* to plot calculated RDF and ADF for amorphous SiO_2.

9. In order to plot RDF:

- Click on *Analysis type* selection box and choose to plot *Radial Distribution*.
- Click on *Selection 1* and *Selection 2* boxes to choose for which element combinations to plot RDF.
- Click *Plot* to generate RDF plots for Si-O, Si-Si and O-O one-by-one.
- Click on the *Inspect* tool to examine the exact RDF values.

Note: Calculated radius values for the 1st coordination sphere obtained from the RDF plot: r_{Si-O} = 1.675 Å, r_{Si-Si} = 3.175 Å and r_{O-O} = 2.675 Å are in a reasonably good agreement with experimental values for fused silica at 300 K: $r_{Si-O_{exp}}$ = 1.62 Å, $r_{Si-Si_{exp}}$ = 3.12 Å and $r_{O-O_{exp}}$ = 2.65 Å[1].

---

10. In order to plot ADF:

- Click on *Analysis type* selection box and choose to plot *Angular Distribution*.
- Click on *Center*, *Neighbor 1* and *Neighbor 2* boxes to choose for which element combinations to plot ADF.
- Click *Plot* to generate ADF plots for Si-O-Si and O-Si-O one-by-one.

Note: Calculated angle values for all the coordination spheres obtained from the ADF plot: θ_{O-Si-O} = 110.5ř and $\theta_{Si-O-Si}$ = 144.5ř are also in a reasonably good agreement with experimental values for fused silica at 300 K: $\theta_{O-Si-O_{exp}}$ = 109.7ř and $\theta_{Si-O-Si_{exp}}$ = 152.0ř[2].

---

1.2.5 NEGF Simulations of Electron Transport in Devices

Version: X-2025.06

In this tutorial, you will learn how to use QuantumATK NanoLab GUI to

- Set-up and analyze electron transport simulations in the Si p-n junction device using the Non-equilibrium Greens function (NEGF) method with the Semi-Empirical Tight-Binding model.
- Analyze results, such as Hartree difference potential, projected local density of states (PLDOS), transmission spectrum and spectral current.

All the workflow, input and output files can be found in the **Example Project - X-2025.06 → Si-p-n-device folder.**

Prerequisites

•Video Introduction to QuantumATK NanoLab GUI

•Video tutorial on the Workflow Builder tool

•Video tutorial on the Job tool

•Tutorial *Geometry Optimization*

•Tutorial *Band Structure, Projected Density of States and Effective Mass Calculations*

•Manual *NEGF: Device Calculators*

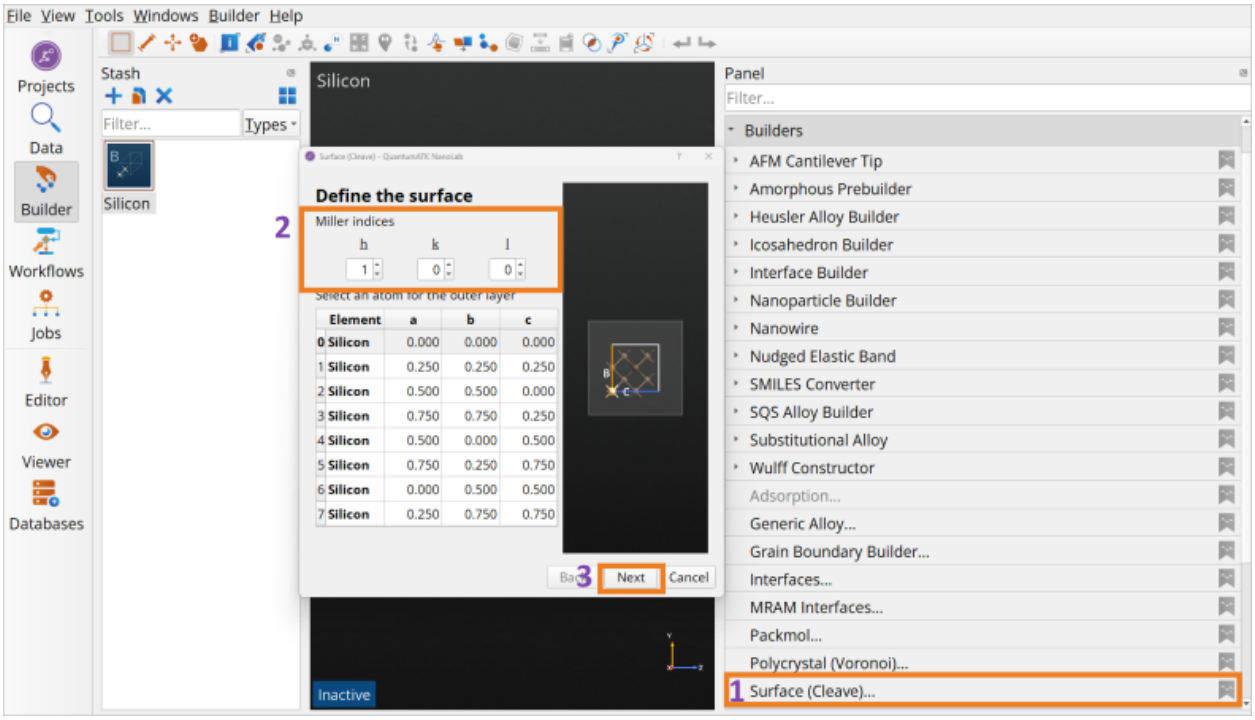
Building Si p-n Junction Device

1.Follow the tutorial *Geometry Optimization* to import the structure of bulk Silicon (alpha) from NanoLabs *Crystal Database* to the **Builder**.

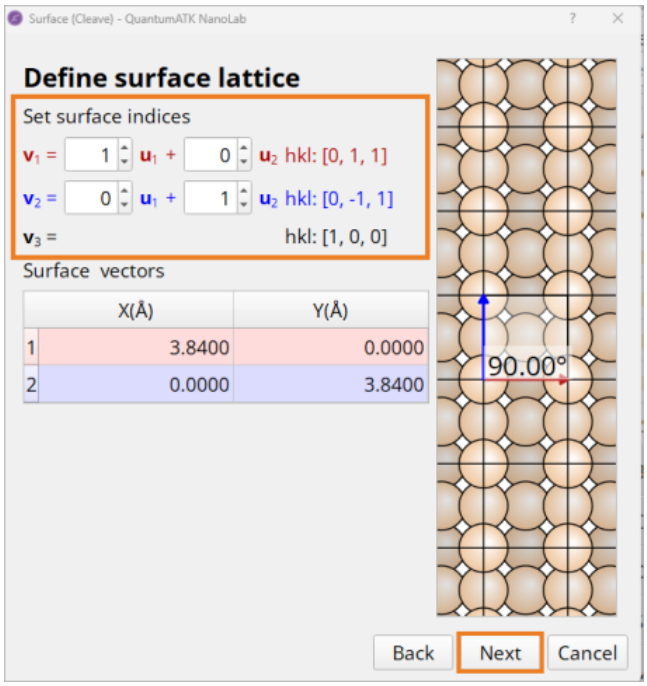
2.Create a Si(100) surface using the **Builder** tool.

•Navigate to *Builders* → *Surface(Cleave)* in the *Builder Panel* (1).

•In the *Surface(Cleave)* window, choose the [1,0,0] Miller indices (2) and click *Next* (3).



•Keep the 1Œ1 surface unit cell and click *Next*.



•Select a thickness of 78 layers and click *Finish*.

Note: The 78 layers will constitute the central region of your device as explained in the NEGF manual *NEGF: Device Calculators*. You need such a relatively long device (~20 nm) because of the long screening length in the silicon semiconductor.

3.Construct a device with the transport direction along (100).

•Navigate to *Device Tools* → *Device From Bulk* in the *Builder Panel*.

•Keep the default parameters for minimal electrode lengths and electrode extension lengths.

•Click *OK*.

•The created device configuration is automatically saved in the *Builder Stash* and has the central region, left/right electrodes and lef/right electrode extensions.

Tip:

1.When using a Semi-Empirical Tight-Binding models for NEGF electron transport, one can use the electrode extensions as small as possible, in particular for Nearest Neighbor models, such as Bassani.

2.When performing DFT-NEGF simulations, it is recommended to use longer electrode extensions. The required length will depend on the basis set and xc-functional. In particular when using hybrid DFT functionals - electrode extensions should be 2-3 times longer than for non-hybrid functionals.

3.QuantumATK will print a warning if the elecrode extension is too short.

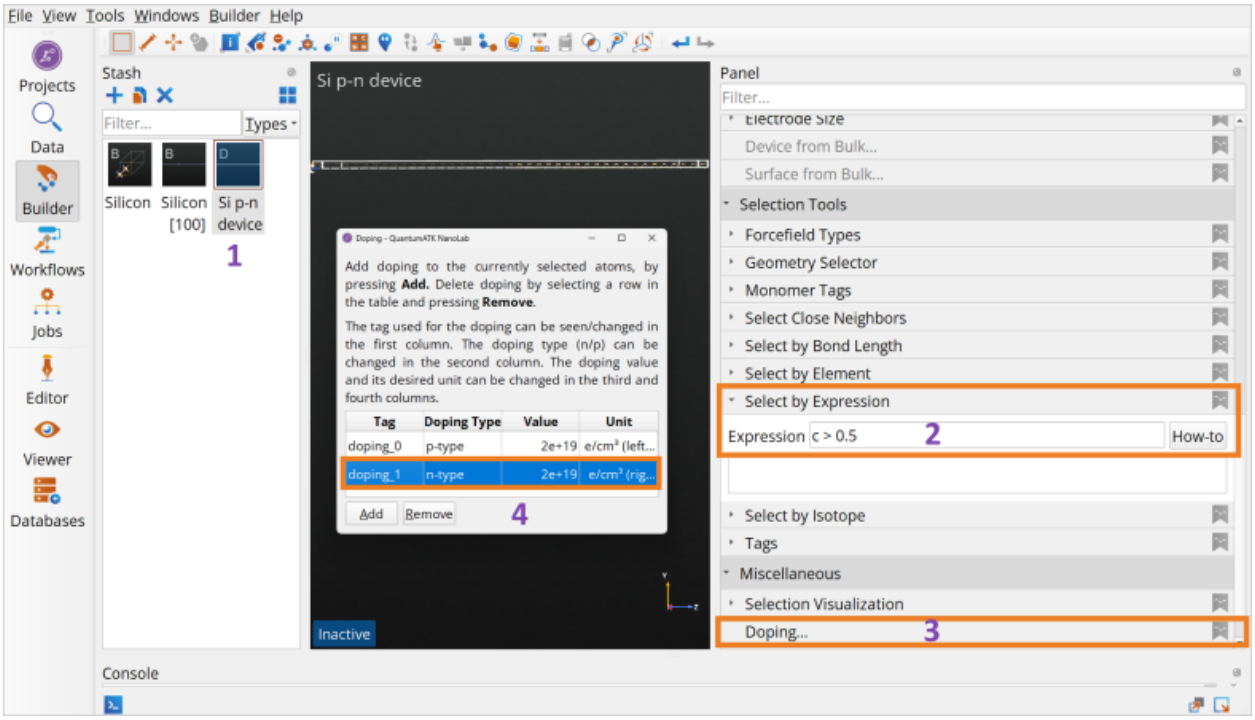
4.Set up p/n doping to have a Si p-n junction.

- Highlight the device configuration in the *Builder Stash* (1).
- Go to *Selection Tools* → *Select By Expression* in the *Builder Panel* (2).
- Type in $c < 0.5$ and press *Enter* to select all atoms in the left hand side of the device (2).
- Go to *Miscellaneous* → *Doping* in the *Builder Panel* (3).
- Click *Add* to add doping for the left side, set the doping type (p-type) and the doping concentration (Value) of $2 \cdot 10^{19}$ cm^{-3} (4).
- Follow the same procedure to select atoms with $c > 0.5$ to select all atoms in the right hand side of the device (2) and set the doping type (n-type) and doping concentration of $2 \cdot 10^{19}$ cm^{-3} to those atoms (4).



Setting up Electron Transport Simulations for the Si p-n Junction at 0 V Bias

You will use the Non-equilibrium Greens function (NEGF) method *NEGF: Device Calculators* with Semi-Empirical Tight-Binding Bassani model parametrized for Si to calculate the *ProjectedLocalDensityOfStates* (PLDOS), *HartreeDifferencePotential* and *TransmissionSpectrum* for the p-n doped silicon junction at 0 bias. Calculating these properties will give you insights into the Si band gap on the p- and n-type sides of the device, band bending, depletion layer width and potential barrier at the p-n interface, left and right electrode chemical potentials and transmission spectrum, which can then be related to the current in the device.

To create a workflow for electron transport NEGF calculations at 0 V bias in the **Workflow Builder**, follow the step-by-step protocol described below.

1. Click on the *Send content to other tools* button to send the created device configuration from the **Builder** to the **Workflow Builder**.

2. Go to the *Block Catalog* → *QuantumATK* tab → *Calculators* category on the right hand panel and drag-and-drop the *Set DeviceSemiEmpiricalCalculator* block to the middle *Workflow Area* → *Build* tab. Set the following parameters:

   - Use the default *Slater-Koster Hamiltonian*.
   - Leave the default *Bassani.Si Parameter set*
   - Uncheck *No SCF Iteration* box.
   - Use the default medium k-point density of 4 Å x 4 Å x 150 Å, which will result in a sampling of 7 x 7 x 174.
   - Under *Poisson Solver*, leave the default *FFT2D Solver*, which applies *Periodic* boundary conditions in A and B directions and open *Dirichlet* boundary conditions in the transport C direction.
   - Under *Electrode*, leave the default 0V bias voltages and 300 K temperatures for electrodes.

Tip:

1. Many k-points are needed in the transport (Z/C) direction in the electrode calculation to match the electronic structure of the electrodes and the central region. But it is relatively inexpensive since these k-points are only used in the electrode calculation, which is the smaller and faster part of the full computation.
2. Often you can use Semi-Empirical models in NEGF simulations, which are faster than DFT-NEGF, but DFT is more generally applicable and allows simulation of devices without the restriction of an available Semi-empirical model.

---

3. Go to the *Block Catalog* → *QuantumATK* tab → *Analysis* category on the right hand panel and drag-and-drop the following analysis object blocks to the middle *Workflow Area* → *Build* tab.

   - *HartreeDifferencePotential* block
   - *ProjectedLocalDensityOfStates* block
   - *TransmissionSpectrum* block.

4. *HartreeDifferencePotential* has no adjustable parameters.

5. Edit the *ProjectedLocalDensityOfStates* block parameters:

   - For the *Energies*, increase the number of points from 200 to 401 in the -2.0 to +2.0 eV energy range for finer sampling.

8. Click on the *Send content to other tools* button and choose *Jobs as a script* to send the workflow to the **Jobs** tool to submit this job on a local machine or a remote cluster. Read these technical notes on *Parallelization of QuantumATK calculations* to learn how to best run NEGF simulations in parallel.

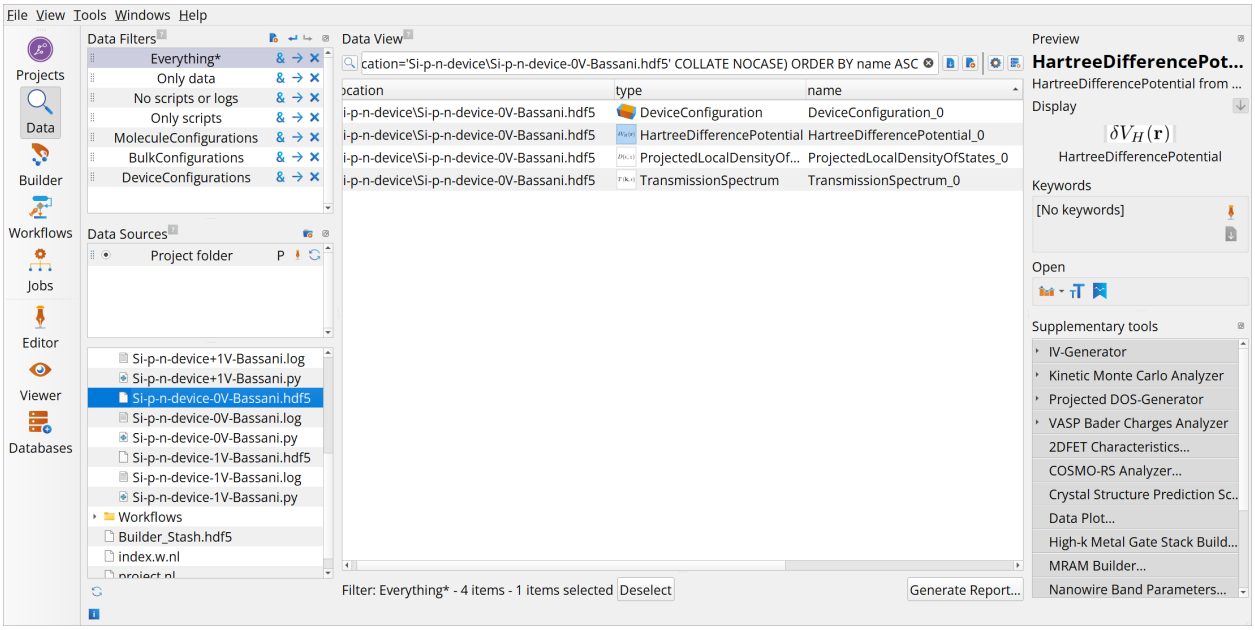
9. This also generates a Python script `Si-p-n-device-0V-Bassani.py`, based on this workflow. It can be opened and edited with the **Editor** tool and then sent to the **Jobs** tool.

Analyzing Results at 0 V Bias

Once the calculation has finished, we are ready to analyze the results.

1. Go to the **Data View** tool.

2. In the *Data Sources*, select the file `Si-p-n-device-0V-Bassani.hdf5` to see the list of calculated objects, *HartreeDifferencePotential*, *ProjectedLocalDensityOfStates* and *TransmissionSpectrum* in *Data View*.



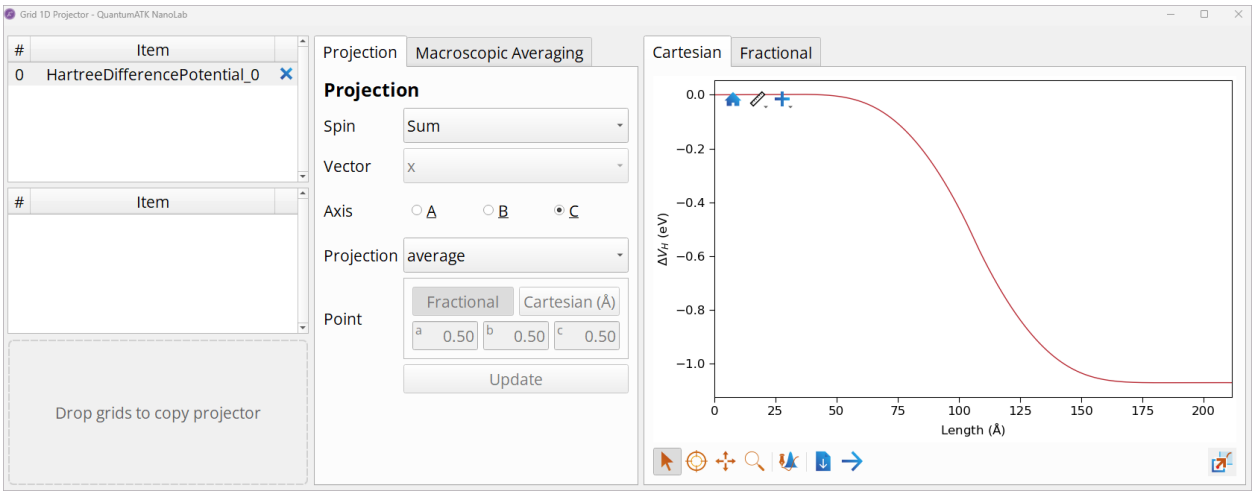
3. Double-click on the *HartreeDifferencePotential* to open it with the *Grid 1D Projector* and observe Hartree difference potential plotted along the devices central region, which is ~20 nm long.

Note: The Hartree difference potential in the simulated Si p-n junction is flat towards the electrodes, indicating that the device is long enough, i.e., the number of Si layers in the left and right ends of the central region provide sufficient screening (the results are converged wrt. the length of the device). See the NEGF manual *NEGF: Device Calculators* for more info.

---

4. Double-click on the *ProjectedLocalDensityOfStates* object to open it with the *Projected Local DOS Analyzer* and investigate the projected local DOS of the Si p-n junction along the transport direction of the device.

- Check the box *Band Edges* to visualize band edges.



•Right-click to *Add measurement* → *Measure (vertical)* or *Add measurement* → *Measure (horizontal)* to measure a band gap, E_g, along the devices central region, depletion-layer width, W_{dep}, and the built-in potential, ϕ_{bi}.

Note:

1.*Projected Local DOS* shows that far from the p-n interface, we have a p-type semiconductor on the left side (with valence band maximum, E_V, close to the Fermi level, $_L$) and the n-type semiconductor on the right side (with conduction band minimum, E_C, close to the Fermi level, $_R$).

2.Measured Si band gap on the left (p-type) and right (n-type) sides of the device is ~ 1.18 eV, which is in a good agreement with the band gap calculated for bulk Si in Tutorial *Band Structure, Projected Density of States and Effective Mass Calculations* with the HSE06 hybrid DFT functional, GW[1] and experimental results[2]. This confirms that the Bassani tight-binding model parametrized for Si model gives reliable results in this case.

3.At the p-n interface (middle of the device) there is a depletion layer with W_{dep} 16.5 nm, where E_C and E_V are not flat (band bending) due to different doping types, resulting in the built-in potential across the junction (potential barrier at the junction), ϕ_{bi} 1.05 eV, which opposes both the flow of holes and electrons across the junction.

5.Double-click on the *TransmissionSpectrum* object to open it with the *Transmission Analyzer* to analyze transmission spectrum $T()$ at 0 V bias.

Note:

1.The transmission $T()$ is zero in the band gap.

2.The electrical current I is calculated using the Landauer formula by intergating T across the energy range: $I = 2e/h \int_{-} dT()[f(-\mu_L)/(k_B T_L) - f(-\mu_R)/(k_B T_R)]$, where is electron energy and μ_L and μ_R are the left and right electrode chemical potentials, respectively. See the manual on *TransmissionSpectrum* to learn more.

3.At 0V bias the $\mu_L = \mu_R = 0$, and so the current is 0.

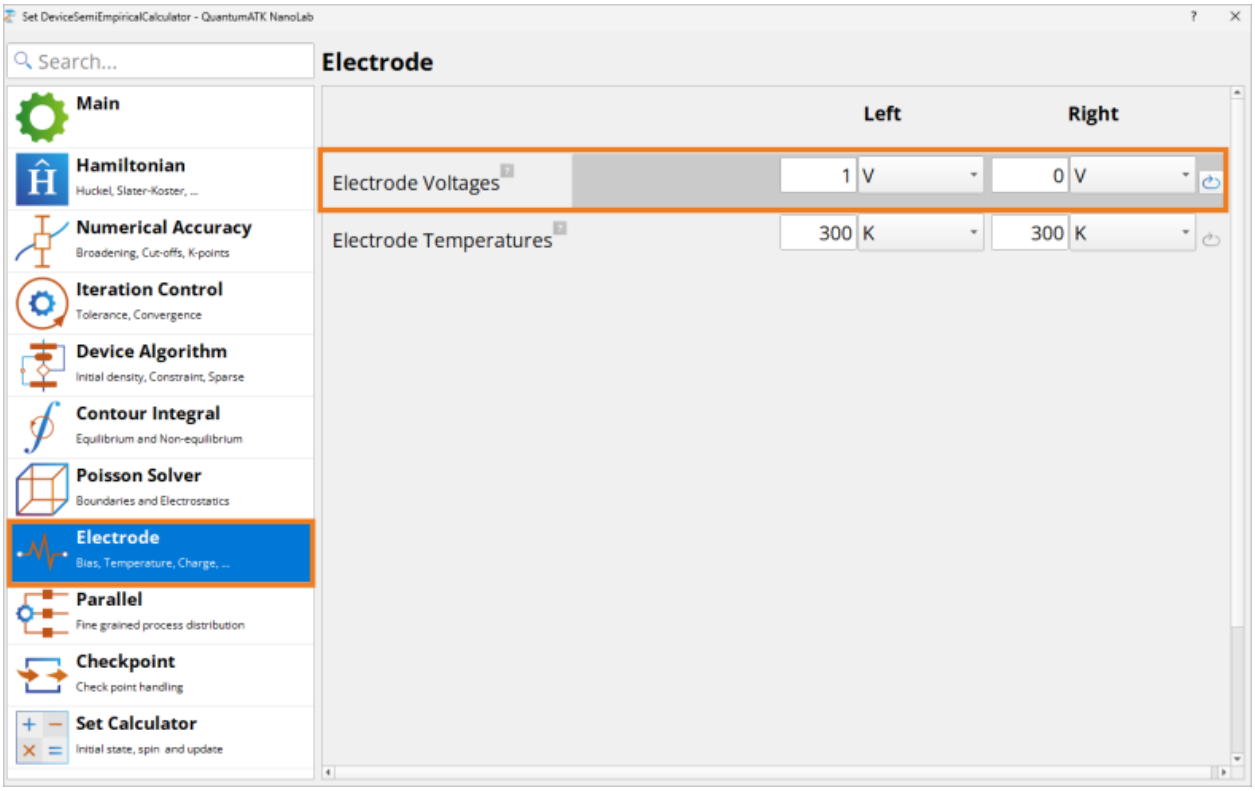
You have just finished with analyzing Hartree difference potential, potential barrier, left and right electrode chemical potentials from the projected local density of states, and transmission spectrum for the Si p-n junction at 0 V bias. You will next perform the finite bias simulations to see the impact of the forward (+1 V) and reverse (-1 V) bias on the potential barrier, left and right electrode chemical potentials and transmission spectrum, which can then be related to the calculated current in the device.

Setting up Electron Transport Simulations for the Si p-n Junction at Finite Bias

To create a workflow for electron transport NEGF calculations at finite bias in the **Workflow Builder**, follow the step-by-step protocol described below.

1. To set up finite bias (V_{bias} = -1 and 1 V) simulations:

- Go back to the **Workflow Builder**.
- In the *Workflow Stash*, right-click on the 0 V bias workflow *Si-p-n-device-0V-Bassani*, choose *Duplicate* and do this twice.
- Rename the two duplicates to *Si-p-n-device-1V-Bassani* for -1V and *Si-p-n-device+1V-Bassani* for +1V.
- Double-click on the *Set DeviceSemiEmpiricalCalculator* block.
- Under *Electrode*, change *Electrode Voltages* to -1V (left electrode) and 0 V (right electrode) to set up V_{bias} = -1 V.
- Under *Electrode*, change *Electrode Voltages* to 1 V (left electrode) and 0 V (right electrode) to set up V_{bias} = +1 V.
- Leave the rest of the settings unchanged.



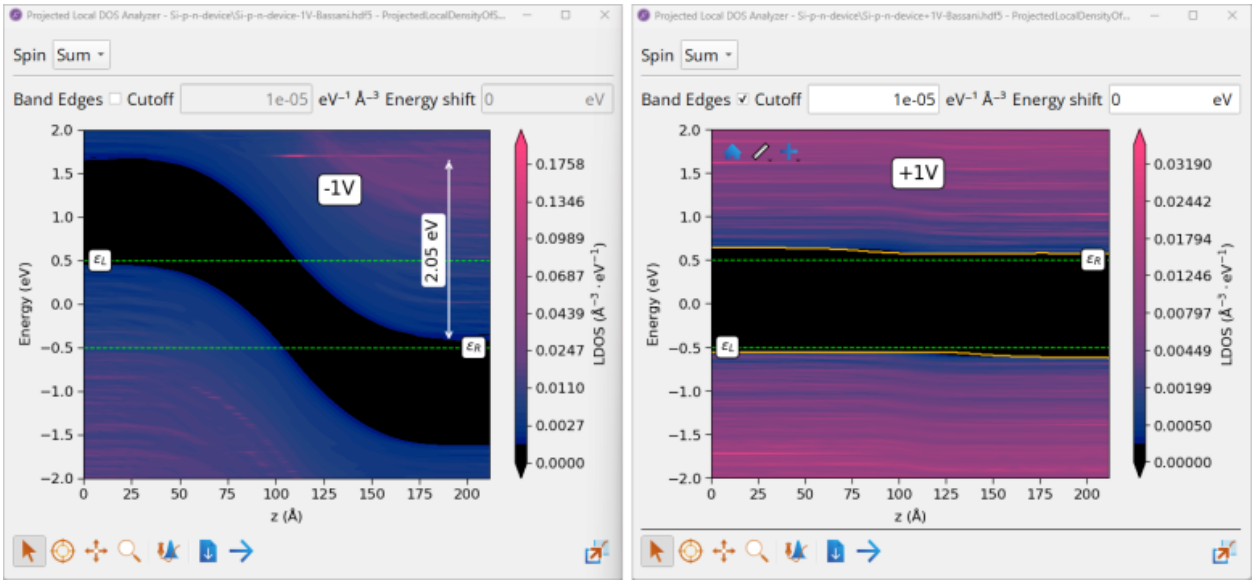
Tip: When running finite bias calculations, there is a possibility to restart from 0 V bias or lower bias calculations to improve and speed-up the SCF convergence. To do this, use *Load from file* block in the workflow to set up from which calculation to restart and check *Set with initial state* box in the *Set DeviceSemiEmpiricalCalculator* block → *Set Calculator* tab.

Analyzing Results at Finite Bias

Once the calculation has finished, we are ready to analyze the results.

1.To analyze projected local density of states at finite bias (V_{bias} = -1, +1 V):

- Go to the **Data View** tool.
- In the *Data Sources* window, select a relevant hdf5 file (Si-p-n-device-1V-Bassani.hdf5 for -1V and Si-p-n-device+1V-Bassani.hdf5 for +1V).
- In the *Data View* window, double-click on the *ProjectedLocalDensityOfStates* object to inspect the PLDOS plot for each bias value.
- Right-click to *Add measurement* → *Measure (vertical)* to measure the built-in potential, ϕ_{bi}.
- Right-click to *Add decoration* → *Label* to add labels.



Note:

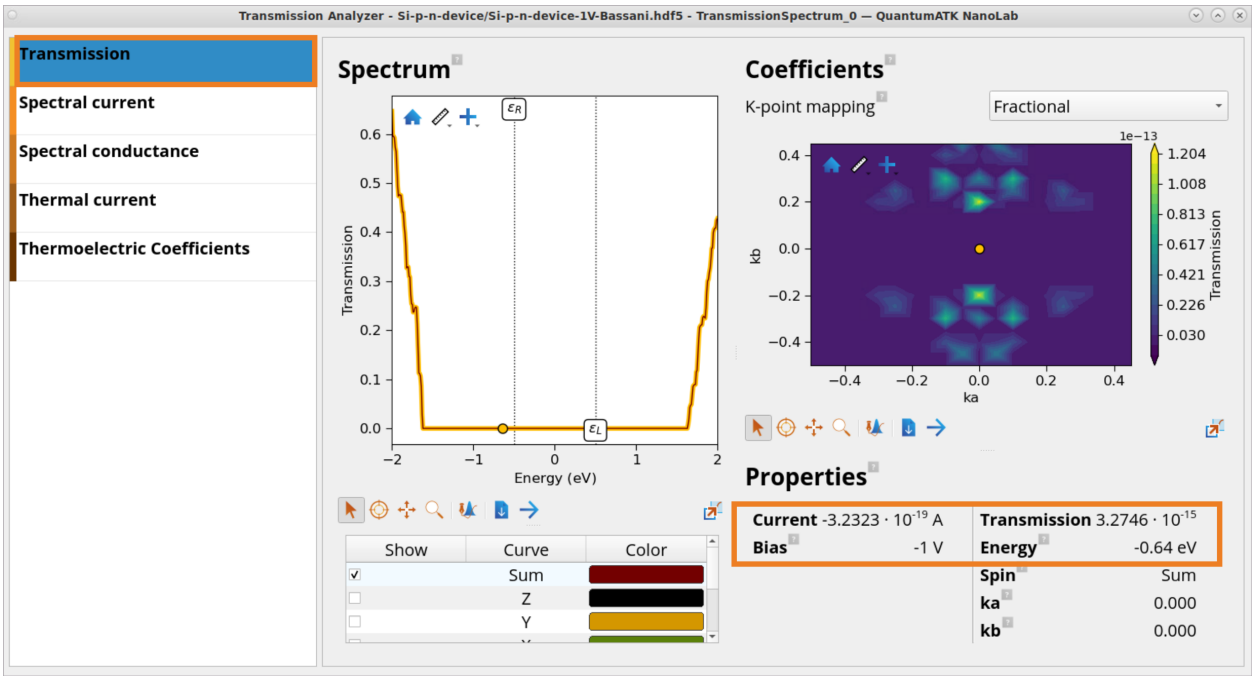
1.PLDOS at -1V (reverse bias) shows that $_L$ = +0.5 eV and $_R$ = -0.5 eV and the potential barrier is increased beyond ϕ_{bi} by 1eV (2.05 eV in total).

2.PLDOS at +1 V (forward bias) shows that $_L$ = -0.5 eV and $_R$ = +0.5 eV and the potential barrier is decreased beyond ϕ_{bi} by 1eV (to negligible ~ 0.05 eV in total).

2.To analyze transmission spectrum at finite bias (V_{bias} = -1, +1 V):

•In the *Data Sources*, select a relevant hdf5 file (Si-p-n-device-1V-Bassani.hdf5 for -1V and Si-p-n-device+1V-Bassani.hdf5 for +1V) and in *Data View* double-click on the *TransmissionSpectrum* object.

•Click on the *Transmission* panel to inspect the transmission spectrum for each bias value. *Spectrum* window shows the transmission plotted as a function of energy, whereas *Properties* panel reports the total current and a transmission value at a chosen energy in the *Spectrum* plot.



Note:

1.According to the Landauer formula shown above, electrical current I is calculated by intergating T across the energy range, and so the size of transmission has an impact on the observed current.

2.Under reverse -1 V bias, due to the increased potential barrier observed in the PLDOS plot, the transmission T around the bias window is close to 0 (e.g., 3.3 10^{-15} at -0.64 eV) and so is the current, I = -3.23 10^{-19} A.

3.Under forward +1 V bias, due to the decreased potential barrier observed in the PLDOS plot, the transmission T around the bias window is much higher (e.g., 0.08 at -0.64 eV and rapidly increases when going to larger energy values) and so the current is much larger: I = 8.9 10^{-10} A.

4.This shows as expected, that the Si p-n device acts as a diode, which allows current to flow easily in one direction, but severely restricts current from flowing in the opposite direction.

3.Click on the *Spectral current* panel to investigate which energy states contribute most to the current, I, at forward V_{bias} = +1 V bias, as the current depends not only on the size of transmission, but also available states that can transmit the current.

Note:

1.Energy states at ~ -0.64 eV and 0.66 eV contribute most to the current, I

2. One can obtain *TransmissionEigenstate* and *TransmissionEigenvalues* by adding *TransmissionEigenstate* and *TransmissionEigevalues* blocks to the workflow.

3. It is also possible to vary the temperature of the Fermi-Dirac distribution in the left and right electrodes to see the temperature impact on the current, I, in this case of an ideal structure. Note that this does not include electron-phonon coupling, which is beyond the scope of this tutorial.

Tip: Though there were no convergence issues in electron transport NEGF simulations of the Si p-n junction, sometimes one can encounter challenges in converging NEGF calculations to obtain the electronic ground state. In these cases, read the *NEGF Convergence Guide* which provides a list of action points for troubleshooting poorly converging NEGF calculations.

Summary and Outlook

In this tutorial, you have learnt how to set up and analyze projected local density of states, transmission spectrum and spectral current for a few bias points to demonstrate the principles of NEGF calculations of electron transport in devices. For more realistic studies, such as full I_dV_d and I_dV_g curves, we recommend to perform *IVCharacteristics* simulations. This is a combined framework for running multiple source-drain/gate voltage calculations and collecting and analyzing the results with smart SCF restart functionality from lower bias simulations for faster and better SCF convergence.

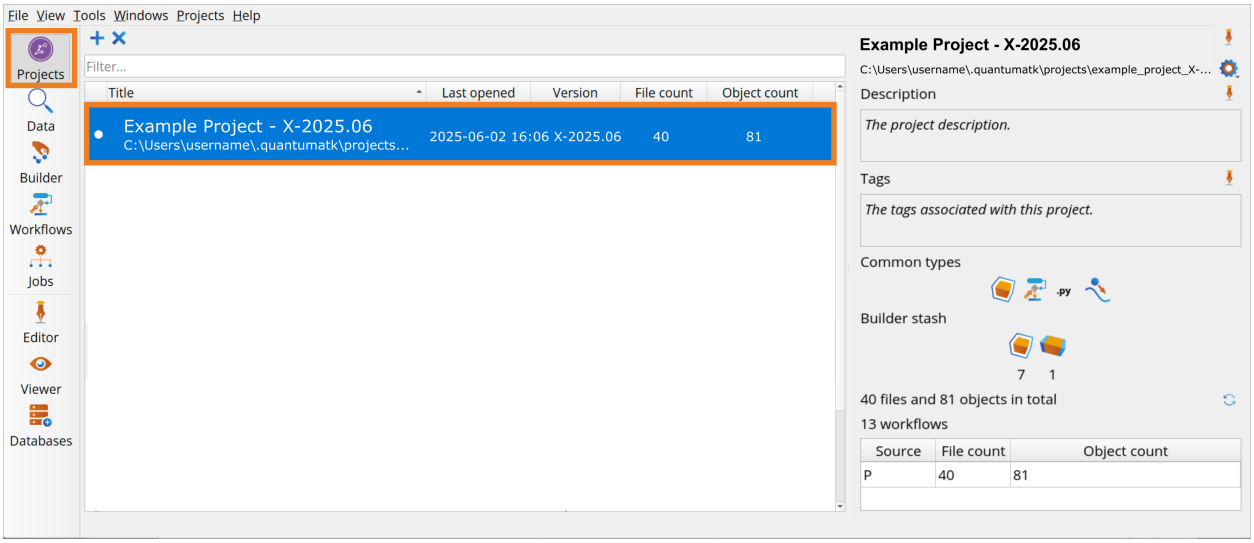
References

Workflow, input and output files from the tutorials above can be found in the **Example Project** of the QuantumATK X-2025.06 release or can be downloaded from the tutorial pages.

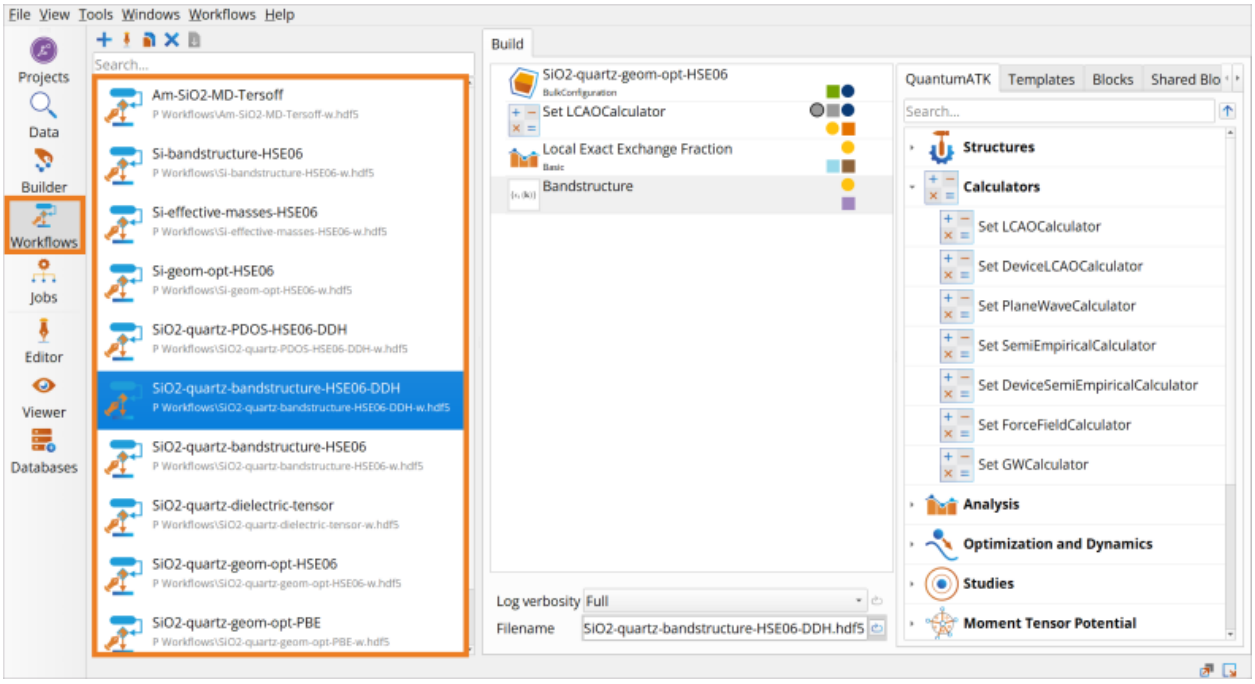
1. Open **QuantumATK NanoLab**.

2. Click on **Projects**.

3. Double-click on the *Example Project - X-2025.06*.



4.Click on the **Workflow Builder** to inspect/rerun all the simulation workflows used in the above introductory tutorials.



5.Click on the **Data View** -> *Data Sources* to find dedicated folders for each tutorial, containing input (.py) and output files (.hdf5).

1.3 Feature List

1.4 Referencing QuantumATK

QuantumATK is an *integrated platform of electronic and atomic-scale modeling tools* written in Python and C++. It gives you access to a powerful set of simulation engines for R&D at the atomic scale:

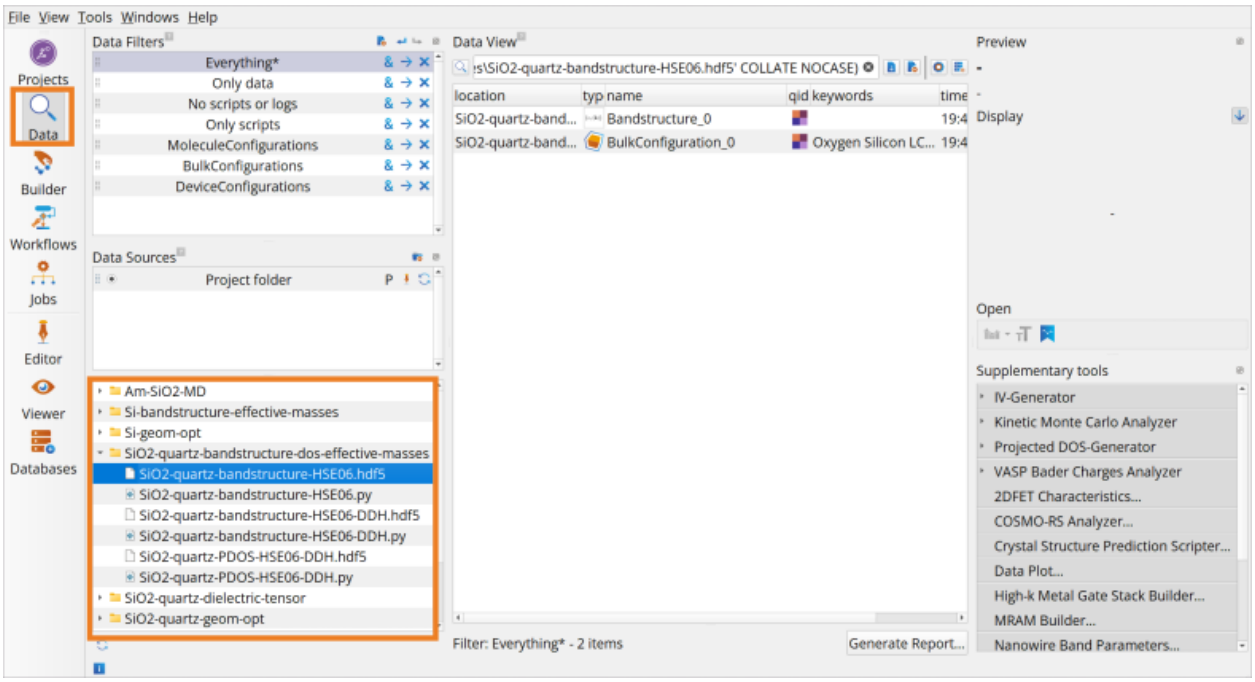
•Density Functional Theory (DFT)

•Many-Body Perturbation Theory Method GW

•Semi-Empirical Tight Binding

•Classical Conventional and Machine-Learned Force Fields

•Non-Equilibrium Greens Functions (NEGF) Method for device simulations



A QuantumATK installation comes with two executables – **atkpython** and **quantumatk**. The first one is an enhanced Python interpreter that includes the QuantumATK simulation engines. It is meant for running QuantumATK simulations via Python scripts directly from a terminal. The second executable launches **QuantumATK NanoLab** which provides an intuitive graphical user interface (GUI) on top of the QuantumATK engine.

The recommended way of using QuantumATK is via **NanoLab**. It helps you focus on your modeling task rather than technical details, by assisting you with the preparation steps. **NanoLab** also offers important tools for data analysis.

CHAPTER

TWO

NANOLAB GUIDES

Here you will find an overview of the user interface in *QuantumATK NanoLab*. When a new version is released, we recommend checking out this section to get acquainted with the latest updates and newly added features.

The *QuantumATK NanoLab* section will get you familiar with the user interface layout and tools such as *Data*, *Builder*, *Jobs*, and *Plots*. You will learn how to organize, search, import, and export files and structures using the *Data* tool. You will get an overview of the *Builder* tool and its plugins with which you can create, load, or edit various atomic-scale structures. The *Jobs* tool overview will show you how to execute scripts on a local or remote machine and get calculation results, which you can then plot with the *Plots* tool.

In the *QuantumATK NanoLab* section, you will also find guides on the newly added features and updates of the current tools.

If you have already installed *QuantumATK NanoLab* and you are familiar with its most recent features, we recommend you to continue to the *Tutorials* category, where you will learn how to use the program and its vast number of features in a meaningful way through many concrete examples starting from a beginner to an expert level.

Guides to QuantumATK NanoLab

2.1 Overview of NanoLab

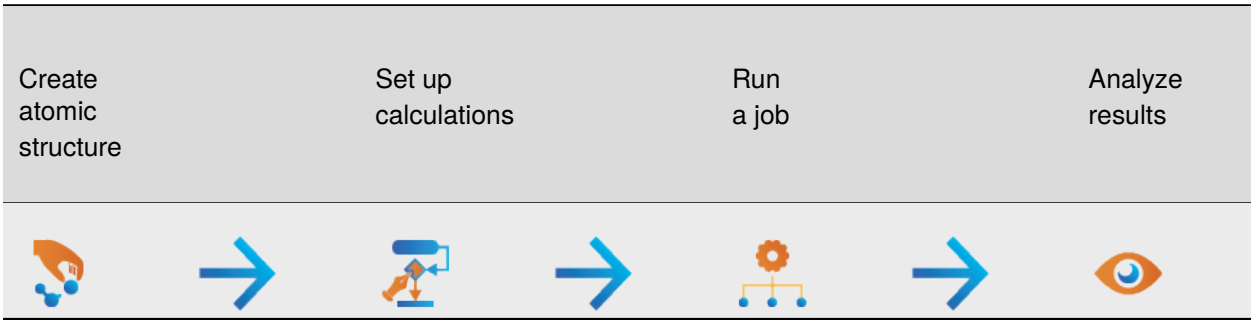
Note: We will assume that a working copy of QuantumATK has already been installed, as described in the *Installation Guide*.

Table of Contents

- *Typical workflow*
- *Create atomistic structure*
- *Set up calculation*
- *Run a job*
- *Analyze results*

2.1.1 Typical workflow

The recommended way of using QuantumATK is through NanoLab. It helps you focus on solving your problem, by assisting you with the preparation steps. A typical workflow in NanoLab consists of the following steps:



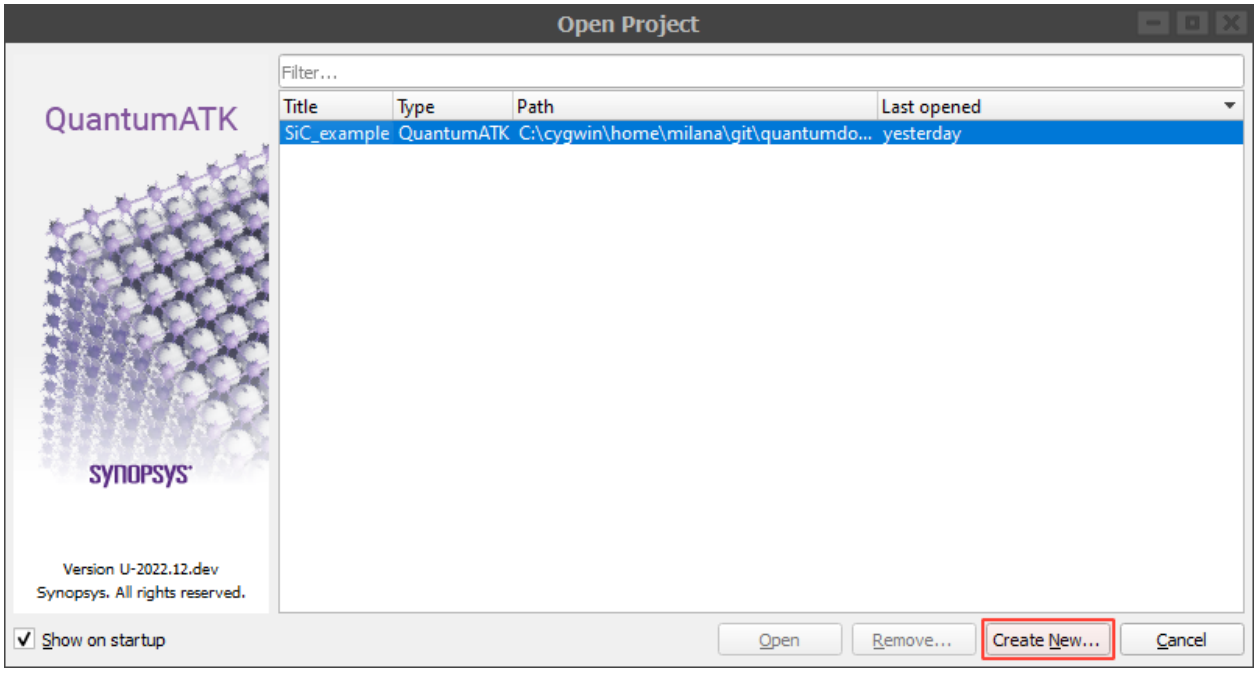
We will demonstrate each workflow step through a very simple example in which we will be calculating the **bandstructure of a SiC crystal**. In the next tutorials, we will show how to use QuantumATK to calculate many other properties and teach you how to choose the simulation parameters to best suit your goals.

2.1.2 Create atomistic structure

Lets start by opening NanoLab. There are two different ways to do it:

1. by clicking the QuantumATK NanoLab icon on the Desktop;
2. by executing the **quantumatk** command in a terminal.

The *Open Project* window will appear where you can create *new projects* and open existing ones. We will start by creating a new *QuantumATK project* with the title *SiC_example*.

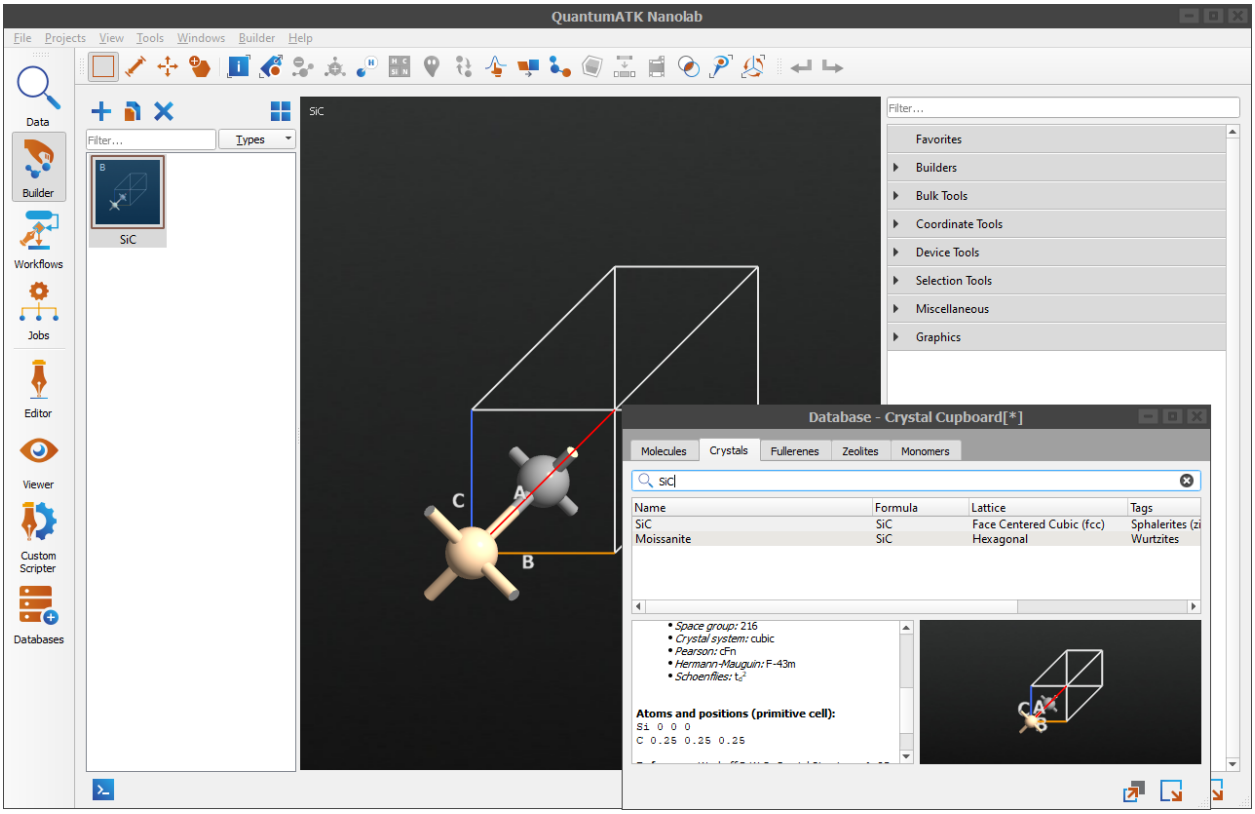


Once you open a *new project*, you will see the main window of NanoLab showing the contents of the new *SiC_example* project folder. The project is currently empty.

We will start by loading a SiC `BulkConfiguration` using the *Builder* tool. The *Builder* tool is used to load, build, edit, visualize and inspect atomic configurations. It contains a plethora of built-in plugins for manipulating atomic configurations, as well as databases with built-in atomic configurations.

Lets load a SiC crystal in the *Builder* tool. To open the *Builder* tool, click the icon in the vertical toolbar on the left. Once you are in the *Builder* tool, lets load a SiC crystal from the *Database*.

To open the *Database* click the and select *From Database*. Make sure you are at the *Crystals* tab, and type *SiC* in the text search. Double click the *SiC* configuration from the list to load it to the *Builder*.



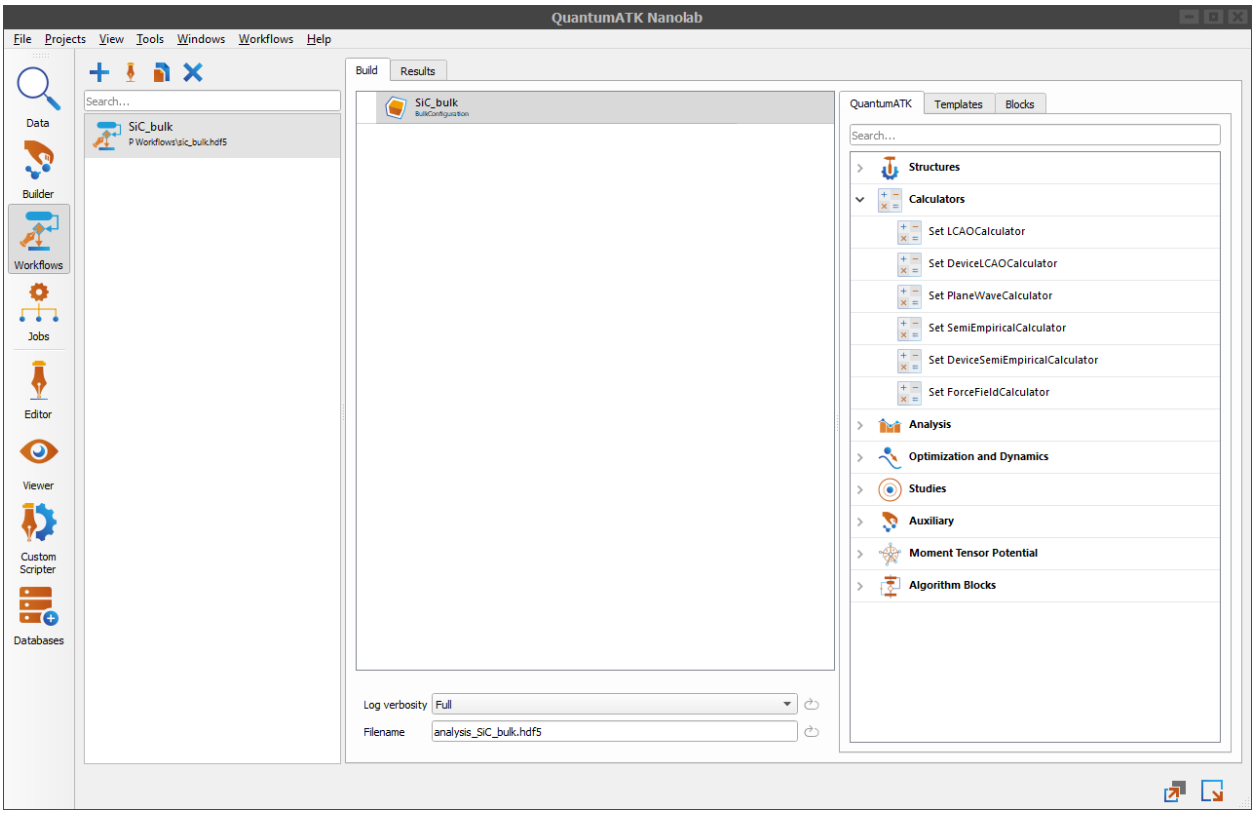
The SiC crystal should now be visible in the *Builder*. In the window on the right, you will see a small icon corresponding the SiC crystal. This window is also called *Builder stash*. It contains all the atomic configurations that you have created or loaded in the *Builder*.

In the central window of the *Builder* you will see a 3D graphical model of the SiC crystal. The central window is also referred to as the *3D Viewer*. From here you can click, rotate, zoom or pan the atomic configuration selected in the stash window.

2.1.3 Set up calculation

Lets create a bandstructure calculation for the SiC crystal loaded in the *Builder* tool. We will start by sending the SiC crystal from the *Builder* to the *Workflows* tool.

To send the SiC crystal from the *Builder* to the *Workflows* tool, click the **Send to** button and choose **Workflows** from the drop down menu. The *Builder* window is automatically replaced by the *Workflows* window.



The *Workflows* tool is used to assemble calculation steps, which can be run through the *Jobs* tool. Each calculation step can be one QuantumATK object. A catalog of built-in blocks, or calculation steps, are available under the *QuantumATK* tab in the right window.

We can see that the *Workflows* tool already contains the SiC crystal. This will be our first calculation step. Lets complete the calculation steps in the current workflow by adding a calculator and an analysis object.

In the *QuantumATK* tab on the right find the *Set LCAOCalculator* block and a *Bandstructure* analysis block. Drag the blocks from the list of QuantumATK blocks to the central window.

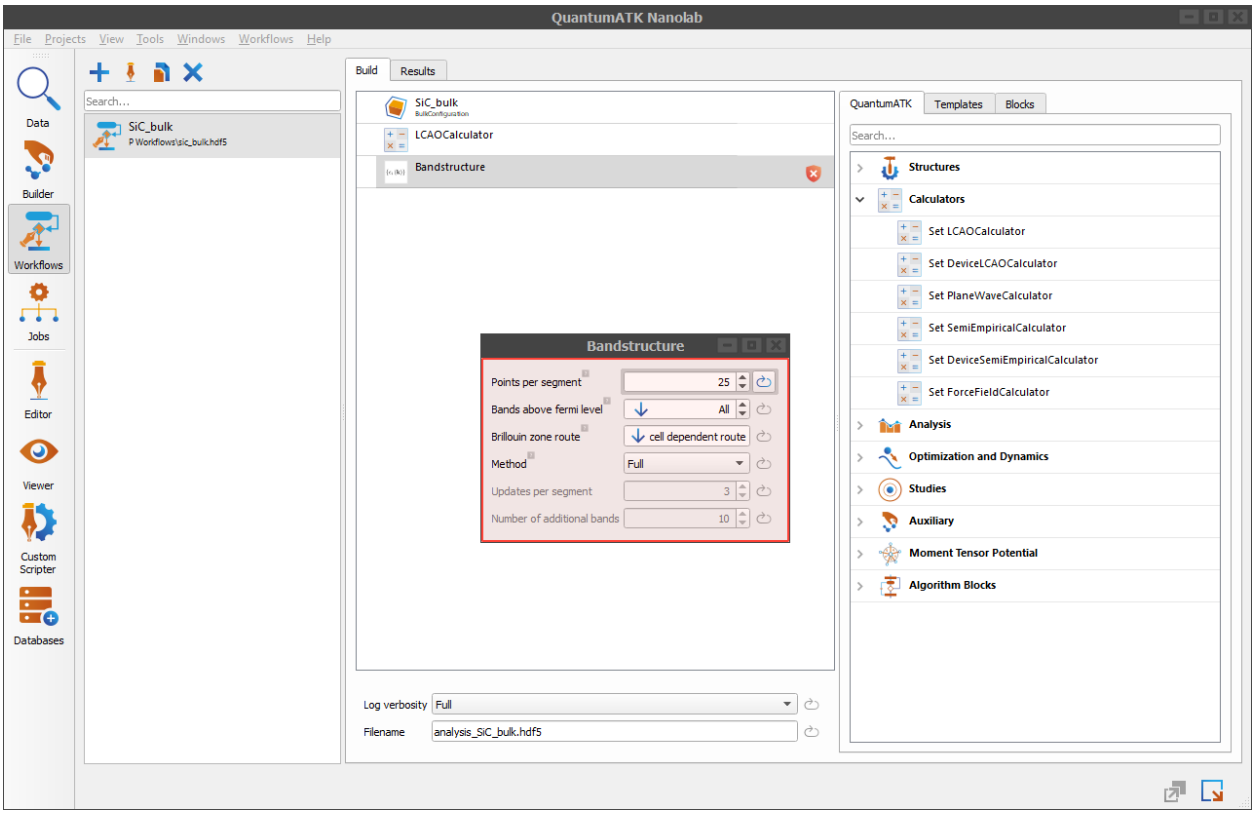
We have now created a workflow tree with one configuration, a calculator, and an analysis block. The *Set LCAOCalculator* block will get the SiC crystal as an input, which is a `BulkConfiguration` object. The output of the block will be the `BulkConfiguration` object with an attached `LCAOCalculator` object. The *Bandstructure* block will get the `BulkConfiguration` with the attached `LCAOCalculator` as an input, and will output a `Bandstructure` object. After we run the workflow, the `Bandstructure` object will be the final result.

The created workflow was automatically saved as the `SiC.hdf5` file in the `Workflows` folder. The file has extension `.hdf5` and is available in the *stash* of workflows on the right, as well as in the *Data*.

Note: **HDF5** is a data model, library, and file format for storing and managing data and is the format used for files storing QuantumATK objects.

The calculator computes the electronic ground state of the SiC crystal with DFT. It contains a wide range of settings, all of which have sensible default values. However, you will most often need to change at least a few of them in order to make the calculation match your scientific goals. Double-click the dropped LCAOCalculator block when you wish to edit it.

The Bandstructure block performs electronic ground state analysis of the SiC crystal. Double click the Bandstructure block to open its editor and to increase *Points per sampling* to *25*.



Note: When changing the value of a field in the Bandstructure block editor, make sure to confirm the change by hitting *Enter* before closing the dialog. Otherwise, the change will not get saved.

At this step we can generate a Python script based on this workflow by clicking and sending it to the **Editor** tool.

We are now prepared to run the calculation on our local machine or a supercomputing cluster.

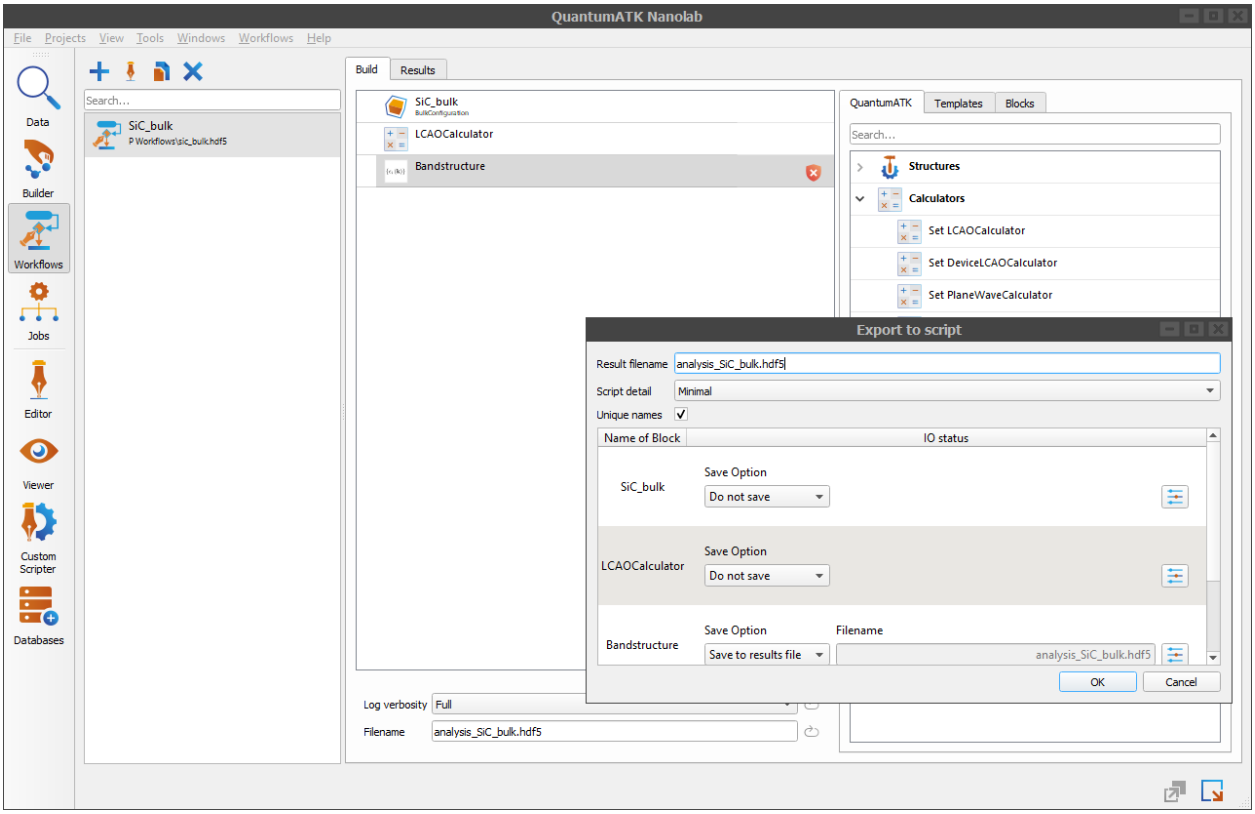
2.1.4 Run a job

There are different ways to run the created workflow. For example, we could export it to a script and run it from a terminal:

```
atkpython analysis_SiC_bulk.py > analysis_SiC_bulk.log
```

A very convenient alternative is to use the *Jobs* tool to run the script directly from inside NanoLab:



•Click the in the lower-right corner of the *Workflows*, and select *Jobs as script* from the menu.

•The *Export to script* dialog appears, prompting you to export the workflow to a Python script and make sure it is saved. After saving the script, the *Jobs* window will open followed by the *Submission Settings* dialog.

•Choose a *Local* machine type. This is your current machine. This option is automatically created after the installation of NanoLab. When you click *OK*, the QuantumATK Python script will be added to the job queue of the chosen machine.

•Select your script and click the button to start executing the calculation.

Tip: See the *Jobs* tutorial for more instructions on using the Jobs for multi-CPU execution of QuantumATK Python scripts on your local machine and on remote supercomputers.

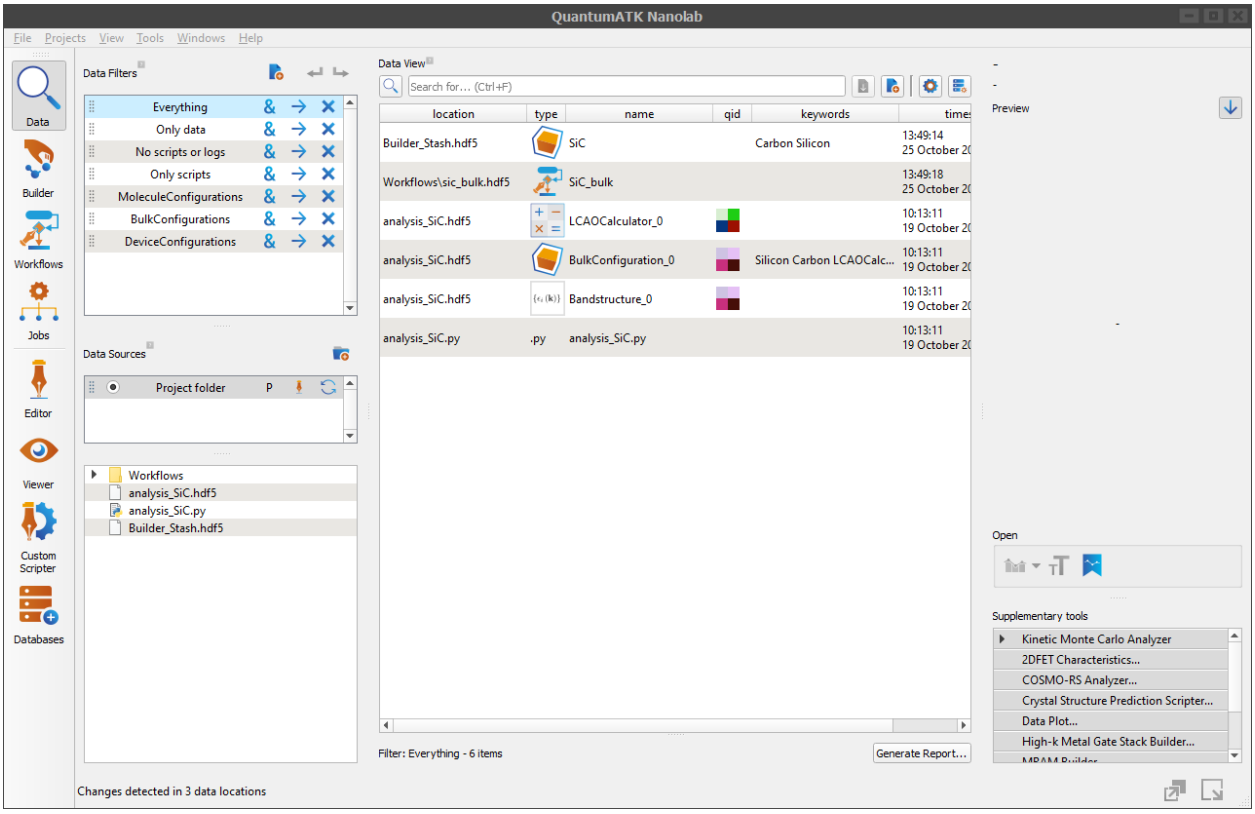
2.1.5 Analyze results

The calculation should last for about 20s. After it has finished, a new `.hdf5` result file will appear in the *Data* tool. New `.hdf5` files will be automatically scanned and their contents displayed in the central window of the *Data*.

You should be able to search and see the contents of the result file, `analysis_SiC.hdf5`. The content should include *Bandstructure_0*, *BulkConfiguration_0* and *LCAOCalculator_0*, which correspond to the calculated *Bandstructure* object, the SiC crystal and the same SiC crystal with the attached *LCAOCalculator*.

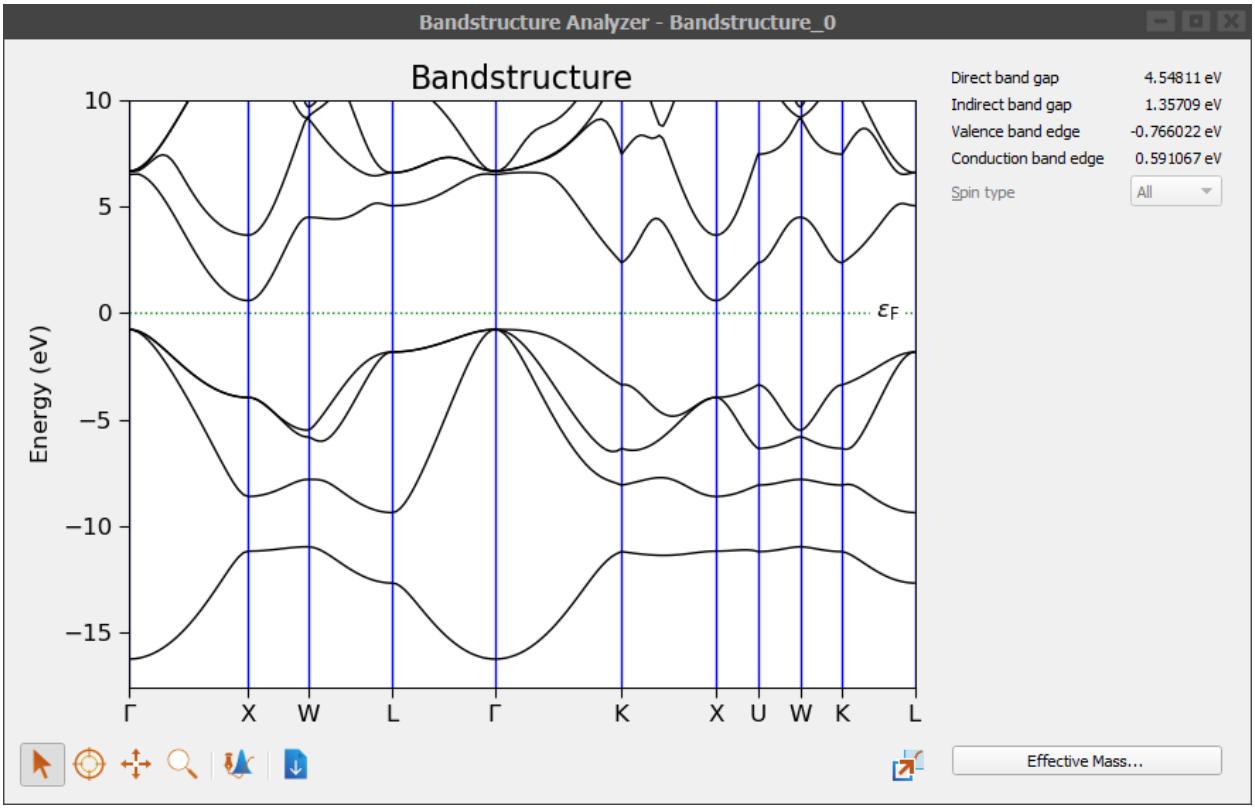
Other files you will see include the `Builder_Stash.hdf5`, the `sic_bulk` workflow and the Python script `analysis_SiC.py`.

The `Builder_Stash.hdf5` contains atomic configurations from the *Builder* stash. Currently there is only one *BulkConfiguration*. The workflow `sic_bulk` is the workflow which we have just created. The `analysis_SiC.py` is the `sic_bulk` workflow exported as a Python script.



To analyze the bandstructure results, search a bandstructure item in the *Data* and double click it to launch the *Bandstructure analyzer*. Both the direct and indirect band gaps are given by the analyzer.

Looking at the band gap results you can clearly see that they are inaccurate. This is because we were using default parameters in the *LCAOCalculator* and the *Bandstructure* blocks. To calculate the band gaps of SiC crystal the right way, follow the tutorial *Calculate the band structure of a crystal*.



2.1.6 Whats next

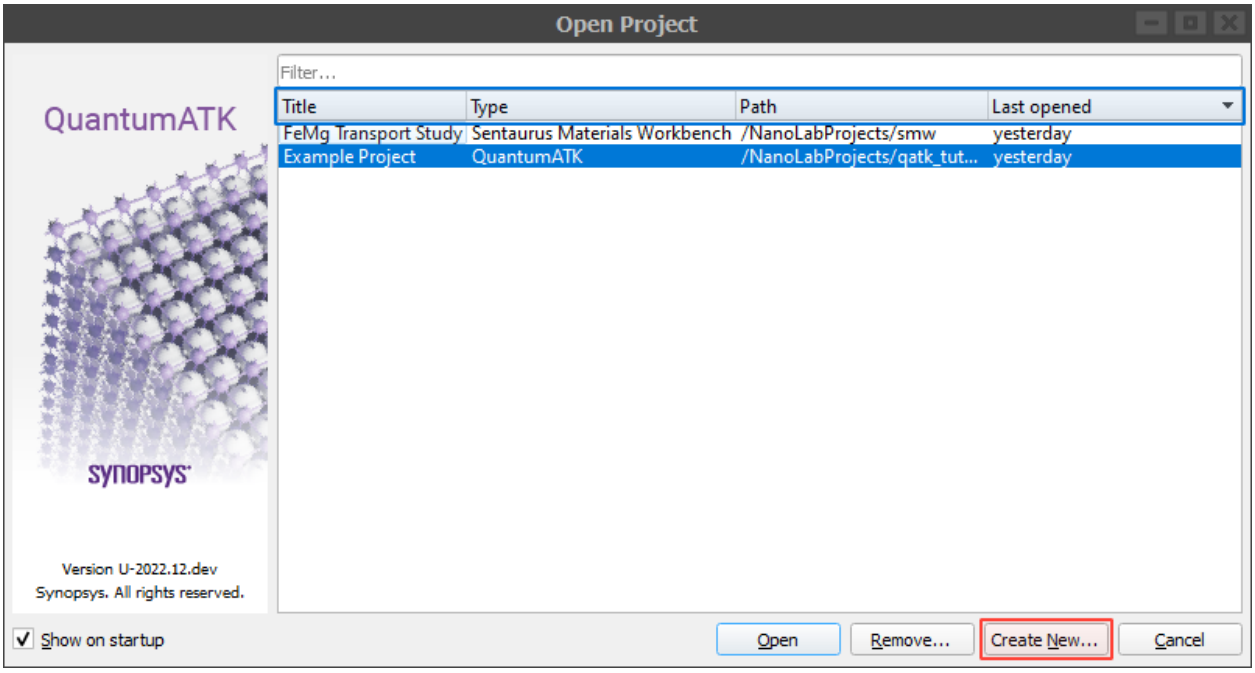
In the Introductory Tutorials we will show how to use QuantumATK to calculate many other properties and teach you how to choose the simulation parameters to best suit your goals. You can find them here: *Introductory Tutorials*.

2.2 Projects in NanoLab

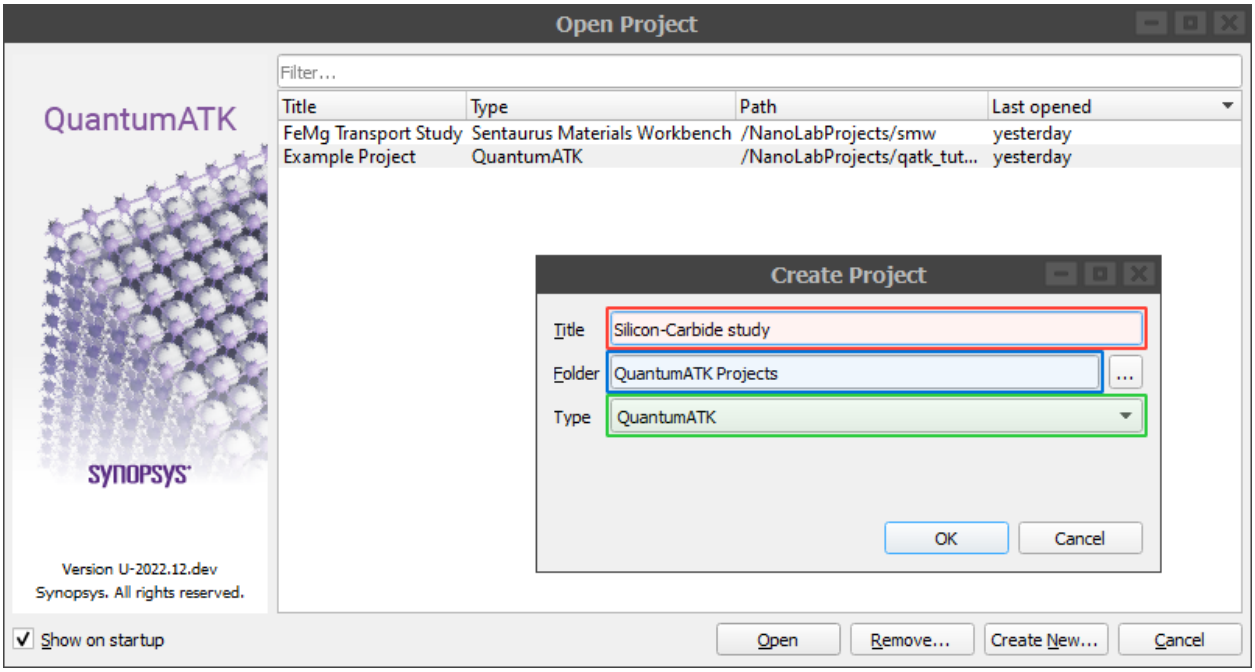
Here you will learn how to create a new project in *QuantumATK NanoLab*.

Lets start *QuantumATK NanoLab* by clicking the QuantumATK NanoLab icon on the Desktop. You will briefly see a splash screen followed by an *Open Project* window. Here you can manage projects, open one of them or create a new one.

In the *Open Project* window you will see a list of your existing projects, specifically their titles, types, paths and the last time they were opened. To create a new project click the *Create New* button.



A new dialog *Create Project* will appear. Each new project must be given a suitable title, type and a local path for storing project files.



Give the project a *Title* (here: Silicon-Carbide study), select the folder where data will be stored (here: QuantumATK Projects), select the *QuantumATK* type and then click **OK** and **Open** to start the project.

After creating a new project, *QuantumATK NanoLab* will generate a new file called `project.nl`. You will find it in the folder of your project. The *project.nl* will store general information about your project, such as the *data sources* and the *data filters* imported and created in the *Data* tool, atomic configurations from the *Builder* tool or workflows from the *Workflows* tool.

The following sections will introduce the main parts of *QuantumATK NanoLab* and the functionalities each part offers.

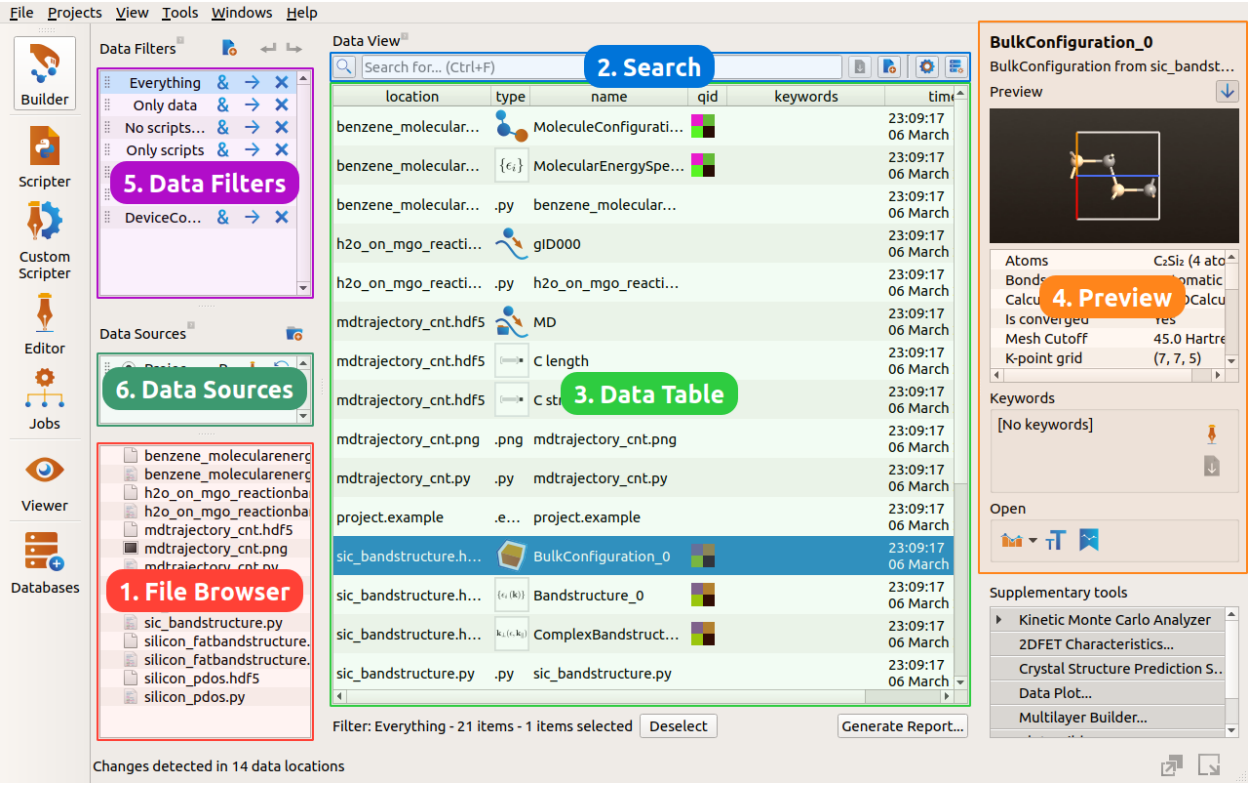
2.3 Organize your data in the Nanolab data view

Working with ab-initio simulations require a lot of data and it can be challenging to manage and organize data from many different simulations.

When opening Nanolab. the first window that shows up, is the Nanolab data view. The Nanolab data view makes it possible to filter, analyze and summarize all the constructed structures and calculated results.

2.3.1 The Nanolab Data View

This introduction to the Nanolab data view, will explain the 6 main parts of the data view:



2.3.2 1. The File Browser

The tutorial starts in the lower left corner, where you will find a familiar file browser showing the contents of the current project folder.

Select a file, and the data table (to the right of the file browser) will display the structures and results saved in that file. Select multiple files by holding down `ctrl` or `shift` while clicking the files with the mouse.

2.3.3 2. The Search Field

It is also possible to search through your data using the search bar at the top of the Nanolab data view. Type in search queries to quickly locate your data. Note that it will search across several columns in the data view – including folders, filenames, data type, object ids and keywords.

This makes it possible to quickly find, e.g. all **Bandstructures** or **MDTrajectories** within a relevant folder.

It is also possible to use more advanced SQL queries to create custom views on your data. It make take some effort to create the most powerful queries, and therefore the queries can be saved as what we call Data filters. Such saved filters can quickly be applied and combined with other queries in order to properly limit your search.

The advanced SQL search

In addition to normal free-text search terms, the search field also accepts SQL queries. It is even possible to combine text search and SQL search together in the search field. Here are some examples of how the search field can help locate relevant data.

This query search for all results of type **Bandstructure**:

```
type='Bandstructure'
```

This query searches for all data items that have a name starting with Electron. Note the use of the `%` sign to signify wild card matching.

```
name LIKE 'Electron%'
```

In addition to searching, the data can be sorted by e.g. the last changed time. Here the specifier `ASC` sorts the timestamp in ascending order. Similarly sorting can be done in descending order by using the `DESC` specifier.

```
name LIKE 'Electron%' ORDER BY timestamp ASC
```

Multiple queries can be joined by OR or AND. Here we search a specific subfolder for all bandstructures.

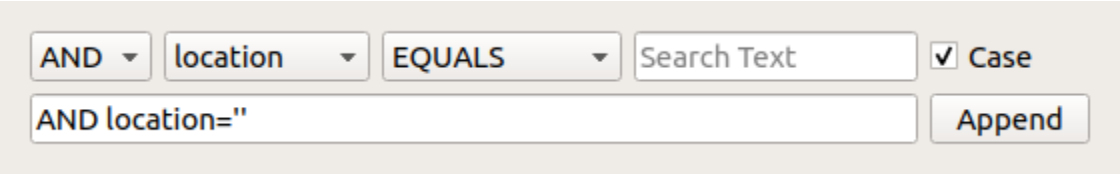
```
location LIKE 'my_subfolder%' AND type="Bandstructure" ORDER BY timestamp ASC
```

Also, normal search terms can be combined with SQL. Let us search for anything related to silicon of type Bandstructure and ordered by timestamp.

```
type='Bandstructure' AND silicon ORDER BY timestamp ASC
```

The Query Builder

Advanced SQL-searches can be difficult to master, and as a help Nanolab provides the advanced query builder. Click the cog-button to show the query builder. Fill in menus and text fields to construct the relevant queries.



2.3.4 3. The Data Table

The main data table shows all the data that matches the current search query. Each piece of data is represented as a single row in the table (in the following called a data item).

The columns displays the data location (folder and filename), data type, object id, Quantum ID (qid), keywords and last changed time.

Each data item can be double clicked. This will open a window with a relevant analysis, that will display the scientific data contained in the data item. Try double-clicking an atomic structure to open the 3D Viewer, a **Bandstructure** to show a plot of the band diagram or an **MDTrajectory** to show the time-evolution.

For more detailed options, right-click a data item. This will open a detailed menu with several options:

- **Open**. This will open the default analysis.
- **Open with**. Displays a menu of all available analysis for this data type.
- **Delete**. Some items support deletion. Note that deletions cannot be undone.
- **Unpack**. Show nested data (see explanation below).
- **Export** the selected data items to specific file formates (.hdf5, .xyz, .mol and so forth).
- **Refine** the search field based on the right-clicked data item, by choosing Refine

The Quantum ID (qid)

Calculations done with LCAOCalculator, PlaneWaveCalculator or SemiEmpericalCalculator are all marked with a unique number called a quantum ID (qid). The number can be cumbersome to work with, so in the data view it has been encoded as 4 colors. The four-colored squares can quickly be used to distinguish different calculations, since analysis done with the same calculator all share the same quantum ID.

Unpack

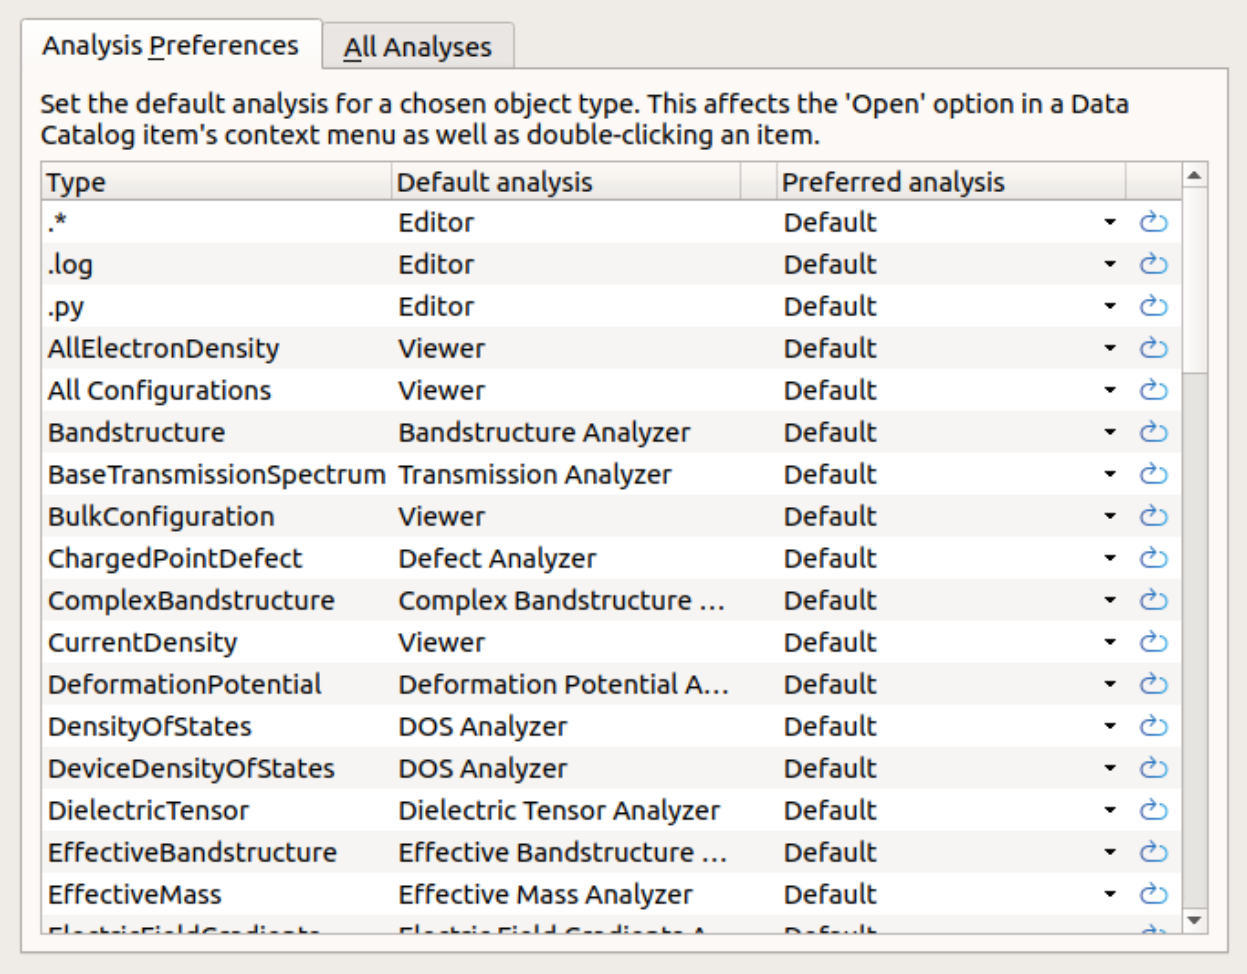
Some data may contain nested data. MDTrajectories will for example sometimes contain custom measurements of stresses and strain. All data items containing nested data are marked with a folder-like unpack icon .

Right click one of these items and choose **Unpack** to show the contents of the data. The nested data can then be inspected and analyzed like all other data.

Analyzers and Preferences

Double-click a data item to open it with its default analyzer. Bandstructures will open to reveal the band diagram, atomic structures will open in the 3D Viewer and so forth. Additional analyzers can always be found in the right-click menu.

It is possible to change the default analysis for a given type of data. Open the analysis preferences by clicking the bookmark button and you are presented with a list of types and analyzers. For each analyzer you can see the default and make a user-defined change. Those changes apply across all projects.



2.3.5 4. The Data Preview

Clicking a data item will display a preview of the relevant data in the preview panel to the right of the data table.

For atomic structure configurations the preview includes a 3D view of the atomic structure along with relevant data like bonds and unique elements. If the structure has a calculator attached, it is also possible to inspect the calculator settings. Many different data types items expose some results or settings in the preview pane.

The 3D view can be disabled by clicking the arrow-down button. This may be convenient when working on slower machines or with very large structures.

The Keywords

Data items can also be annotated by keywords that can be used for categorization and search. Atomic structures will also automatically embed the unique elements and its calculator name as keywords.

The preview panel also contains a keyword editor, where it is possible to add custom keywords to your data items. This can be a convenient way to attach additional data to your data items, or for enabled special searches or filters.

2.3.6 5. The Data Filters

In the upper left corner is a list of saved searches known as **Data Filters**. Per default each project starts with a few standard filters that has been given appropriate names. The **Only molecules** filter for example corresponds to the advanced search query `type='MoleculeConfiguration'`.

Each filters can be applied by clicking their arrow button . This will replace the currently active search query with the filter query. It is also possible to combine multiple filters by using the button.

This & feature makes it very easy to perform advanced searches like for example all molecules within the MyStructures folder:

1. Click the MyStructures folder in the folder view.
2. Click the next to the Only molecules default filter.

2.3.7 6. The Data Sources

The data sources specify what data belong in the current project. The table shows the list of current sources.

Each project always a contains single folder (the project folder) as the main data source, but it is possible to add additional folders as sources. Simply click the button and navigate to the desired folder in order to add it to the current project.

Each source has a unique name. The project folder is always named `P` while subsequent sources are named `S0`, `S1`, etc. Clicking the source name will limit the search to the corresponding source by changing the search query to e.g.,

```
source='S0'
```

The settings for each data source can be accessed by clicking the pen button . In these settings the current source folder can be changed along with the activated data inspectors.

Data Inspectors

A data inspector can turn files into data in the data table. A standard source is capable of automatically import data from QuantumATK files, .xyz files, .cif files, LAMMPS files, VASP files and QuantumEspresso files.

However, NanoLab supports many different file format inspectors that can be activated in the settings menu. Simply tick off the desired inspectors to enable them, and wait a few seconds for Nanolab to re-index the files.

2.4 Builder Manual

2.4.1 Introduction

The **Builder** is an essential part of the QuantumATK graphical user interface to the QuantumATK calculator engines. The Builder provides a range of powerful tools for building advanced atomic-scale structures, e.g. bulk crystals, 1D nanowires, 2D nanosheets, clusters, and device configurations with either one or two probes. After a structure is built, it can be used either in QuantumATK calculations or be exported to external file formats for use in other atomic-scale simulation packages.

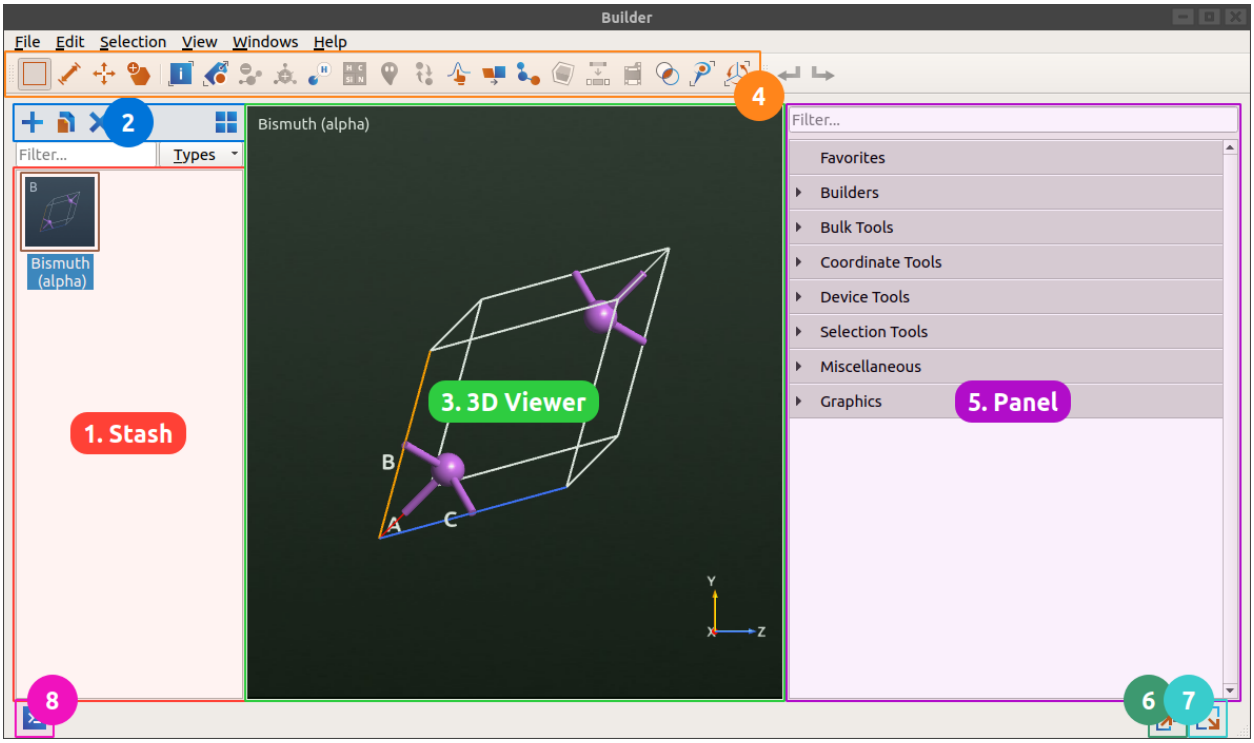
This manual provides an overview of the Builder functionalities. For specific advice and tips for building atomistic structures, please refer to the QuantumATK Tutorials website and visit the public QuantumATK Forum, where specific questions may be answered by experienced users.

Layout and basic operations

When the Builder starts up for the first time in a QuantumATK session, it is empty. You will soon learn how to add structures to it, but let us first get an overview of the Builder main window.

As illustrated below, the main parts of the Builder are:

1	Stash	Storage for all created structures.
2	Stash toolbar	Tools for adding items to the Stash, and for copying and deleting Stash items.
3	3D viewer	Visualization of active Stash items.
4	Toolbar	Simple plugins for modifying Stash items, e.g. moving a particular atom.
5	Panelbar	Advanced plugins for editing Stash items, e.g. creating a device configuration.
6	Drag-and-Drop	Use the mouse to drop the active Stash item onto another QuantumATK tool.
7	Send-to button	Use a menu list to send the active Stash item to another QuantumATK tool.
8	Console button	Use a console to execute python code.



Stash

All structures you are working on in the Builder are stored in the Stash. Each Stash item is represented by an icon, and corresponds to a single configuration.

Stash items can be **selected** and/or **active** – there is a difference: You can select more than one structure, but only one can be active. Some Builder plugins operate on more than one Stash item at a time (e.g. to combine two configurations into one), and you can therefore select other items than the currently active one.

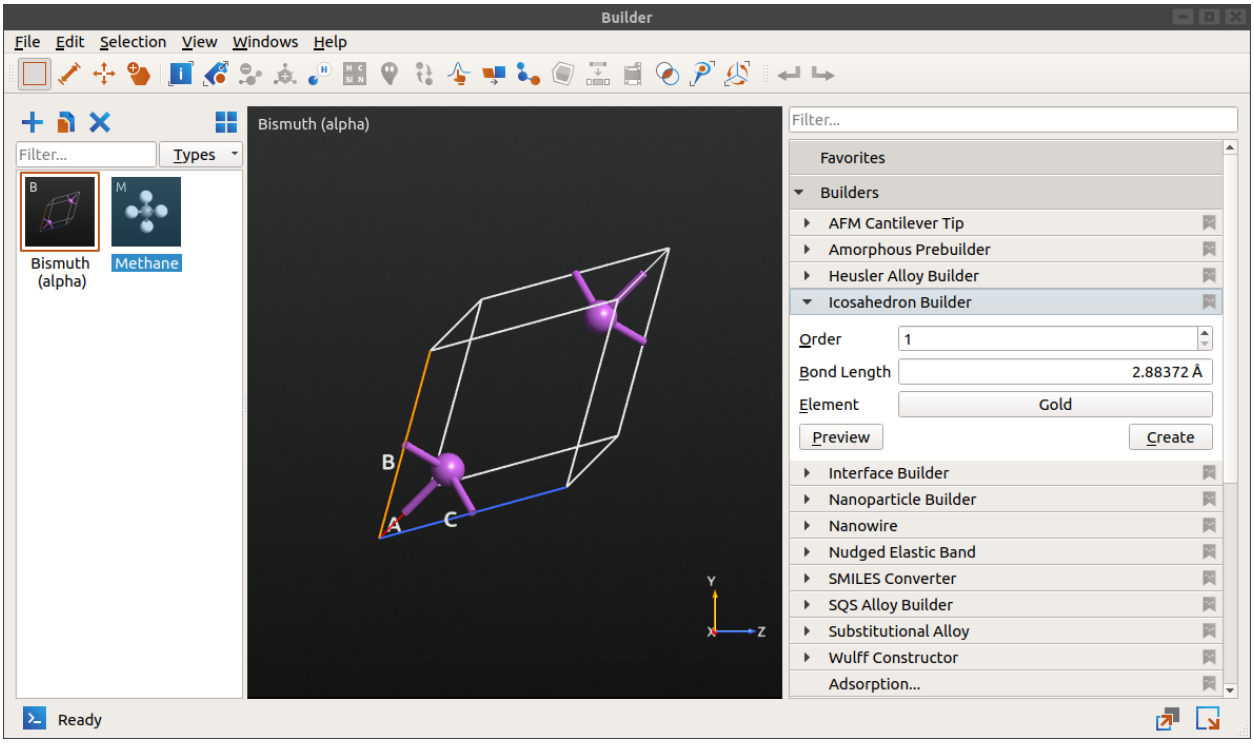


Fig. 2.1: The Stash item named Bismuth (alpha) is **active**, as indicated by the red line around the icon. The active item is always the one shown in the 3D viewer, and operations like delete atom or change lattice constant will be carried out on this structure. The Stash item named Methane is merely **selected**, which is indicated by the gray background.

Stash operations

There are several ways to add new structures to the Stash:

- You can simply **drop** configurations from the QuantumATK main window onto the Builder. The structure is automatically added to the Stash. See the tutorial introduction_quantumatk0 for an introduction to the QuantumATK main window.
- You can use the **Stash toolbar** to add completely new structures to the Stash. The **Add** menu contains a range of tools for creating configurations from scratch.
- You can also use **Add** menu to import structures from predefined databases and saved files.

The Stash toolbar also allows you to **Copy** and **Delete** active items. When you copy an item, a new and identical item is added to the Stash.

Right-click a Stash item to open its context menu. This allows you to rename, copy, delete, and in various ways save/export the structure to files, or send the structure to another QuantumATK tool.

Tip: The keyboard shortcut **F2** may be used for renaming Stash items, while pressing the **Delete** key is a shortcut to the Delete operation.

Plugin tools

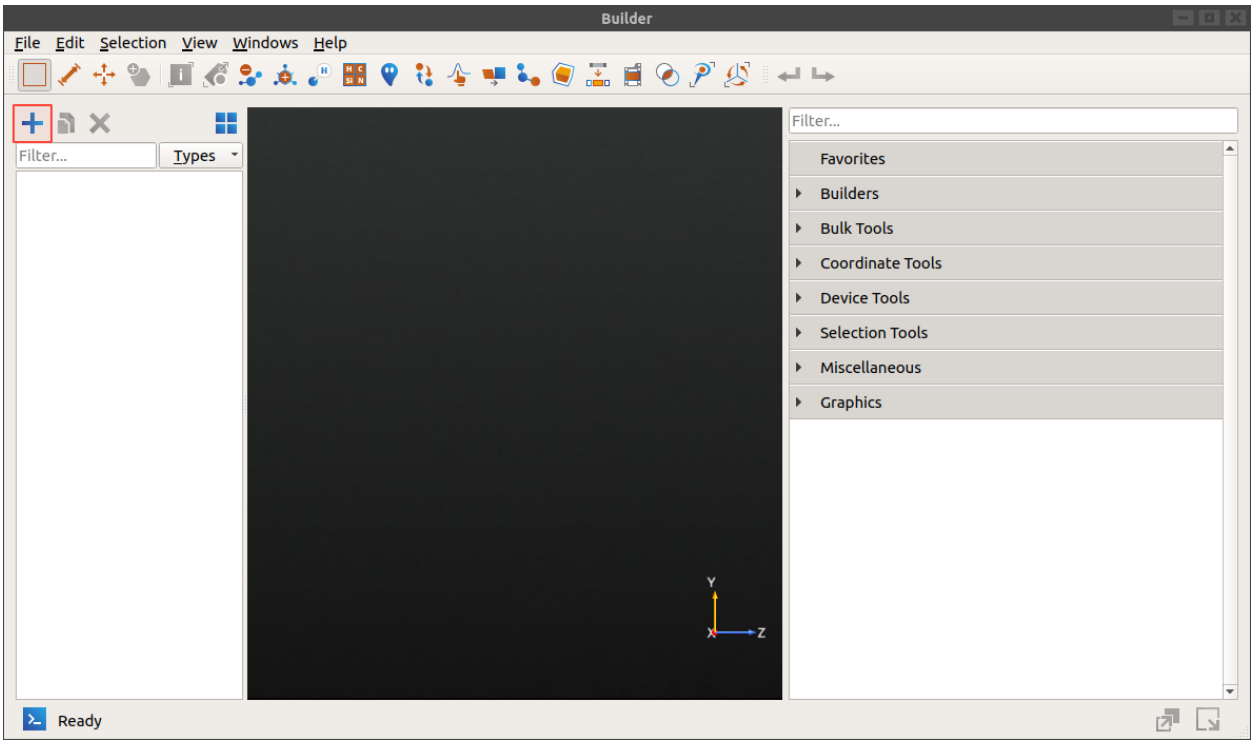
As indicated in Fig. 2.1, the horizontal **Toolbar** above the 3D viewer and the vertical **Panelbar** to the right of the 3D viewer both contain plugin tools for interacting with Stash items, and for applying more or less complex operations on the active Stash item, e.g. change the lattice constant of a bulk configuration. Note that each plugin tool usually operates on the active Stash item only.

The horizontal Toolbar plugins are applied by clicking the icon. Hover the mouse over each icon to see a tooltip describing it.

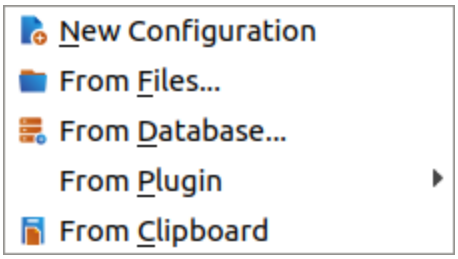
The vertical Panelbar plugins are grouped in panels, e.g. *Bulk Tools* and *Device Tools*. Click a panel to expand it – a list of relevant plugins is revealed. You can also read more about each plugin in our *Overview of built-in Builder plugins*.

2.4.2 Importing, adding, and exporting structures

There are several ways to **insert new structures** into the Builder. Most of them can be accessed selecting **Add** highlighted in red on the Stash menu.



The window highlighted in red, that opens when clicking the button, shows the different options to add a new structure.



Adding an already existing structure

Add a structure from a file

A structure can be **added** from a file by choosing *Add* → *From Files*. For a list of **supported file formats**, see the *Plugins section*.

If the file is a **natively supported file format** (currently QuantumATK Python/HDF5, XYZ, CIF, CAR, VASP) you can also **drag and drop the file from a file browser** (like Explorer in Windows, or the built-in file browser in QuantumATK) onto the open Builder window or onto the Builder icon on the toolbar in the main QuantumATK window to import the file.

It is also possible to **drag and drop a Python script (as text)**, e.g. from an Editor, onto the Builder. Finally, you can **paste a Python code from the clipboard** into the Builder by choosing *Add* → *From Clipboard*.

Tip: If you select multiple files, they will be imported as individual Stash Items.

Structure databases

QuantumATK contains an **internal database** with several hundred crystals, molecules and fullerenes. To add a structure from this database, click *Add* → *From Database*, and select the relevant database from the tabs (for example, *Crystals*).

In the *databases* window, type the name of the desired structure in the search field to filter the list.

Once you have located and selected the desired structure, click the icon highlighted in red to add it as a new Stash Item. You can also double-click selection to add that structure.

Creating a new structure

New configuration

To **create a brand new structure**, click *Add* → *New Configuration*. This will insert a molecule with a single hydrogen atom, and then you can manipulate this further by using a combination of the plugins available in the Builder such as the *Molecular Builder*.

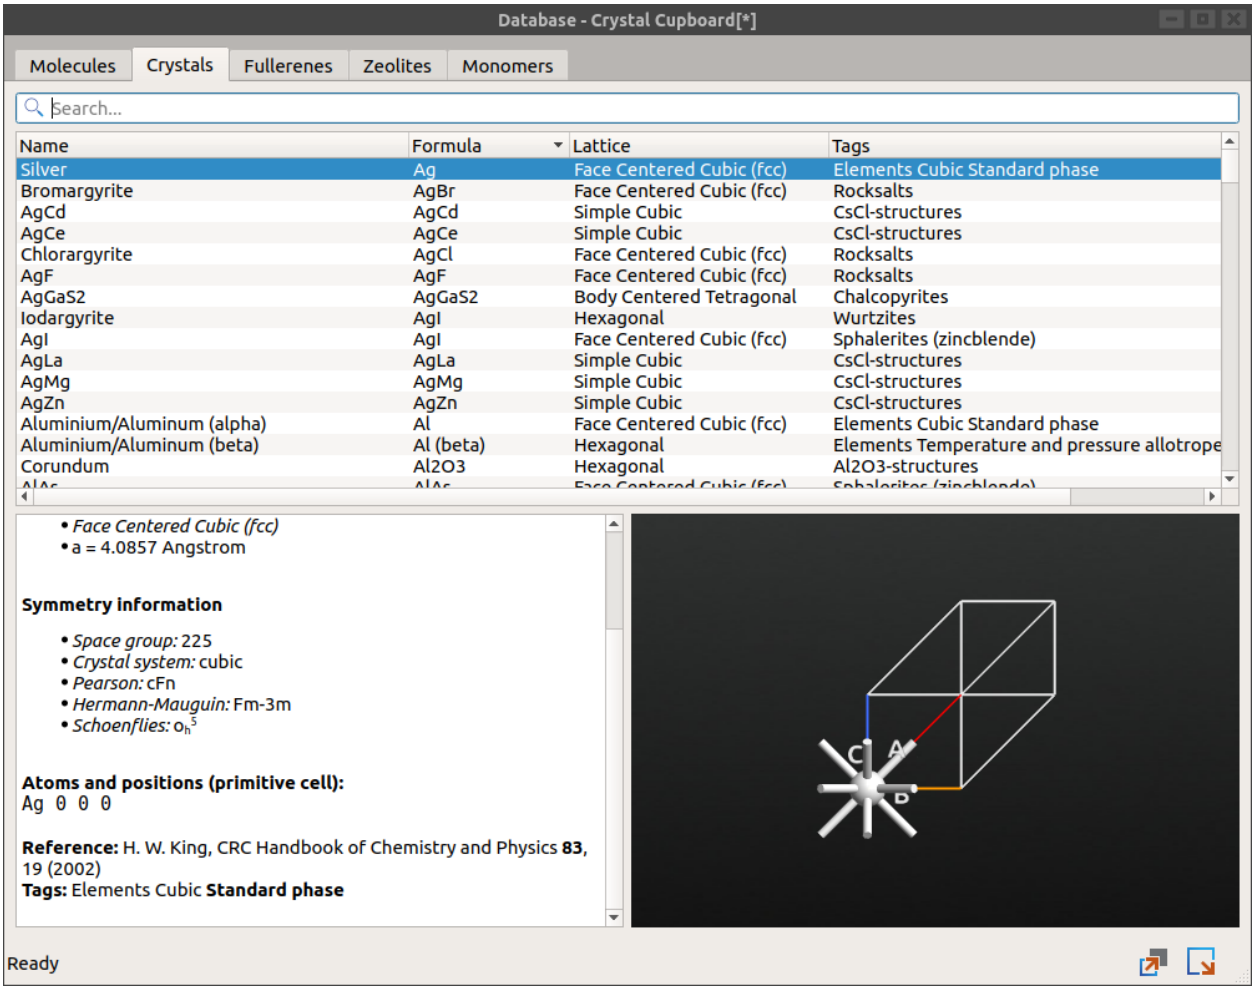


Fig. 2.2: Use the tabs to select between the Crystal, Molecule, Fullerene, Zeolite and Monomer databases.

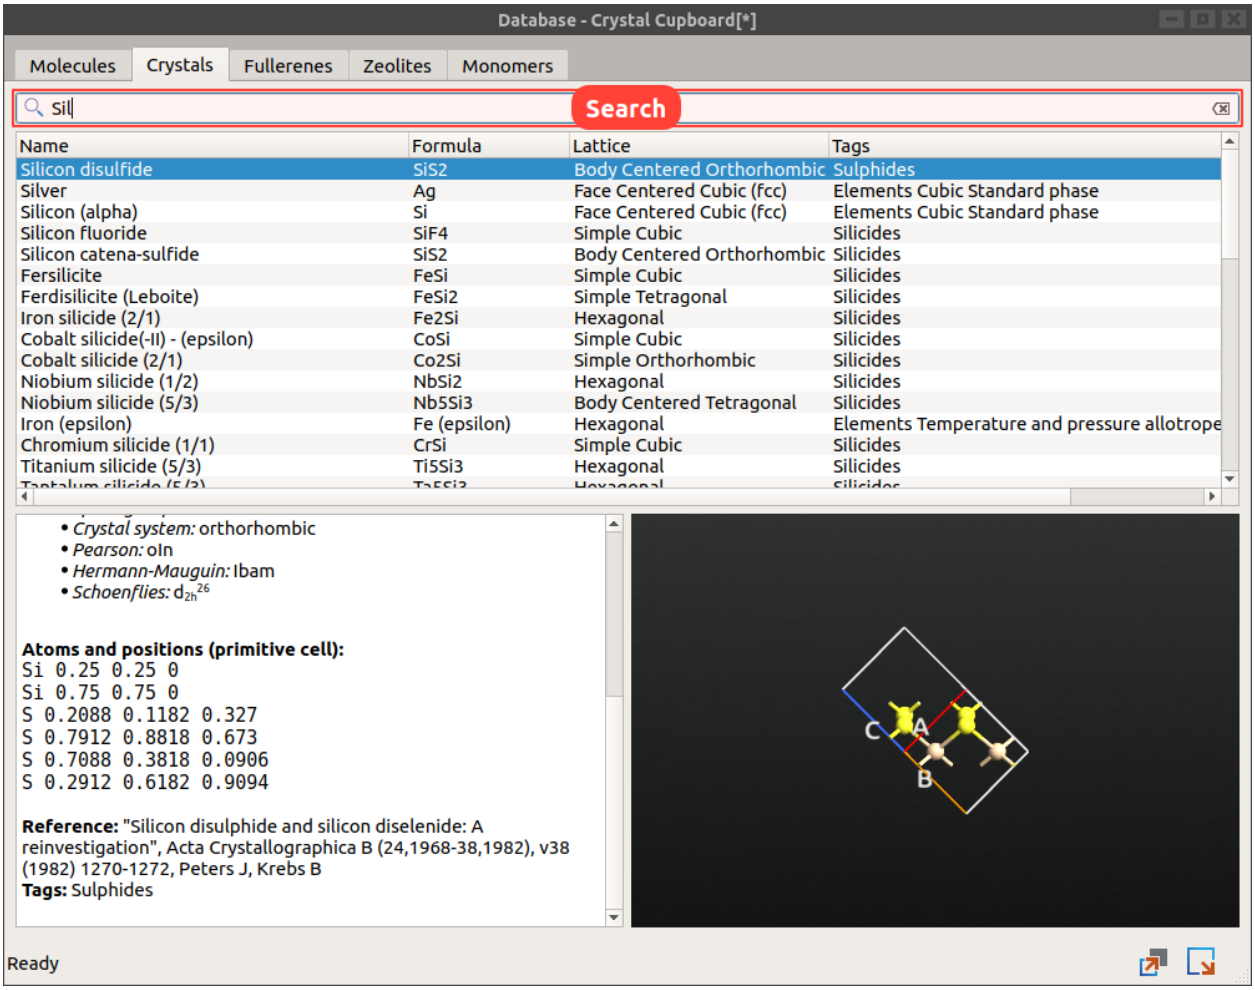

Fig. 2.3: The Crystal database. Use the search field to look for your desired crystal structure.

Custom builders

Each entry in the *Add → From Plugin* menu is associated with a plugin. These plugins can be simple and just take a few parameters, or use a very elaborate interface to create complicated structures.

Note: While other plugins normally operate on existing Stash Item, these plugins create a new Stash Item.

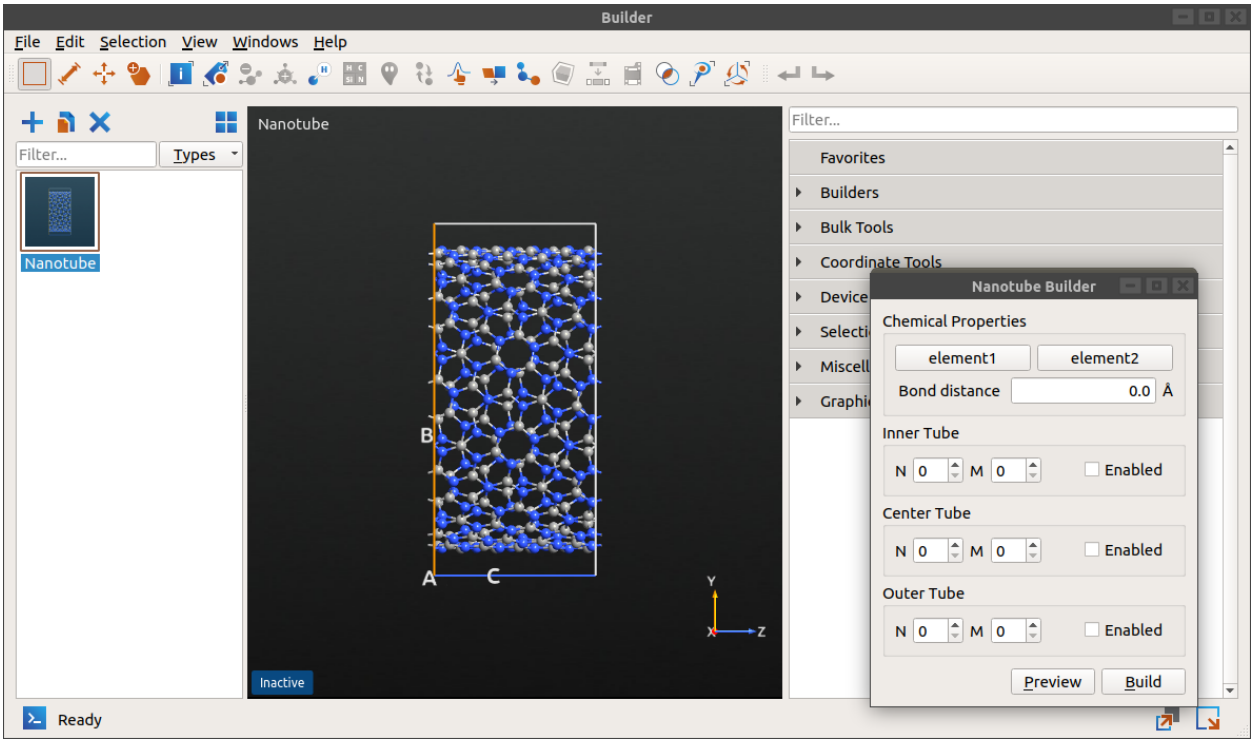

Fig. 2.4: Building a nanotube, also multiwall, in QuantumATK is very easy - just use *Add → From Plugin → Nanotube*.

The Builder comes with the following **built-in plugins**:

•Nanotube

•Nanoribbon

•Nanosheet

•*Crystal builder*

•Magnetic Tunnel Junction

Tip: In addition to the built-in plugins, you can also *write your own plugin or download and install new addons* to extend the list, to make it easier to build a particular new type of structure.

Combining, modifying and converting structures

In many cases it is necessary to **combine** two structures into one, or to **convert** one type of configuration to another, e.g. bulk to device.

In the Builder there are plugins that can be used to modify or combine structures for special purposes. They are located in the plugin panel on the right-hand side of the Builder. Two examples are:

- the *Interface Builder*, for combining two structure to form an interface, which can be accessed by clicking on *Builders* → *Interface*;
- the **Surface (cleave)** plugin for cleaving a crystal, which can be accessed by clicking on *Builders* → *Surface (Cleave)*.

Another possibility to is to **drop a Stash Item from the Stash onto the 3D window**; this will add the atoms of the dropped item to the active configuration (only the atomic positions are used, not unit cells or other properties). When you do this, the **Builder** activates the **Move Tool**, which is a powerful way to interactively translate and rotate fragments. For more details, see the dedicated *Move tool section*.

To **convert a bulk structure to a device**, use *Device Tools* → *Device From Bulk*. Similarly, to **convert a bulk structure or slab to a surface**, use *Device Tools* → *Surface From Bulk*. To go back, click the button on the toolbar. You can also **convert a periodic structure to a molecule** (removing the unit cell) using the button.

Saving and exporting structures

Once you have created a structure, you may want to **save it as an QuantumATK Python/NetCDF file** or **export it to a non-ATK format**.

Save

To save the active Stash Item into a Python or HDF5 file, press `Ctrl + S` (or use the menu *File* → *Save as*) and use the file dialog to specify the file type and location.

> **Warning:** When saving into HDF5 files, the structure is appended if the file exists.

Export

To export the active Stash Item to a non-ATK file format (like XYZ, CIF, etc), press `Ctrl + E`, or use the menu *File* → *Export configuration*.

Note: To save or export another Stash Item than the active one, right click it and choose *Save as* or *Export* from the context menu.

Sending the structure to other QuantumATK tools

As all instruments in **QuantumATK**, the **Builder** window has a **script drag** button and **Send To** button in the lower right-hand corner (see Fig. 2.1). Using these, you can transfer the active structure to e.g. the **Script Generator** to set up a calculation. To send a particular Stash Item to e.g. the Editor, right-click it and choose *Send To* from the context menu.

2.4.3 Mouse and key operations

In this section, you will learn how to operate the 3D view and manipulate atomic structures in a simple way, including how to select a specific atom or a group of atoms.

Controlling the 3D view

Using the **right button** and **scroll wheel** of the mouse, you can perform the following operations for the 3D view.

- **Rotate** can be done by moving the mouse while holding down the right mouse button.

  If the mouse pointer is near the center of the 3D view, the rotation will be done as a full 3D view rotation.

  Having the mouse pointer at the 3D view edge constrains the rotation to the view plane. If you first align a particular axis with the screen normal, this function will then allow you to rotate the structure around this axis in a controllable manner.

- **Zoom** can be easily done by rolling the **scroll wheel** of the mouse.

  If you do not have the scroll wheel, you can do **Zoom** by holding down the **Ctrl** key, simultaneously pressing the right mouse button, and then moving the mouse back and forth to actually zoom the structure.

- **Pan** can be easily done by pressing the **scroll wheel** down, and then moving the atomic structure with the mouse.

  If you do not have the scroll wheel, you can **Pan** by holding down the **Shift** key, simultaneously pressing the right mouse button, and then moving the mouse to actually pan the structure.

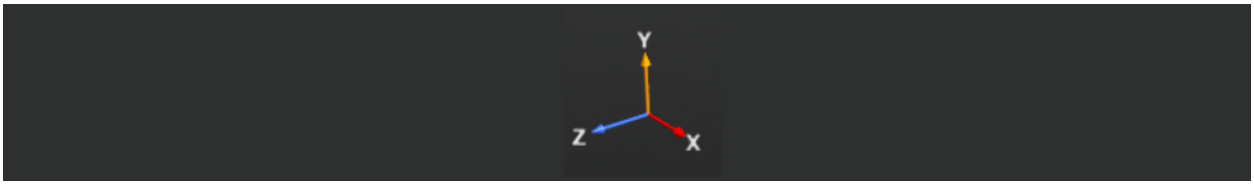

Fig. 2.5: The compass in the upper right-hand corner helps you to orient yourself when rotating the 3D view.

Press **Ctrl+R** to reset the 3D view to the default orientation and zoom.

For a periodic system, the crystal axes labeled as **A**, **B** and **C** are given with the red, yellow and blue sides of the periodic cell, respectively. The coordinate origin is placed at the cell vertex where all the three crystal axes do intersect.

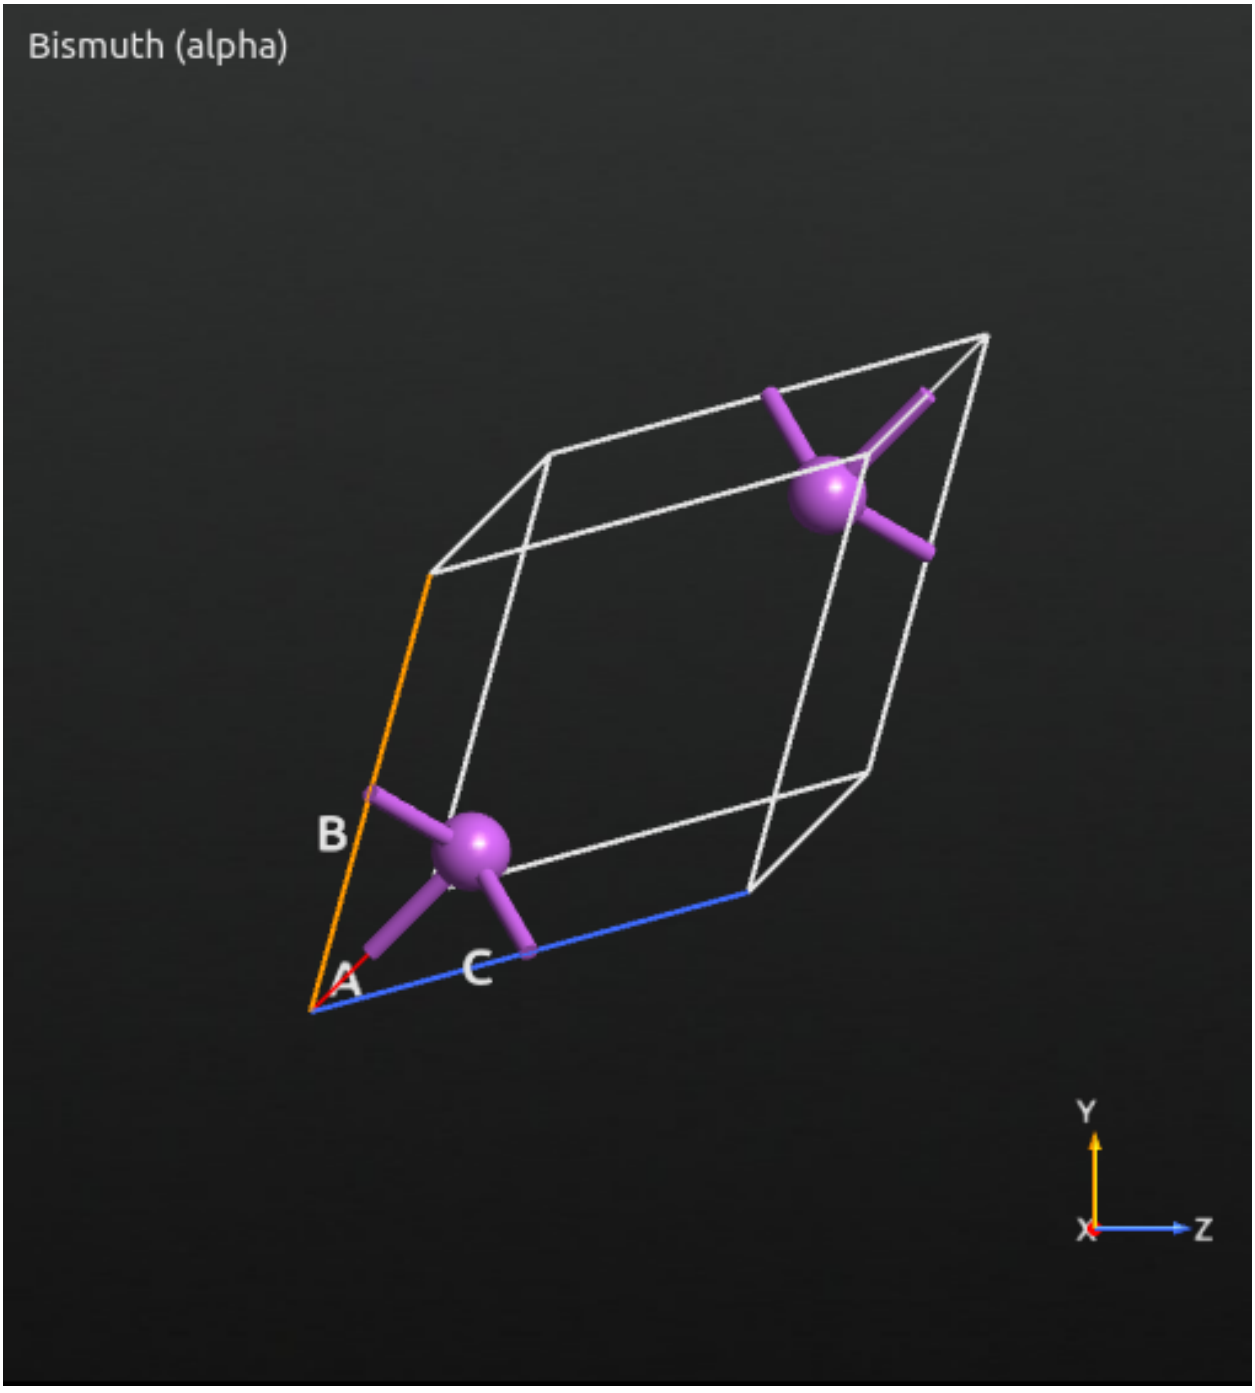

Fig. 2.6: The red, yellow and blue box edges are used to indicate the A, B, and C crystal axes for a periodic structure, respectively. These are the same colors as used on the *compass* for the X, Y, and Z axes of the Cartesian coordinate system. In general, the crystal axes are not parallel to these coordinate axes, even for a cubic cell.

Preview mode

Some of the plugins have a **Preview** button, and may even update the preview when some of the parameters are changed. The preview state is indicated by the red background color and a text in the upper left corner of the 3D window.

Important: Keep in mind that the stash item has not been modified yet. To confirm the operation, you actually need to press the relevant button, often called **Apply**.

To dismiss the preview, you can just click on the 3D window. You can then bring it back by clicking on the plugin **Preview** button again.

Note: All the other plugins become unavailable when a preview is shown. It is meant to avoid confusion about which structure you are operating on.

Selection

Selecting an atom or a group of atoms is often an initial step for those plugins that allow us to manipulate the atomic structure in the Builder. A number of plugins apply their operations on selected atoms only. There exist some plugins that act on the whole structure if no atoms are selected.

The Builder therefore has many ways to select atoms and manipulate selections. The selected atoms are indicated by a yellow halo.

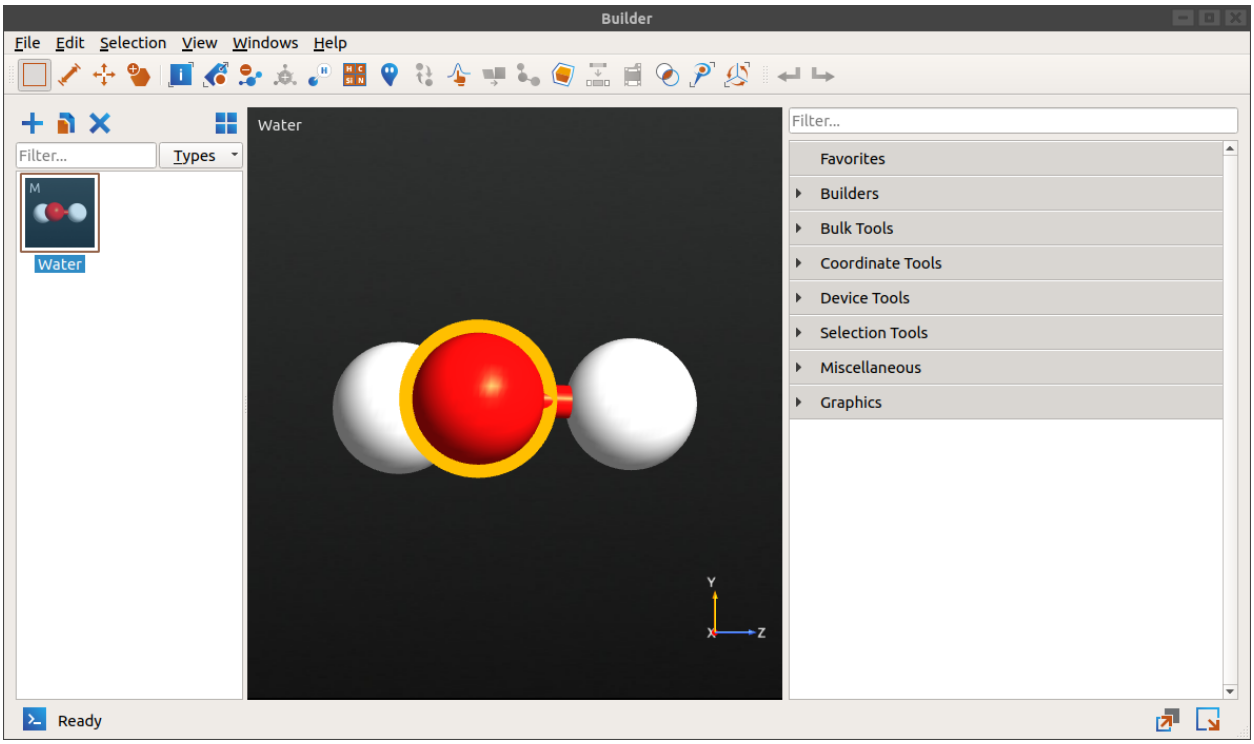

Fig. 2.7: The oxygen atom in this water molecule is selected, as indicated by the yellow halo.

To **select an individual atom**, click on it with the **left mouse button**. Note that this operation will cancel any existing selection of atoms that has already been made in the structure.

To **add an atom** to an existing selection, hold down the **Ctrl** key and then click on this atom. If you click on an already selected atom, this atom will be removed from the selection.

To **select a group of atoms**, you may make use of the **shape select tool** by first clicking on the icon in the top toolbar, and then choosing one of the following shapes for the selection area.

- **Rectangle** .
- **Circle** . The circle is centered at the initial mouse position.
- **Lasso** (free-form) .

Subsequently, the **left mouse button** can be exploited to draw a figure of the chosen shape to enclose the atoms of interest.

Note that the shape select tool operates on all the atoms that are visually inside the shape drawn by the mouse as well as on those atoms that may be hidden behind the other atoms, but are virtually projected on the shape. The single-click mouse select operation only applies on the atom you have clicked on.

The selection operations can be modified in various ways using the **Ctrl** and **Shift** keys.

- To **add a group of atoms** to an existing selection, hold down the **Ctrl** key and select the atoms of interest with the shape select tool. In this case, the already selected atoms that may appear inside the new selection area will not be deselected.
- To **undo the selection** for the already selected atoms, hold down the **Shift** key and draw a shape with the shape select tool to enclose the atoms to be deselected.
- **Double-click** on an atom in a **fragment** (a fragment is a set atoms connected by bonds) with the **left mouse button** to select all the atoms of this fragment. If you hold down the **Ctrl** key and double-click on an atom of the fragment, all the fragment atoms will be added to the existing selection, or removed if the clicked atom was already selected.
- By holding down the **Shift** key and **double-clicking** on an atom, you can **select** all the atoms of **the same chemical element** as the doubled-clicked atom in the atomic structure. If you simultaneously hold down the **Ctrl** and **Shift** keys, and then **double-click** on the atom in the fragment, the fragment atoms will then be added to the existing selection, or removed from the selection if the double-clicked atom of that fragment was already selected.

There exist several other useful keyboard tricks.

- To **deselect** all atoms, left-click on the background of the 3D window, or press the **Esc** key.
- Press the **Ctrl+A** keys to select all atoms.
- Press the **Ctrl+I** keys to invert the selection. In this case, the atoms of the original selection will be deselected, wheres all the other atoms of the atomic structure will be included in a new selection group.

Advanced select

Sometimes the atoms you want to select are not easily accessible with the mouse, or you need a detailed control of the precise atoms to select. In this case, you can use a set of the following plugins available under *Selection tools*.

- **By Expression** plugin allows you to select atoms based on logical expressions.

For example, you want to select all the oxygen atoms with a Z coordinate larger than 1.5 Å or an X coordinate smaller than -0.5 Å. This can be easily achieved by typing

$$e = 0 \quad and \quad (z > 1.5 \quad or \quad x < -0.5)$$

in the *Expression Select* input field, and then pressing the **Enter** or **Tab** key.

•Using **By Element** plugin, you can select atoms of a particular chemical element.

•**Close Neighbors** plugin is designed to locate completely or almost overlapping atoms.

The overlapping atoms may occur, for example, as a result of a mirror operation, or a translation. This kind of atoms are hard to spot visually, but they must be removed to perform any further calculation for the atomic structure constructed in the Builder.

Select by tags

In the *Selection tools*, there exists an additional selection feature **Tags** that allows for assigning one or multiple tags to an atom or a group of atoms. So, each atom can then have many tags, and the same tag can apply to many atoms in the atomic structure. A tag can be any label that identifies an atom or a set of atoms.

One of the purposes of having tags is that you can assign them to a set of atoms when you build the structure, and then use them later on, e.g., in the Script Generator, to assign a special basis set, or initial spin to those atoms. Instead of making a list of the atom indices for all those atoms of special interest, you would just say *use basis set X for atoms with tag Y*. For example, for a work function calculation one might use a basis set with a longer range for the surface atoms than for the bulk atoms in the structure.

To **add, remove and modify tags** on atoms, use the plugin *Selection* → *Tags* plugin. This placement of the plugin indicates that tags are also a handy tool for selecting atoms. The fastest way of selecting atoms with tags is to click on the icon in the top toolbar.

Deleting atoms

To **delete atoms**, you should first select them in the structure, using any selection method discussed above, and then press the **Delete** button on the keyboard.

Tip: It is possible to delete atoms from the structure, using *Coordinate Tools→Coordinate List*. You can also **insert atoms** with this tool.

Undo

Any operation (except selection) in the Builder can be undone by pressing in the top toolbar. The undone operation can also be redone using the icon, if needed. The keyboard shortcut for undo is the **Ctrl+Z** keys, while the **Ctrl+Y** keys stand for redo.

Note: Some of the plugins do not change the atomic structure in the stash item in which you have initiated the change, but they rather create a new stash item for the structure with the change implemented. In this case, there is obviously nothing to undo but delete the new item if it is not what you wanted.

2.4.4 Using the Move Tool

The Move Tool in the Builder is used to move, rotate, and align atoms, using either the mouse or exact coordinate and vector control. This section will explain the basic features and how to use them.

To **activate** the Move Tool, click the button on the toolbar. The Move Tool will also automatically be activated if you drop a system from the stash onto the 3D window (see *below*).

When the Move Tool is active, a widget appears in the panelbar in the right side of the window, where you can set some parameters that control the operations.

There are four modes of move interaction - Translate, Rotate, Align and Advanced Move. Each mode can be activated either by selecting buttons available in the 3D window, or by selecting one of the tabs in the widget.

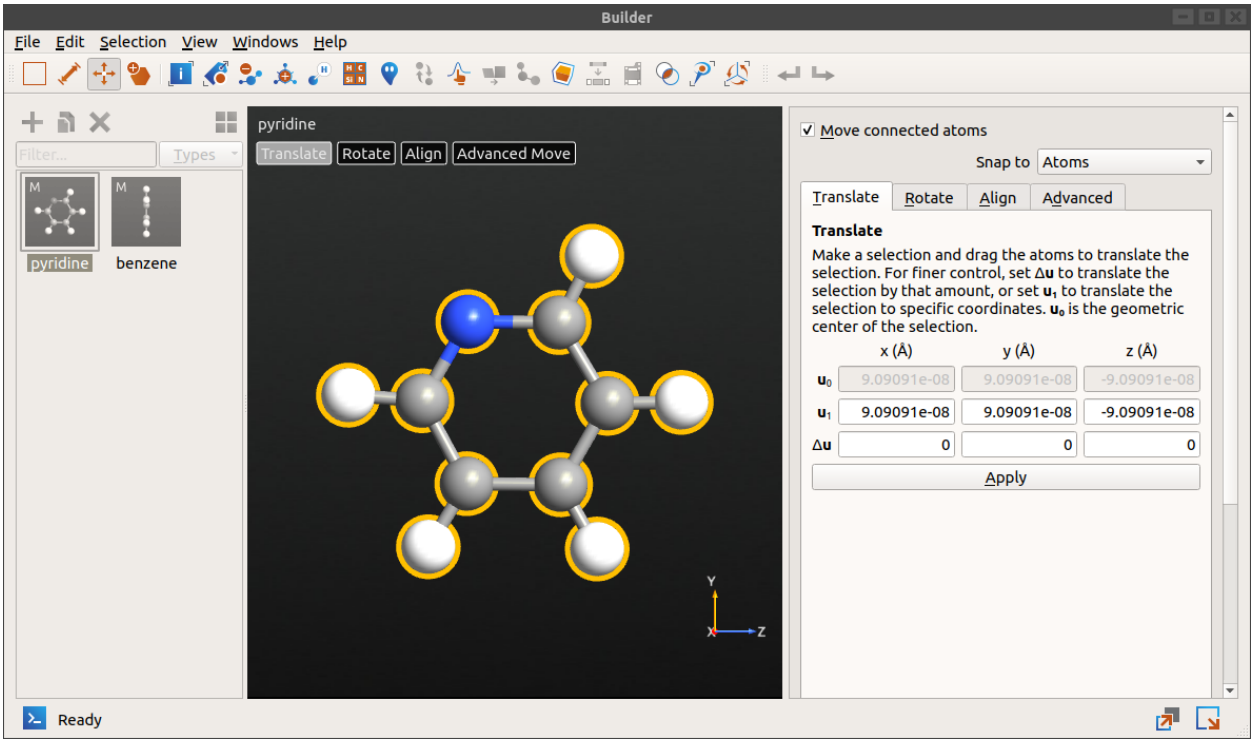

Fig. 2.8: Benzene molecule as an active Stash Item. Move Tool was activated by clicking .

Also note that when the Move Tool is active, all other plugins are unavailable, to avoid interference (in the same way other plugins are disabled in *Preview mode*). To **use any other plugin**, you must first **exit** the Move Tool, either by closing the widget, or by clicking the shape select button on the toolbar at the top of the window.

Selection control

The Move tool **operations** are applied to the atoms which are selected. In Fig. 2.8 all atoms in benzene molecule are selected.

Tip: If you **hold** your mouse on an atom or a bond in the window, you can get detailed **information** on that atom or bond.

Translation

To **move (translate)** the selection **drag** one of the atoms in the selection group to a new position, holding down the left mouse button. If multiple atoms are selected the entire selection group will follow rigidly, i.e. the same translation vector will be applied to each selected atom.

The translation is carried out in the view/screen plane (except for *snapping*, as explained below).

Position or move the center of the selected group by entering its new cartesian coordinates in the table given to the right of the window. Change the row for u_1 to set a new position, or row u to move the center of selected group for a specific amount. The center of the group is given in the row u_0.

Anchor atoms

Another way to activate the Move Tools is to drop a structure from the Stash onto the 3D window. In the Fig. 2.9, benzene molecule has been dropped with the pyridine. In a addition, three anchor atoms have been selected (red markers).

When the Move Tool is active, you can **select** up to three atoms within the selection group, which are used to guide the actual **move operations**. These atoms will be indicated by **red selection markers**, and will also be marked by the numbers 0, 1, and 2 to show the selection sequence. These are called **anchor atoms**. In Fig. 2.9 you can see that anchor atoms have been selected.

You can also see in Fig. 2.9 that when the anchor atoms are selected, the three **table rows in the widget** are populated. The three rows show:

- r_0, the position of the first anchor atom (index 0).
- $r_1 r_0$, i.e. the vector from the first to the second anchor atom.
- $r_2 r_1$, i.e. the vector from the second to the third anchor atom.

The significance of these vectors, or rather how to use them in a powerful way, will become more obvious in the following sections. As a general rule, select:

- **One** anchor atom to **translate (move) the fragment**,
- **Two** anchor atoms to **adjust the angle** between two bonds,
- **Three** anchor atoms to **adjust a dihedral angle**.

To **deselect** all anchor atoms, click the **background** with the left mouse button. To deselect one anchor atom, just left-click it again (if you deselect the first anchor atom, all anchor atoms are deselected, and if you deselect the second anchor atom, the third one is also deselected).

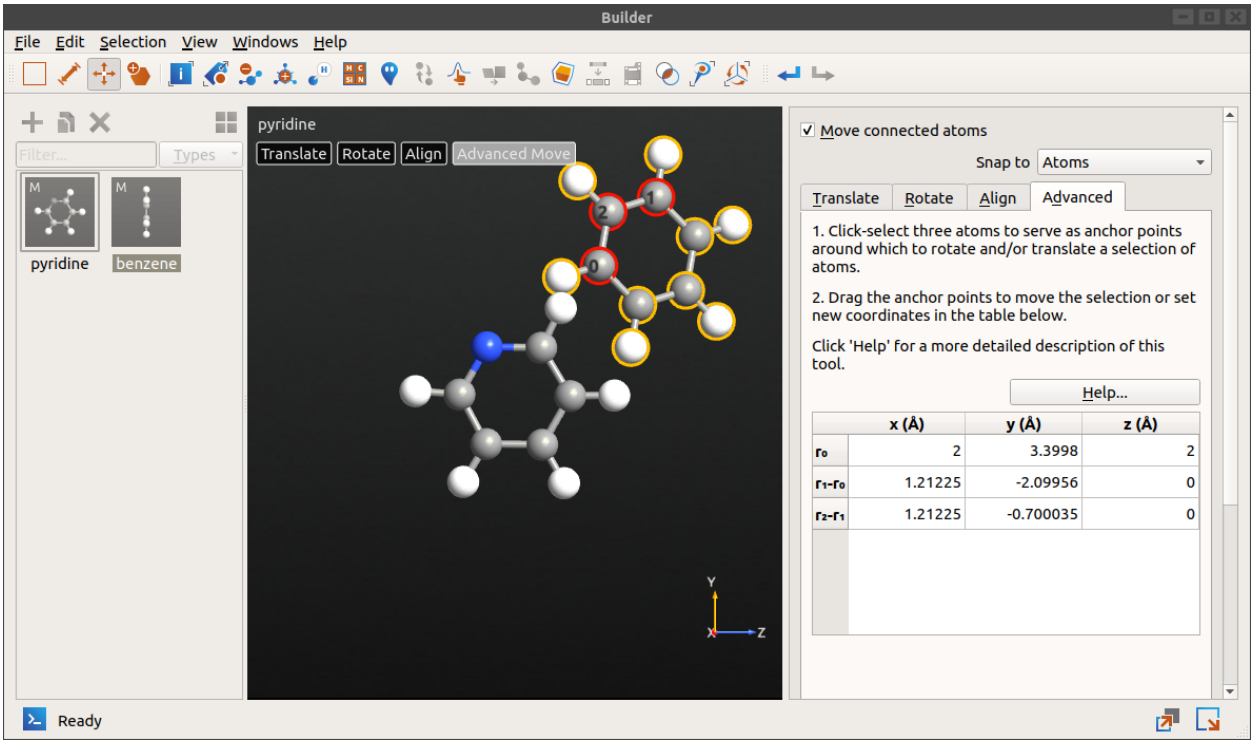

Fig. 2.9: The three anchor atoms on the pyridine molecule are indicated by an index and red markers.

Snap and fuse

If *Snap* is checked when you translate by mouse, the anchor atom will snap to the positions of other atoms, if you come close enough to them. This can be used to place the anchor atom exactly at the position of another atom, which does not belong to the selection group.

Important: The configuration obtained just after snapping is not valid, which will be indicated by the label showing that there are overlapping atoms. There may be more than one atom pair overlapping as a result of the translation. Click *Fuse* to delete the overlapping atoms not belonging to the selection group.

The *snap* option defines the translation vector that is applied to the entire selection group in all 3 directions; **X**, **Y**, and **Z**. Thus, using the *Snap* option may bring the selection out of the screen plane if the snap atom does not have the same **Y** coordinate as the anchor atom (in the example case of translation in the **XZ** plane).

Tip: A very powerful way to use snapping is to add alignment atoms at the positions where you want to place an atom or molecule. This alignment atom could be in a high-symmetry position, e.g. an fcc site a certain distance above a crystal surface. The alignment atom itself is sacrificial, and will be removed by the *Fuse* operation.

Note: It is common that there are **atoms which are close, but not exactly overlapping**, after a move operation. In this case *Fuse* cannot be used, but instead the plugin *Selection Tools* → *Close Neighbors* is useful to find and delete atoms which are close to each other. Make a habit of **checking the structure** with this tool after a complex operation, e.g. with the Move Tool, or after mirroring or rotating structures.

Advanced Move

If you select **two anchor atoms** and start moving either one with the mouse, the selection group will rotate, using the **first** anchor atom as the **rotation center** and the **vector** between the two anchor atoms as the **rotation axis**. During the rotation, you can **snap** to any other atom for more exact control.

Alternatively, you can **type in** the direction vector between the two anchor atoms $r_1 r_0$ in the widget, to **realign** the structure with regard to the cartesian directions. Only the direction of this vector matters, not its magnitude. For example, if you want the group to be realigned such that the vector between the two anchor atoms becomes parallel to the Z-direction, enter $r_1 r_0 = (0, 0, 1)$.

Finally, if you select **three anchor atoms**, you can use the mouse to control the dihedral angle between the plane spanned by two of the anchor atoms and the current mouse position. *Snap* works as above, as well as editing directly in the widget.

To **align** the group such that the three anchor atoms lie in the **XY**-plane, enter $r_1 r_0 = (0, 1, 0)$ and $r_2 r_1 = (1, 0, 0)$. The cross product of these two vectors is $(0, 0, 1)$, which is the **XY**-plane normal.

2.4.5 Overview of built-in Builder plugins

The Builder contains a lot of tools. Each tool allows one to do an isolated operation, for instance, repeating a periodic structure, rotating a selected atom around a specified axis, passivating selected atoms with hydrogen, and many other operations on the atomic structure. The true power of the Builder comes from the possibility of combining these operations in numerous ways to build complex atomic structures.

In the following, we give a quick overview of the basic plugins shipped with the QuantumATK package. This overview provides a broad picture of the functionalities of the Builder. The plugins are designed to be simple to use, and many of them have instructions built into the QuantumATK interface. You may also take advantage of the tooltips to find out about a particular plugin parameter.

Builder Toolbar plugins

Shape select uses the mouse to paint a shape to select atoms. Hold the mouse over the toolbar at the icon to switch between the three shape select modes: rectangle, circle and lasso.

Measure tool measures distances, angles and dihedrals between atoms.

Move tool manipulates an atomic structure by moving and/or rotating its fragments (groups of selected atoms) in a controllable way. See also the section *Using the Move Tool*.

Molecular builder builds a molecule from the library of chemical elements and fragments.

Information tool displays information about an active configuration.

Tags allow for a quick selection of atoms labeled with user-defined tags.

Delete atoms deletes selected atoms of an active configuration.

Centroid places an atom in the geometrical center of the group of selected atoms. This is especially handy for creating alignment points to be used with the *Move Tool*. Note that you should select at least two atoms for the Centroid operation to do anything.

Passivate adds hydrogen or pseudo-hydrogen atoms to passivate dangling bonds for selected atoms, or the whole structure if no selection has been made prior to passivation. This operation preserves the periodicity of the original unit cell structure.

Periodic table allows you to replace the selected atoms of a certain chemical element with atoms of some other chemical element from the Periodic Table, which is displayed when you click on the icon.

Ghost converts selected atoms to ghost atoms, or to regular atoms if the selected atoms were already ghost atoms.

Swap positions swaps positions of two selected atoms.

Rattle randomly displaces each of the selected atoms in the atomic structure, with a maximal deviation of 0.125 Å from the original atom position in any direction. If no atoms are selected prior to the Rattle operation, all the atoms of the atomic structure will be randomly displaced.

Niggli form reduces the unit cell and related atom positions to the Niggli form.

Convert to molecule converts the unit cell atomic structure to an isolated molecule-like structure, removing periodic boundary conditions of the unit cell. For a device structure, this operation removes the electrodes, converting the central region of the device to the corresponding non-periodic structure.

Convert to bulk converts an isolated molecule or any non-periodic atomic structure to a periodic unit cell structure, e.g., to describe the molecule in a periodically-repeated cell. For a device structure, this operation removes the electrodes, converting the central region of the device to the corresponding periodic structure.

Split device splits a device, creating separate stash items for the electrodes and the central region, and imposing periodic boundary conditions on each of the item structures.

Extract image extracts the active image from a Nudged Elastic Band (NEB) configuration, and then adds it to the stash as a new configuration.

Overlapping atoms tool checks for overlapping atoms in an active configuration.

POVRay Generator generates a POV-Ray processed image.

Camera controls the view plane of the currently active 3D window.

Builder Panelbar plugins

Builders

Basic plugins for converting or combining atomic structures into new complex structures.

AFM Cantilever Tip builds an AFM-Tip with a cuboid shaped block. This operation cuts the tip area, using a selected material on the stash by controlling the size and the orientation.

Amorphous Prebuilder creates an amorphous structure with a given density, according to a sum formula.

Icosahedron Builder creates an icosahedron crystal.

Interface creates an interface between two bulk structures, e.g., SiO_2 and Si, to represent the oxide on a Si surface. This operation automatically searches for an interface configuration with minimal average strain by doing various rotation and repetition operations of the two input bulk structures, using the coincidence lattice method.

Nanowire builds a nanowire with a given radius and surface energies in the main crystallographic directions, using the Wulff construction method.

Nudged Elastic Band creates a NEB path between two end configurations, using one of several different methods. The created path can then be manipulated in the tool to remove or insert images, or further refine the path between the two images.

Substitutional Alloy creates an alloy structure by replacing the selected atoms in the stash item structure with another element, by specifying a percentage (concentration) of the substitutional atoms in the alloy. The tool is also able to create vacancy sites with a certain concentration.

Wulff Constructor creates an atomic cluster with a given radius and surface energies in the main crystallographic directions, using the Wulff construction method.

Generic Alloy creates a random alloy by combining different, but similar, unit cells in a larger supercell. The percentage of each configuration in the alloy can be specified in the plugin as well as the size of the alloy that can be controlled by changing the number of repetitions in each direction. The tool has an option of choosing the algorithm, Normal distribution or Fixed fraction, for generating the alloy structure.

Packmol creates an amorphous configuration containing the molecules (or any non-periodic atomic structures) listed in the plugin table.

Polycrystal (Voronoi) generates the polycrystal from the crystal structures taken from the stash. It creates the polycrystal by controlling the grid points and a crystal type.

Surface (Cleave) cleaves a bulk structure to create a surface, device electrode, or a slab. This tool has a variety of options when creating the surface cell.

Bulk Tools

These plugins primarily operate on the unit cell of a periodic atomic structure.

Crystal Symmetry Info detects the symmetry of the atomic structure if one clicks on the *Detect* button. The tool gives information on the space group of the structure in Hermann-Mauguin, Hall and Schoenflies conventions. If one clicks on the *More information* button, more information can then be obtained about the symmetry properties of the atomic structure.

Fit Cell attempts to fit a cell to the structure by looking for periodic patterns.

Merge Cells merges two periodic structures in a simpler way than the Interface pluging in the Builders does. That can be of particular interest when merging 1D or 2D structures, e.g., merging two nanotubes to create a 1D junction.

Repeat repeats a periodic structure in A, B, and C.

Stretch Cell allows you to stretch the unit cell. One can then choose whether the selected atom positions should be either moved rigidly or stretched in the unit cell. This tool can be used to strain a structure, or make a 2D junction (e.g., bilayer graphene) with partial overlap.

Supercell applies a 3x3 matrix operation to a unit cell to make a supercell structure. The atoms are then repeated as needed to fill the supercell. This operation is of particular interest for converting the primitive cell to a conventional cell, or a hexagonal to an orthorhombic cell.

Swap Axes swaps the unit cell axes A, B and C, and/or the coordinate system axes X, Y, and Z. In most cases, this operation should be applied twice to end up with a right-handed cell, not a left-handed one.

Wrap wraps the atoms (which are outside of the unit cell) back into the cell. This option can be of interest if some atoms appear outside of the unit cell during atomic structure operations.

Brillouin Zone Viewer shows the Brillouin zone and reciprocal lattice vectors of the crystal in the Cartesian coordinate system.

Lattice Parameters allows one to change the lattice type as well as the actual lattice vectors and related lattice parameters of the crystal structure.

Coordinate Tools

These plugins primarily operate on the atom coordinates.

Center puts the geometrical center of the unit cell atomic structure (considered as a group of atoms) in the geometrical center of the corresponding unit cell, or with respect to the origin in the case of a molecule or non-periodic atomic structure such as an atomic cluster.

Custom Passivator passivates dangling bonds of undercoordinated atoms with hydrogen or pseudo-hydrogen atoms. This passivation tool has an option to manually set the bond distance between the hydrogen and passivated atom.

Mirror mirrors a group of selected atoms with respect to a given mirror plane. Optionally, one may copy the atoms from their original to their mirrored positions to have both the mirrored and original atoms in the structure.

Quick Optimizer runs a geometry optimization of the atomic structure using an ATKClassical potential, provided that there is a classical potential available in the classical potential database for each of the chemical elements in the structure.

Rotate rotates a group of selected atoms with respect to a given axis. Optionally, one may copy the atoms from their original to their rotated positions to have both the rotated and original atoms in the structure. Note that the *Move Tool* provides an alternative way to rotate the group of atoms with the mouse.

Sort sorts the atomic coordinates. This operation can also be done in the Coordinate List.

Transform by Expression applies a coordinate transformation given by a mathematical expression to the coordinates of selected atoms, e.g., $x \rightarrow x + \sin(y)$. This plugin supports all mathematical functions available in the Python math module, and interprets the variables x,y,z as atomic coordinates, and a,b,c as lattice vectors of periodic systems.

Translate moves a group of selected atoms by a given distance. Optionally, one may copy the translated atoms to their original (prior to translation) positions to have both the translated and original atoms in the structure. Note that the *Move Tool* provides an alternative way to move the group of selected atoms with the mouse.

Coordinate List allows one to directly edit the coordinates of atoms in a sortable coordinate list. You should right-click on the table to use the context menu to insert or delete atoms. Selecting rows in the table automatically selects the corresponding atoms.

Z-matrix is a direct way of editing the Z-matrix of selected atoms.

Non-default Coordinate Tools

If needed, other plugins for building very specific atomic structures can be added to the Coordinate Tools. These plugins are not available in the Coordinate Tools by default, but they can be installed from the AddOnManager, see *Help* $\rightarrow$ *AddOn Manager*. For example, the following plugin can be installed from the TubeWrapper and FunWithGraphene packages in the AddOnManager.

Buckler applies a buckling by modulating the x-coordinate of an initially flat structure.

Tube Wrapper wraps a periodic system onto a circular arc, or a tube if the angle is 360 degrees. Subsequently, the original B(Y) axis will be mapped onto the arc, while the tube axis will lie along C(Z). If helical rise is non-zero, a helix is then created such that a difference in the Z coordinate between the beginning and end is the specified helical rise.

Twister twists the structure by a given angle around the Z axis. The non-twisting zone defines a distance from the edges of the system in the Z direction, which are left unmodified to maintain periodicity.

Device Tools

These plugins create or modify a device geometry.

Central Region Size allows for changing the size of the central region after a device structure has already been created in the Builder, using the *Device from bulk* or *Device from surface* plugins. Using this tool, one may also add or remove atomic layers in the central region, enlarging the right and/or left electrode extensions.

Electrode Size allows for changing the size of the electrodes after a device structure has already been created in the Builder, using the *Device from bulk* or *Device from surface* plugins. This is similar to the Central Region Size plugin.

Device from Bulk is the main tool to automatically create a device in the Builder. The tool converts the bulk configuration item in the stash to the device central region structure with no periodicity in the C-transport direction unlike the original bulk structure. It then attaches the left and right electrodes of the device to its central region. The electrodes are constructed from the edge atomic layers (electrode extensions) of the central region. The electrode length can be set by default or manually in the plugin.

Surface from Bulk is the tool to automatically create the surface structure by converting the bulk configuration structure in the stash to the central region of a one-probe device. The tool then attaches the left electrode to the device central region. The electrode is constructed from the left edge atomic layers (electrode extension) of the central region. The electrode length can be set by default or manually in the plugin. To create a real surface, some of the atoms have to be manually deleted from the one-probe device central region (or original bulk structure) to create a vacuum layer above the surface of interest.

Graphics

Properties opens a window with the many graphical options available in QuantumATK.

Miscellaneous

Various plugins that do not fit in any other category.

Doping adds doping charge to the group of currently selected atoms. One may also undo doping by selecting a row in the table. This tool is of particular interest to modeling of doping effect in a atomistic semiconductor device without explicitly introducing dopant atoms.

Spatial Regions allows one to add and remove metallic and dielectric regions in the device structure. This tool is of particular interest to building a semiconductor device with the dielectric spacer between the gate electrode and channel region of the semiconductor device. Note that the metallic and regions are given by the continuum model in a TCAD fashion, unlike the channel region that is treated at the atomistic scale.

Select Tools

Plugins for advanced selection of atoms.

By Bond Length selects atoms by a range of separation distance between the atoms.

By Element selects atoms by a type of chemical element.

By Expression selects atoms using a logical expression, e.g., setting e=H and x<10 will select all the hydrogen atoms with X coordinate less than 10 Å.

Close Neighbors helps to identify overlapping atoms. It is a very useful tool to detect those atoms that are on top of each other, and then delete duplicate atoms. This must be done before sending the structure from the Builder to the Script Generator to avoid any numerical issues upon running the QuantumATK calculations.

Tags allow one to add, edit or remove tags on an atom or a group of selected atoms. One may also select atoms by this plugin, but the *Tag Select* button in the toolbar is a faster option for atom selection with tags.

Custom builder plugins

Under the Stash menu *Add* → *From Plugin*, you will find a list of template builders, which are plugins designed to build a particular structure based on a simple or complex set of rules, and add a new item to the Stash.

In the default installation of the QuantumATK, you will find the following plugins for adding new stash items.

Nanotube builds a nanotube with a given chirality, such as boron-nitride and carbon nanotubes as well as multiwall nanotubes with up to 3 walls.

Crystal Builder builds a crystal by selecting the space group and lattice parameters of the crystal.

Databases chooses molecules, crystals, fullerenes or monomers from an extensive list of predefined structures.

Nanoribbon builds one-dimensional ribbons cut out from a nanosheet. Optionally, one may passivate the ribbon edges with hydrogen atoms.

Nanosheet builds infinite two-dimensional sheets, such as graphene monolayers and similar 2D hexagonal materials, aligning the C-axis with a given chiral vector. Note that the C-axis is the default direction for QuantumATK transport calculations.

Magnetic Tunnel Junction (FeMgO-style) builds a magnetic tunnel junction (MTJ) such as the Fe|MgO|Fe MTJ, which is a two-probe device with a layer of insulator or semiconductor material placed between two ferromagnetic electrodes.

Supported file formats for import and export

In addition to QuantumATK Python and HDF5 files, the following file formats are supported in the QuantumATK package for import and export of atomic geometries.

•XYZ

•CAR

•CASTEP (.cell and .geom)

•CIF

•FHI-aims

•OpenBabel (.acr, .alc, .arc, .bgf, .box, .bs, .c3d1, .c3d2, .caccrt, .can, .ccc, .cdx, .car, .cssr, .dmol, .fract, .fs, .ins, .sy2)

•Quantum ESPRESSO

•ASE

•MBN Explorer

•VASP (POSCAR and CONTCAR, and their gz, gzip and zip versions)

Support for additional file formats, not listed above, becomes regularly available in the form of plugins that can be installed in the *AddOn Manager*.

Third-party plugins

When you add a new plugin to QuantumATK, either from add-ons that you have developed yourself, downloaded via the *AddOn Manager*, or obtained directly via third-party (or QuantumATK) as a zip-file, they are always seamlessly integrated in the proper place where they belong. It means that if you add your own import filter, it will then automatically appear in the dropdown list of file filters in the *Add → From Files* dialog.

2.4.6 Managing plugins using the AddOn Manager

Each functionality in the Builder is a **plugin**. A plugin is a small or large piece of Python code that defines its functionality.

An **add-on** is a collection of plugins; some contain just one, to define a single button/filter etc, while others contain a whole set of plugins which are related to each other.

Using the **AddOn Manager** (*Help→AddOn Manager*) you can automatically update installed add-ons, or install new ones to extend the functionality of QuantumATK, either by downloading them from the QuantumATK add-on server, or installing them from `.zip` files or a folder by clicking **Install zip/folder**. Normally you can just update the add-ons by clicking the Update or Update All buttons in the AddOn Manager in QuantumATK. If, however, you are behind a firewall that prevents QuantumATK from accessing the add-on server directly, you can instead download the add-on and install it manually by clicking the *Install zip/folder* button highlighted in red.

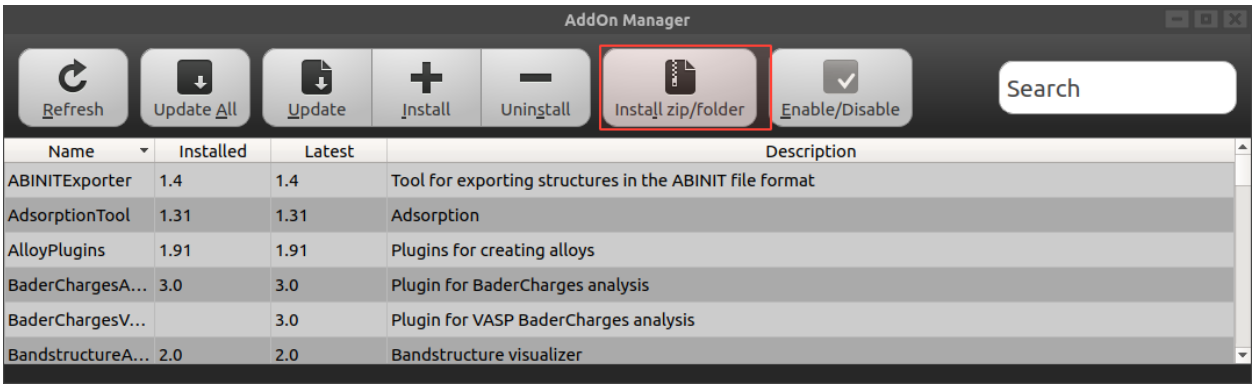

Fig. 2.10: The add-on can be manually installed by clicking the button *Install zip/folder* in the AddOn Manager in QuantumATK. Restart QuantumATK to activate the new add-on.

Tip: Make it a habit to check the AddOn Manager now and then, to see if there are any updates available.

Add-ons are installed in `quantumatk/lib/site-packages/AddOns` on Windows and `quantumatk/lib/python2.7/site-packages/AddOns` on Linux, relative to the QuantumATK installation directory. There you can inspect the source code of almost all plugins provided with QuantumATK, and use them for inspiration to create your own!

2.5 Workflows Manual

2.5.1 Introduction to the Workflow Builder

Downloads & Links

`bandstructure.hdf5` `bandstructure_rerun.hdf5` `multiple_calculators.hdf5` `multiple_configurations.hdf5` `block_of_blocks.hdf5`

The *Workflow Builder* is one of the core features of the *QuantumATK NanoLab*. It enables you to easily set up a calculation as a *workflow* of different calculation steps. These calculation steps can form one or more branches of execution, which can then be run though the *Jobs* tool.

With the Workflow Builder you will be able to create iteration loops and iterate over integers, floats, `PhysicalQuantity` values, and atomic configurations. You will be able to group multiple calculation steps and save it for later use, as well as save and share the entire workflow with your colleagues.

In the next sections you will learn more about the Workflow Builder and its user interface through a set of simple examples. You will learn how to create workflows with one or more atomic configurations, you will learn how to split a workflow into more branches of execution, as well as how to run workflows though the *Jobs* tool and how to reuse results from the previous calculations.

In the *Downloads & Links* sidebar you will find a list of all the workflows that are created in the following examples.

Note: Users familiar with the *Script Generator* will find the Workflow Builder to be very similar. The Workflow Builder replaces the Script Generator that was available in the previous versions of the *QuantumATK NanoLab*.

The Workflow Builder supports all the features of the *Script Generator*, and it also introduces new ones, such as support for multiple branches of execution or support for looping over custom `PhysicalQuantity` values or atomic configurations.

What is the Workflow Builder?

The *Workflow Builder* is a powerful feature of *QuantumATK NanoLab* where you can easily set up and run calculations. It is placed in the side toolbar on the left in the main *QuantumATK NanoLab* window.

In this tool, you can create new objects called *Workflows*, which can be saved, shared, re-opened and edited within the Workflow Builder Valid workflow can be converted directly to one or multiple scripts that can be run through the *Jobs* tool.

Workflows are *automatically* saved as `.hdf5` files and are visible in both the Workflow Builder and the *Data* tool. To *share a workflow*, simply share its `.hdf5` file.

A workflow consists of one or more components called *Blocks*. A block represents one or more calculation steps and it exposes calculation parameters. Calculation parameters can be edited from the Workflow Builder. Creating a workflow is as easy as assembling blocks from a catalog of built-in blocks. To read more about blocks, jump to the section *What is a workflow block and how to edit it*.

A workflow can contain sets of calculations. This is because a workflow block can contain lists of objects and their parameter values. A workflow can then iterate over the given lists to perform the same calculation with different inputs. To increase the calculation throughput, you also can split a workflow into more execution branches.

You can export a workflow as a single Python script or as multiple Python scripts. Each script would represent one branch of execution in the workflow. Having multiple scripts enables you to run a workflow in parallel instead of sequentially, which can significantly improve the calculation speed.

The Workflow Builder overview

This guide assumes you are familiar with the *Data* tool and the *Builder* tool in the *QuantumATK NanoLab*. The *Data* tool is used for managing files and analyzing results. The *Builder* tool is used for creating, manipulating and inspecting atomic configurations.

Start by opening the *QuantumATK NanoLab* and creating a *new project*. After opening the program, the first window you will see is a *Data* tool window.

To select the *Workflow Builder*, click the icon located in the side toolbar on the left. A new *Workflow Builder* window will appear with three main areas - Workflow Stash, Workflow Area and Workflow Catalogs.

The *Workflow Stash* is on the left highlighted in red. Here you will find all the existing project workflows. From here you can also create new workflows or delete, rename or duplicate the existing ones. The Workflow Stash is currently empty.

The *Workflow Area* is in the center under the *Build* tab, highlighted in blue. It shows the contents of the currently selected workflow in the Workflow Stash.

Note: There are three levels of the log verbosity - *Full*, *Minimal* and *Silent*. Use the *Full* verbosity for troubleshooting, *Minimal* for inspecting only the most significant steps and *Silent* when you do not need any calculation feedback.

The *Workflow Catalogs* of pre-made workflow blocks is on the right highlighted in green. These are the building blocks of a workflow. In the catalog you will find three tabs – *QuantumATK*, *Templates* and *Blocks*. The blocks from the catalogs are available across all projects.

The *QuantumATK* tab contains a list of built-in blocks divided into different categories, such as *Structures*, *Calculators* or *Analysis*. This list of blocks cannot be edited.

Note: If you are familiar with the Script Generator of previous *QuantumATK NanoLab* releases, you will recognize most of the blocks under the *QuantumATK* tab.

Each QuantumATK block can be a container of objects or a single object from the *QuantumATK Engine*, such as a `BulkConfiguration`, `LCAOCalculator` or a `Bandstructure`. There are also special blocks, such as the *Iterator* block or the *Custom* block. To read more about workflow blocks, jump to the section *What is a workflow block and how to edit it*.

The *Templates* tab contains built-in single blocks and *groups* of blocks chained together to calculate a specific property such as a *Constant Density Melt Quench (DFT)* available in the *Molecular Dynamics* sub-category. Among the *Templates* you will also find single blocks with specific parameters values, such as a *Metal (Low)* block which is an `LCAOCalculator` block with a low k-point density.

Note: If you are familiar with the Script Generator of previous *QuantumATK NanoLab* releases, you should note that the *Templates* play a similar role in the *Workflow Builder* as well. The difference is that Templates in the *Workflow Builder* cannot be modified and its list also includes single blocks.

The *Blocks* tab is a place where you can save your custom blocks across projects. Workflow Blocks can be grouped together in a container block called the *Block of Blocks*. Since Block of Blocks can can be saved, this allows for re-use of even very complex calculation setups. To learn how to save blocks under the *Blocks* tab, jump to the section *How to save a block from a workflow*.

What is a workflow block and how to edit it

A workflow block is a basic building unit of a workflow. It can be though of as one calculation step in a workflow. A block typically represents a single object from the *QuantumATK Engine*. It can require specific input *QuantumATK Engine* objects and can provide specific output *QuantumATK Engine* objects. Blocks are added one after the other to form a branch of execution in a workflow. If a block has an invalid input, it will show an error message.

To edit a block in a workflow just double click it. All block editors indicate non-default values and allow for direct reset to default. Editors contain default settings of the underlying *QuantumATK Engine* object and can be changed by the user.

If you have made a change to some of the default settings and would like to revert to a default value instead, click the reset button near the value you were editing, like the *Maximum step size* parameter highlighted with red in the *Optimize Geometry* block (see the figure below).

You will know the value is default when the reset button becomes disabled (grayed out), like the *Maximum number of steps* parameter highlighted with blue.

Beside blocks which represent a single *QuantumATK Engine* object, there are also special blocks, such as *Configurations (Split Parallel)* and *Split Parallel* blocks. These blocks implement simple parallelization. They can contain a list of sub-blocks and then each sub-block in the list would belong to a separate branch of execution. The resulting workflow script will loop over each sub-block, hence producing simple parallelization mechanism akin to loop unrolling.

The simplest example is the Configurations (Split Parallel) block, that enables one to run the same (parallel) calculation for multiple atomic configurations.

Workflows with *Configurations (Split Parallel)* or *Split Parallel* blocks should be run in parallel as explained in the section *Workflow with multiple branches*.

Other special blocks include *Iteration*, *Block of Blocks*, *Custom* blocks as well as the *Load from file* block.

With the *Iteration* block you can specify integers, floats, `PhysicalQuantity` variables of different types, and atomic configurations. These values can then be used as inputs to some of the other blocks in the workflow. Using the *Iteration* block you can iterate over a different set of atomic configurations, basis sets, densities, etc

The *Block of Blocks* can group existing blocks in the workflow. Use this block to save a sequence of blocks specialized to calculate or analyze a set of properties, which you can later reuse in other workflows.

The *Custom* blocks are very powerful and flexible blocks. They support insertion of custom QuantumATK scripts. The script, desired inputs and the produced outputs can be defined directly in the *Workflow Builder*. The output from a custom block can also be used in subsequent blocks, thus allowing Custom blocks to serve as an interface to a complex calculation setup. The Custom Block can also be saved to the *Blocks* catalog for easy reuse.

The *Load from file* blocks supports the inclusion of already calculated results. All QuantumATK objects can be loaded and used directly within a workflow. The obvious example is the calculation of additional analyses from an already updated configuration.

Creating a simple workflow

Lets create a simple workflow which calculates a `Bandstructure` of a `BulkConfiguration` using an `LCAOCalculator`. To do this we would need to add three workflow blocks, each representing one of these *QuantumATK Engine* objects.

We will start by adding a `BulkConfiguration` from the database in the *Builder*.

Sending an atomic configuration from the Builder to the Workflow Builder

Lets load a `BulkConfiguration` from the *Builder* to the *Workflow Builder*.

Start by opening the *Builder* by clicking the icon from the side toolbar on the left. This will open a new window.

Once we are in the *Builder* click the *Add* icon and select *From Database*. This will open a Database with a list of built-in atomic configurations we can load in the *builder stash*.

Lets load an atomic configuration called *Silver*. You will find *Silver* under the *Crystals* tab. To quickly find it type *Silver* in the *Search*. To add *Silver* to the *builder stash* just double click it. You will see the atomic configuration in the *builder stash* and its graphical representation in the *3D Viewer*.

To send the *Silver* configuration from the *Builder* to the *Workflow Builder*, click the in the lower right corner and select *Workflow Builder*.

Script Generator

Selecting this option will open the *Workflow Builder* window. In the *Workflow Builder* you will notice a new workflow object called *Silver* in the *Workflow Stash* on the left. It was automatically created after sending the *Silver* configuration. The workflow contains one `BulkConfiguration` block which represents the *Silver* configuration.

Lets rename the created workflow. In the Workflow Stash, click the to change the name of the current workflow to *bandstructure*.

It is important to know that the workflows in the *Workflow Stash* are project-specific. You can still import workflows from other projects like you would import any other `.hdf5` file in the *QuantumATK NanoLab*. Jump to the section *How to share a workflow* to learn more about exporting and importing workflows.

Note: To see the file location of a workflow, right click it in the *Workflow Stash* and select *Open location*.

Currently, we have one workflow with one `BulkConfiguration` block called *Silver*. This will be our atomic configuration block. At this point we can inspect the configuration from the blocks editor.

Lets now open an editor of the configuration block in the *bandstructure* workflow. From there we can visualize and inspect the added atomic configuration. To open the editor, double click the *Silver* configuration block in the central window of the *Workflow Builder*, i.e. the Workflow Area.

The loaded atomic configuration will appear in the list of atomic configurations on the left and the 3D window will display its graphical representation. In the *Definition* list you will see a summary of its properties such as type, unique elements, tags, lattice type and regions.

To add new tags or regions to the atomic configuration, use the *Tags* or *Spatial Regions* plugins in the right window.

We have now added an atomic configuration to the workflow. The next step is to create a calculator and attach it to the loaded atomic configuration.

How to add a calculator

To add a calculator, go to the catalog of QuantumATK blocks, expand the *Calculators* category and choose *Set LCAOCalculator* block from the list of available calculators.

Adding the *Set LCAOCalculator* block requires an atomic configuration as an input. It outputs the same atomic configuration with an attached `LCAOCalculator`.

The calculator block uses the default parameters of the underlying `LCAOCalculator` object. Double click the block to see its default values. Here you can inspect or edit calculator properties. In this example, we will continue with the defaults.

Our workflow currently contains an atomic configuration and a calculator attached to it. The next step will be to perform an analysis on the given configuration.

How to add an analysis object

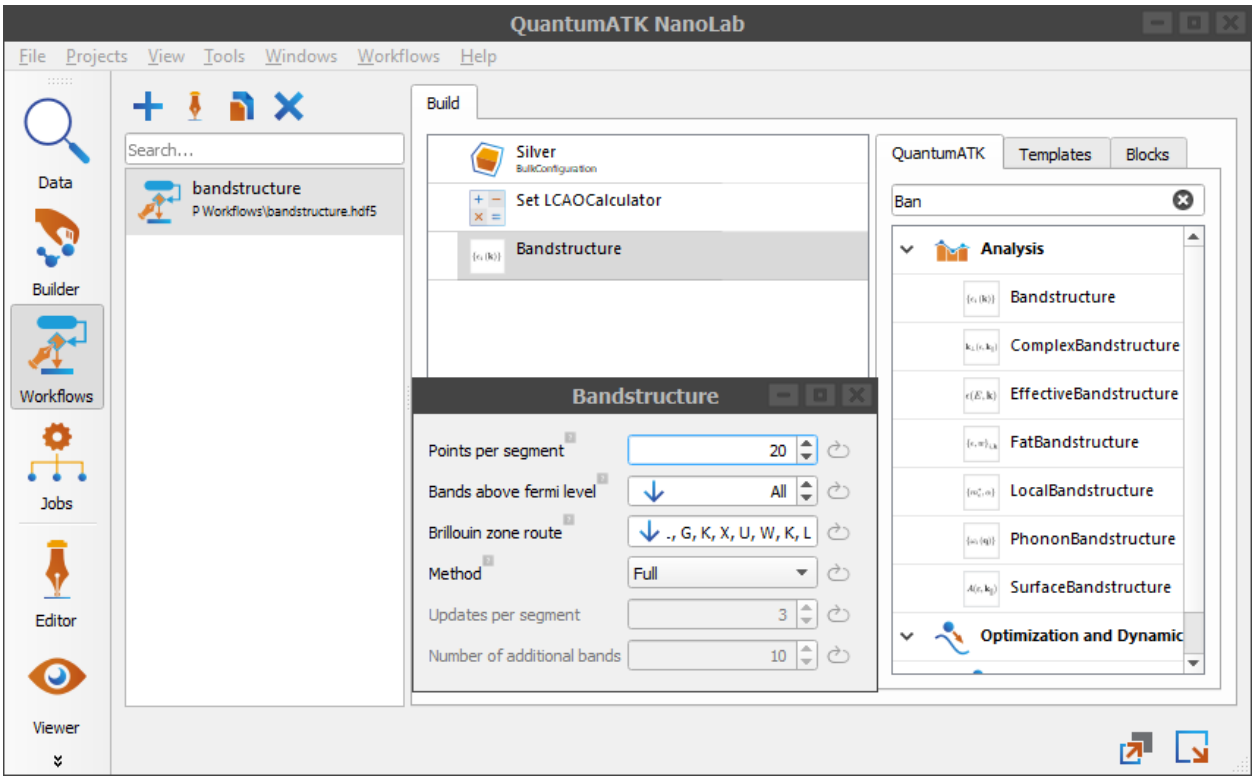
A complete list of all analysis blocks can be found in the catalog of QuantumATK blocks under the *Analysis* group.

Lets add a *Bandstructure* analysis block to the workflow.

To find a *Bandstructure* analysis block in the long list of analysis blocks, we recommend a text search. Then double click or drag and drop the *Bandstructure* block from the catalog onto the Workflow Area.

The *Bandstructure* block requires a *BulkConfiguration* with an attached calculator as an input. It outputs a *Bandstructure* analysis object. The block uses the default parameters of the underlying *Bandstructure* object. We will not edit the blocks parameters and will continue with the default values.

Since the block input is valid and it reports no errors, lets run the current workflow.



How to run a workflow

A workflow can be exported as a Python script, which can be run with the *Jobs* tool.

To execute the `bandstructure.hdf5` workflow from the current section, click the button in the lower right corner and select *Jobs as script*. This will launch an *Export to script* window where you can specify *Script exporting options*. Lets change the result filename to *bandstructure_results.hdf5*. Leave the rest of options to default and click *OK*.

Note: Using the options highlighted in red at the bottom of the Workflow Area window you can specify a default name of the result file and the log verbosity of the calculation.

After setting the export options you will need to follow the steps to send a script to the *Jobs* tool.

Start by clicking the *Ok* button in the *Export to script* window. This will open a save dialog. Choose a place to save your script and click *Save*. Next you will see the *Submission Settings* window where you can select run options, such as the machine where the script will be run. After you have set the submission options, click the *Submit* button.

To learn more about running scripts through the *Jobs* tool, follow the *Jobs* tool guide.

After the *Jobs* tool finishes, the result file `bandstructure_results.hdf5` should appear in the *Data* tool. The result file should contain two saved objects – a `BulkConfiguration` with an attached `LCAOCalculator` and a `Bandstructure` object.

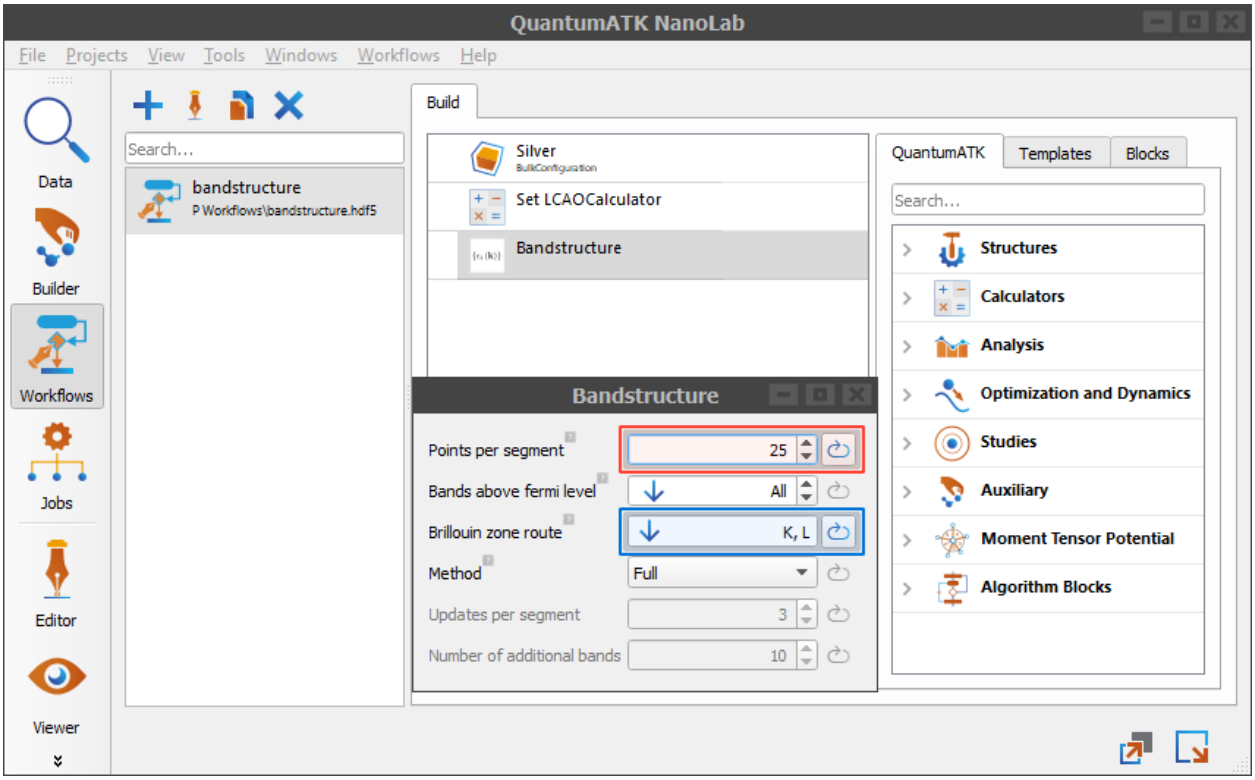
Re-running a workflow

Lets make a change to the `bandstructure.hdf5` workflow from the previous section. Go ahead and double click the *Bandstructure* block to open its editor. Increase the sampling by setting *Points per segment* to 25 and set the *Brillouin zone route* to *K, L*.



After the change, there are two ways to re-run the workflow.

- Run the entire workflow from scratch
- Reuse some of the saved objects from the previous calculations

We can always run the entire workflow from scratch. This way we are not going to use any of the results saved in the previous run. This is the easiest way, but not a very economic one.

The other way is to use some of the saved objects from the previous calculation found in `bandstructure_results.hdf5`. It is crucial that the object we intend to reuse in a new calculation are not affected by the change.

The previous calculation saved two objects – a *BulkConfiguration* with an attached *LCAOCalculator* and a *Bandstructure* object. In this example, it is easy to see that the first object can be used again in the new workflow, because it is not affected by the changes in the *Bandstructure* block. To include this object in the workflow, we will reuse a *Load from file* block.

The second way is obviously economical and can be faster, but you need to be extra careful when cherry-picking object to use in the new calculation.

Load from file

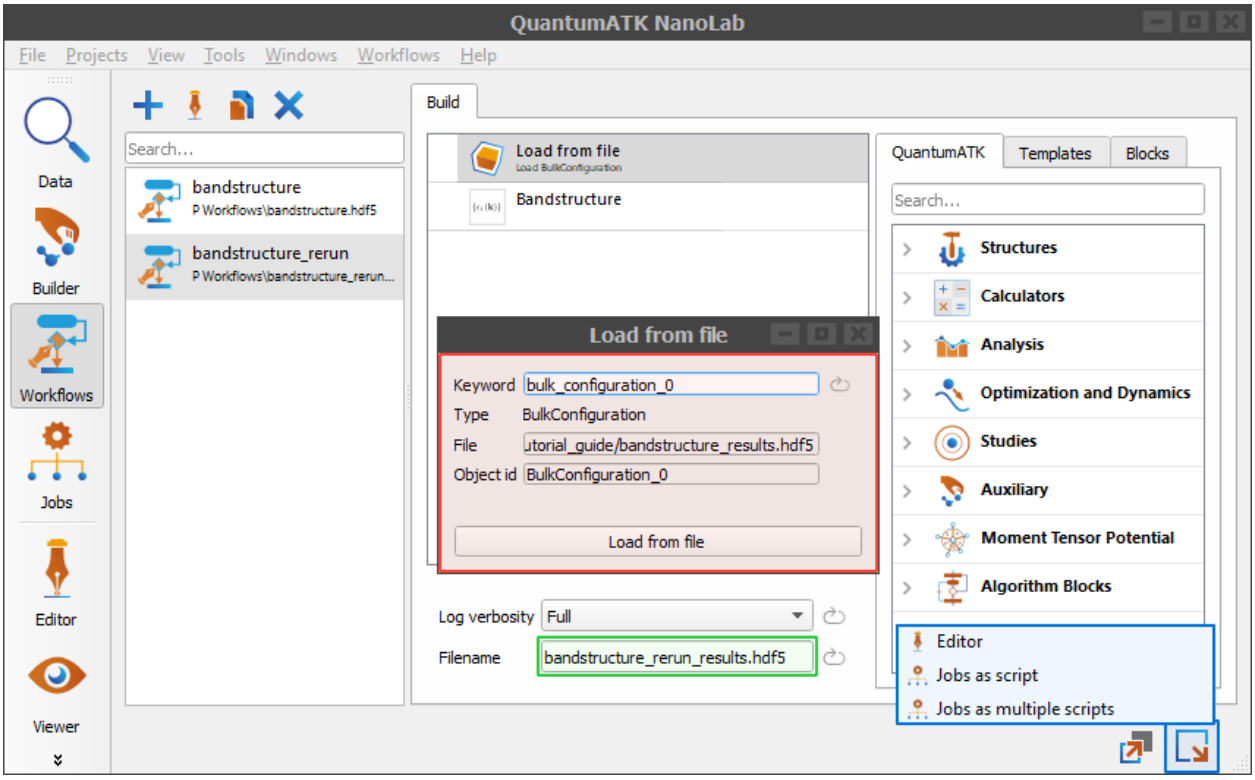
This block is very simple, but powerful. It enables you to reuse already calculated parts after making a change to the same workflow. With this block you can simply load an object from a result file.

In the previous section *Re-running a workflow*, we have modified the `bandstructure.hdf5` workflow by changing one of the properties in the *Bandstructure* block. Now we want to re-run the workflow using the same configuration object with the attached calculator, which were unaffected by the change.

Lets start by creating a duplicate of the `bandstructure.hdf5` workflow by clicking *Copy*. button in the Workflow Stash on the left. This will duplicate the current workflow. Change the name of the copy to *bandstructure_rerun*. Then go ahead and delete the existing configuration and calculator blocks. We will provide both objects from the result file of the previous calculation.

In the catalog of QuantumATK blocks under the *Algorithm Blocks* group find the *Load from file* block and place it as the first block in the workflow. You should now have only two blocks in the workflow - *Load from file* block and the *Bandstructure* block.

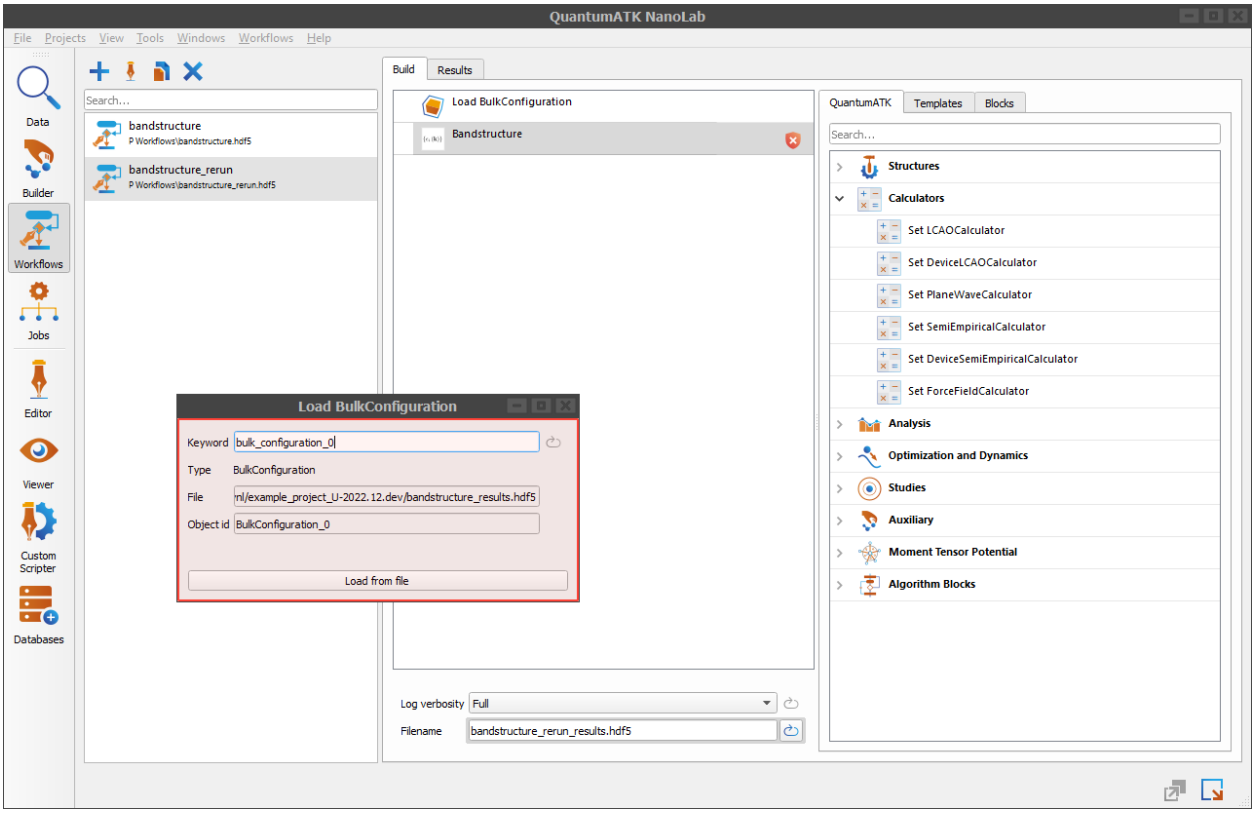
Note: To change the order of the blocks in the workflow, just drag and drop them within the Workflow Area window.



You will notice that both blocks have errors. A *Load from file* block is missing a file to load *QuantumATK Engine* objects from, and a *Bandstructure* block needs a `BulkConfiguration` with an attached calculator.

To resolve errors, we need to load a bulk configuration with an attached calculator using the *Load from file* block.

To open its editor, double click the *Load from file* block. To load objects click the *Load from file* button at the bottom of the editor. Select the result file from the previous calculation, `bandstructure_results.hdf5`, and load the bulk configuration with the attached calculator.



After loading the bulk configuration in the *Load from file* block, all the errors should be gone and you will see some details in the editor window like the bulk configuration type, its file location and its object id.

Change the result file name of the new workflow to the *bandstructure_rerun_results.hdf5*. The filename option is placed at the bottom of the Workflow Area window.

Run the workflow by clicking the button to send it to the *Jobs* tool. Select *Jobs as script* option and follow the script export steps and *Jobs* tool steps the same way as in the previous section.

After the *Jobs* tool finishes, you should get results similar to the `bandstructure_rerun_results.hdf5`.

Workflow with multiple branches

The new workflow feature makes it much easier to run several calculations with only a small difference, e.g., calculating the `Bandstructure` for the same atomic configuration, but with different calculator settings.

To do this we could make copies of the same workflow and then tweak calculator settings in each of the copies. This is not a very good way, because keeping the track of all the workflows can become very cumbersome.

What we should do instead is split the workflow into multiple branches of execution. To do this we will need to use the *Split Parallel* block from the *Algorithm Blocks* section in the QuantumATK catalog of blocks.

Lets start by creating a new workflow with one `BulkConfiguration` block and one `Bandstructure` block.

Send a *Silver* configuration from the *Builder* to the *Workflow Builder* as described in *Sending an atomic configuration from the Builder to the Workflow Builder*. This will create a new workflow with one configuration block.

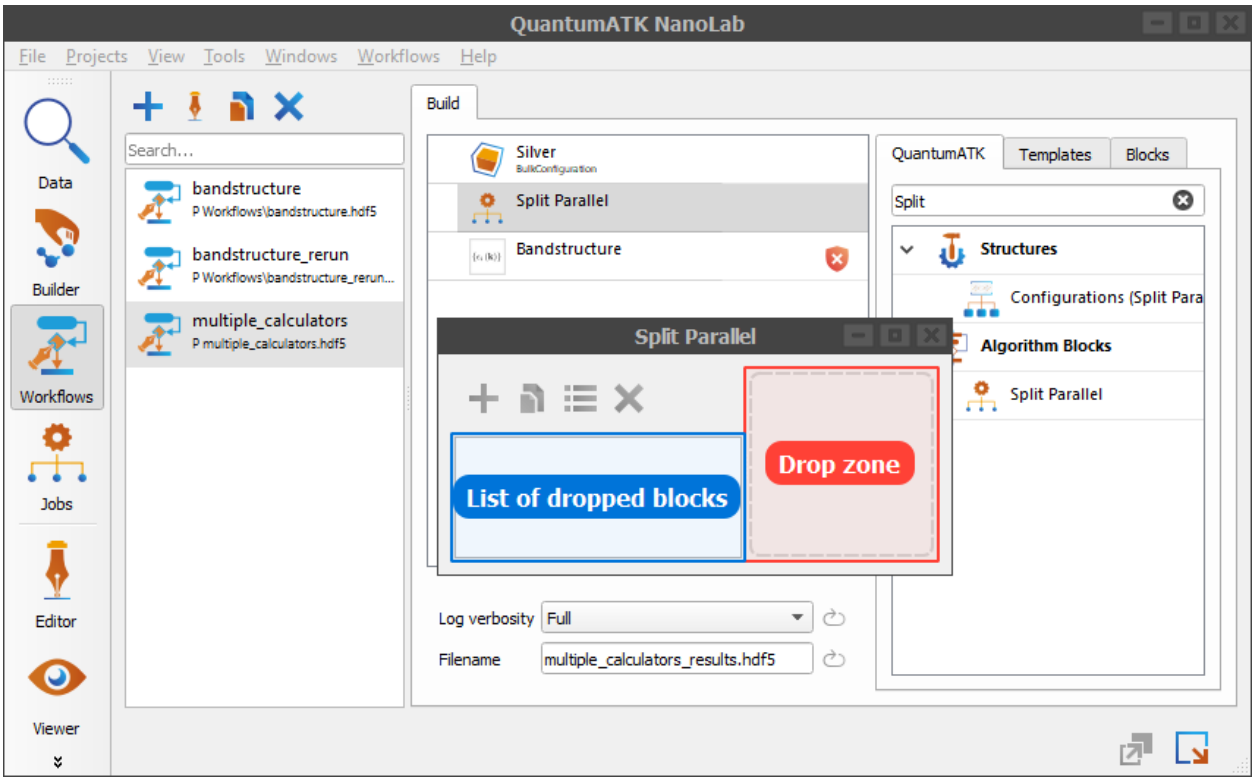
Now add a `Bandstructure` block as described in *How to add an analysis object*.

Rename the created workflow to *multiple_calculators*, since we will be using multiple calculators in the same workflow.

We want to have two separate branches of execution. Each branch of execution should calculate a `Bandstructure` of the same *Silver* configuration, but with different `LCAOCalculator`-s.

To split the execution of the workflow, go ahead and drop *Split Parallel* block from the QuantumATK catalog under the *Algorithm Blocks* group. In the workflow, the new block needs to be placed between the `BulkConfiguration` and the `Bandstructure` blocks.

Double click the added *Split Parallel* block in the Workflow Area to open its editor (see the figure below).

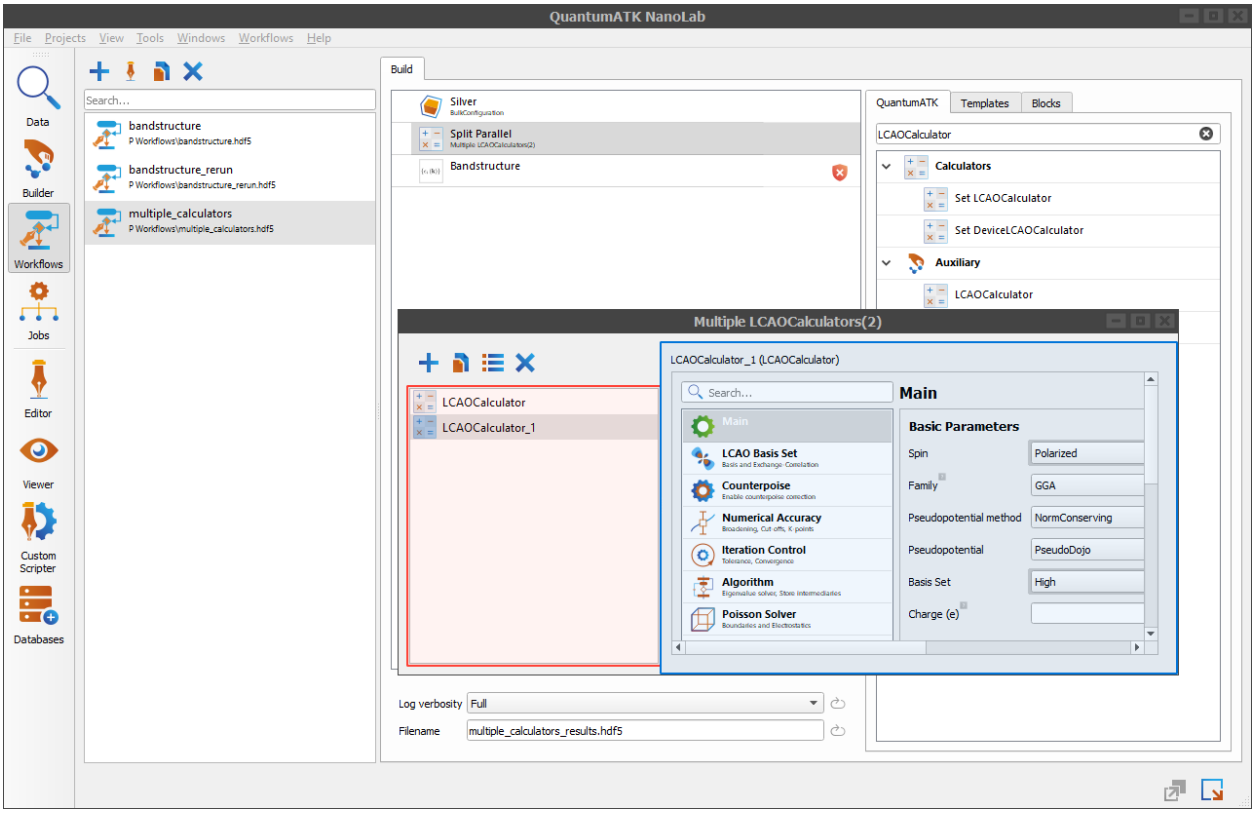


On the right highlighted in blue you will see a *drop zone* – an empty space to drop blocks from the catalog of blocks. On the left highlighted in red is a list of dropped blocks, which is currently empty.

Each block in the list will belong to a separate branch of execution. In other words, each block in the list will create one branch of execution. If we add one block in the list, there would be only one branch of execution. If we add ten blocks, we would be creating ten branches, etc

We want to have two separate branches of execution, each containing different `LCAOCalculator`-s. To do this, we will add two calculators to the *Split Parallel* block.

To add the first `LCAOCalculator` calculator, find an *LCAOCalculator* block in the QuantumATK catalog under the *Auxiliary* group and drop it to the drop zone. To add the second calculator, just click the + button. This will create a copy of the first calculator block (see the figure below).



In the list of blocks highlighted in red on the left, we now have two *LCAOCalculator* blocks, one named *LCAOCalculator* and the other named *LCAOCalculator_1*.

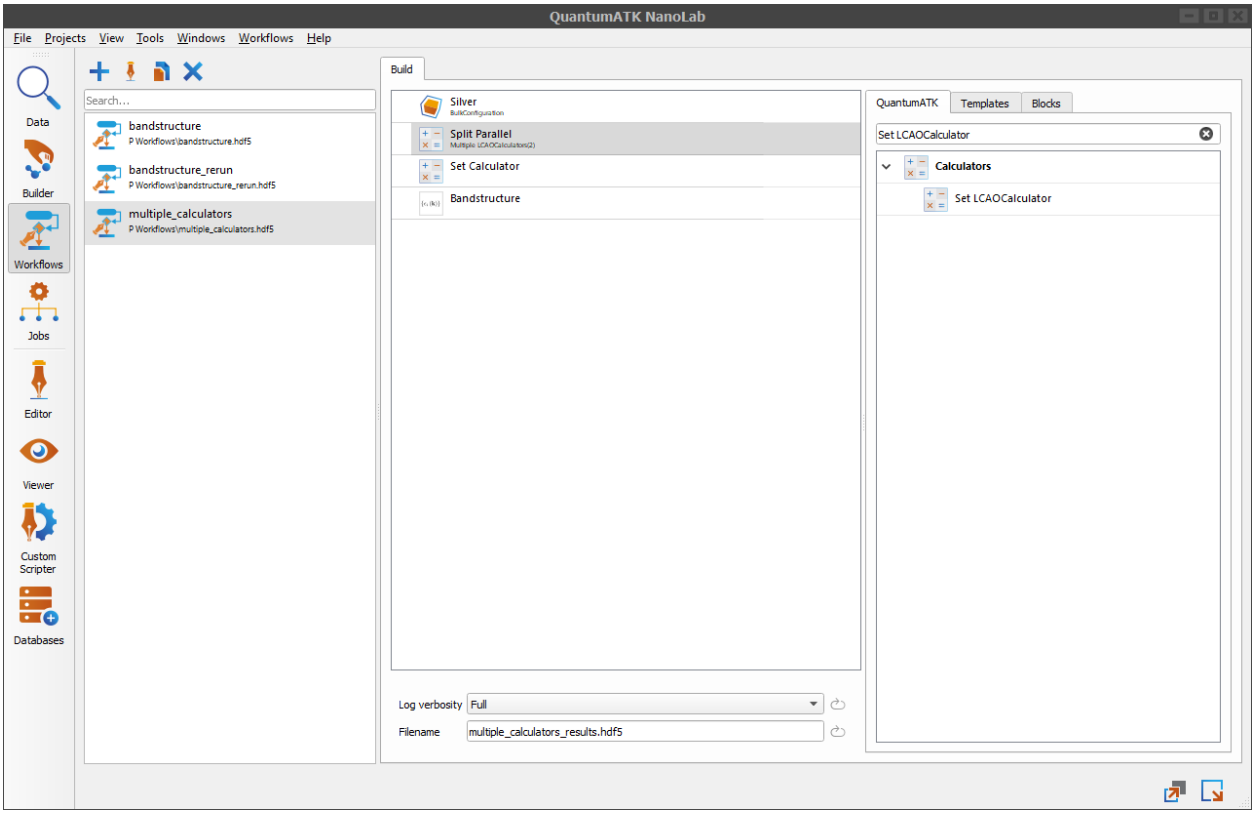
In the same window on the right highlighted in blue you can see an editor of the selected calculator block in the list. We can use the editor displayed on the right to change the settings of the calculators.

Lets change some of the settings in the second calculator. Select the second calculator in the list on the left and change its spin from *Unpolarized* to *Polarized* and the *Basis Set* from *Medium* to *High*. Both options are under the *Main* editor tab.

In the workflow you will notice some errors reported by the *Bandstructure* block saying that a `BulkConfiguration` with an attached calculator is missing. Even though we do have both the `BulkConfiguration` and the `LCAOCalculator`-s, we havent linked them. To resolve this problem, add a *Set Calculator* block right after the *Split parallel* block.

The *Set Calculator* block requires two inputs – an atomic configuration and a calculator. Its only purpose is to attach the calculator to the configuration.

Note: Note that there are *LCAOCalculator* and *Set LCAOCalculator* blocks. The first one just creates an `LCAOCalculator` and the other both creates the calculator and attaches it to a configuration.



Note: Note that the icon of the *Split Parallel* block has changed to , since the block has two calculators inside.

In the workflow you should now have four blocks - *BulkConfiguration* block, *Split Parallel* block, *Set Calculator* block, and `Bandstructure` block.

The workflow should now be ready for execution. There are different ways to execute it, as described in the section *How to run a workflow*.

The recommended way to run the workflow is to run it in parallel, as described in the next section *Running a workflow with multiple branches*.

After the *Jobs* tool finishes workflow execution, you will get results similar to `multiple_calculators_results.hdf5`.

Running a workflow with multiple branches

Workflows containing *Split parallel* blocks can have multiple branches of execution - one for each sub-block in the list. The recommended way to run such workflows is to export them as multiple scripts, send them to the *Jobs* tool and run them all at once. Each exported script will contain one branch of execution.

Note: The *Configurations (Split Parallel)* block also causes multiple branches of execution - each branch for every loaded atomic configuration.

In the lower right corner, click and select *Jobs as multiple scripts*. Follow the script export process, which is similar as exporting a workflow as a single script. See *Script exporting options* for more script exporting details.

Workflow with multiple configurations

You can increase the calculation throughput by increasing the number of configurations.

To show an example, lets first make a copy of the first workflow we have created: `bandstructure.hdf5`. Rename the copy to *multiple_configurations*.

Note: Alternatively you can create a new workflow with a default `LCAOCalculator` and a `Bandstructure` blocks. Follow the section *How to create a new workflow* to check how to create a workflow from scratch.

We will need to add more than one configuration to the workflow. The first block in the copied workflow is limited to hold only one configuration. Go ahead and delete that block.

To add more configurations to the workflow, we will need to use the *Configurations (Split Parallel)* block. You can find this block in the catalog of QuantumATK blocks under the *Structures* group.

Add the block by double clicking it or dragging and dropping it from the catalog to the Workflow Area. The block should be the first one in the workflow.

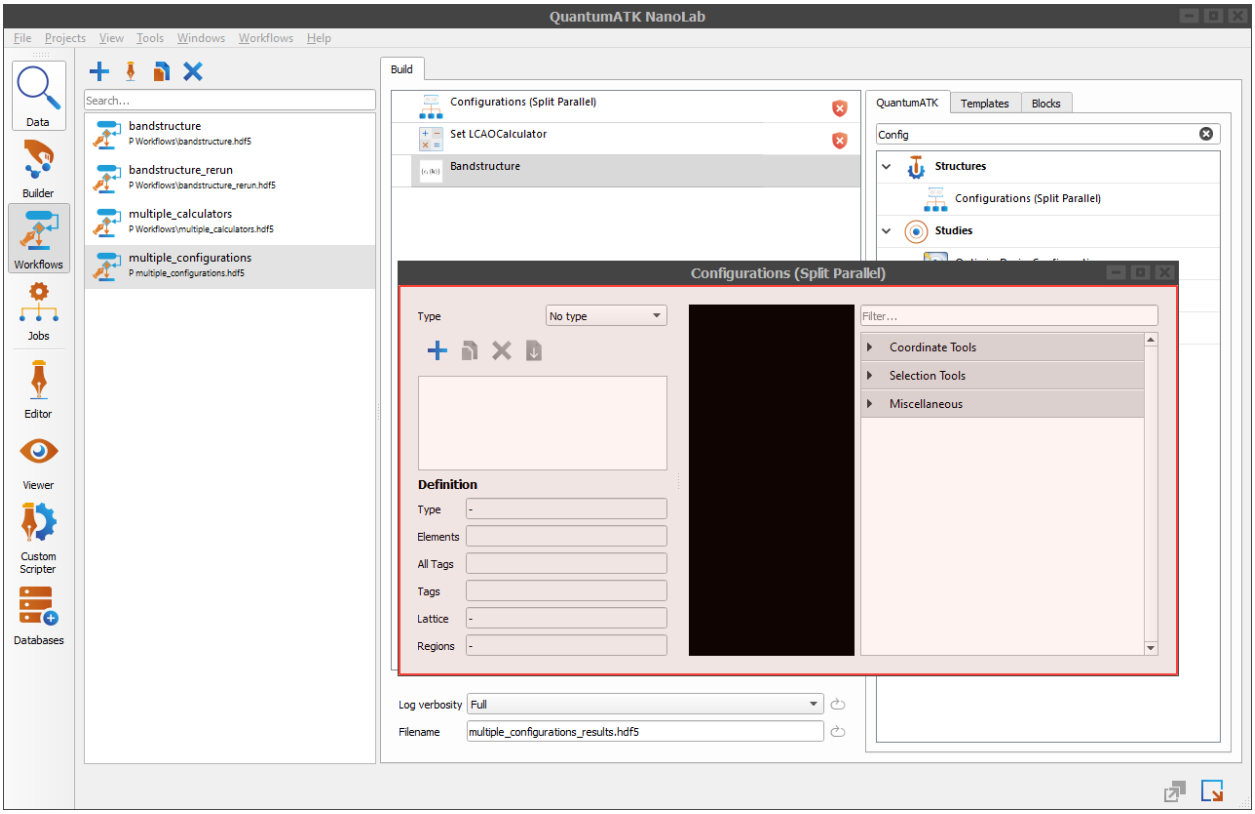
After adding the block, you will notice an error icon. Double click the icon to see the error message. The message should say that *a configuration is missing*. This is because the block is initially empty and does not have any atomic configurations, which is not very useful.

We will load two atomic configurations from the *Builder_Stash.hdf5* file.

Note: The *Builder_Stash.hdf5* file is automatically created by the *QuantumATK NanoLab*. It is project-specific and it contains atomic configurations from the *builder stash* in the *Builder* tool. You can find the file in the project folder. It is also present in the *Data* tool.

Before we can load atomic configurations from a *Builder_Stash.hdf5* file, we will need to create them in the *Builder* tool and add them to the *builder stash*.

To achieve this, we are going to use the *Crystal* database from the *Builder* tool. The steps to load a configuration from the *Crystal* database to the *builder stash* are similar to what we already did in the section *Sending an atomic configuration from the Builder to the Workflow Builder*.



In the *Builder*, in addition to the *Silver* configuration, load the *AgCd* configuration as well. After you load these configurations from the *Crystal* database, you should see the two configurations in the *builder stash* under names *Silver* and *AgCd*.

When you load the *Silver* and *AgCd* configurations in the *builder stash* return to the *Workflow Builder* window by clicking the icon located in the side toolbar on the left.

We are now ready to load two atomic configuration from a *Builder_Stash.hdf5* file.

To load configurations, open the blocks editor by double clicking the *Configurations (Split Parallel)* block in the Workflow Area. In the editor click the button. This will open a file browser within the current project directory.

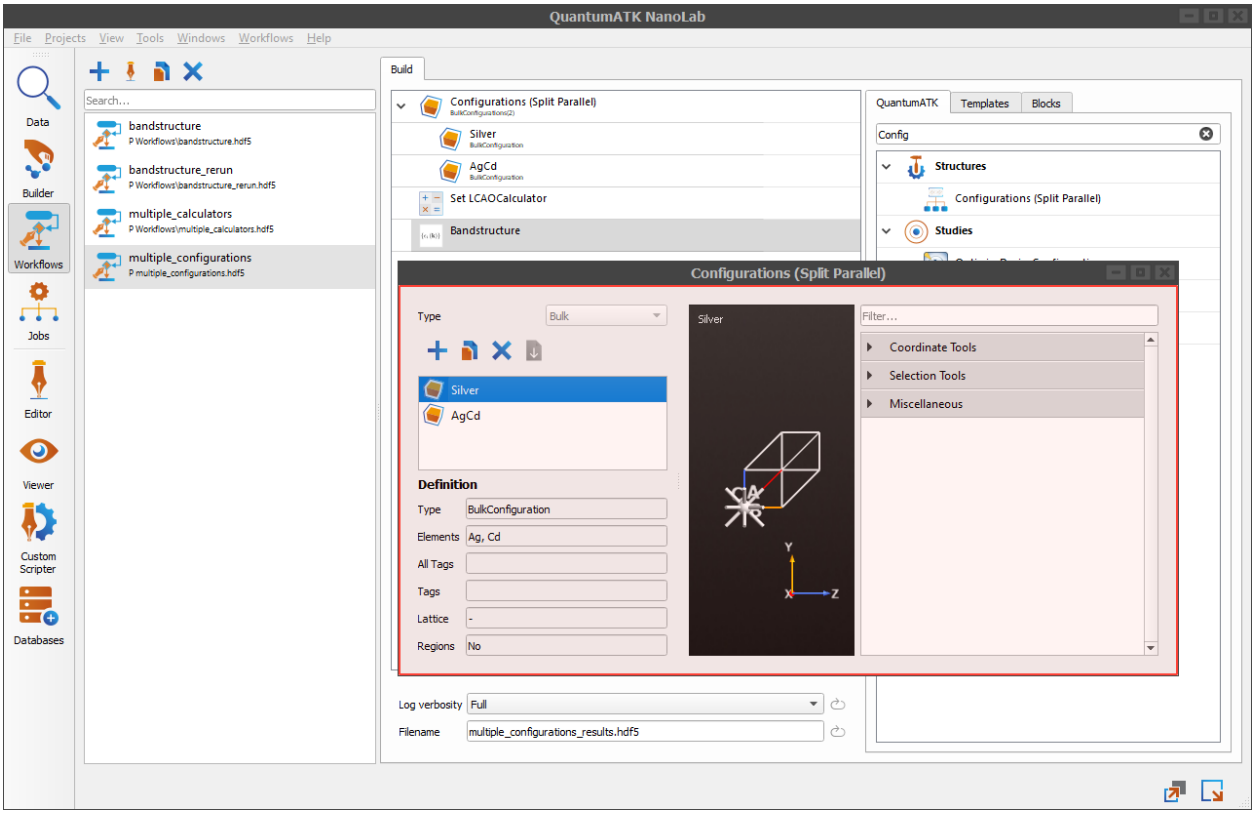
The central window of the file browser contains a list of files in the current directory. Note that the file list also includes the *Builder_Stash.hdf5* file. The window on the right displays the contents of a file selected in the central window of the file browser.

Select the *Builder_Stash.hdf5* file and choose two `BulkConfiguration`-s from its contents - the *Silver* and *AgCd*.

Click *Load* to load the selected atomic configurations.

Note: If you do not see these configurations in the *Builder_Stash.hdf5* file, go to the *Builder* and load the *Siliver* and *AgCd* configurations from its database. Follow the *Builder* guide if you are unfamiliar with the tool.

The loaded atomic configurations will appear in the list of atomic configurations on the left and the 3D window will display graphical representation of the currently selected one.



In the *Definition* list you will see a summary of the configuration properties common for both of the atomic configurations in the list. The type, tags, lattice and regions show common properties found in each configuration, while the elements and tags include unions of all the unique elements and tags.

To add new tags or regions to any of the atomic configurations from the list, use the *Tags* or *Spatial Regions* plugins in the right window.

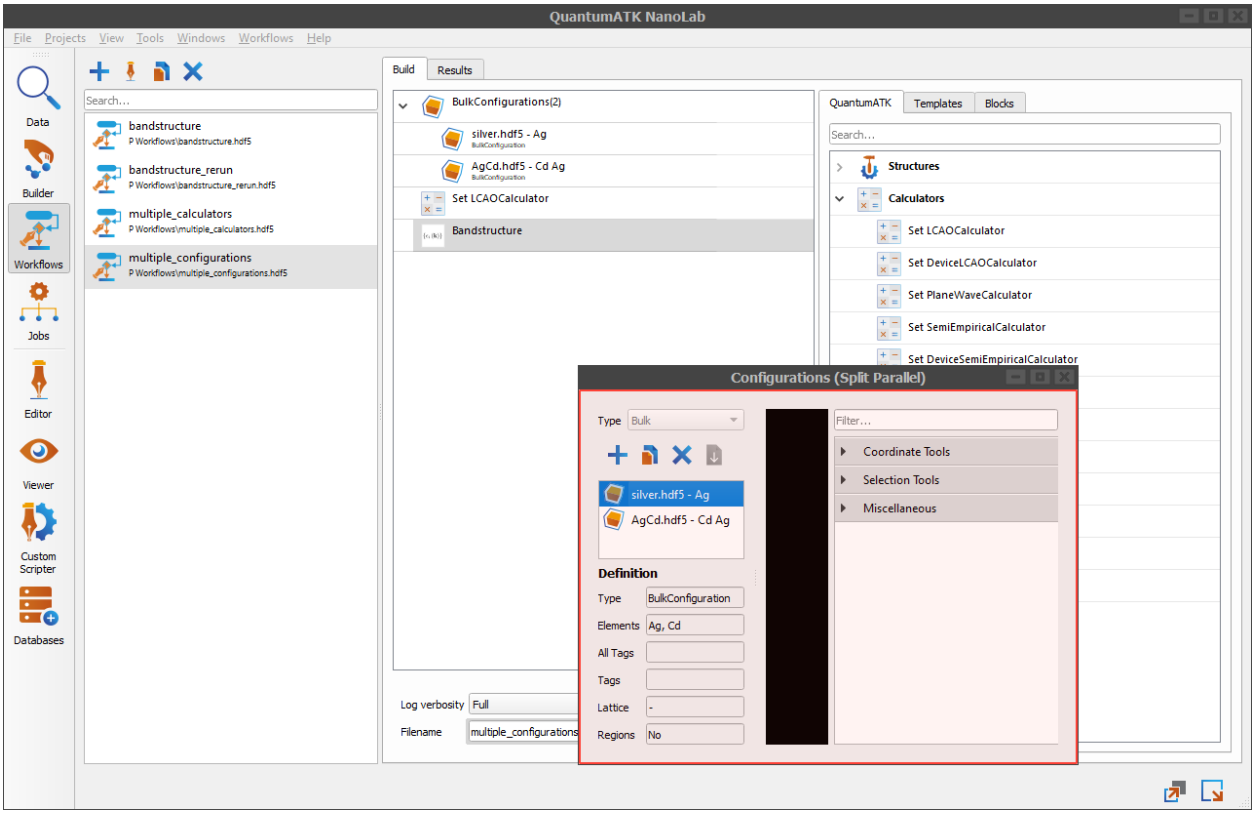
Adding additional atomic configurations in the same block is similar as before. The only constraint now is that subsequent atomic configurations have to be of the same type, i.e. `BulkConfiguration`.

If you now close the block editor and look at the Workflow Area, you will notice some changes in the block – the blocks icon has changed from to *BulkConfiguration*, and two sub-blocks, one called *Silver* and the other called *AgCd*, corresponding to the just loaded `BulkConfiguration`-s.

We can now run a `Bandstructure` calculation for each of the `BulkConfiguration`-s from the *Configurations (Split Parallel)* block. Adding two bulk configurations creates two branches of execution, which we can run in parallel for better efficiency.

Change the result file to *multiple_configurations_results*. Run the workflow in parallel as described in the section *Running a workflow with multiple branches*.

After the *Jobs* tool finishes execution of the workflow, you should get the same results as in the `multiple_configurations_results.hdf5` file.



Block of blocks

Lets append more analysis blocks in the `bandstructure.hdf5` workflow. In addition to the *Bandstructure*, lets also calculate *BornEffectiveCharge* and *BlochState*. Start by duplicating the `bandstructure.hdf5` and rename the copy to *block_of_blocks* - the name will make more sense a bit later.

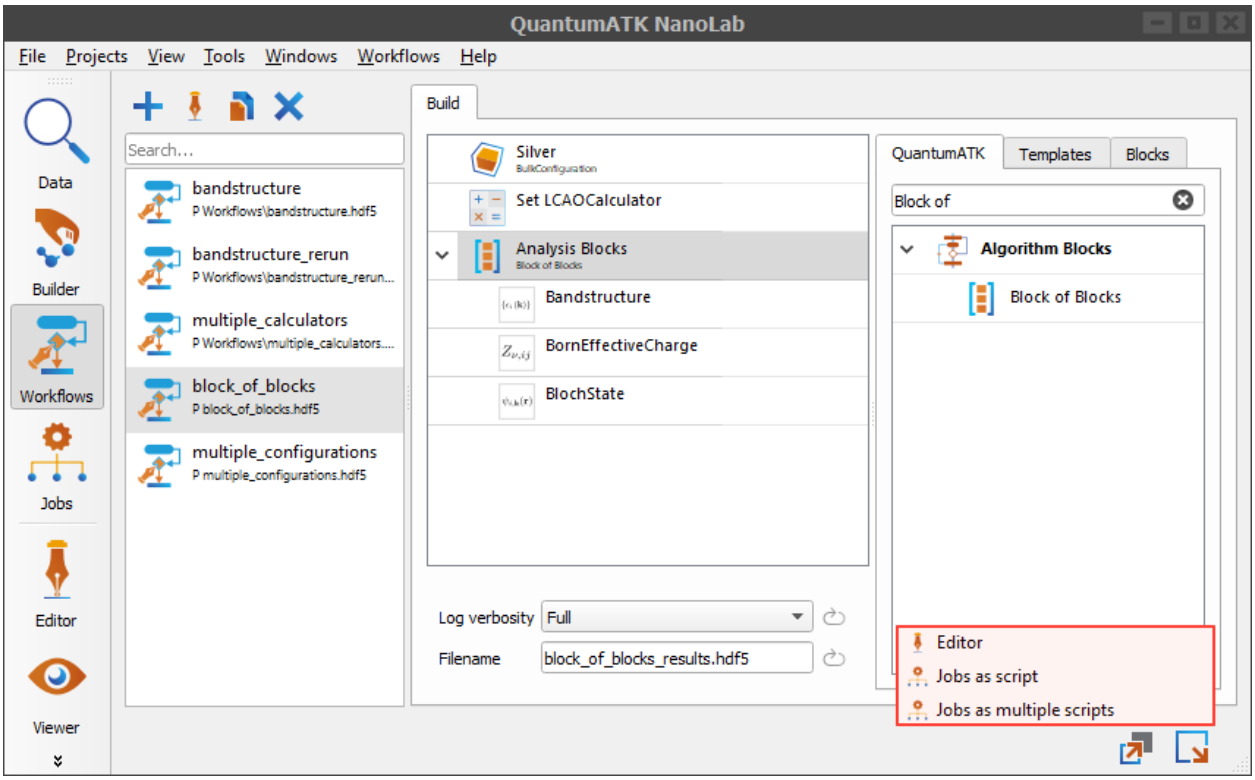
Now append the two new analysis blocks to the workflow. You can find both blocks in the catalog of QuantumATK blocks under the *Analysis* group. We can now look at the workflow as a three step calculation – bulk configuration loading, attaching an LCAO calculator and analyzing.

We can group the last three analysis blocks under a single block. To do that, we will use *Block of Blocks*. You can find it under the *Algorithm Blocks* category.

Add the *Block of Blocks* at the end of the workflow and then drag and drop analysis blocks under it. The analysis blocks should appear as three sub-blocks under the *Block of Blocks*. Rename the *Block of Blocks* to *Analysis Blocks* by right clicking it and selecting *Rename* from the drop down menu.

The *Block of Blocks* is used for grouping multiple blocks into one for easier managing. Use this block to save a sequence of blocks specialized to calculate or analyze a set of properties, which you can later reuse in other workflows. To learn how to save custom blocks for later reuse, see the section *How to save a block from a workflow*.

We can now run a calculation with multiple analysis objects. Change the result file to *block_of_blocks_results*. The workflow contains only one branch of execution, so we can only run it sequentially.



Lets send the workflow to the *Jobs* tool. Click the in the lower right corner and select *Jobs as script*. Follow the script export process. See *Script exporting options* for more script exporting details.

After the *Jobs* tool finishes execution of the workflow, you should get the same results as in the `block_of_blocks_results.hdf5` file.

Note: Note that the last workflow example can contain only one branch of execution. This is because the *Split Parallel* block requires blocks of the same type and the analysis objects in the workflow had different types.

Common operations in the Workflow Builder

In the next sections you will learn about the common operations you will use in the *Workflow Builder*, such as how to create a workflow from scratch, how to save a current workflow and a custom workflow block, as well as how to share saved blocks and workflows.

You will also learn about the workflow exporting options, as well as the ways to run a workflow through the *Jobs* tool.

How to create a new workflow

To create a new workflow click the in the Workflow Stash window. A new workflow should appear in the Workflow Stash with a generic name. Since the new workflow is empty, the Workflow Area does not show any contents yet. Click the to change the name of the workflow to *bandstructure*.

The workflows in the Workflow Stash are project-specific. You can import workflows from other projects like you would import any other `.hdf5` file.

Note: To see the file location of a workflow, right click it in the Workflow Stash and select *Open location*.

How to save a workflow

All workflows are saved automatically, and every change is permanent. There is no *Save* button. You can find workflows in the Workflow Stash in the *Workflow Builder* or in the *Data* tool.

It is important to know that the workflows in the *Workflow Stash* are project-specific. You can still import workflows from other projects like you would import any other `.hdf5` file.

How to share a workflow

Workflows are saved as `.hdf5` files, which means they can be exported and imported like all other QuantumATK objects or files.

You can find your workflows among files in the *Data* tool and in the Workflow Stash of the *Workflow Builder*. Workflow files can be easily spotted in the *Data* tool by the icon. To find a location of a workflow file, just right click it from the *Data* or from the Workflow Stash in the *Workflow Builder* and select *Open location*.

Once you know the location of the workflow file, you can import it in the current project by selecting *File -> Import File* from the top menu.

When you import the workflow file, it will automatically become available in the *Data* tool and in the *Workflow Builder*, as the *QuantumATK NanoLab* takes care of finding workflow files present in the current project folder.

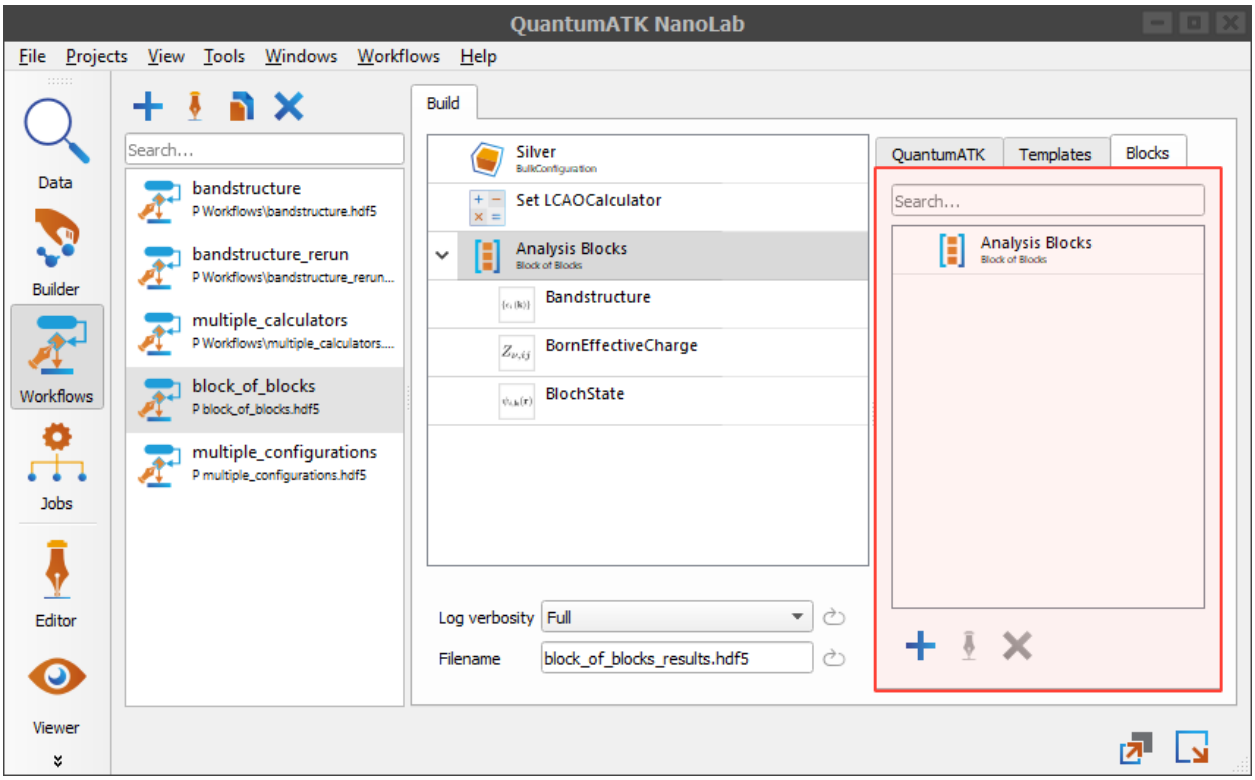
How to save a block from a workflow

Lets say you have a calculator block with a specific set of settings or a group of blocks which do some specific analysis you would like to reuse, like the *Analysis Blocks* block in the `block_of_blocks.hdf5` workflow.

To save a block, simply drag and drop it from the Workflow Area to the *Blocks* window in the catalog of blocks.

Lets save a block in the `block_of_blocks.hdf5` workflow. Drag and drop the *Analysis blocks* on the catalog window under the *Blocks* tab. You can rename the saved block, or add it under a new category. This way the block is permanently saved and can be reused in new workflows.

It is important to note that the saved blocks are shared across all projects.



How to run a workflow

A workflow can be sent to the *Editor* or the *Jobs* tool. To send a workflow to either of these two tools, click the send to button in the bottom right corner of the *Workflow Builder*. This will show a send-to-menu with three options:

- Editor
- Jobs as script
- Jobs as multiple scripts

The first option will open the workflow as a single Python script in the *Editor*. From here you can inspect, edit or save the workflow script.

Option *Jobs as script* and *Jobs as multiple scripts* would export a workflow as a single or multiple Python scripts. You can control the export options such as saving calculation objects at different calculation stages or keeping object unique names. Follow the section *Script exporting options* to read more about the exporting options.

The advantage of multi-script export versus single-script export is obvious in cases when a workflow contains multiple configurations. One script would be generated for each execution branch of the workflow containing a different configuration. These multiple scripts can then be executed in parallel using the *Jobs* tool.

Script exporting options

To generate a script based on the current workflow, click and select *Editor* from the drop menu. A new *Export to script* window will open where you can tweak some of the exporting options. In the following section you can read about script exporting options:

•Result filename

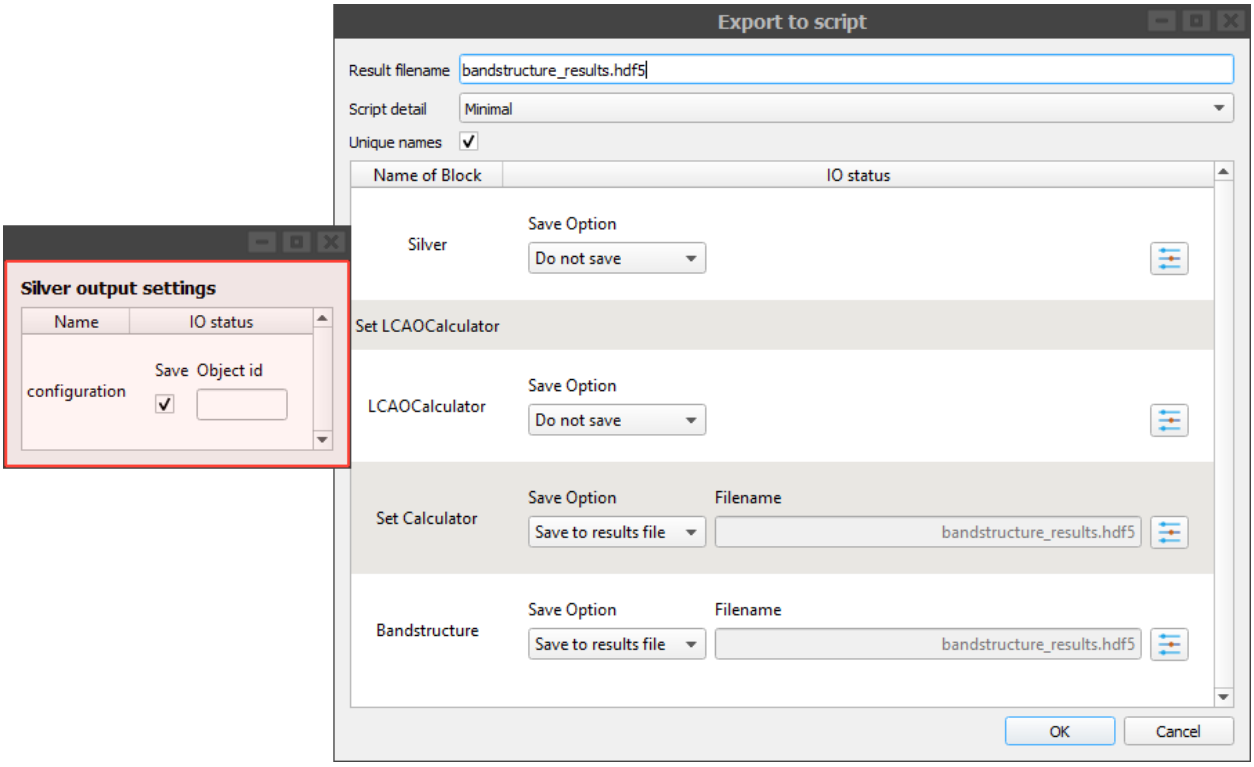
•Script details

•Unique names

•Save options

•Output savings

In the next sections we will refer to the figure below. It shows script exporting options available for the `bandstructure.hdf5` workflow in the section *How to run a workflow*.



Result filename

This will be the filename of the calculation results file. A default filename is the same as the *filename* field at the bottom of the Workflow Area window of the *Workflow Builder*.

Script details

A script can be generated with higher or lower level of detail. The *Report all* option will script all the default values, while the *Minimal* option should only script the values directly or indirectly changed by the user.

Minimal option will result in a more compact script with only the most important parameters visible, while the *Report all* option will give a long and detailed script, which can be useful for troubleshooting.

Unique names

If checked, the script will have unique object names. Otherwise, it will overwrite them once they are not needed anymore by the previous calculation. A typical scenario is when there is more than one configuration in a configuration list. With this option unchecked both configuration variables would have the same name.

Save options

During the calculation you might want to save objects from a workflow not only at the end of calculation, but also at specific calculation stages. This can help when analyzing results and re-starting a calculation with certain parameter changes.

For example, the result file in the `bandstructure.hdf5` workflow would include objects such as a `BulkConfiguration`, an `LCAOCalculator` and a `Bandstructure`. Beside saving the `Bandstructure` and a final `BulkConfiguration` object with an attached `LCAOCalculator`, you could also save the initial `BulkConfiguration` before attaching the calculator. This way you could reuse the same configuration for another calculation with a different calculator.

Saving objects during certain calculation stages can be useful and this is what the save options enable you to do. You can save an object in the final result file, a custom file or skip its saving.

For example, each row in the referenced figure corresponds to a block in the `bandstructure.hdf5` workflow, and each block corresponds to an *QuantumATK Engine* object at a certain stage:

- Silver - controls the saving of the *Silver* configuration right after its construction
- Set LCAOCalculator - a header for the next two rows
- LCAOCalculator – controls the saving of the calculator object
- Set Calculator - controls the saving of the *Silver* configuration after attaching the `LCAOCalculator` to it
- Bandstructure - controls the saving of a `Bandstructure` analysis object.

Output settings

When saving a *QuantumATK Engine* object to a file you can index it by specifying a unique identifier. This helps finding a specific object when reading the file later. To set the object identifier, click on the . This will open a *Silver* *output settings* window - highlighted in red in the referenced figure from this section. From this window you can set an *object id* field - the object identifier.

2.5.2 Using Tables in the Workflow Builder

Downloads & Links

`showcase_table.hdf5` `iteration_block_with_table.hdf5` `table_iteration.hdf5`

The *Table* is a powerful tool that can be used in a variety of situations. The main purpose is to collect data, for later analysis. *Tables* are also used as a container to pass initial training data to the ActiveLearningSimulation, etc.

In the next sections you will learn how to use the *Table* block and *TableIteration* block, through a set of simple examples:

- **Table**. The block that collect data in a table.
- **TableIteration**. The block that iterate over rows of a table.

These two blocks can be found in the Workflow Catalogs under *Algorithm*, and are very convenient ways to first collect data, and later process the collected data.

In the *Downloads & Links* sidebar you will find a list of all the workflows that are created in the following examples.

Table of Contents

- *How to collect data in a table*
- *How to collect data in a table using an Iteration block*
- *How to extract data from a table using a TableIteration block*

How to collect data in a table

The most simple workflow is to add a Configuration to a Table. Thus in this example we have placed a single *Configuration* block followed by a *Table* block.

The purpose of the *Table* block is to collect data in columns and rows, thus we need to specify how many columns the table should have, and which data type the column should accept.

Double click to edit the *Table* block. In this case we want a single column that contain a BulkConfiguration. Thus, the data type of the first column should be BulkConfiguration. Click on the *Add* button to add a column to the table specification.

Note: A Table consists of columns with different types of data and rows for each entry. The different data types for a column will be explained below.

Several column options are available:

- **Type**. This is the most generic column type. You simply need to specify the type of the objects to collect.
- **PhysicalQuantity**. Collects a `PhysicalQuantity`, and requires the unit of the `PhysicalQuantity` to collect.
- **Configuration**. Collects a Configuration, and a large array of setting for further specification. Such as to only collect *`MoleculeConfiguration`*, or only collect *`BulkConfiguration`* with a calculator attached, or only collect *`BulkConfiguration`* with a Simple Cubic Bravais lattice type, etc.

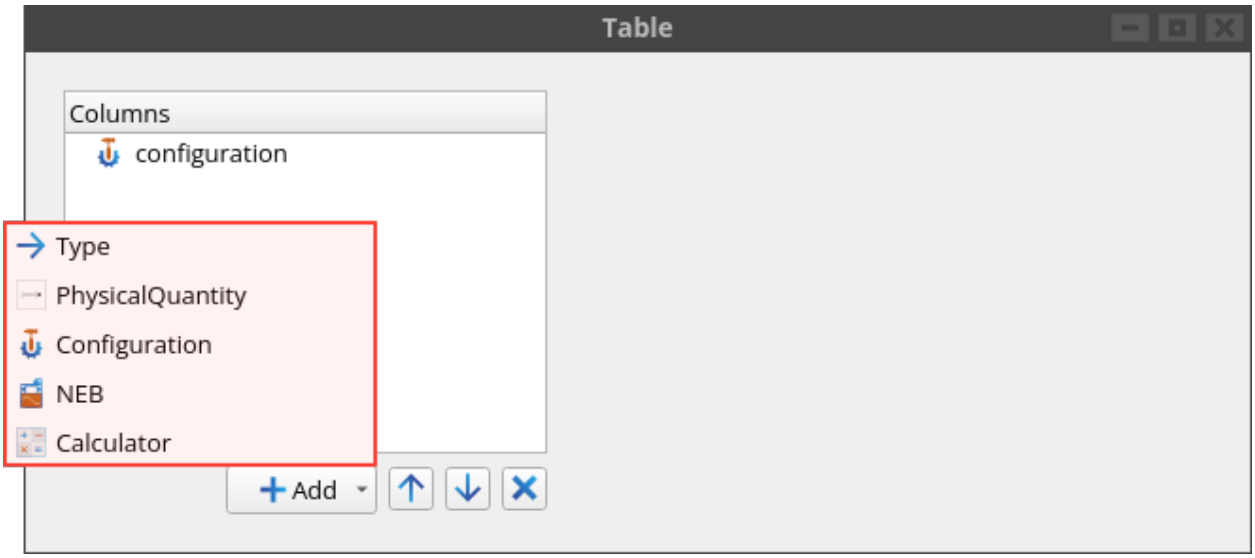
configuration
Add

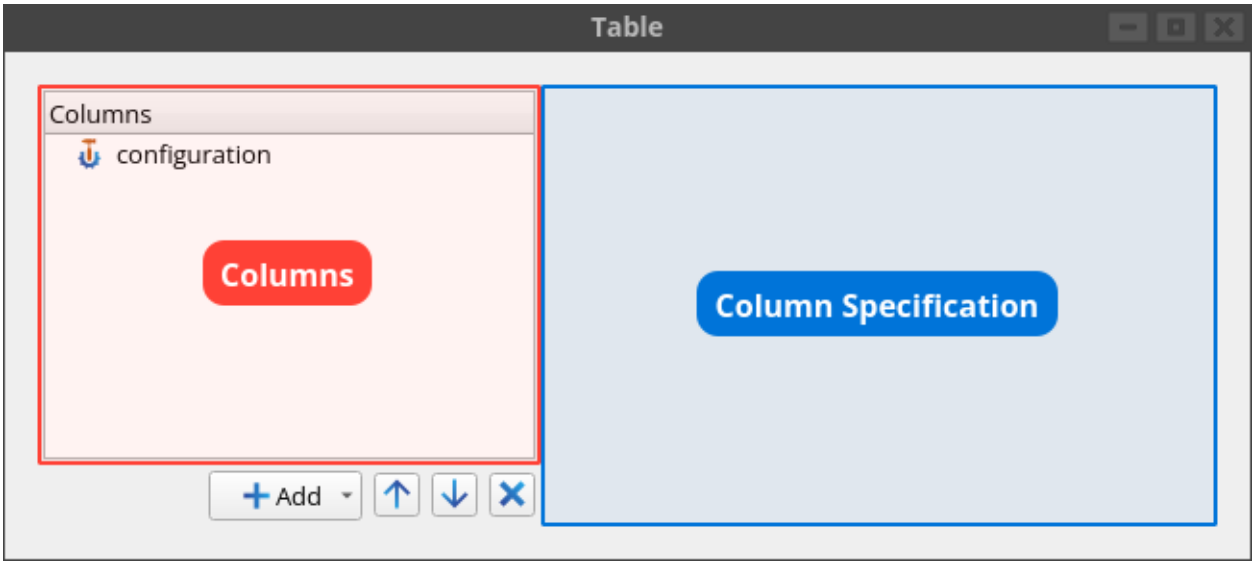
- **NEB**. Collects a `NudgedElasticBand`, and a large array of settings for further specification
- **Calculator**. Collects a Calculator, and a large array of settings for further specification, such as the type of calculator and supported elements.

Note: *Type* should only be used when one of the more specific column options cannot be used. Thus if we want to collect BulkConfigurations, we could do this using the *Type* column, but the *Configuration* column, allows you to specify more information, such as if the configuration have spatial regions, etc.

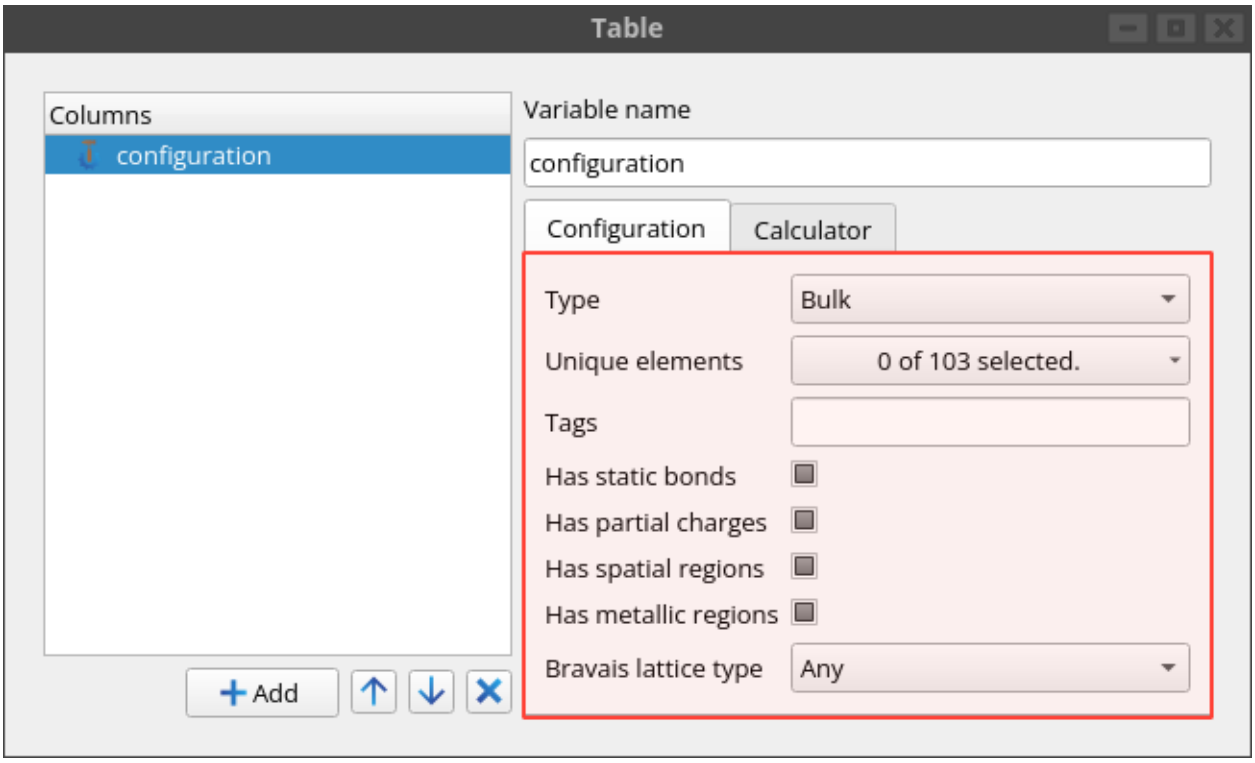
Select *Configuration* in the menu, in order to specify a column with a `BulkConfiguration`. We will later in this guide also use the *Type*, and the *PhysicalQuantity* column options.



Once the *Configuration* column have been added it should be visible in the list of columns, and it can be selected. Once selected the settings for the *Configuration* column become visible on the right in the *Column Specification*.



Specify `BulkConfiguration` as the configuration type in the widget.



The resulting workflow will place the provided bulk configuration into the table, resulting in a table with a single column and a single row.

Naturally this is a very simple example that is not very useful on its own. So in the next example we will go through a bigger more useful example.

How to collect data in a table using an Iteration block

A standard use case for the Table is to collect results using an *Iteration* block `iteration_block_with_table.hdf5`.

In this example we first define an *Iteration* block, where we loop over a k-point sampling parameter. The goal in this examples to determine if a k-point sampling of (9,9,9) is converged.

To specify the k-point sampling parameter we open the editor for the *Iteration* block. We click on the *Add* button to add an iterator to the *Iteration* block.

In this case we select the *List of integers* in the menu.

Fill in the name and values of the iterator. In this case we want to loop over the values (1,3,5,7,9).

Tip: *Range of integers* could also be used. For this example that would mean setting the *Start* to 1, *Step size* to 2, *Steps* to 4, resulting in a *Stop* of 9.

The attentive reader would notice, that the range specification is over determined. Thus changing *Start*, *Step size* or *Steps* will update *Stop*, while changing *Stop* will update *Start*.

The *Iteration* block, works as a *Block of Blocks* (see the *Block of blocks*) block and in this case it consist of 5 blocks:

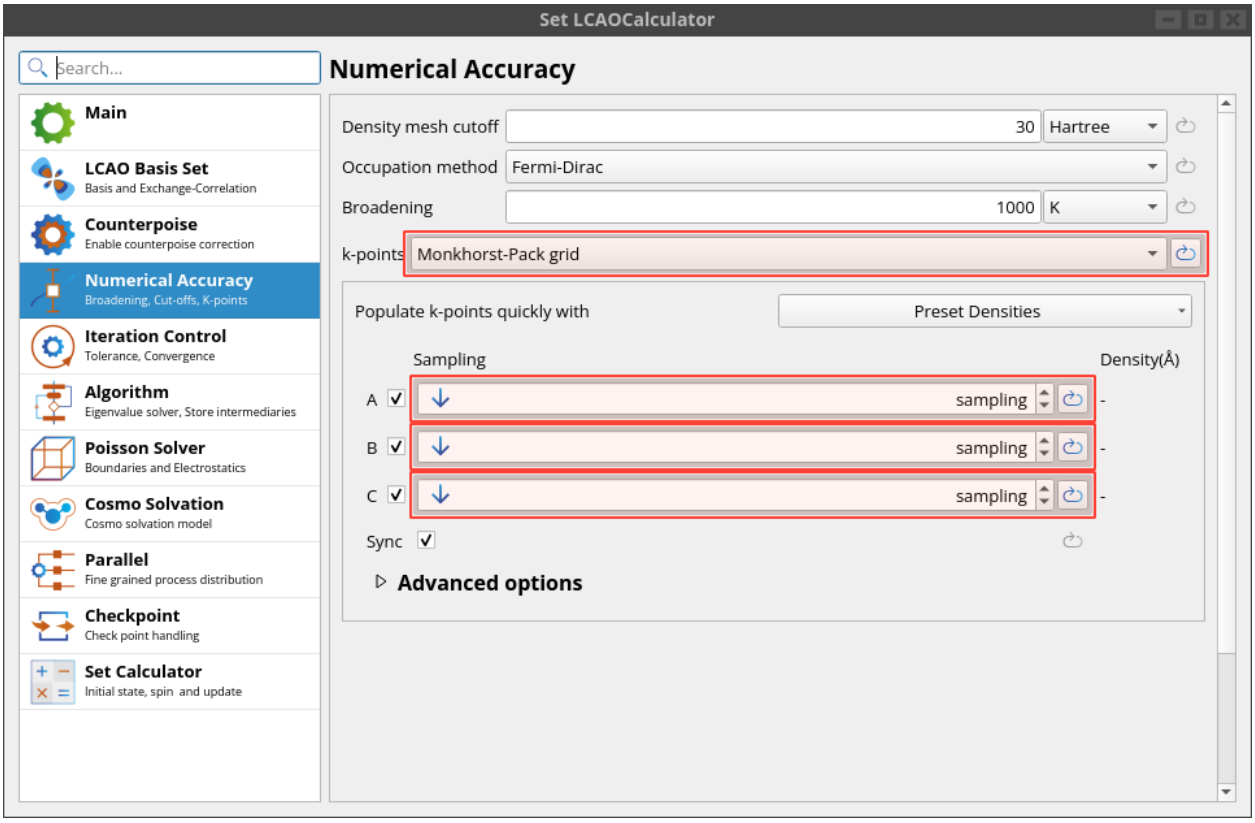
- **Configuration**. This will create a configuration.
- **Set LCAOCalculator**. This will create a `LCAOCalculator`, set it on the configuration and update the configuration.
- **TotalEnergy**. Calculates a `TotalEnergy` analysis object.

E_{Total}

- **Extract total_energy**. A Custom block that extract the total energy in eV from the TotalEnergy analysis object.
- **Table**. The table block.

First we modify the LCAO calculator to use the iterator. First a Monkhorst-Pack grid is selected and then the iterator *sampling* is selected using the in the *A*, *B*, *C* sampling fields

Secondly, we use a Custom block to extract the total energy from the `TotalEnergy` analysis object (see the *What is a workflow block and how to edit it*). The *Custom* blocks are very powerful and flexible blocks. They support



insertion of custom QuantumATK scripts, thus allowing Custom blocks to serve as an interface to a complex calculation setup.

To extract the total energy from the `TotalEnergy` analysis object we must specify in the *Inputs* tab that the *Custom* block requires a `TotalEnergy` analysis object as input.

In the *Outputs* tab we need to specify that the *Custom* block returns a quantity in units of eV.

Finally in the *Script* tab we write the script to extract the total energy from the *TotalEnergy* object.

Running the calculation results in a table, that can be viewed in the *Table Viewer*. (The *Table Viewer* can be open using the data tool *Analyzers and Preferences*)

It is fairly easy to see that the total energy is converged to within 10 meV (or at least 4 significant digits).

How to extract data from a table using a TableIteration block

Imagine the scenario where you have just done the previous calculation, but realize that you also need to check that the direct bandgap is converged.

You can now load the previous Table using a *Load from file* block, and use the *TableIteration* to calculate the bandgap for each row of the table `table_iteration.hdf5`.

Note: When the *Load from file* block is used to load a Table from file. It will recognize it, and adapt the name and the icon of the *Load from file* block to *Load Table* with the Table icon. *Load from file*

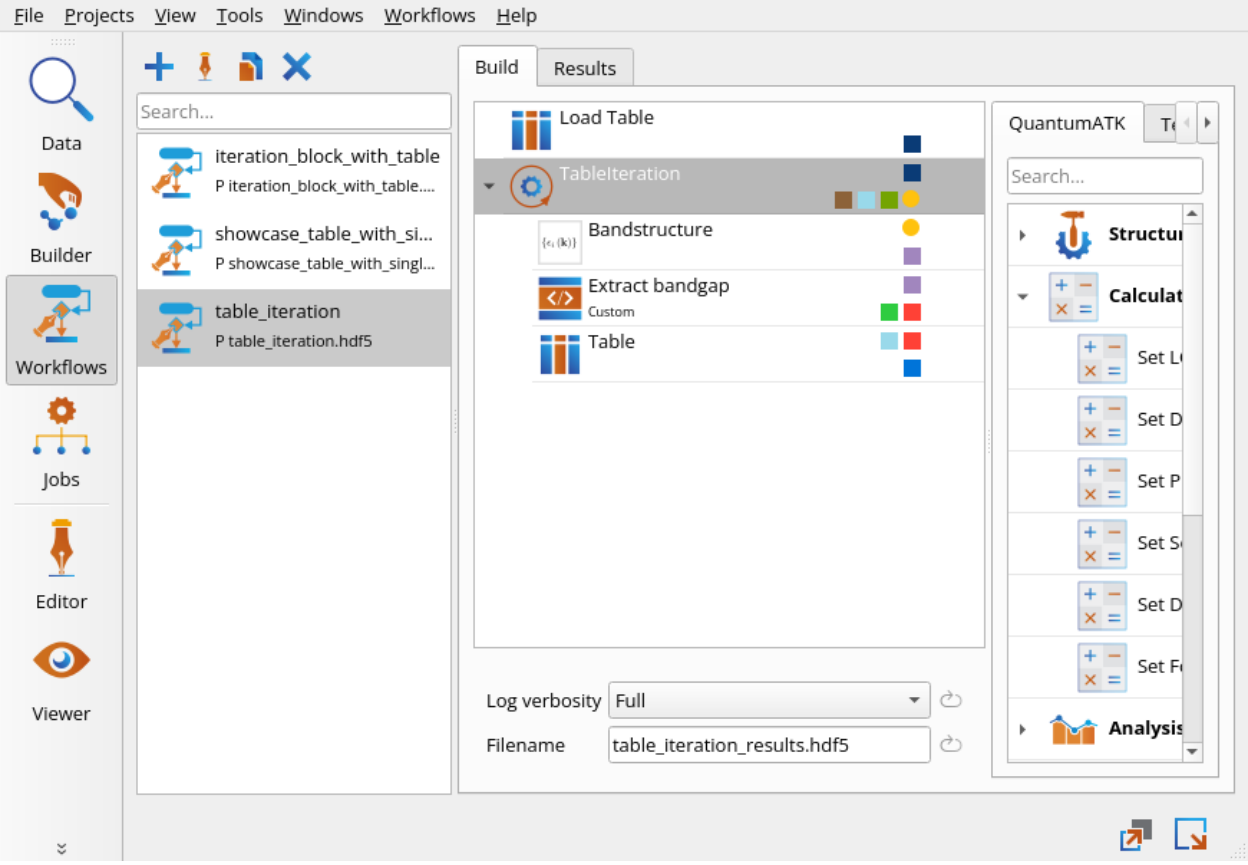
Table - table.hdf5 - table

	Configuration	Sampling	Total_Energy
0	<NL.Com...	1	-212.801968768 eV
1	<NL.Com...	3	-229.411070419 eV
2	<NL.Com...	5	-229.969695432 eV
3	<NL.Com...	7	-230.02498655 eV
4	<NL.Com...	9	-230.032665685 eV



The *Load from file* block is used to load the table. Use the *Load from file* button to specify the table.

The *TableIteration* block takes a table as input and provide the tables row information for each iteration. However, there could be many tables in the workflow and we thus need specify the columns we require to be present in the provided table. In other words we need to align the columns of the *TableIteration* block, with the columns of the Table.

The methodology is similar to specifying the *Table* block. Thus we need to specify a Configuration column, an integer column for the sampling, and a total energy column.

The Configuration column:

The integer column:

The total energy column:

Similar to the last example, we need a Custom block, in this case to extract the direct bandgap of a `Bandstructure` object. Thus we specify the *Script* tab of the Custom block

We furthermore need to specify in the *Inputs* tab of the Custom block, that a `Bandstructure` object is required as input.

In the *Outputs* tab of the Custom block, we specify that a physical quantity with units of eV is provided as output.

Finally we again collect the sampling and bandgaps in a table. Thus we again need to specify a number of columns to collect the data. In this case, lets collect the bandgap and the sampling.

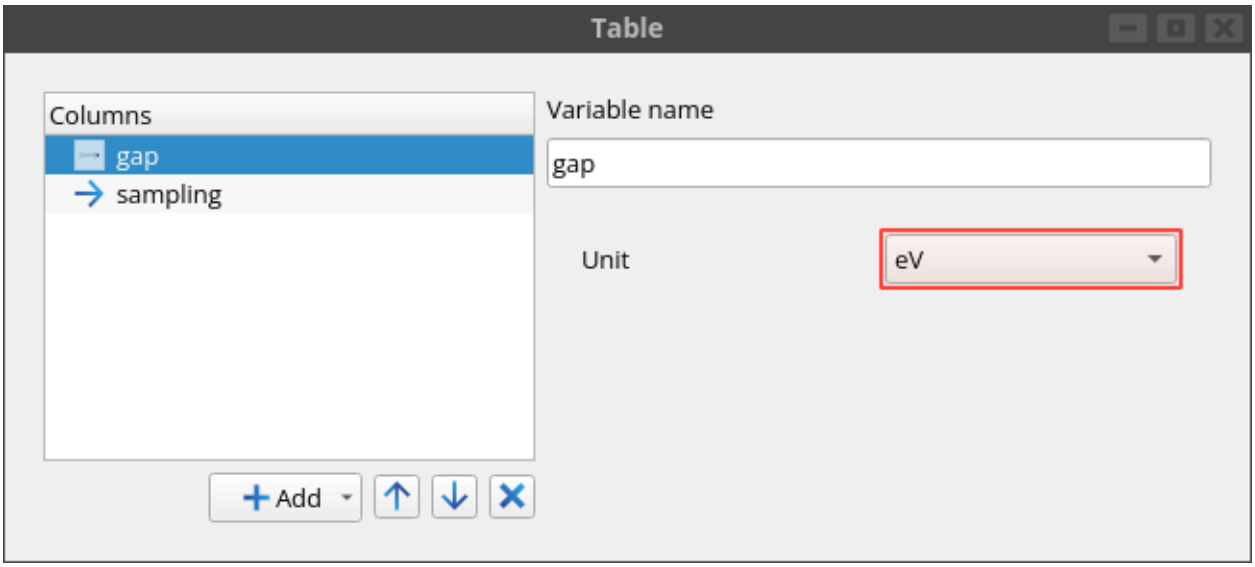
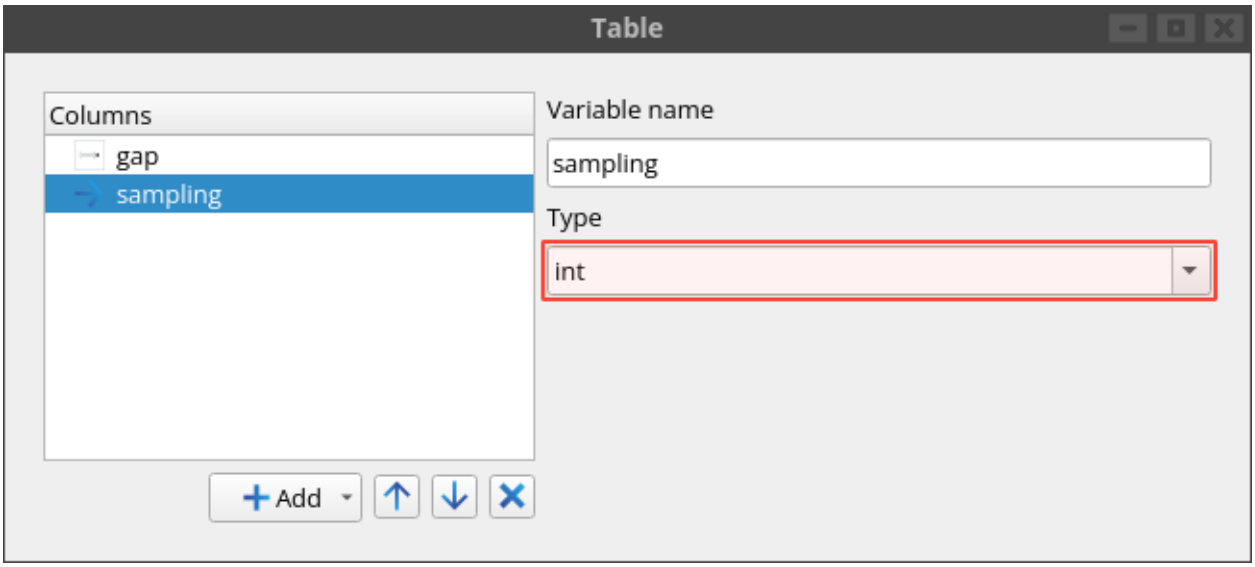
The bandgap specification, is a *PhysicalQuantity* Column with the bandgap in units of eV:



The sampling specification, is a *Type* Column with the type specified as integer.



Resulting in the table, where it is clear that the direct bandgap is converged to within 1 meV (atleast 3 significant digits). (The *Table Viewer* can be open using the data tool *Analyzers and Preferences*)

We have now used the *Table* and *TableIteration* blocks, and hopefully shown how convenient, and versatile these can be. You can collect almost anything in a table, you can easily load a table using a *Load from file* block, and you can easily iterate over rows of a table.

2.5.3 Introduction to Array Jobs

Downloads & Links

`array_workflow.hdf5` `array_workflow_results.py` `array_workflow_results.hdf5`

Often, one wants to run many similar calculations in parallel. Perhaps one wants to scan over a specific set of parameters or calculate specific properties for many different structures.

One way to achieve this is to take advantage of the array jobs feature present in all standard HPC queueing systems such as PBS, LFS or SLURM. Instead of performing all the calculations in one single, huge job an array job allows the queuing system to manage the computation in a much more fine-grained way, where each of the many calculations are only submitted in smaller batches whenever sufficient resources are available. This often leads to much faster computation times, since the job does not have to wait for a single large reservation of computing resources to become available.

While running array jobs comes with a a lot of advantages, they are also much harder to set up and submit compared to regular jobs. Also, once the computation has finished, it is also much harder to gather the data of all the independent calculations.

The QuantumATK Workflow Builder and *Jobs* tool now takes away all the hassle of setup, submission and data gathering for array jobs. They are now essentially as easy to set up as normal computation jobs.

This small guide shows you how you can leverage the power of array jobs in QuantumATK.

Table of Contents

•*How to build an array script in the Workflow Builder*

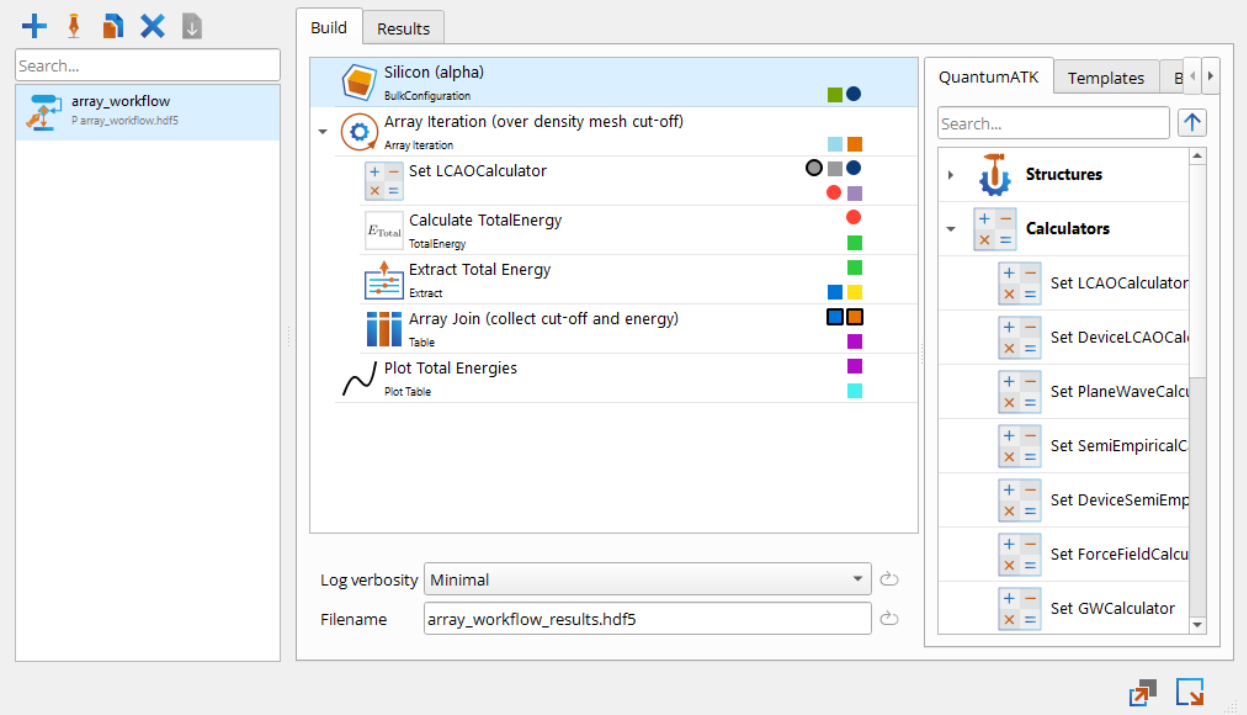
•*How to submit an array script*

How to build an array script in the Workflow Builder

We begin by using the Workflow Builder to set up an array script.

As a quick example, let us imagine that we are interested in Silicon and wish to investigate Silicon using a LCAO-Calcualtor. An important first step is then to converge the density mesh cut-off for the LCAOCalculator. We can do this by calculating the Total Energy of the Silicon system for different values of the density mesh cut-off, and all these independent calculations can be performed in an array job.

Let us set up the following workflow:



The array iteration block creates a density_mesh_cutoff variable that iterates over energies of 10, 20, , 110 Hartree.

Tip: Array jobs can be built using either the Array iteration block or the Array table iteration block.

The density_mesh_cutoff variable is then plugged into the LCAOCalculator block.

All array jobs must collect their result in a Table. In this case we save both the input density mesh cut-off and the resulting total energy in the table.

Note that the workflow also contains a plot of the total energy against the density mesh cut-off, so it is straight forward to gauge the convergence.

Next, in the lower right corner of the Workflow Builder we then click the Arrow and then select Editor as Array script. The resulting script looks like this:

```
# ARRAY prepare 11 finalize

import itertools

# Set minimal log verbosity
setVerbosity(MinimalLog)
```

```
    # Save plot to file.
    Plot.save(plot_model, results_filename)
```

This script effectively splits the calculation up into three different parts. First a common prepare part that sets up the silicon structure, then an array part that calculates the total energy for the different density mesh cut-offs and lastly a finalize part, in which the array results are collected and plotted.

This script is specifically adapted to work with the QuantumATK *Jobs* tool. However, it is also made in such a way that it will still work when submitted as a normal job. Running it like a normal job will of course be a lot less efficient, as it will run entirely in a single process. It is also possible to prepare your own array scripts for submission with the *Jobs* tool by using e.g. the example script above as a template.

Once the script is created, save it in preparation for submitting it in the *Jobs* tool.

How to submit an array script

Start by sending the array script to the *Jobs* tool. In the job creation dialog choose a machine with a queueing system, e.g. LSF, SLURM or PBS.

The submission dialog contains a specific tab for array jobs settings. Note that this tab has already been filled out with the relevant information taken from the first comment line in the array script.

Creating the job and pressing submit, we can follow the progress of the job in log panel. In our case it would look like this:

```
+-------------------------------------------------------------------------------+
| Total Array Jobs                                                              |
+-------------------------------------------------------------------------------+
| Total jobs:                 13                                                |

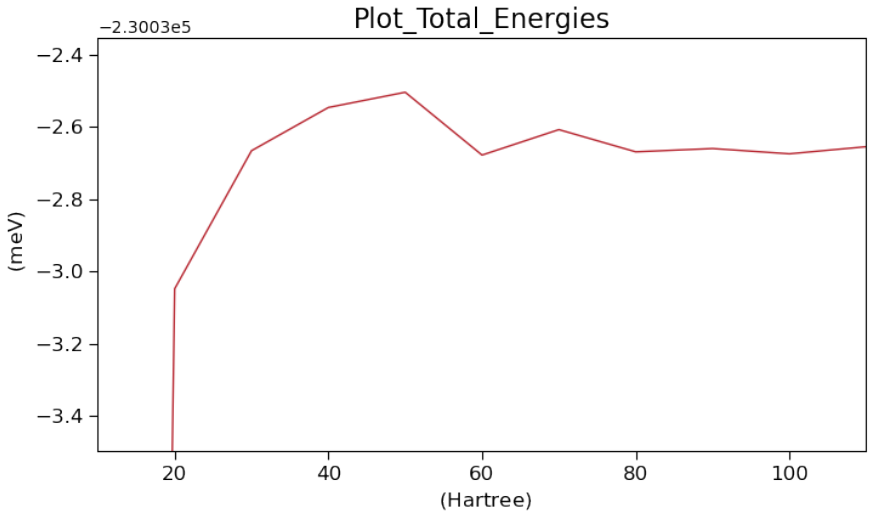
| Finalize                   Queued                                                |
+--------------------------------------------------------------------------------+
```

Tip: The array log files are each put in separate folders, and they can be inspected in the special log files tab.

When the calculations have finished all the main results are downloaded. This includes all outputs from the main part of the workflow, i.e. all results form the prepare and finalize parts and the table from the array part. The created plot looks like this, showing a convergence to less then 1 meV at around 30 Hartree.



2.6 Jobs manual

2.6.1 Job Manager for local execution of QuantumATK scripts

Version: T-2022.03

Downloads & Links

`silicon.py` `cnt.py` `mpi_check.py`

Table of Contents:

•*Execute QuantumATK simulations via the Job Manager*

•*Serial execution*

•*Threading*

•*MPI parallelization*

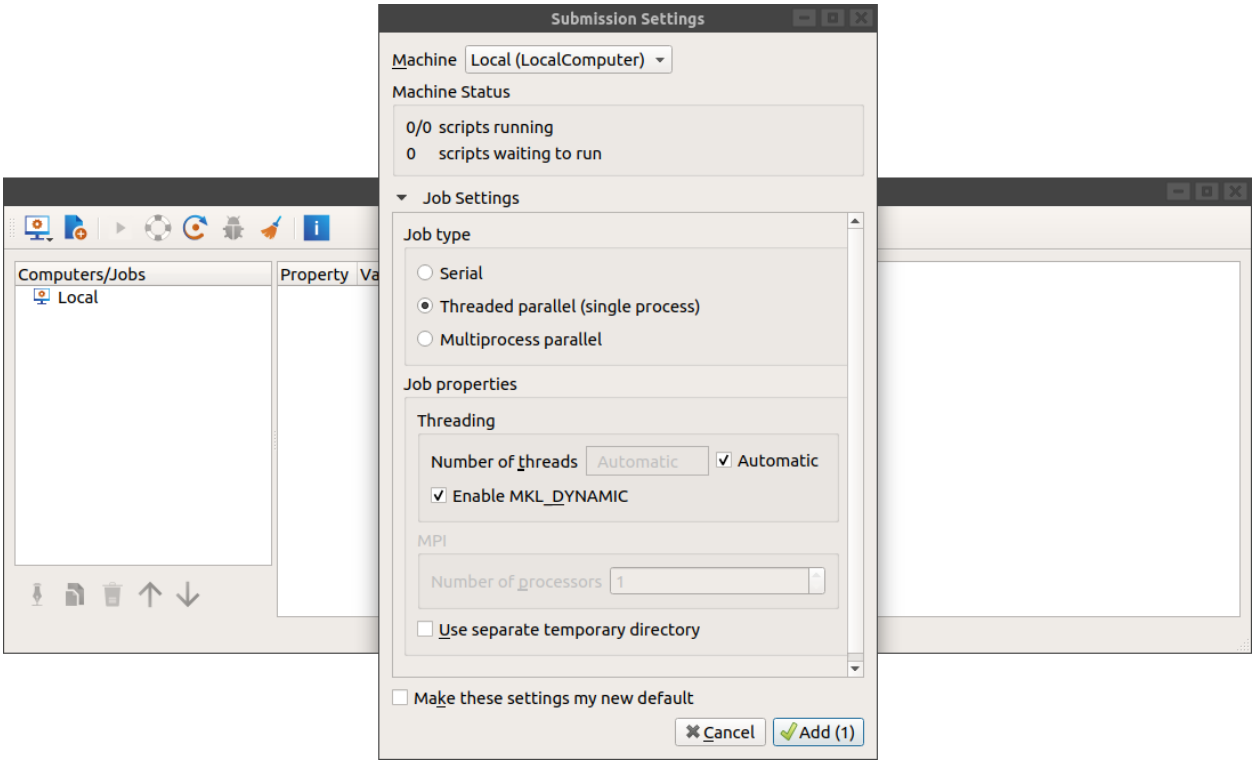
•*Adding Computers*

Execute QuantumATK simulations via the Job Manager

In this section you will learn how to use the **Job Manager** for local execution of QuantumATK scripts. Specifically, you will learn about queuing, running and managing QuantumATK jobs.

Create a new empty project and download the example script `silicon.py`, which runs an ATK-DFT calculation with very many k-points (31x31x31).

Drop it on the **Job Manager** and select a local computer for the job execution.



The **Submission Settings** widget has two basic panels:

•**Job type;**

–*Serial*

–*Threaded parallel (single process)*

–*Multiprocess parallel*

•**Job properties;**

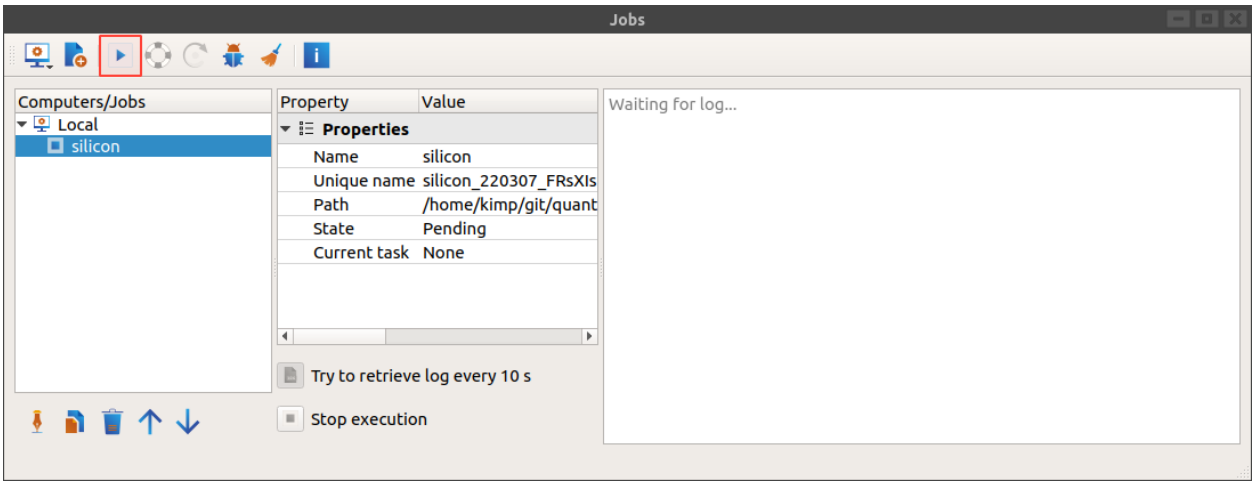
–Threading;

–MPI Parallelism;

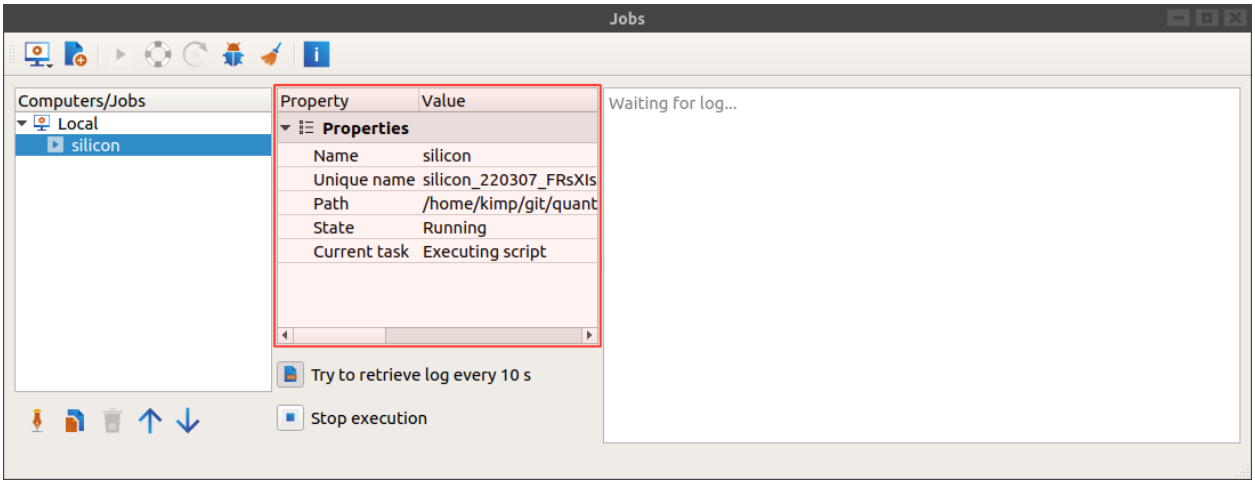
–**Use separate temporary directory** (set this to allow using a non-default working directory for running the job. Note, results will not be appended to existing hdf5 or nc files, but instead a new file will be created.)

Set these settings according to your needs, and click **Add**.

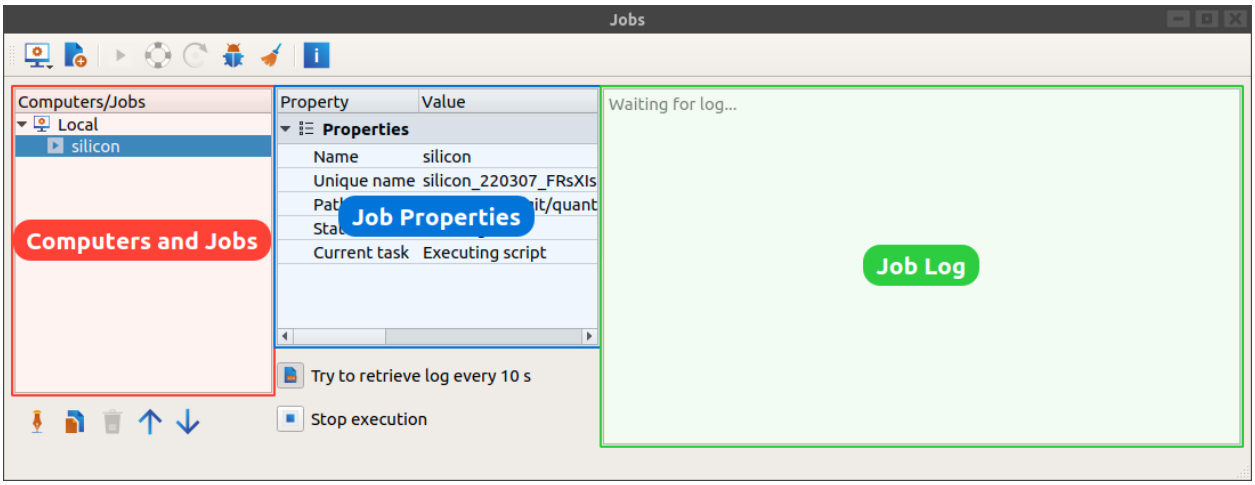
In the **Job Manager**, first select the job. Then click the highlighted **Run** button to start the job.



The task state changes from Pending to Running.



The Job Manager has three main parts. The overview of **computers and jobs** highlighted in red, the **properties of the job highlighted** in blue, and **the log** highlighted in green.



The properties of the job is a Property–Value list which shows all details of the settings used for job execution, including:

•Name of the Python script.

•State.

•Current task.

The job finishes after about 1 minute (2.5 GHz CPU). Note that the task state changes to Finished.

The job output (calculation results) of course appears in the QuantumATK **DataView** after job execution.

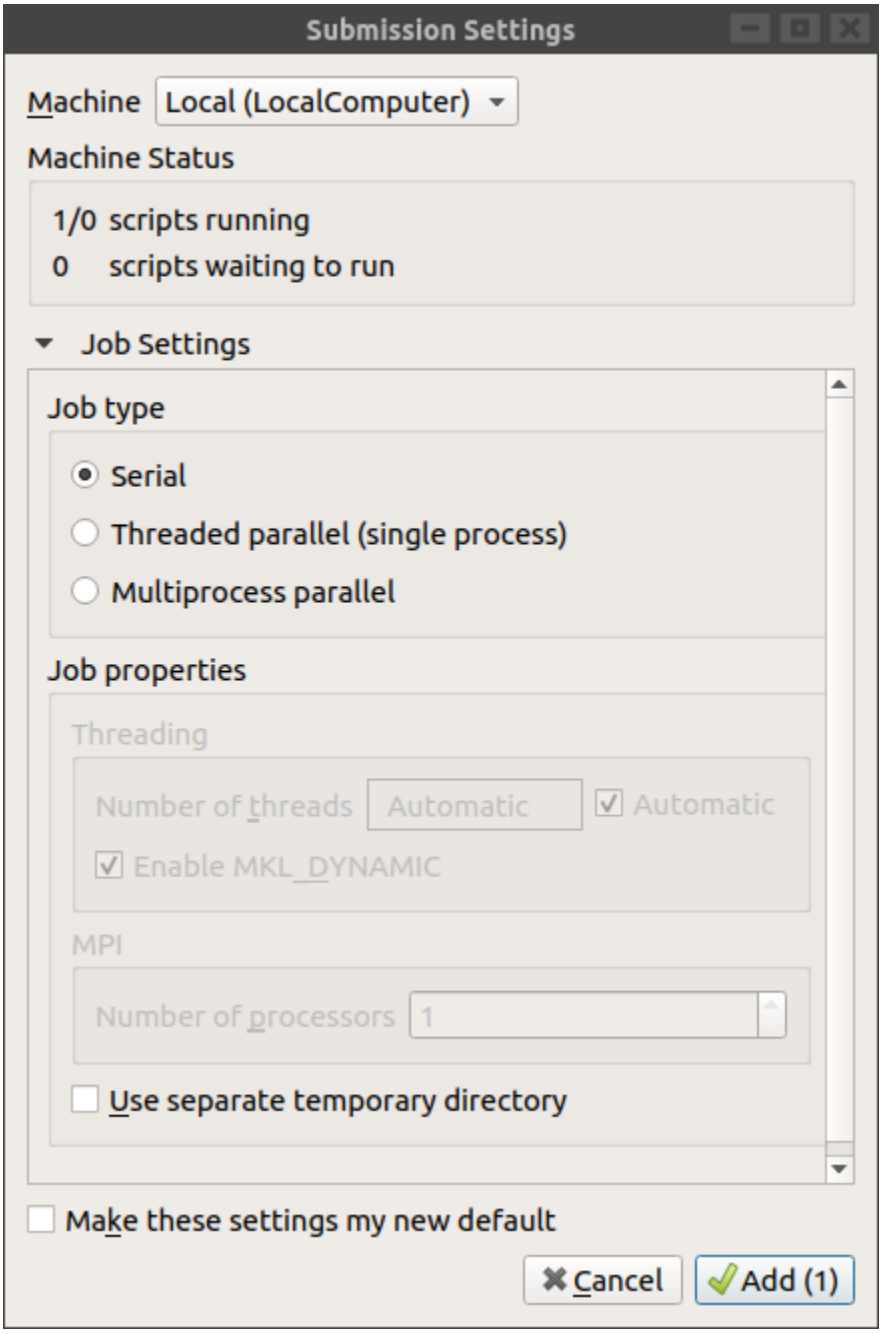
Note: Remember that the default job type is Threaded parallel (Single process). You can change this to Serial or Multiprocess parallel before starting the job.

Use the **Trash** button to remove jobs from the job queue.

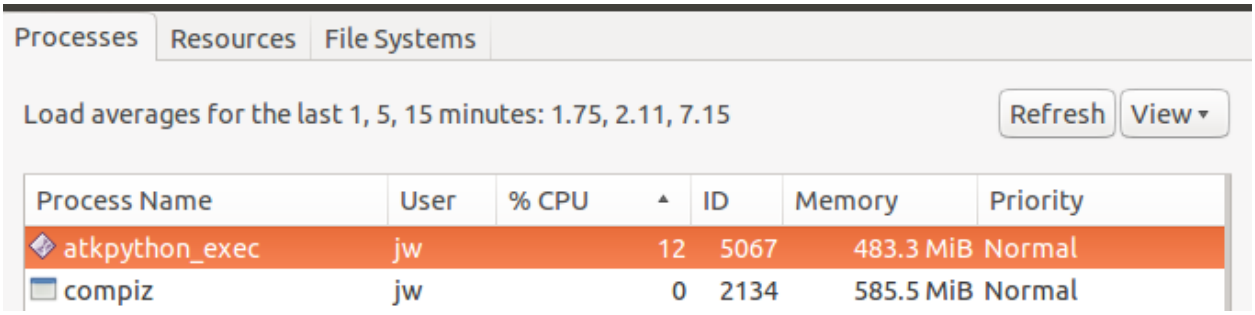
Serial execution

In the **Submission Settings** window select a **Serial** job type as shown in the below figure to run on a single process with no threading.

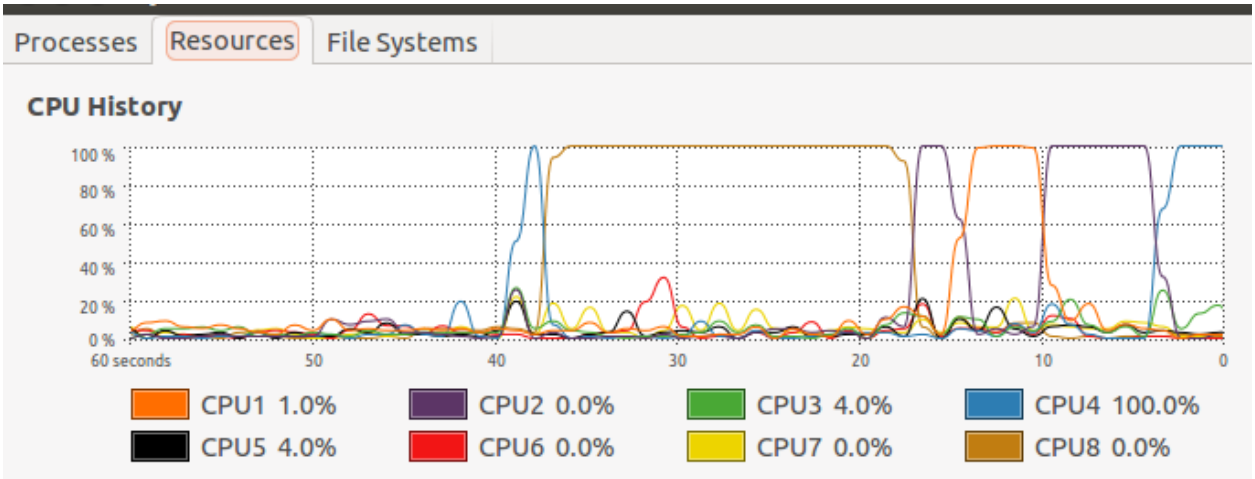
In fact, note that threading and MPI parallelization are not available.



If you check the system load during local execution in serial, you should see that the serial job launches only a single computing task on a single CPU core.

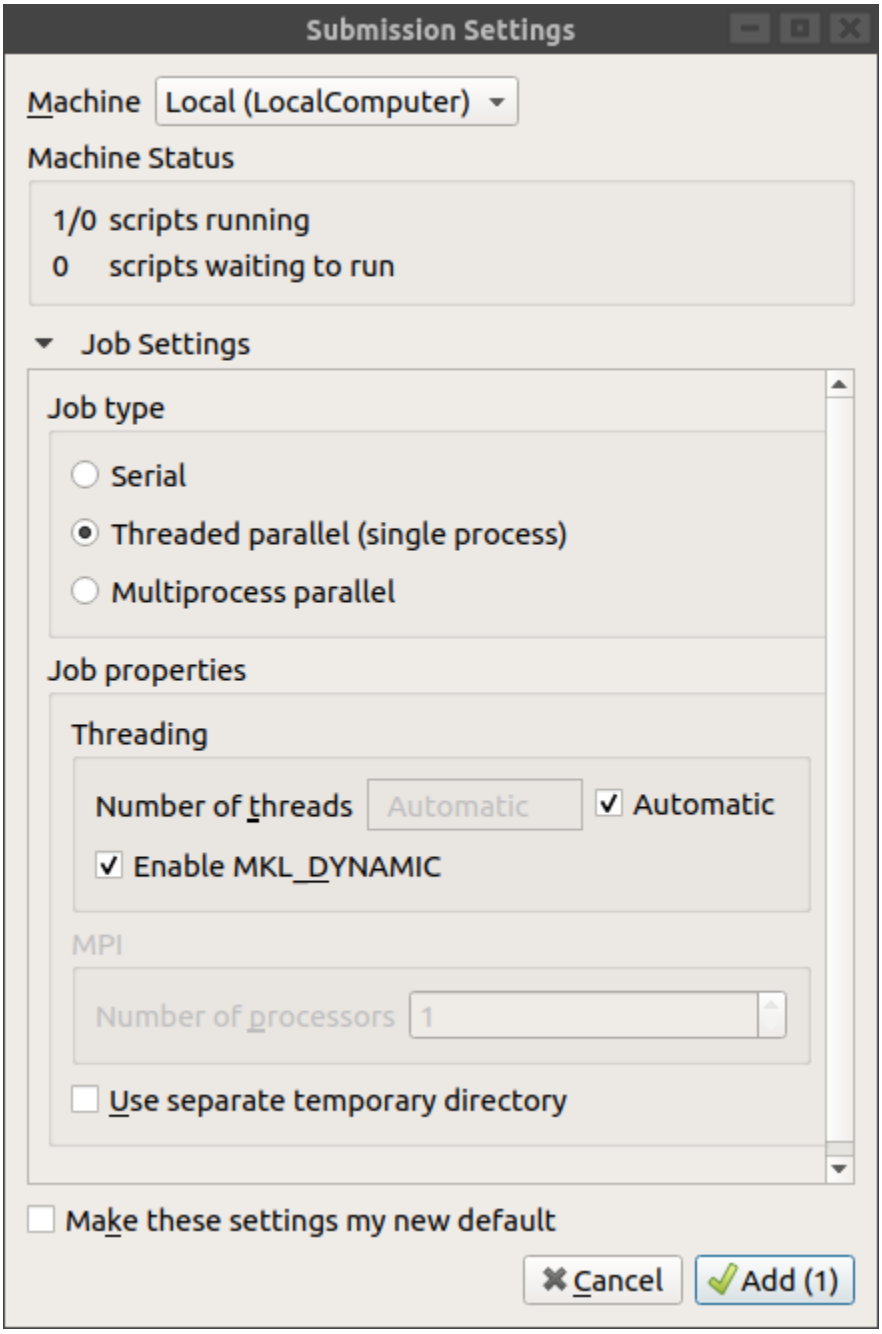


Only one core is used at a time, but the hardware process manager may move the task between cores from time to time.



Threading

In the **Submission Settings** window select a **Threaded parallel (single process)** job type as shown in the below figure to run on a single process with threading.

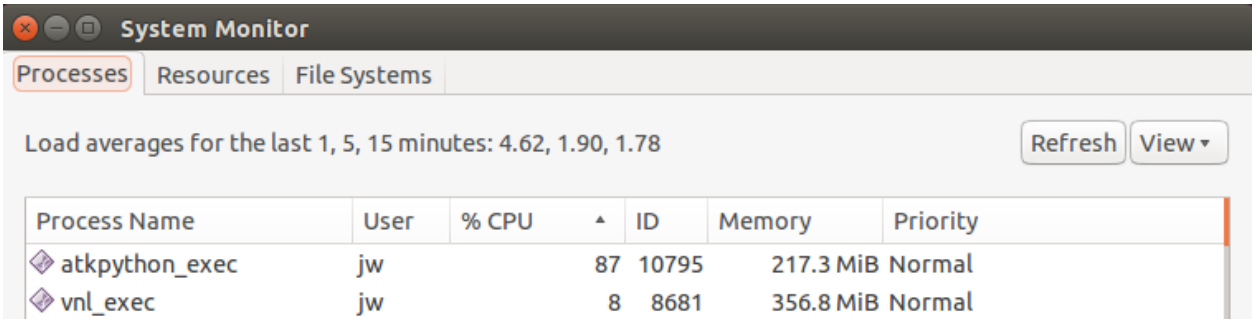


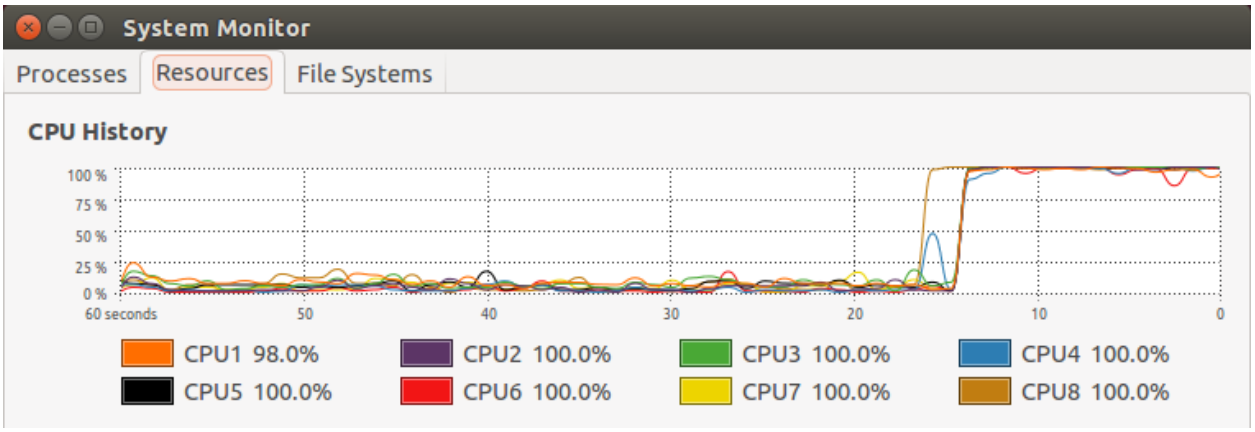
Threading is one way to parallelize a computational job. QuantumATK uses Intel MKL for openMP threading. Note that we do in general recommend *MPI parallelization* over threading for parallelizing DFT calculations. However, threading is often more efficient for parallelizing **ATK-ForceField** calculations, and Hybrid DFT calculations.

Download the script `cnt.py`, which uses ATK-ForceField to calculate the dynamical matrix of a multi-wall carbon nanotube.

Execute it using the **Job Manager**, and choose job type Threaded parallel (single process). It should be pretty fast.

If you check the system load during execution of the calculation, you should see that only a single **atkpython** process is started, even though several cores appear to be busy. This is because the work load of the one process is split into a number of threads that may be distributed on more cores.





Download the script `cnt.py` to test the performance of a ATK-ForceField simulations using threading. This specific example will calculate the dynamical matrix of a multi-wall carbon nanotube. If you also run the calculation in serial, you will see that the wall-clock time used for evaluating ATK-ForceField forces may decrease significantly when threading is switched on. In the example shown below, the time spent on force calculations is roughly halved.

```
==> cnt_threading.log <==
Timing:
--------------------------------------------------------------------------------
Forces                  :      14.22 s       0.00 s      60.63% |=============|
Loading Modules + MPI   :       1.57 s       1.57 s       6.69% |=|
File IO, nlsave         :       0.10 s       0.05 s       0.43% |
--------------------------------------------------------------------------------

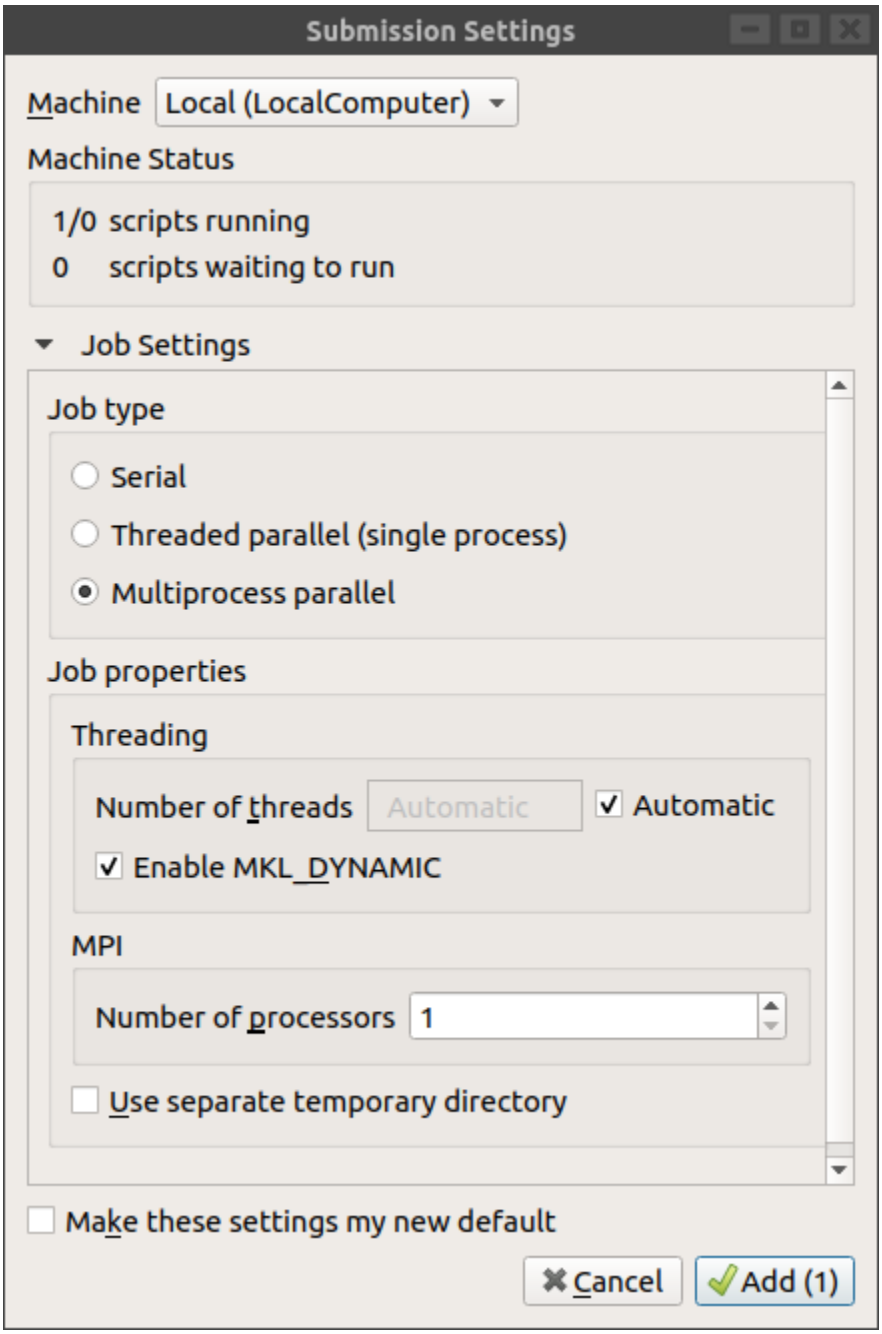
==> cnt_serial.log <==
Timing:
--------------------------------------------------------------------------------
Forces                  :      22.37 s       0.01 s      79.53% |=============|
Loading Modules + MPI   :       1.55 s       1.55 s       5.52% ||
File IO, nlsave         :       0.06 s       0.03 s       0.21% |
--------------------------------------------------------------------------------
```

MPI parallelization

Important: If you are running **ATK 2016 or earlier** you need to have MPI (Message Passing Interface) installed on your local computer.

Both the **Linux** and **Windows** versions are compiled against Intel MPI library. Since **ATK 2017** Intels `mpiexec.hydra` is provided on both Windows and Linux versions - **this is the recommended way to run QuantumATK in parallel**.

In the **Submission Settings** window select a *Multiprocess parallel* and e.g. 4 MPI processes.



Running from the command line

If you wish to run QuantumATK in parallel from the command line you can use the `mpiexec.hydra` binary shipped with QuantumATK and located in the folder `libexec/mpiexec.hydra` present in your installation folder.

In this case you can run parallel jobs with:

```
$ QW_INSTALLATION_PATH/libexec/mpiexec.hydra -n 4 atkpython atk_script.py
```

Hint: Prepend `QW_INSTALLATION_PATH/libexec/` in your `PATH`.

```
$ export PATH=QW_INSTALLATION_PATH/libexec:$PATH
```

This way you will automatically pick up the `mpiexec.hydra` binary shipped with QuantumATK:

```
$ mpiexec.hydra -n 4 atkpython atk_script.py
```

Adding Computers

It may sometimes be convenient to have a predefined local computer that is set up with MPI parallelization as default mode. You can easily add such a computer yourself.

In the Job Manager main window, click to add a new computer and select *New Local*.

Then edit the default job settings of the new computer in the **Job Settings** window that pops up:

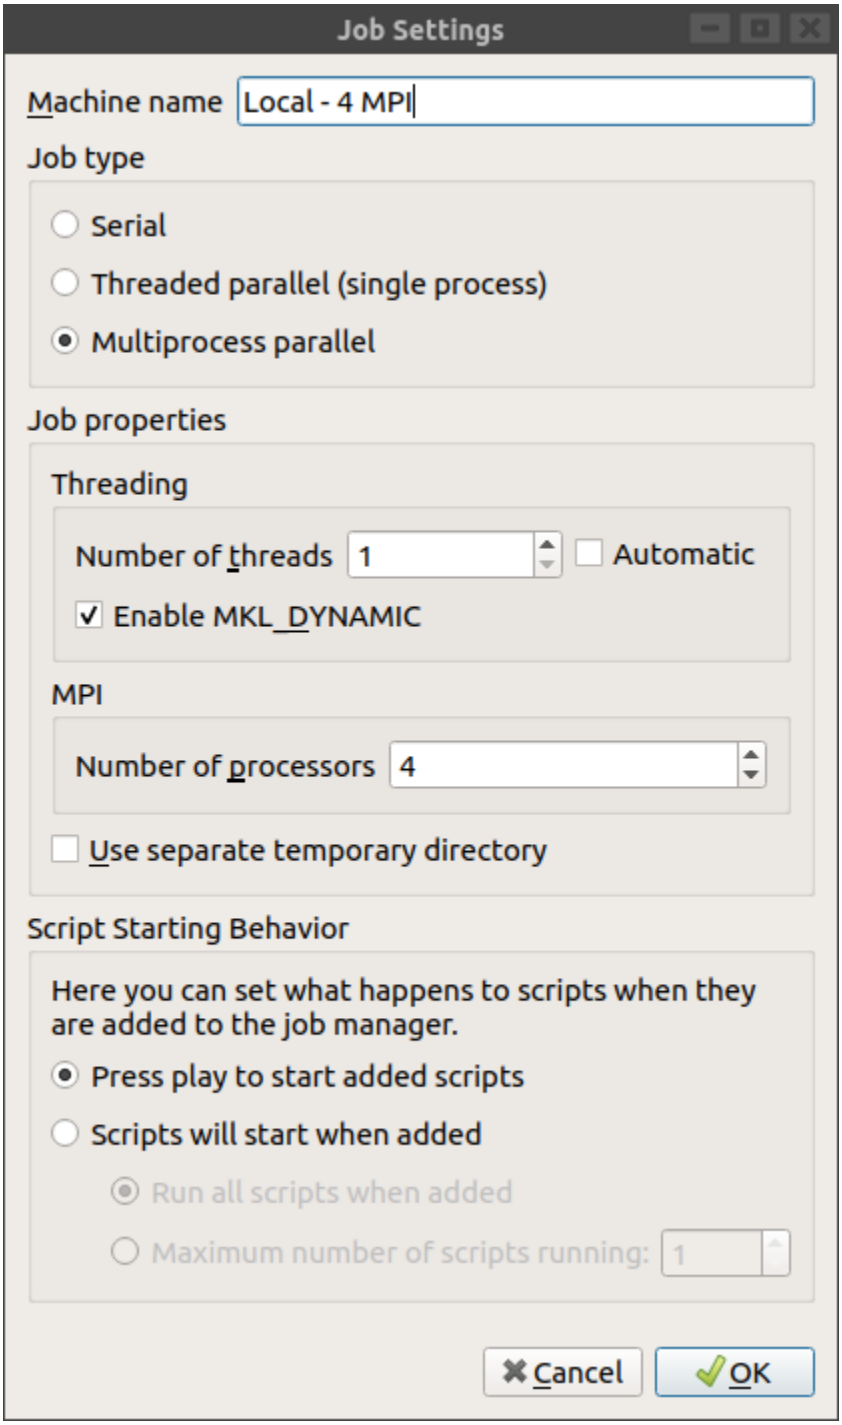
•Name the computer, e.g. Local - 4 MPI.

•Select *Multiprocess Parallel* as job type.

•Make sure threading is turned off (*Number of threads* = 1)

•Choose the default number of processors, e.g. 4.

•Click *OK* to add the new computer.



You can add as many custom computers as you like.

The **Job Settings** widget has an additional panel in addition to *Job type* and *Job properties*:

There are two options. Either you manually press play to run the jobs, or you can automatically start jobs submitted to the computer.

Set these settings according to your needs, and click **Add**.

2.6.2 Job Manager for remote execution of QuantumATK scripts

Downloads & Links

`mpi_check.py` `silicon.py`

In this tutorial you will learn how to use the Job Manager for execution of QuantumATK jobs on remote computing clusters. In particular, you will learn how to:

- add a remote machine to the Computers/Jobs;
- use custom Machine Settings for individual jobs;
- add several different machines and import/export machine settings.

Important: You will set up a remote machine for running jobs in parallel using MPI, as well as with threading. We strongly recommend you go through the tutorial *Job Manager for local execution of QuantumATK scripts* before continuing with this one.

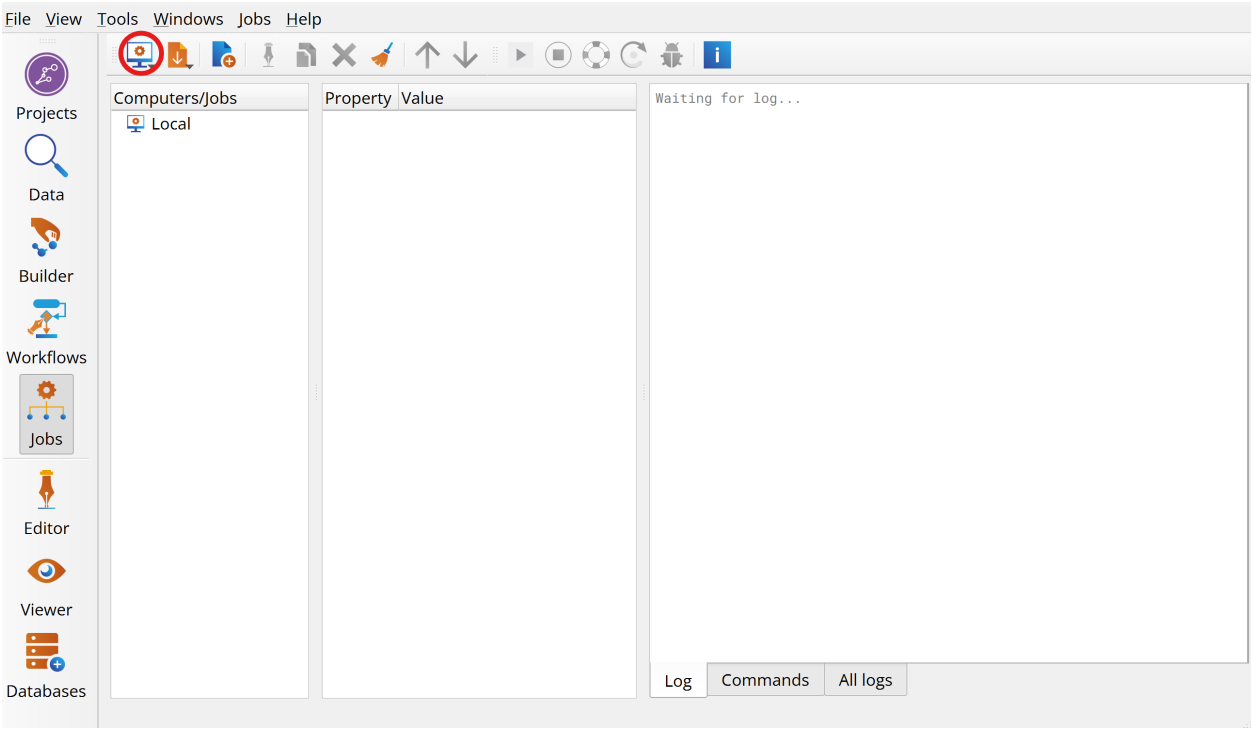
Note: There are two essential requirements when using the Job Manager for executing and managing QuantumATK jobs on a remote cluster. You need:

1. QuantumATK installed on the local machine **and** on the cluster;
2. an SSH connection from your local machine to the cluster.

Please refer to the tutorial ssh_keys if you need help setting up the SSH connection.

A single remote machine

Click on the **Create computer** to add a new machine.



The menu that appears has seven options, *New DirectRemote*, *New Local*, *New LSF*, *New PBS*, *New PBSPro*, *New SGE* and *New SLURM*,.

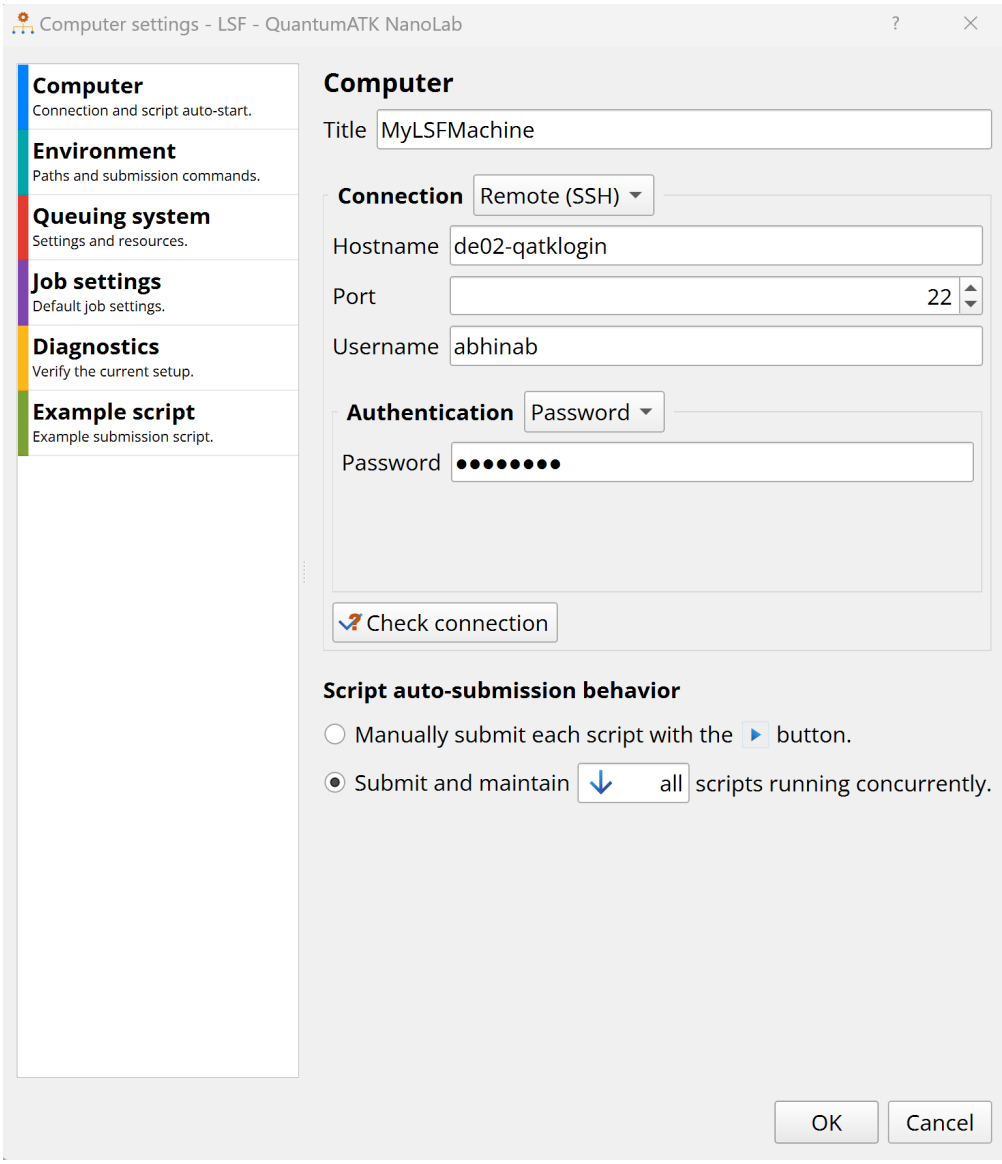
Choose the type of remote machine that matches the job scheduling on your remote Linux cluster, and start setting up the connection. Here, you will choose the *New LSF* machine to set up a machine with a LSF job scheduling system. The option *New DirectRemote* is appropriate for clusters that have no queue system.

The **Computer Settings** widget pops up. It has six main tabs:

- *Computer (Connection and script auto-start)*,
- *Environment (Paths and submission commands)*,
- *Queuing system (Settings and resources)*,
- *Job Settings (Default job settings)*,
- *Diagnostics (Verify the current setup)*,
- *Example script (Example submission script)*.

Computer

Connection to the remote cluster.



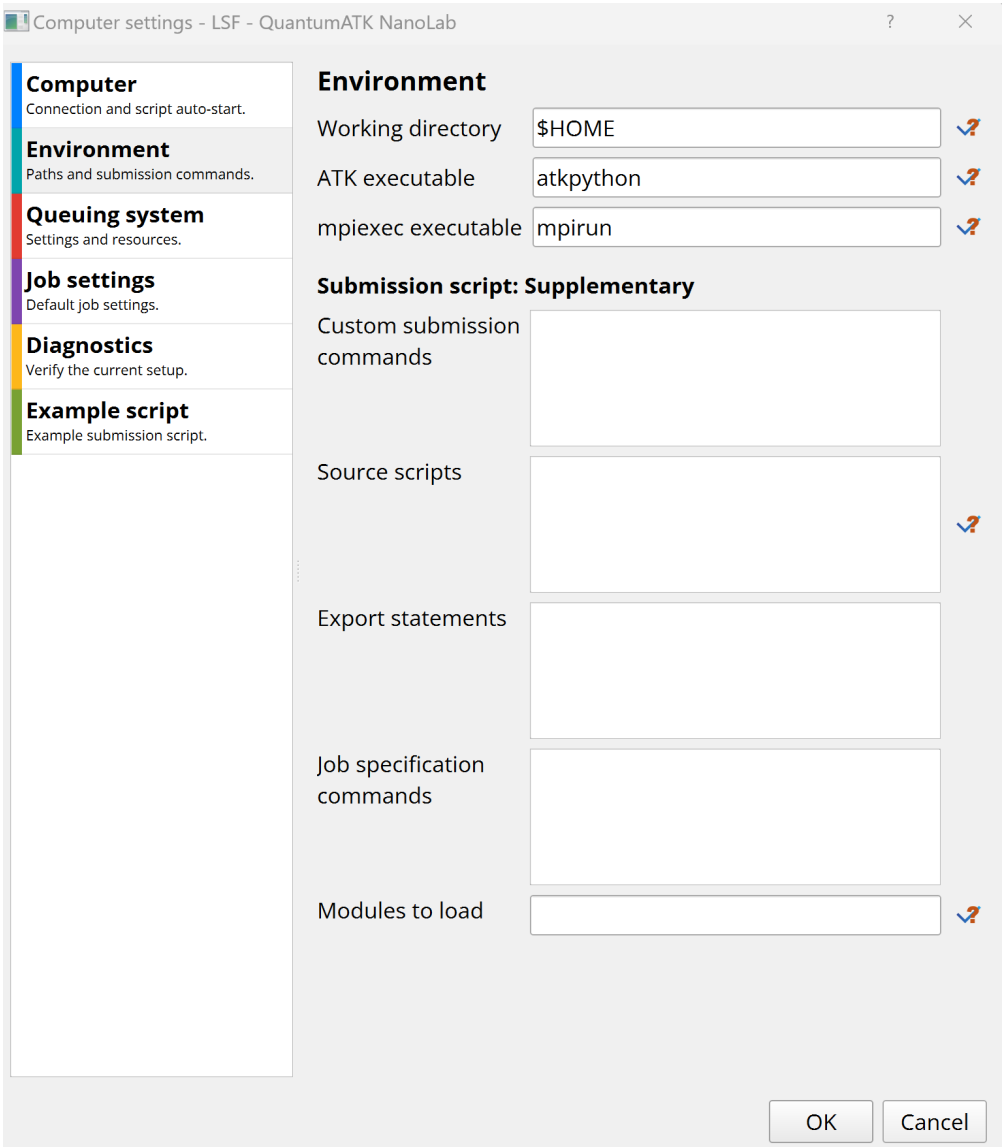
This tab is used to provide the credentials for connecting to the remote cluster of choice. It supports password-based and key-based authentication.

Private key file
The path of your private SSH key, you might already have one or you can generate one following ssh_keys.

Once all settings are added, you can check if they are correct by clicking the **Check connection** button.

Environment

Computing environment on the cluster.



This tab concerns the environment (directories, executables, modules, etc.) on the *remote cluster*, not on your local computer. `$HOME` is therefore the home directory of your user on the cluster, and QuantumATK must of course be installed on the cluster.

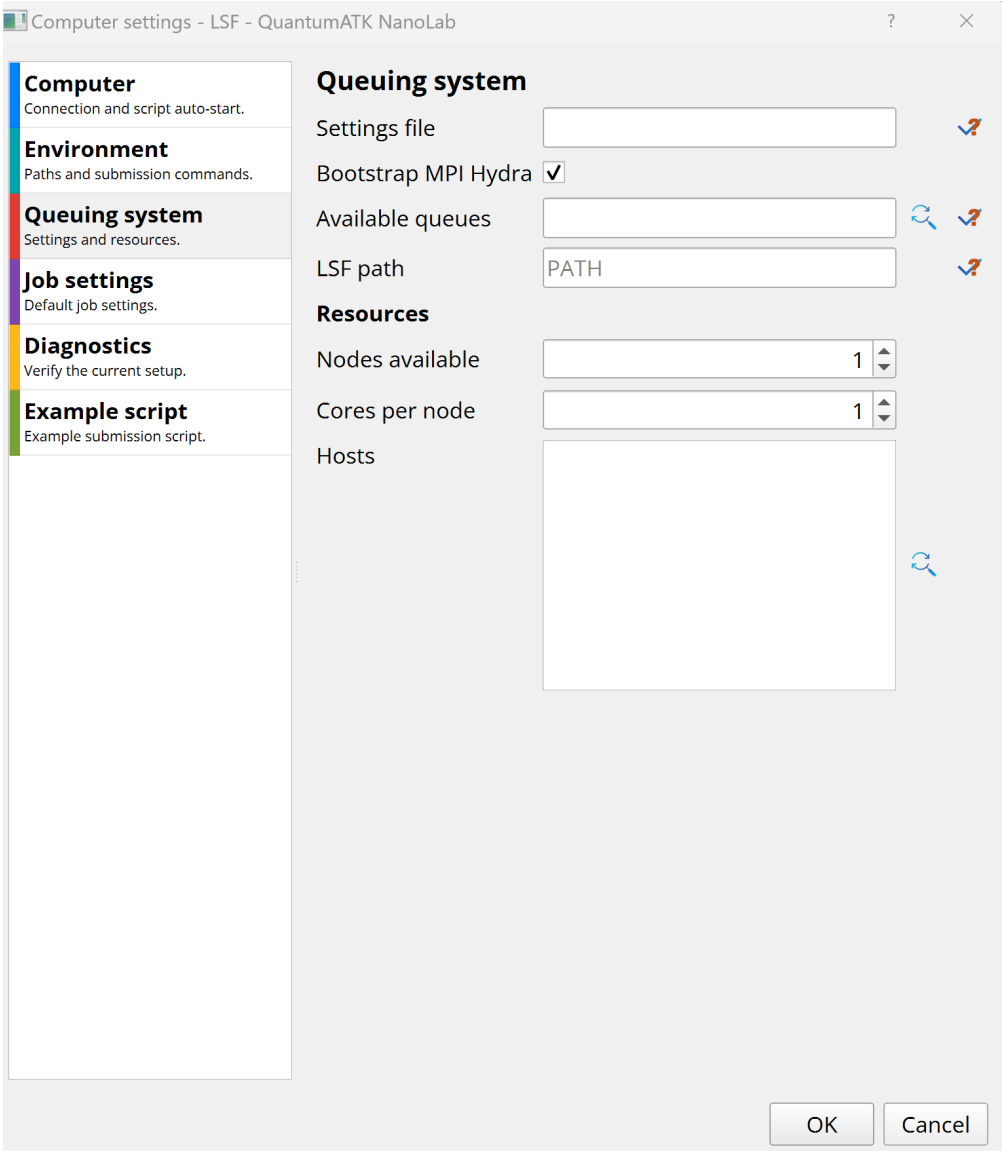
Any scripts that should be sourced in order to get the environment working must be listed. The same goes for required export statements (may be needed to correctly set the `SNPSLMD_LICENSE_FILE`) and cluster modules that should be loaded using the `module load` command (https://modules.readthedocs.io).

You can also provide *custom submission commands*. For example, you can choose a particular queue to submit the job:

```
# Submit job to "myqueue" queue
BSUB -app myqueue
```

Queuing system

Queuing system settings and resources available for job submission.



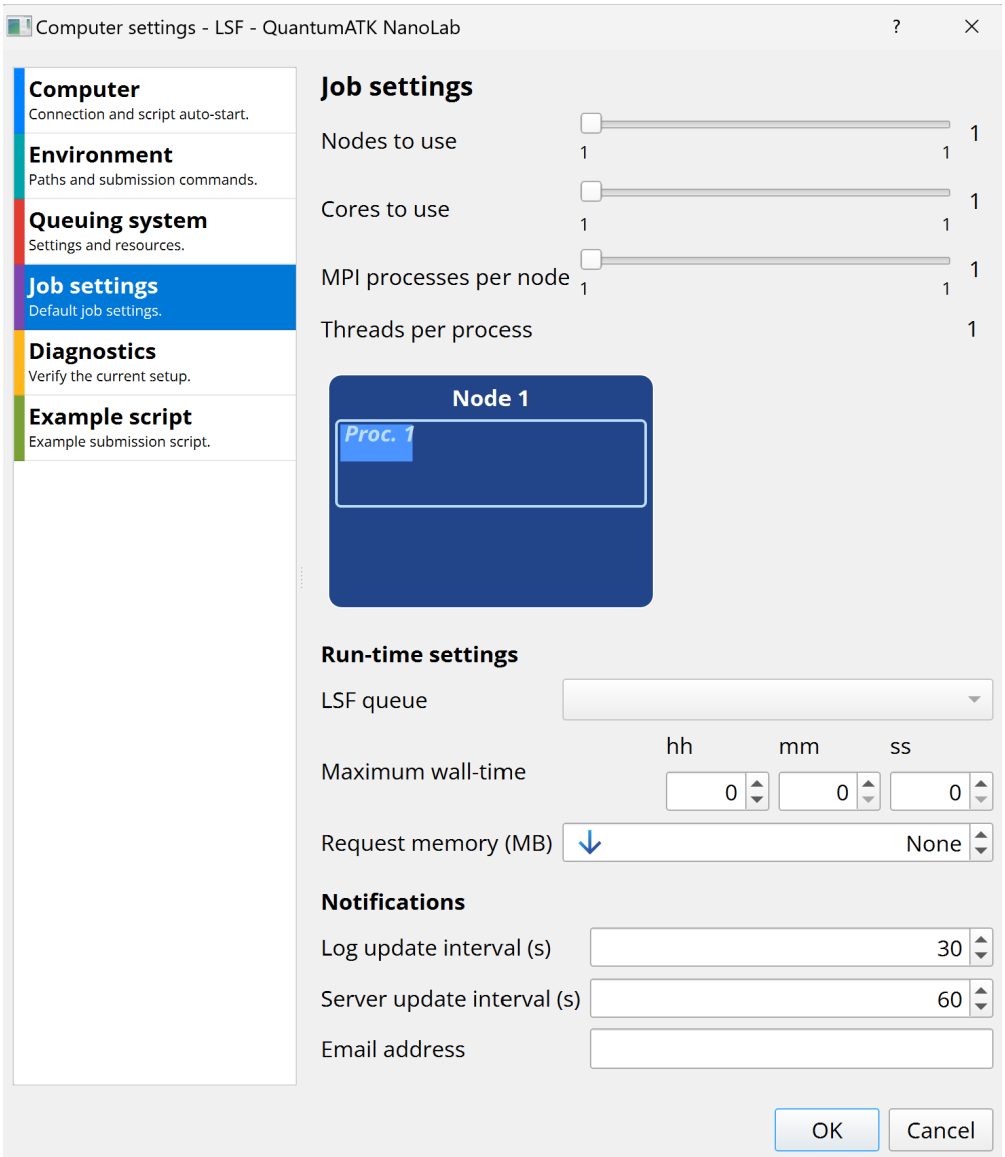
The nodes available and cores per node values are used to determine the default job settings.

LSF path
This is the directory containing `bsub` and other LSF executables. It is not needed if *Settings File* is provided. Log on to the cluster and use the `which` command to locate it:

```
$ which bsub
```

Job Settings

Computing resources requested at job submission.

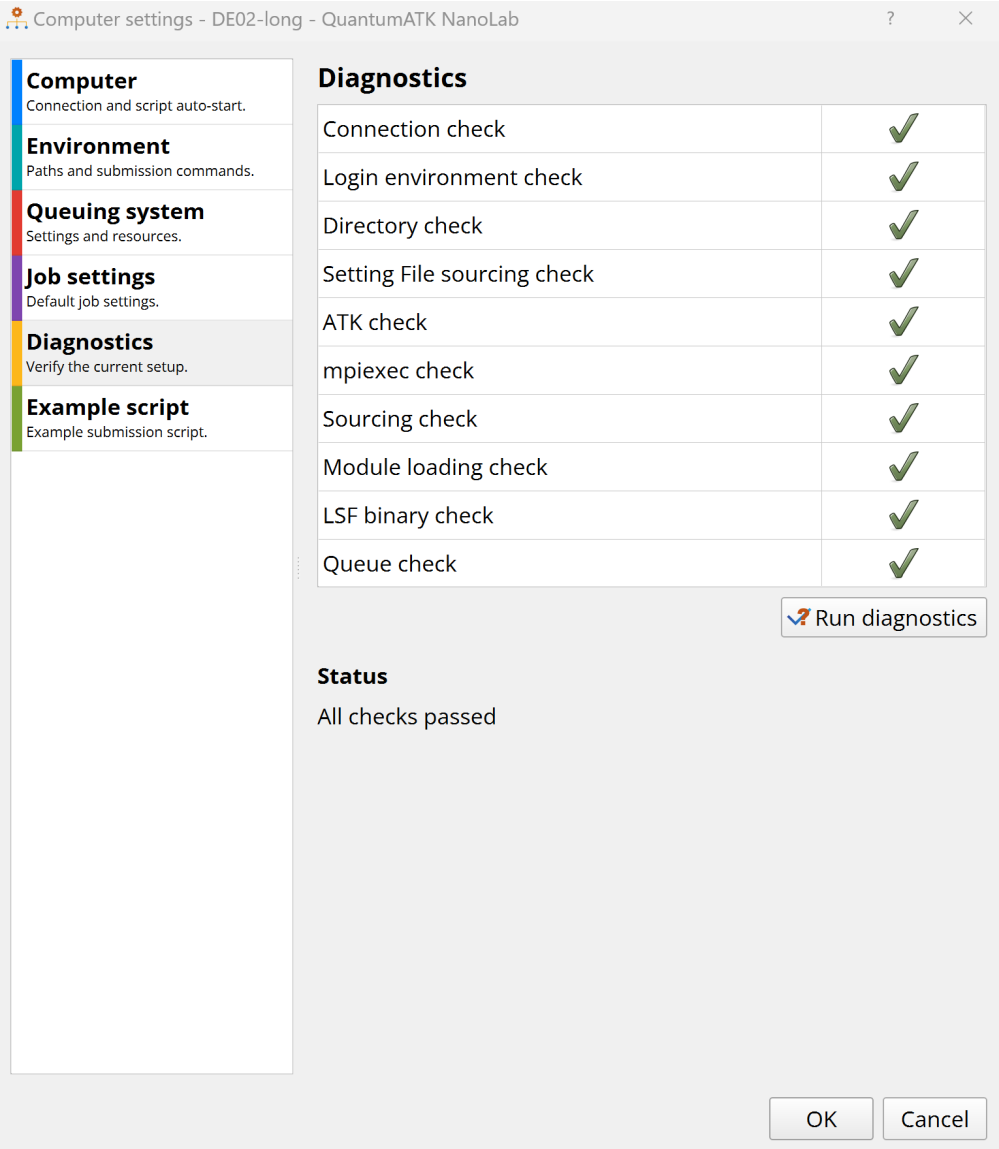


This tab specifies the default computing resources (nodes, cores, queue, time, etc.) requested at job submission. Once the number of cores to use on each node is specified, you can decide how to split them between MPI and threading parallelization. While changing the number of MPI processes, the number of threads per process is automatically adjusted.

The Job Manager will regularly check the job progress on the remote cluster and report it in the log file. You can also receive e-mail notifications from the job scheduler when the job starts, finishes, or terminates. Refer to your cluster administrator to know if email notifications are supported in your cluster.

Diagnostics

Use this tab to test the computer settings. Green check-mark indicates that all settings appear to be OK. Red cross indicates some problem that should be fixed in one of the tabs.



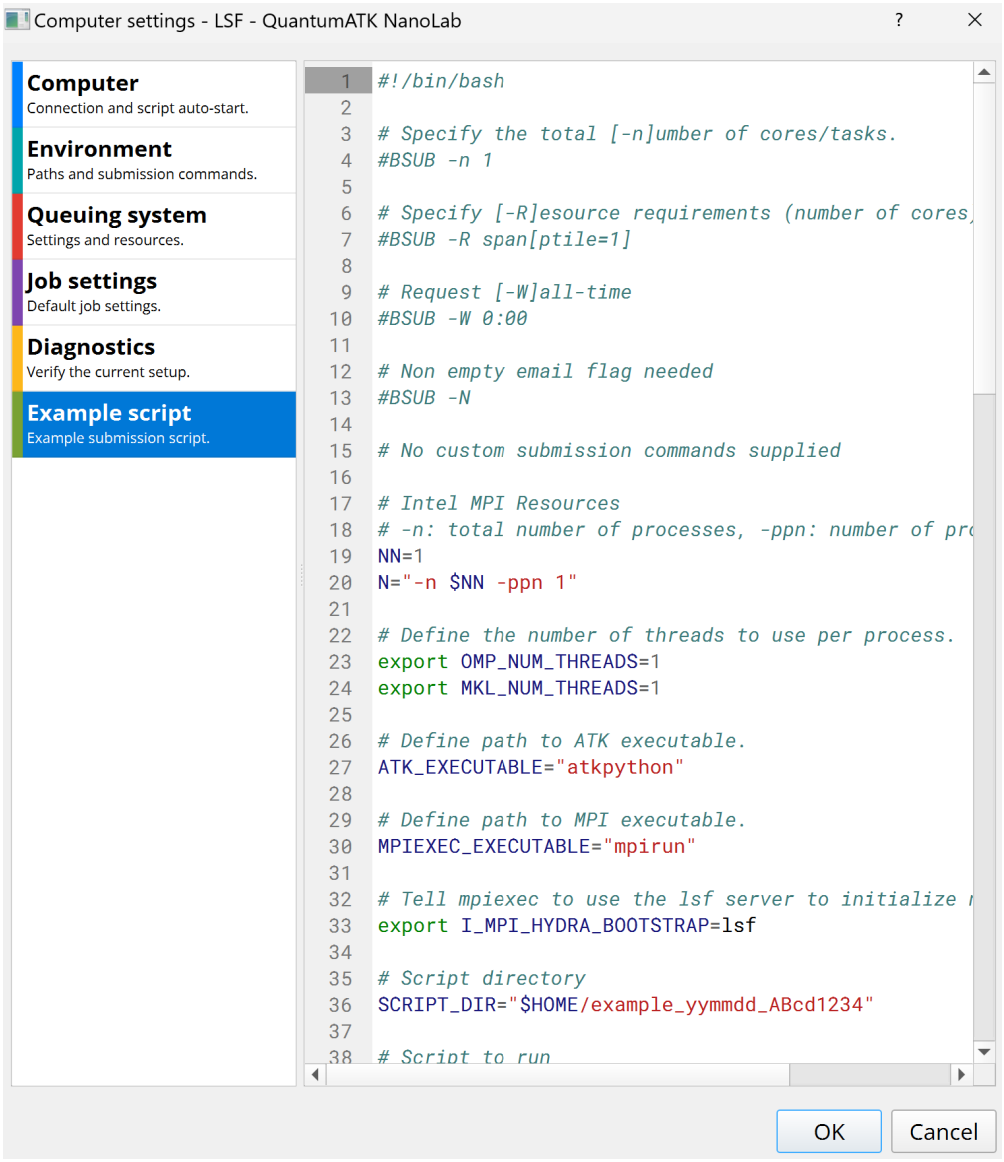
Warning: The Diagnostics tab checks if the options in the **Computer** and **Environment** tabs allow your local computer to connect to the remote cluster and execute the commands needed for job submission and management.

If some field is not specified, the diagnostics will check the default setting. If the connection to the cluster works well with that default, or is at least not disrupted, it will be marked as OK.

You therefore need to run an actual test job to make absolutely sure that all settings are indeed OK.

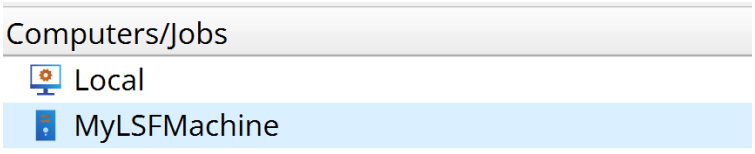
Example script

This shows an example of a job submission script. You can for example check that the options passed to the job scheduler are correct.

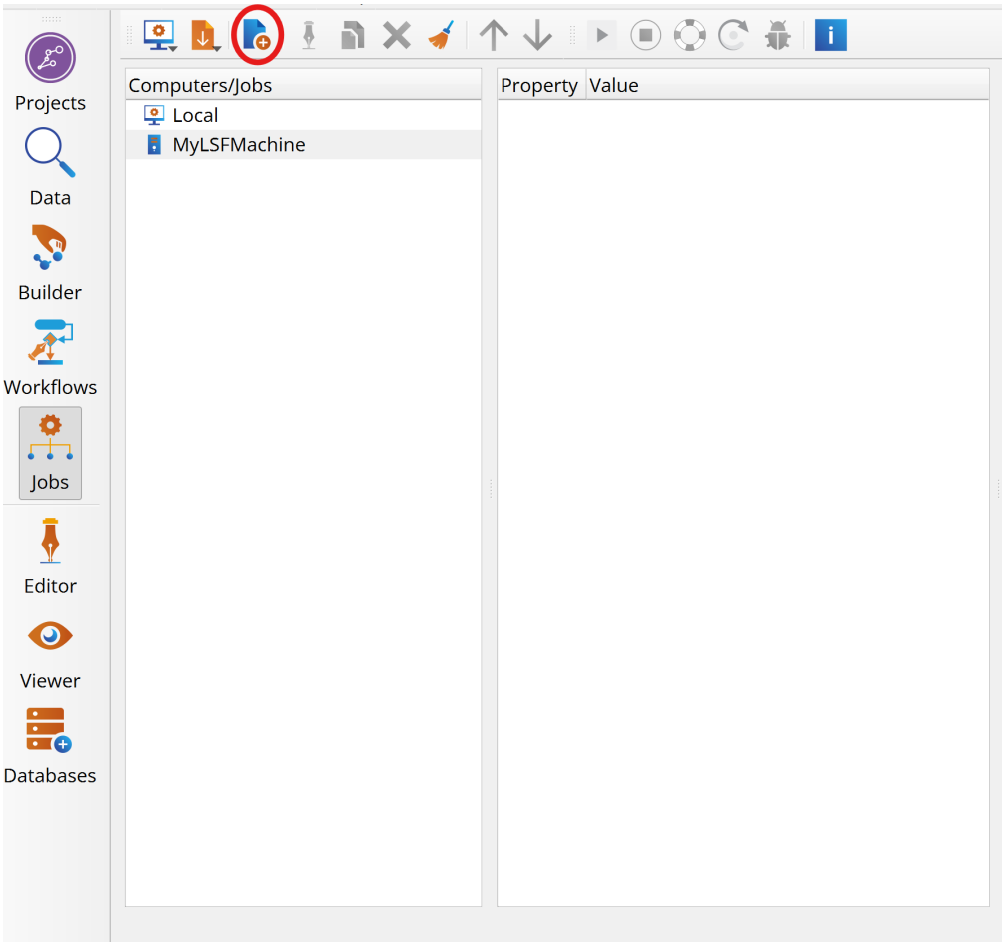


Save and test the new machine

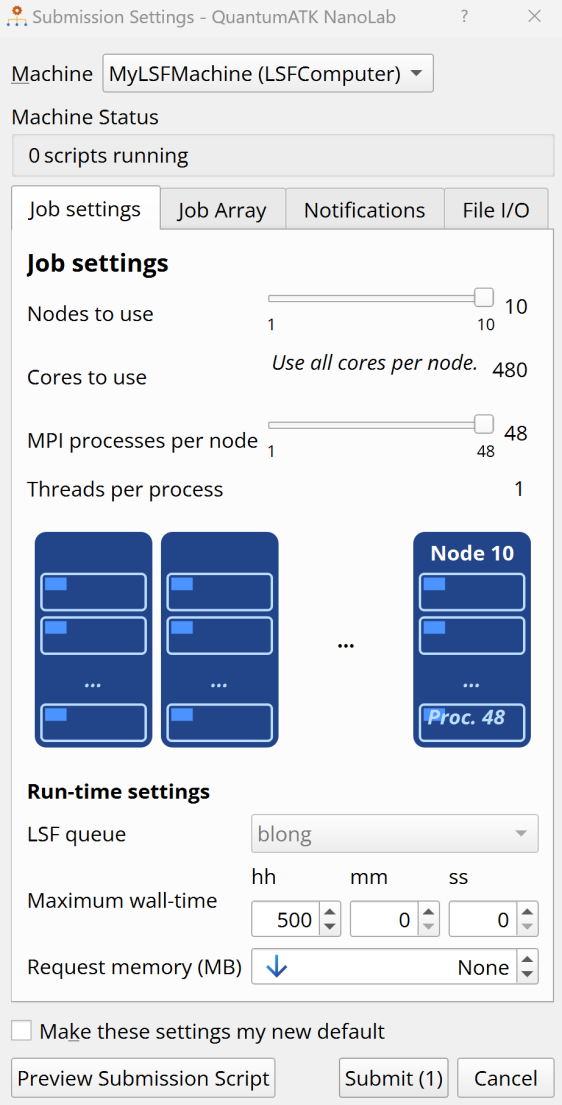
Click *OK* to add the machine to the **Computers/Jobs**.



Next, you should run the test scripts `mpi_check.py` and `test_mpi.py` to test the machine settings. In the QuantumATK main window, click on **Add new job**, then choose the script from the file dialog box, and click *Open*.



This will open the **Computer Settings** dialog box. Choose the remote machine, in this example *MyLSFMachine*, and click *Submit*.



Once a job has finished you should check the log file to inspect the job output to see if the expected number of processes were used. Click the *Log* tab to open the log. In the two examples below, 48 cores were used in total on a single node.

Custom job settings

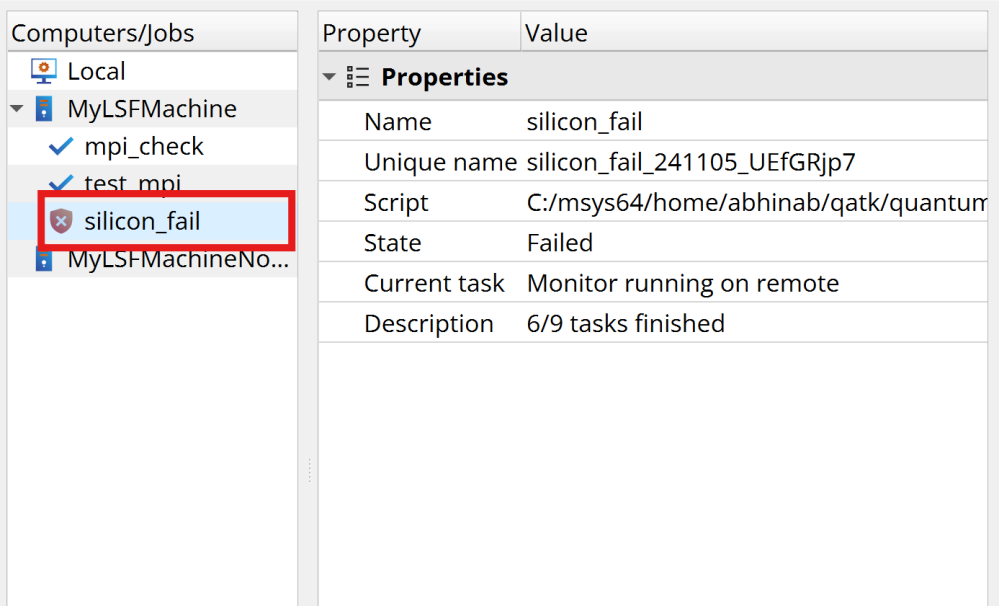
As explained in the tutorial *Job Manager for local execution of QuantumATK scripts*, you can customize many of the job settings before submitting a job. Use the script `silicon.py` as an example QuantumATK script. Download the script, and then *Open* the script from file dialog box by clicking **Add new job**. This will open a **Submission Settings** dialog box.

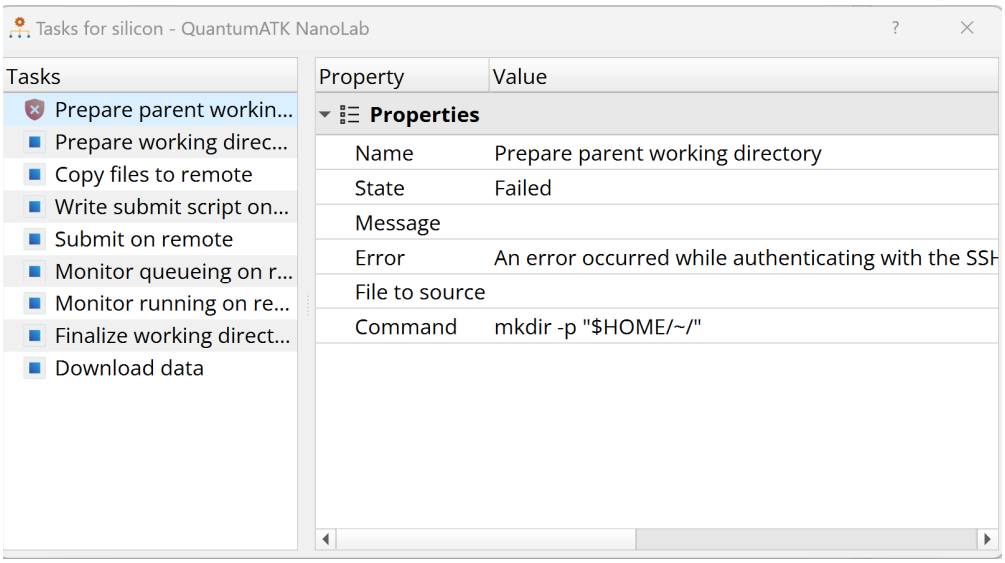
You can now customize the *Job Defaults*, *Job Array*, *Notifications* and *File I/O* tabs, and thereby submit the job with settings different from the default ones you specified above. For example, you can change the number of requested cores and cluster queue and/or maximum wall-clock time.

Set up the job settings as you like, e.g. 4 cores on a single node and 4 MPI processes. Then click *OK* and submit the calculation to the remote cluster.

Debugging

If an error occurs during the execution of the job, this will be indicated by a red icon in the queue, as shown below. You can then click the **Debug logs** icon to open the job debugs information window, which will show you details about the error.





Adding several remote machines

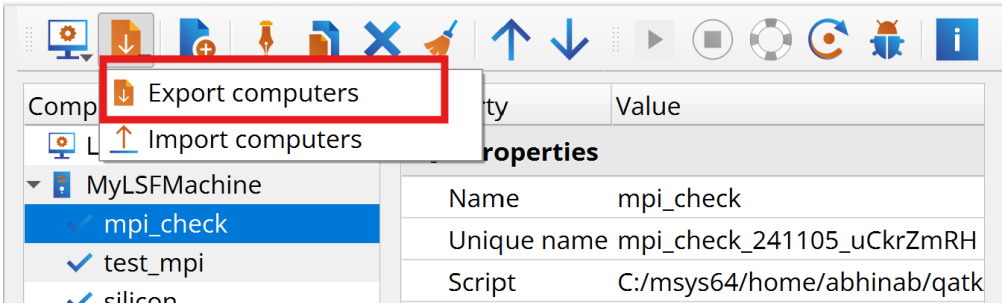
Several remote machines can be added to the **Computers/Jobs**. You can of course add new machines from scratch, but you can also export/import the settings of an existing machine and use those as a template for new machines.

Tip: The import/export functionality is very convenient for sharing machine settings within a group of users.

In the following, you will export the settings of the newly created machine, and then add one more remote machine with different queue and job settings.

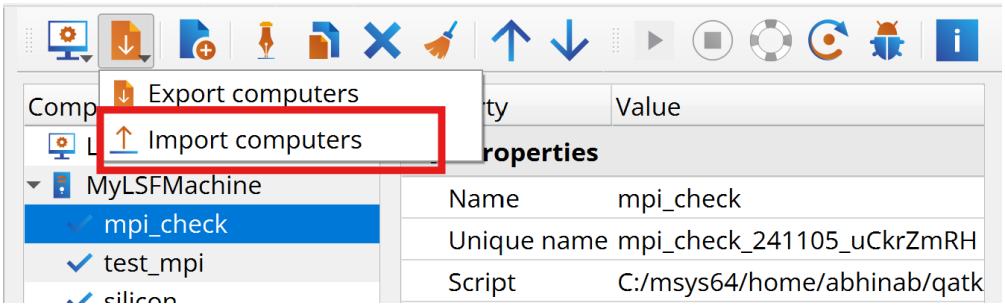
Export

Select the machine and click on *Import or export computers* , then click *Export*, and save the settings in a file.



Import

Next, add a new remote machine with default settings for New LSF. click on *Import or export computers* , then click *Import* and import the settings file you just saved.



You can now modify the settings to create a machine with default settings that are suitable for :

Select the new machine and click *Edit*. This will open the *Computer Settings* dialog box. Give the new machine a reasonable name, e.g. MyNewLSFMachine and set the password, if *Password* is selected for authentication. Then, change the job submission queue to mynewqueue by adding *BSUB -app myqueue* in *Custom submission commands* of the *Environment* tab. Additionally , you can change the *Nodes available*, e.g. to 2, and *Cores per node*, e.g. to 8, in the *Queuing system* tab. Finally, *Run diagnostics* in the *Diagnostics* tab to check if the settings are correct and click *OK*, if it passes all the checks.

2.7 Plots

NanoLab offers a plotting framework for creating publication quality plots. A strong emphasis has been put on interactivity, so plots can easily be modified directly in the NanoLab GUI.

You can learn even more about working with plots in the NanoLab GUI by reading the the tutorial: *Working with Plots in NanoLab*.

You can also create your own plots through scripting, and you can read much more about that in the *NanoLab Plot Reference Manual*.

Working with Plots in NanoLab

Editing, Saving and Merging Plots

Version: Q-2019.12

This guide shows you how to take advantage of NanoLab plotting capabilities to customize, save, merge and re-use plots.

The QuantumATK NanoLab plugins allow you to produce a large variety plots that visualize Bandstructures, Projected Density of States (PDOS), ElectronPhononCouplings, Potentials, etc. Each of these plots can be edited, saved and loaded witin NanoLab. Plots can also be merged together in compound plots that visualize complex relationships between configurations, calculations and analyses. Lastly, those compound plots can be re-used for other calculations and results.

Note: As a simple example this guide uses the Projected DOS and Bandstructure analyses calculated for bulk silicon with a LCAO calculator using the GGA-1/2 PBE exchange correlation.

If you wish to, you may repeat the analysis by downloading the data files here:

- `bulk_si_gga_half_pbe.hdf5`
- `bulk_si_gga_pbe.hdf5`
- `all_plots.hdf5`

Video guide

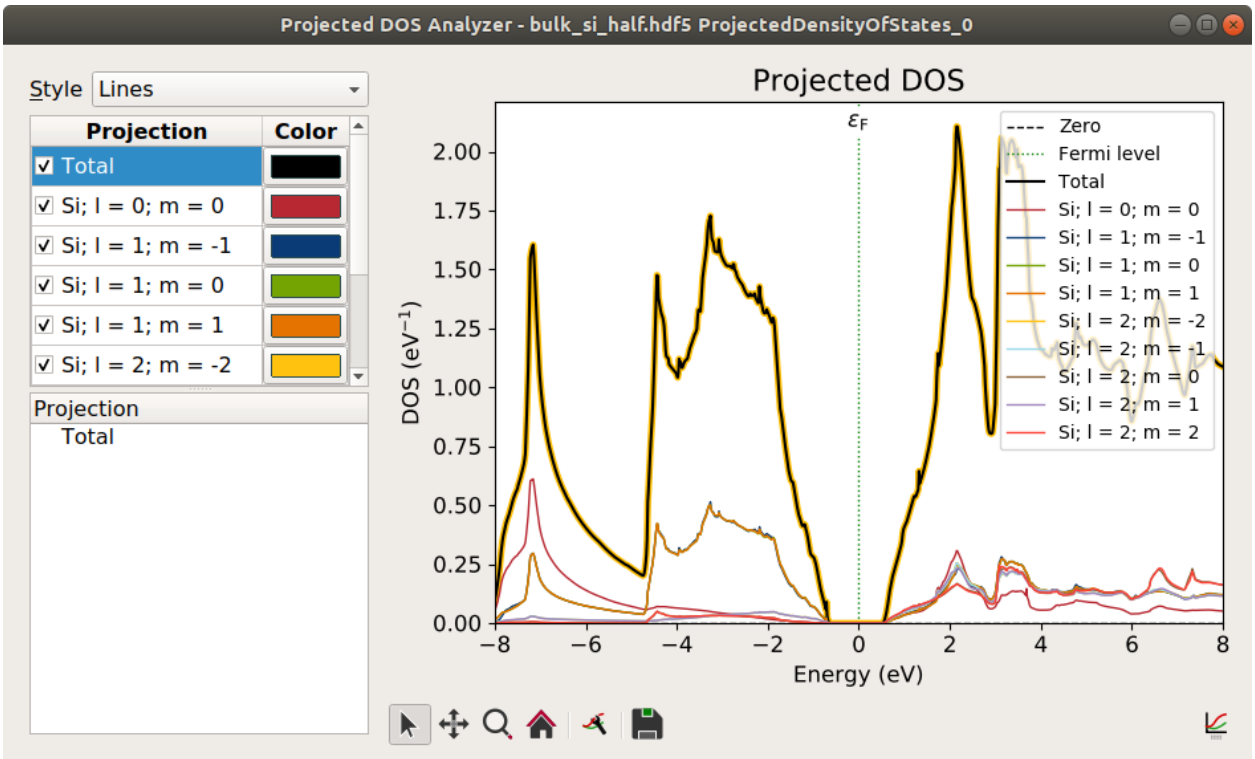
This is a video guide showcasing the NanoLab plotting capabilities. Detailed information is provided in the written guide below.

Plot tools

To facilitate easy editing, all plots are accompanied by a plot tool bar. The toolbar contains these tools:

1. **Interaction tool**, where items can be selected. Right-click on a plot to add arrows, measures and labels to the plot.
2. **Pan tool**. Left-click and drag a plot to change the axis limits. Right-click and drag to zoom.
3. **Zoom tool**. Right-click and drag to draw a zoom-rectangle. Use the mouse wheel to zoom in and out.
4. **Editor tool**. Click this tool bring up the Plot Editor.
5. **Home tool**. Clicking this tool resets the current axes limits.
6. **Save tool**. Click to save the interactive plot in hdf5, export data to txt, or export the plot as an image in e.g. pdf or png formats.
7. **Merge tool**. Drag this icon to merge the plot with itself or other plots.

The PDOS (Projected Density of States) Analyzer plots the density of states projected onto elements, orbitals or shells. For our example bulk silicon calculation the PDOS analyzer looks like this:



Annotate plots

The **Interaction tool** shows helpful tool tips when hovering over different plot items. Once hovered, left clicking selects the item. Right clicking brings up the annotation menu with these options:

- **Autoscale** the plot.
- **Add arrow** annotation.
- **Add label** annotation.
- **Add measure** (general, vertical or horizontal).

When right clicking on a line, the menu also includes these additional options:

- **Add analysis** (average, rolling average, polynomial fit, gaussian fit or a generic curve fit).

Tip: For our example Project DOS plot, one common analysis is to measure the band gap. This can be done by inserting a vertical measure into the plot. The meausure can then be snapped to the lines near the band edges.

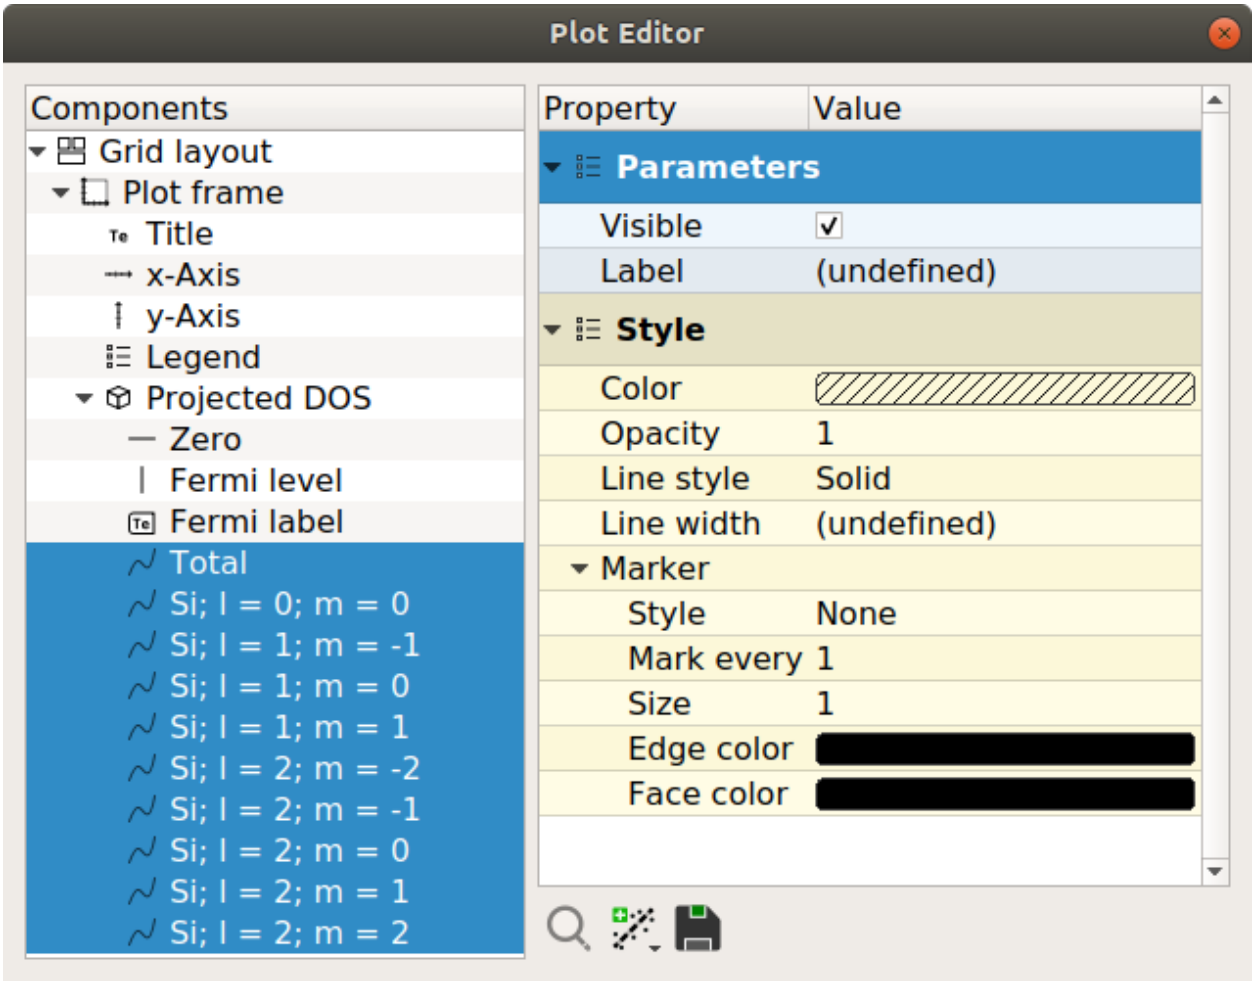
The Plot Editor

Launch the plot editor from the toolbar or by pressing E. The plot editor makes it possible to edit the individual properties of the layout, legend, title, axes, and lines of the plot.

The editor lists all the plot components. At the top level all plots are built from a GridLayout. The layout then contains one (or multiple) Plot Frames. The dimensions of the grid and the position of the individual frames can all be adjusted in the Plot Editor.

Each frame has a title, a legend, an x-axis and a y-axis, and may also contain data from one or more sources. Simply select the different components to edit their color, line-width, text, opacity and so forth.

One such source could be our Projected DOS plot, which consists of some projection lines, a vertical Fermi line and a Fermi label. You can select multiple lines and edit all their properties at once.



The editor also has a few additional tools:

1. **Zoom to item**. Select a single item and zoom to that item.

2. **Add analysis**. Lines support additional analysis that you may add here. You can choose between polynomial fits, gaussian fits, or specify your own fitting function in the curve fit. You can also add an average or a rolling average analysis.

3. Export data. Select the relevant plot items and choose the save icon. This will export data to txt format.

Save and load the plot in the PlotViewer

After editing the plot, you can save it to a file in the hdf5 format. In the file browser MainWindow you can then check the newly created file and the Plot will appear on the Lab floor. Open the Plot using the **PlotViewer** plugin in the Analysis Bar located to the right of the Lab floor.

The opened plot contains all your exiting modifications. You can continue editing, or you can re-open the original analyzer (in our example this would be the PDOS analyzer).

To re-open the analyzer, click the red analyzer icon. This tries to open the original PDOS analyzer. Sometimes the original analysis object is required in order to re-open the analyzer. If the analysis object is missing you can replace the data by dragging and dropping it from the Lab floor. See also the section about Redo analysis.

Note: In our case, we may wish to change from lines to filled stacked lines. This could be done in the PDOS analyzer, so we re-open the analyzer and choose the Stacked style. The PDOS plot is then immediately updated.

Merge plots

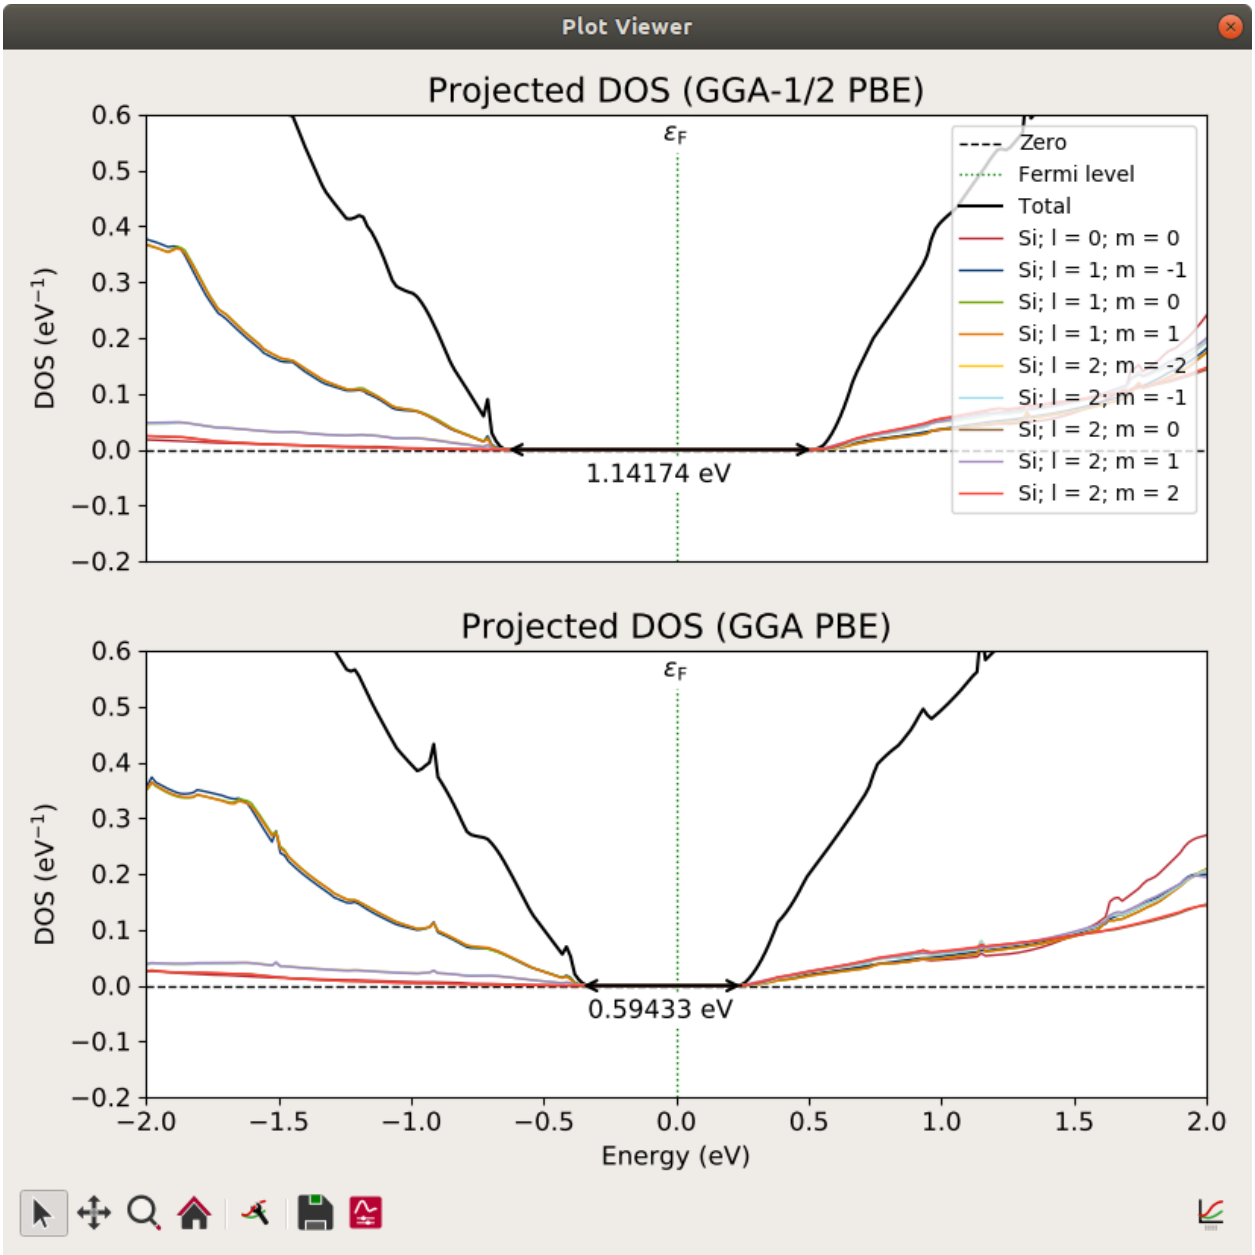
All plots can be merged together by dragging and dropping the plots onto each other. In a plot you can grab the plot by grabbing the merge icon in the plot toolbar, and on the Lab floor you simply grab the Lab floor icon.

In general the plotting framework supports two different ways of merging plots together depending on where you drop the plot.

Drop next to, above or below an existing plot

When dragging a plot, you can drop it on four green areas at the edges of a plot. This will create a new plot containing the original plot along with the dropped plot. Once merged both plots can still be edited and adjusted and their analyzers can still be re-opened.

In our example we also calculated the Projected DOS for bulk silicon with DFT-1/2 turned off. Dropping this PDOS plot next to the GGA-1/2 PDOS plot clearly shows that the two calculations produce a different band gap. Add two horizontal measures and adjust the titles to produce the plot below:



Note: Note that the DFT-1/2 result is very close to the experimentally measured band gap of bulk silicon of 1.14 eV.

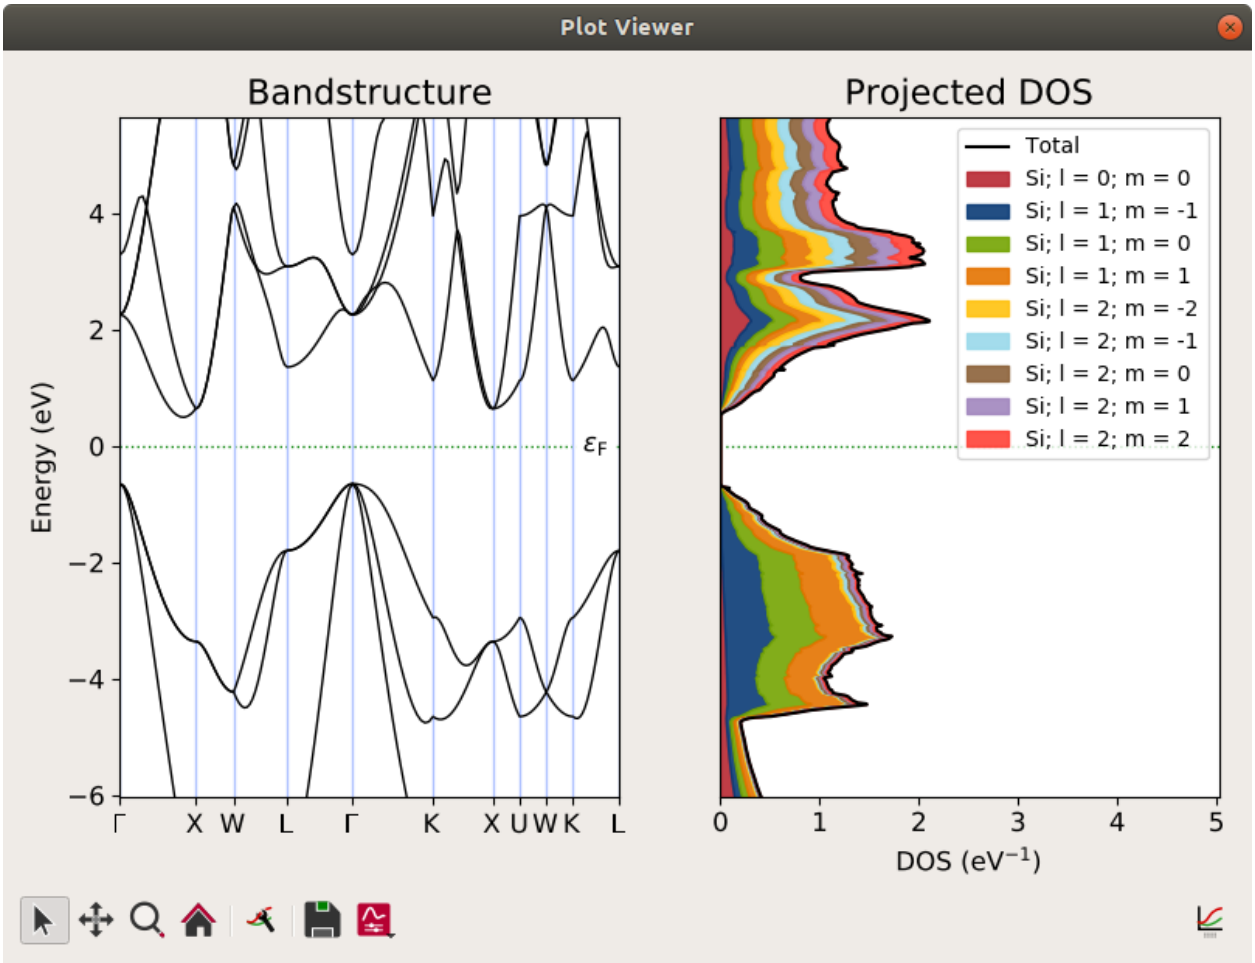
Drop on the existing plot

You can also drop a plot on the middle of another/the same plot. This offers a dialog with some advanced merge options. Depending on the units on the axes of your merged plots, you may have the following options:

1. Overlay with one or two shared axes.
2. Flip the plot and then overlay.
3. Mirror (plot next to each other but with linked axes)
4. Flip the plot and then mirror.

For bulk silicon we also calculated the Bandstructure, and we want to inspect the calculated Projected DOS and Bandstructure next to each other. We grab the merge icon in the Bandstructure plot and drop it on the PDOS plot. In the dialog we choose the option Flip and mirror with shared y-axis.

This creates the following merged plot where the y-axes (the energy axes) on both plots have been linked.



Redo analysis

By merging plots from multiple QuantumATK NanoLab plugins it is possible to create interesting compound plots showing different aspects of your calculated data. In our example the merged plot of the Bandstructure and Projected DOS is one such a plot.

NanoLab allows you to reuse a compound plot. This means that you may easily redo this analysis for another set of calculated results. It is possible to replace data in the following way:

1. Select the data on the Lab floor.
2. Drop the data in the middle of the plot.
3. The plots are then updated with the new data.

You can also create two plots side by side for an easy comparison.

1. Select the data on the Lab floor.
2. Drop the data on the edge of the plot.
3. A new plot is created with the original and the new plot side by side.

In our analysis of bulk silicon we would e.g. select the PDOS and Bandstructure Lab floor items from the GGA PBE calculation (DFT-1/2 disabled) and drop them next to our merged plot. In the compound plot we edited the titles and added two labels to produce the following comparison.

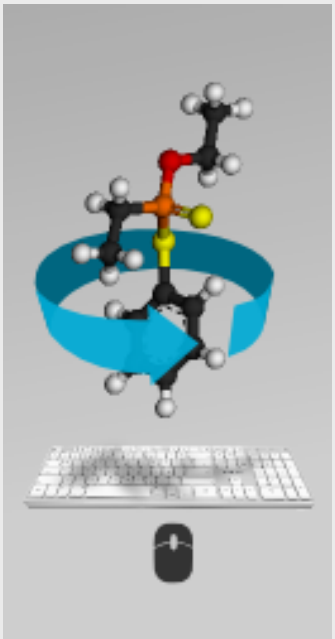
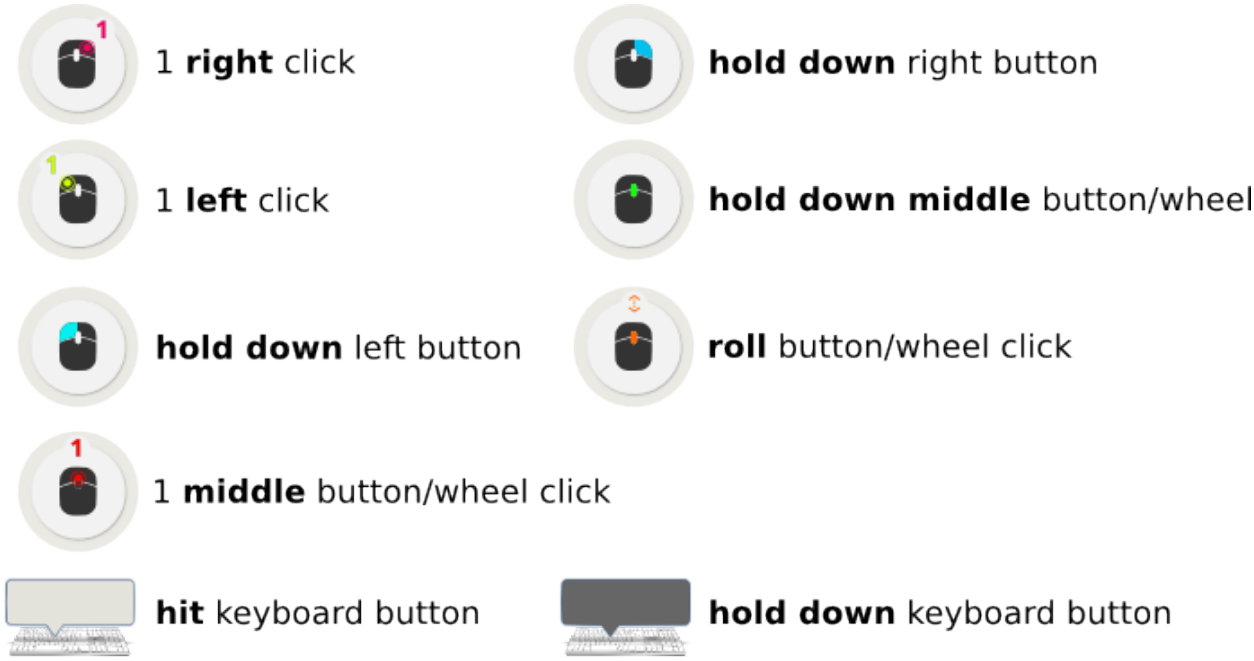
2.8 Manage 3D View and Select Atoms

QuantumATK: 3D functionalities Platforms: Links: BuilderTips2 *In this tutorial you will learn basic functionalities of the Builder and the Viewer. You will learn how to manage the 3D view, and how to select atoms.*



Note: MOUSE AND KEYBOARD HOTKEYS MEMO

The icons below show a list of mouse and keyboard hot keys we will use for the pictures of the tutorial.



The **Builder** and the **Viewer** provide beautiful and easy to use 3D view and selection functionalities. This tutorial explains how to use them.

2.8.1 Rotations

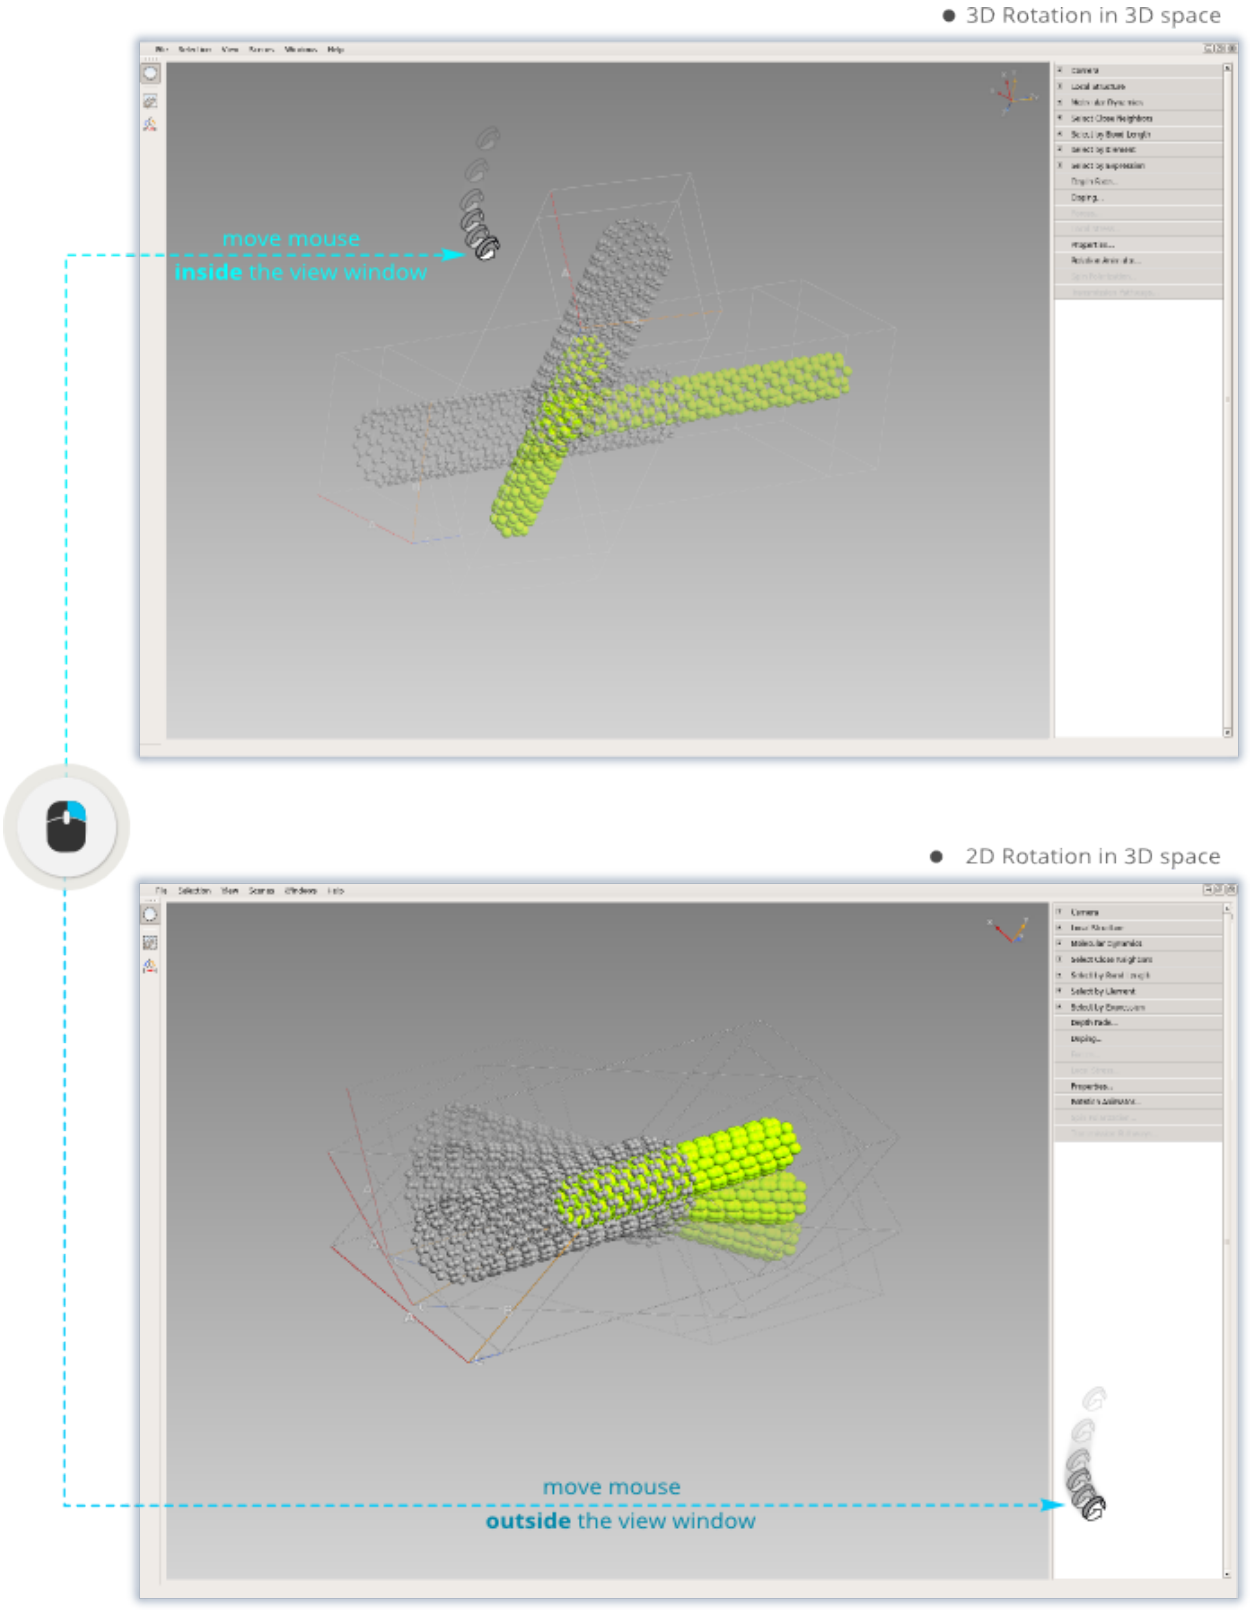
You can do **3D** rotations and **2D** rotations of any configuration: Simply **click and hold down the right mouse-button** and move the cursor using mouse.

Note: 3D and 2D rotations

•moving the cursor **inside the Viewer window** gives you **3D** rotations of your 3D object.

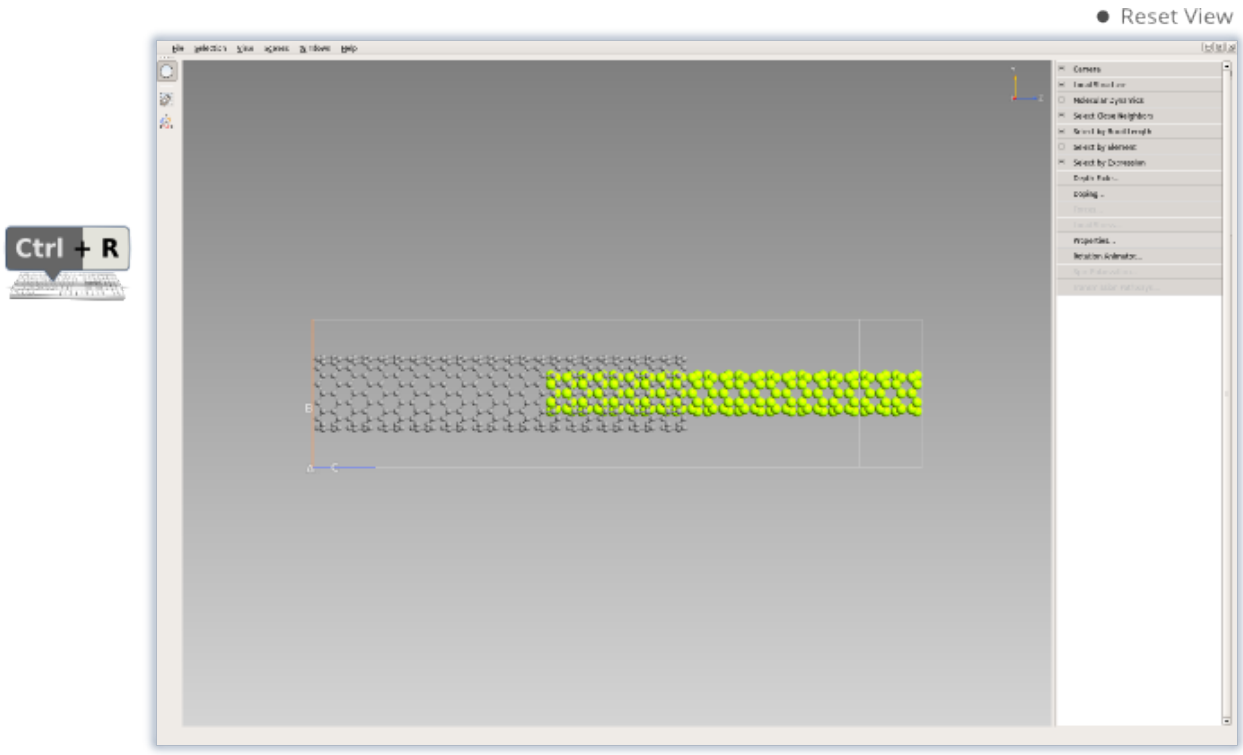
•moving the cursor **outside the Viewer window** gives you **2D** rotations of your 3D object.

•Also note that the cursor changes when you are in rotate mode:



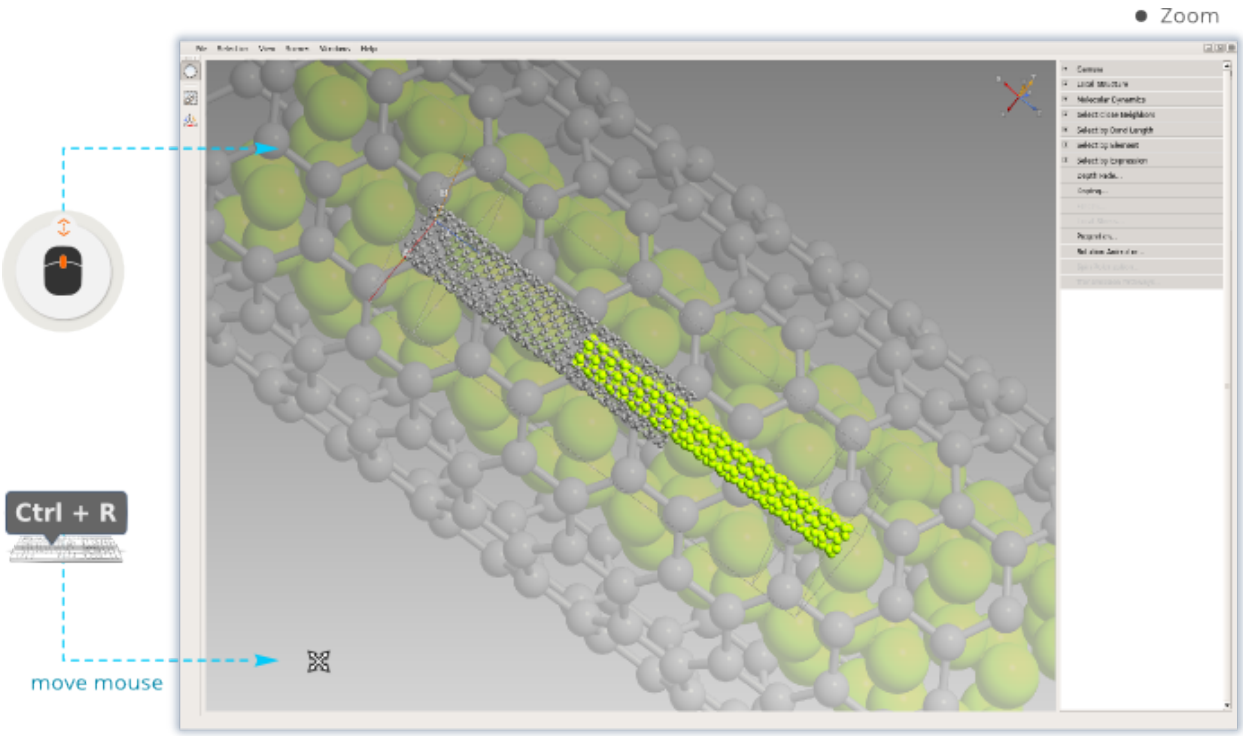
3D Rotation in 3D space
move mouse
inside the view window
2D Rotation in 3D space
move mouse
outside the view window

2.8.2 Reset View



Press **Ctrl+R** on your keyboard to reset the 3D view.

2.8.3 Zoom

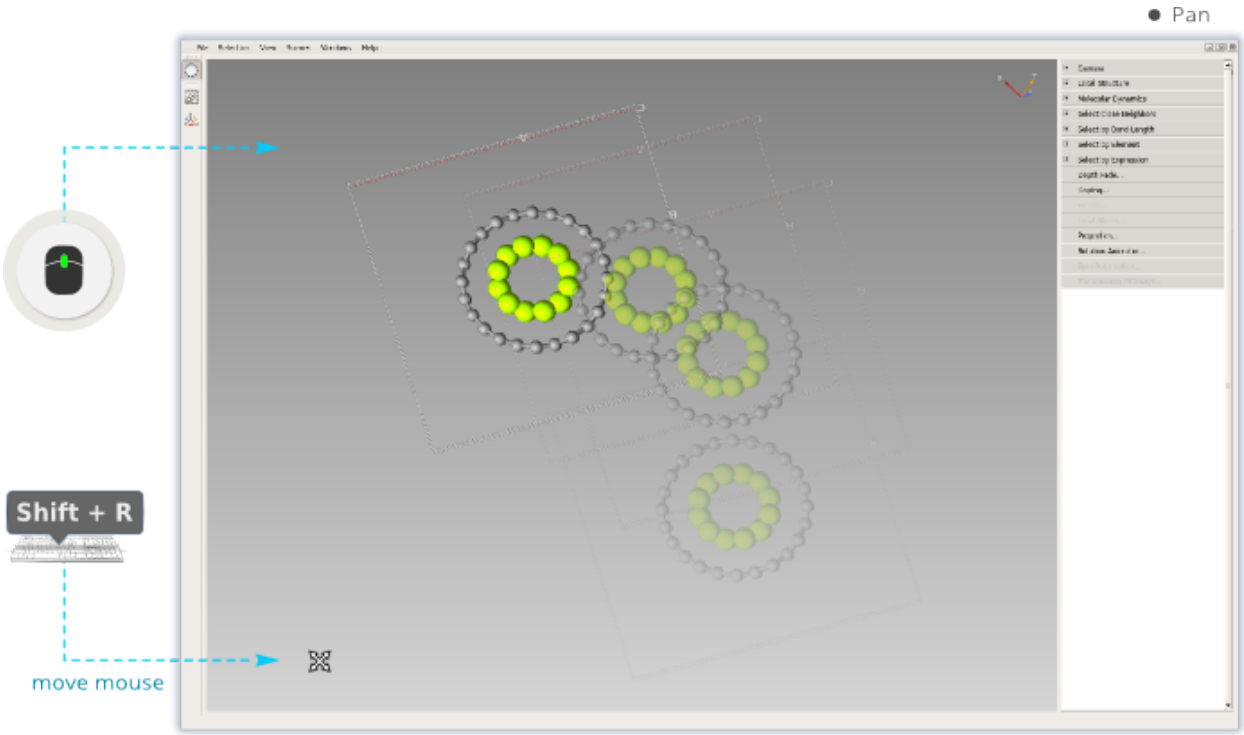


There are two ways to zoom:

1.Use the **mouse wheel**.

2.Hold down **Ctrl** and the **right mouse botton**, and move the mouse cursor up or down ( ).

2.8.4 Drag



There are two ways to toggle the drag function ( ) to move your structure around in the 3D view:

1.Hold down the **mouse middle botton/wheel**.

2.Hold down **Shift** and the **right mouse botton**.

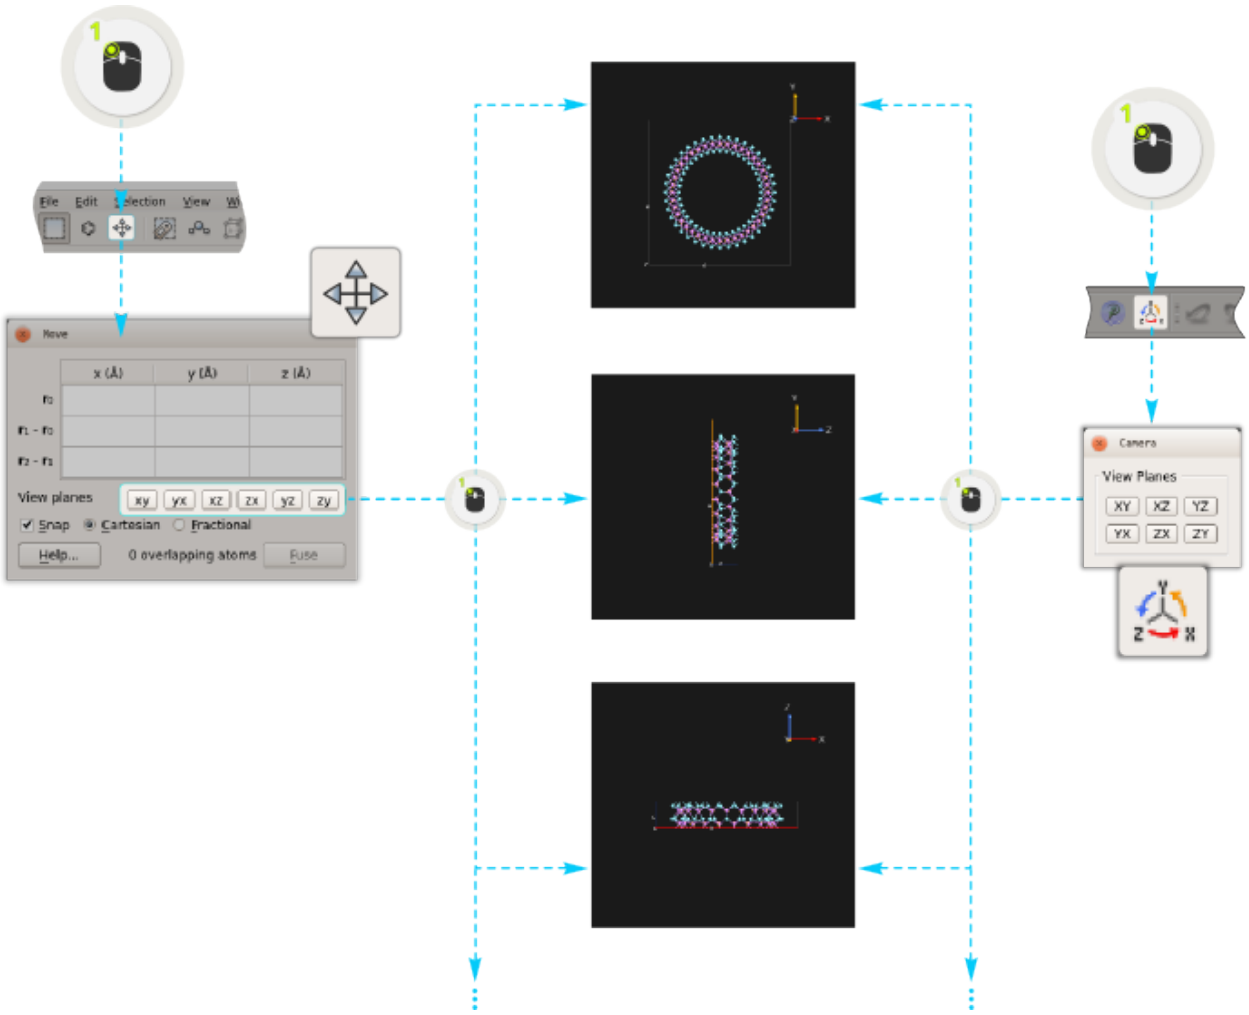
2.8.5 Camera and View Planes

Both the **Builder** and the **Viewer** have functionality that allows you to view a configuration in specific 2D planes: xy, yx, xz, zx, yz, zy.

Note: Camera and Move

•In **Viewer**, you can use the **Camera** plugin to select a 2D view plane.

•In **Builder**, you can use both the **Camera** and the **Move** tool for this.



Note that the **Move** tool puts you in *Move Tool Mode*. If you want to use another tool you must close it first!

2.8.6 Selections

The **QuantumATK** selection and de-selection functionality follows the logic of many other GUIs:

Attention:

•**(hold) Ctrl + [click to object(s)]** : to select object(s)

•**(hold) Shift+ [click to object(s)]** : to de-select object(s) (if they are in selected mode)

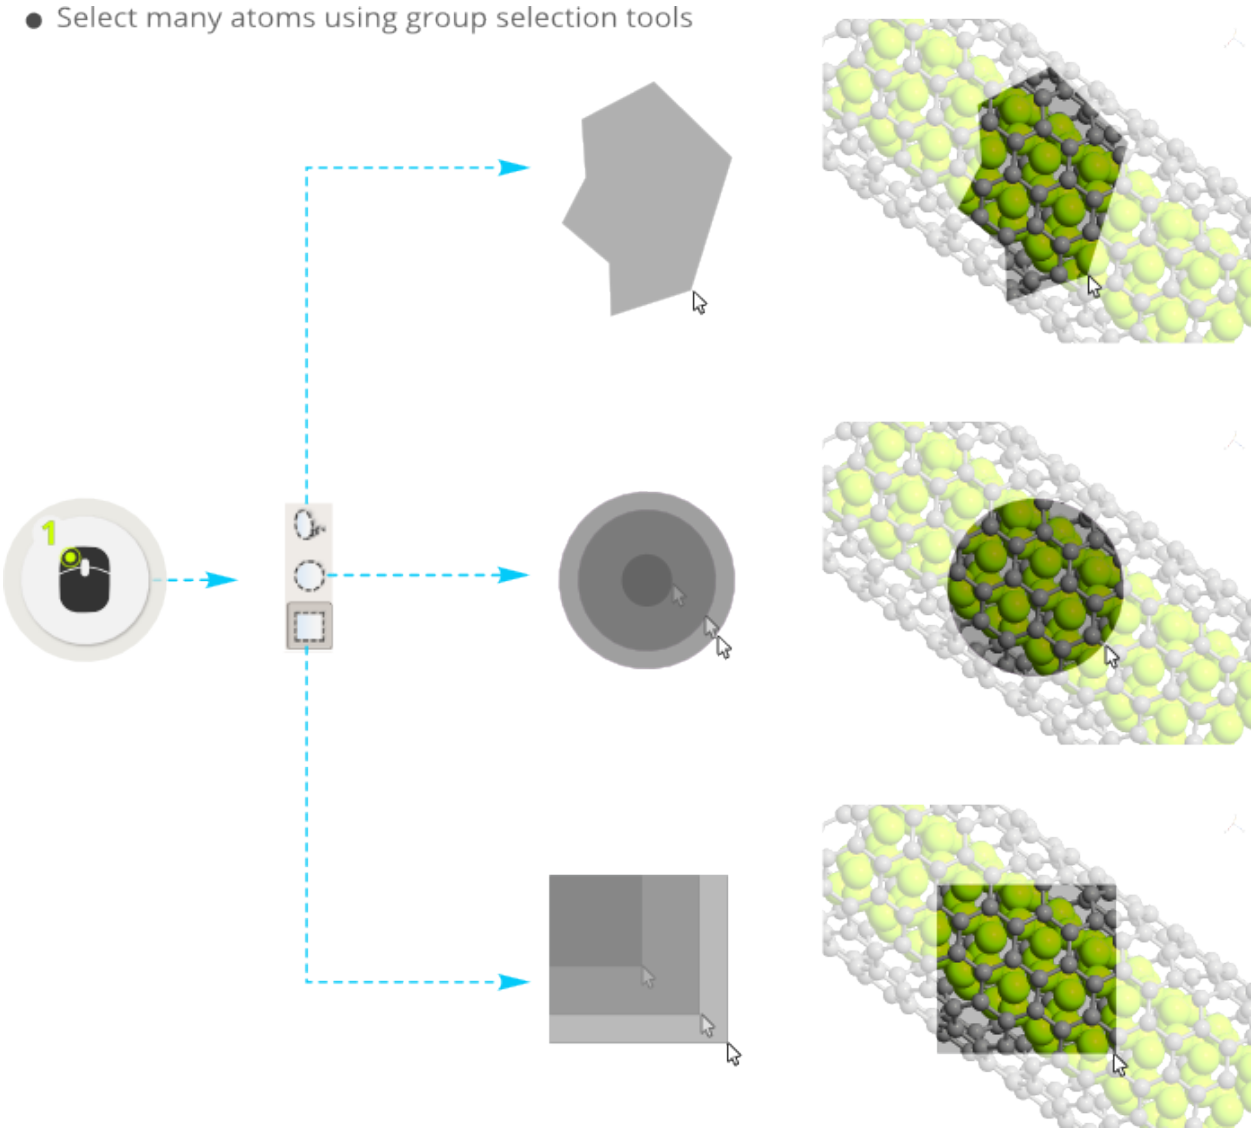
•**(hold) Ctrl + A** : to select all objects

•**Esc** : to de-select everything

•**[click on the background]** : to de-select everything

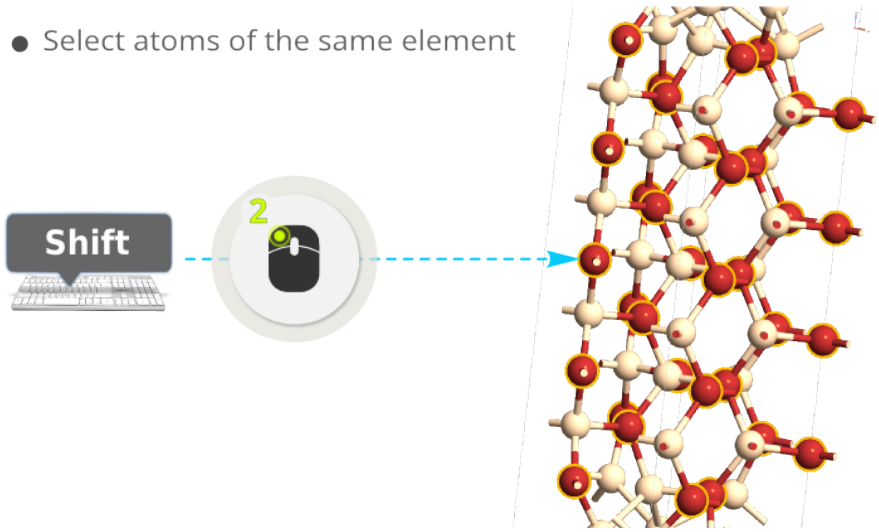
The selected objects/atoms in are indicated by a yellow halo.

•The **Group Selection Tools** allow you to choose a group of atoms using a square, circular or arbitrarily shaped lasso.

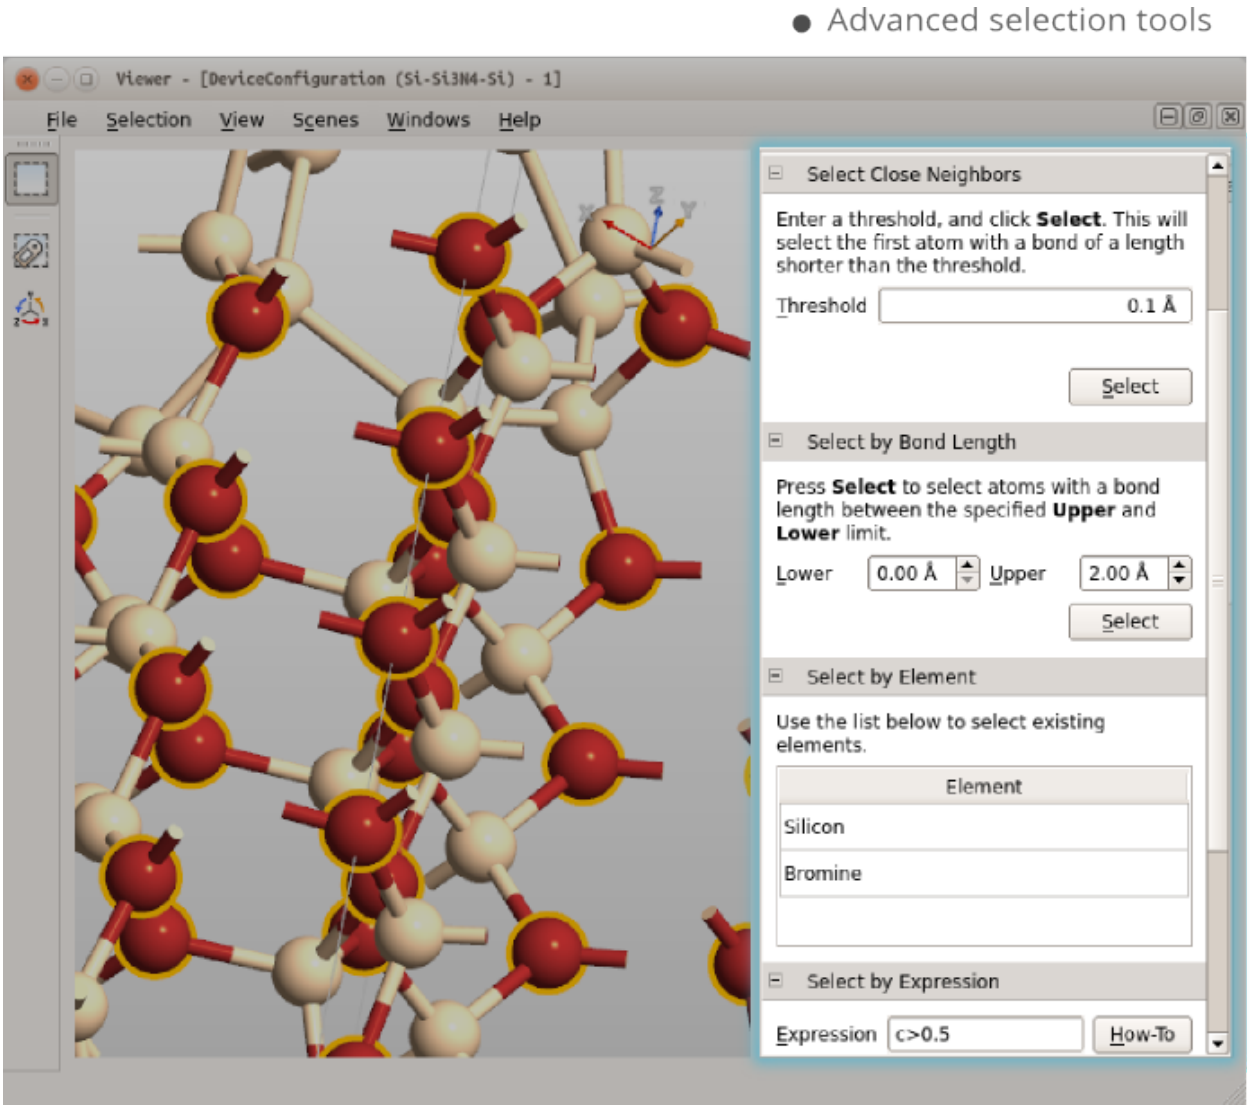


•You can of course use these tools combined with **(hold) Ctrl** to select several groups.

•You can also select all atoms of the same element by double-clicking one of those atoms while holding down the **Shift** key:



More advanced selection tools are also available. In the **Builder** these are located in the **Selection Tools** plugin, while in the **Viewer** they are located as individual **Select** plugins:



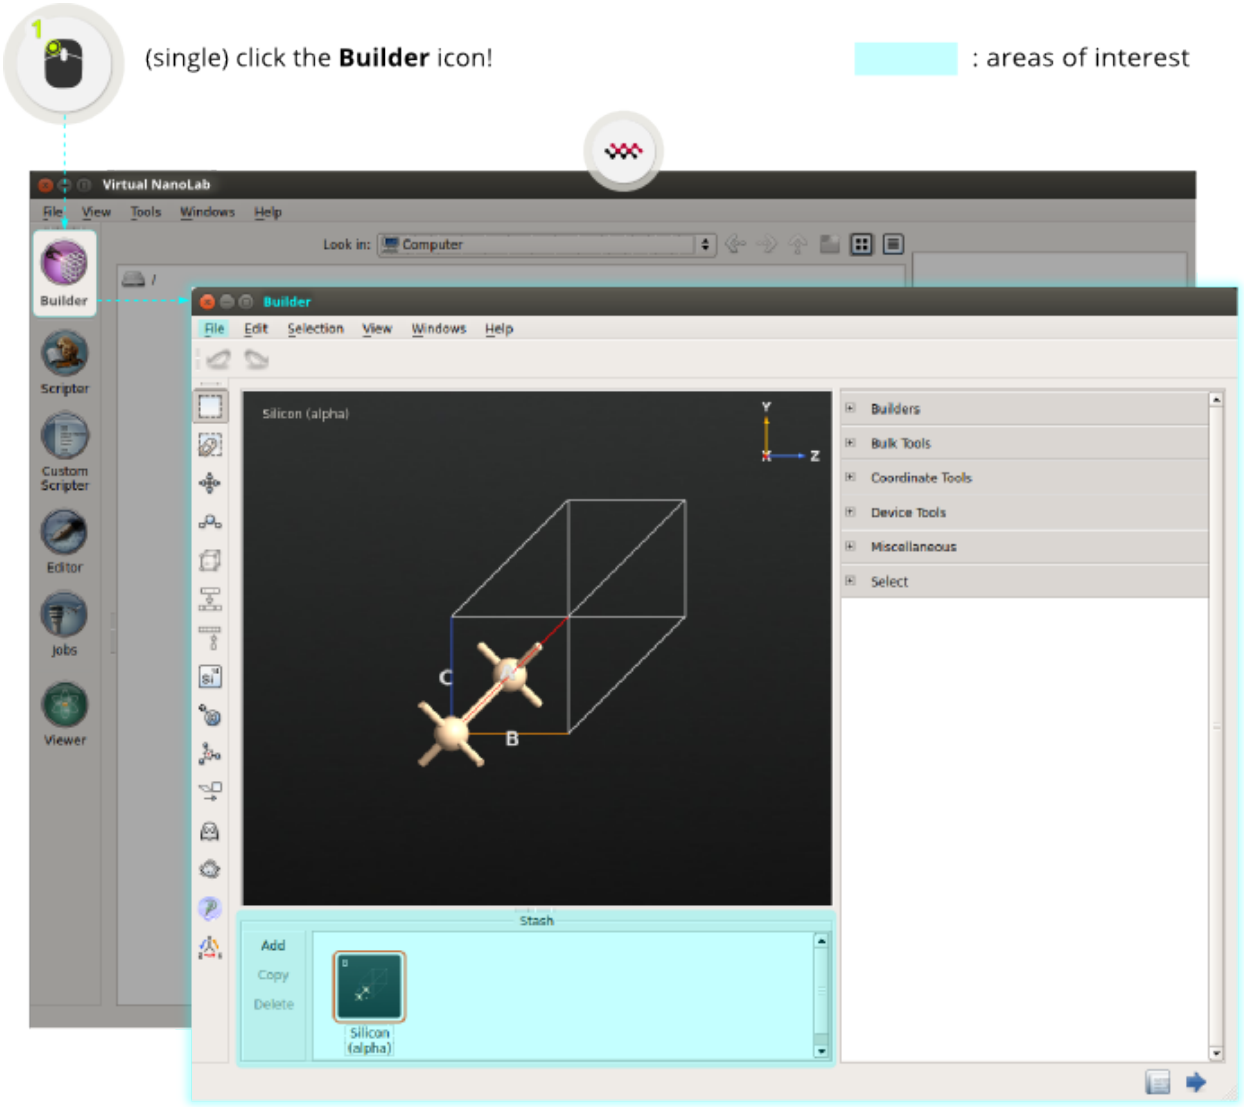
2.9 Importing and exporting files

2.9.1 Import/Export files in QuantumATK

In this tutorial you will learn how to import and/or export files in the QuantumATK **Builder**. The list of supported file types/formats is extensive, including file types `.py`, `.hdf5`, `.nc`, `.xyz`, `.car`, `.in`, `.cell`, `.geon`, `.cif`, `POSCAR`, `CONTCAR`, `.traj`, `.fdf`.

•Open **QuantumATK** and click the **Builder** icon at the top left column of the vertical menu.

•The **Builder** window appears:



Stash Items

Attention: The **Stash** is like a small desktop for all your structures! You can delete, add, and copy structures. Double-click any of the structures in your **Stash** to visualize it.

The **Stash** functionality is simple and intuitive. The illustration below highlights a few main options and functionlity.

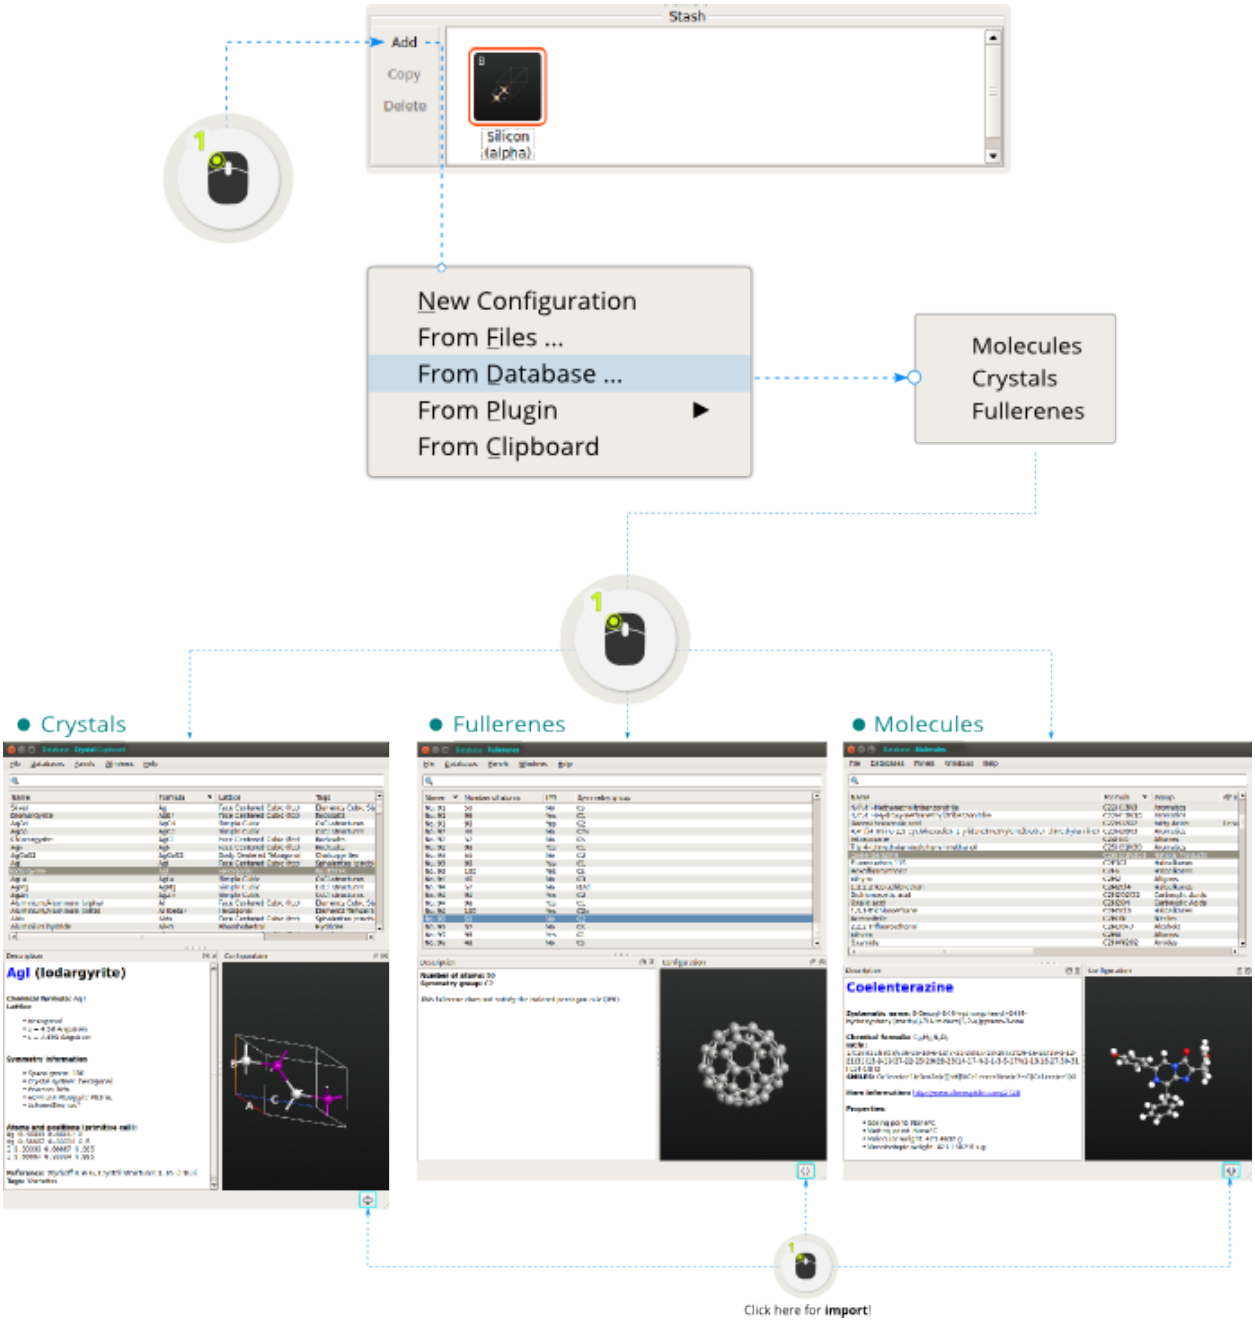
Add from Database

One of the easiest ways to set up structures is by using the **QuantumATK database**.

•Simply use *Add* → *From Database* to add a known structure to the **Stash**:



The available structures are grouped into three different categories: **Crystals**, **Molecules**, **Fullerenes**.

•You can search for structures and choose them from a list of matches.

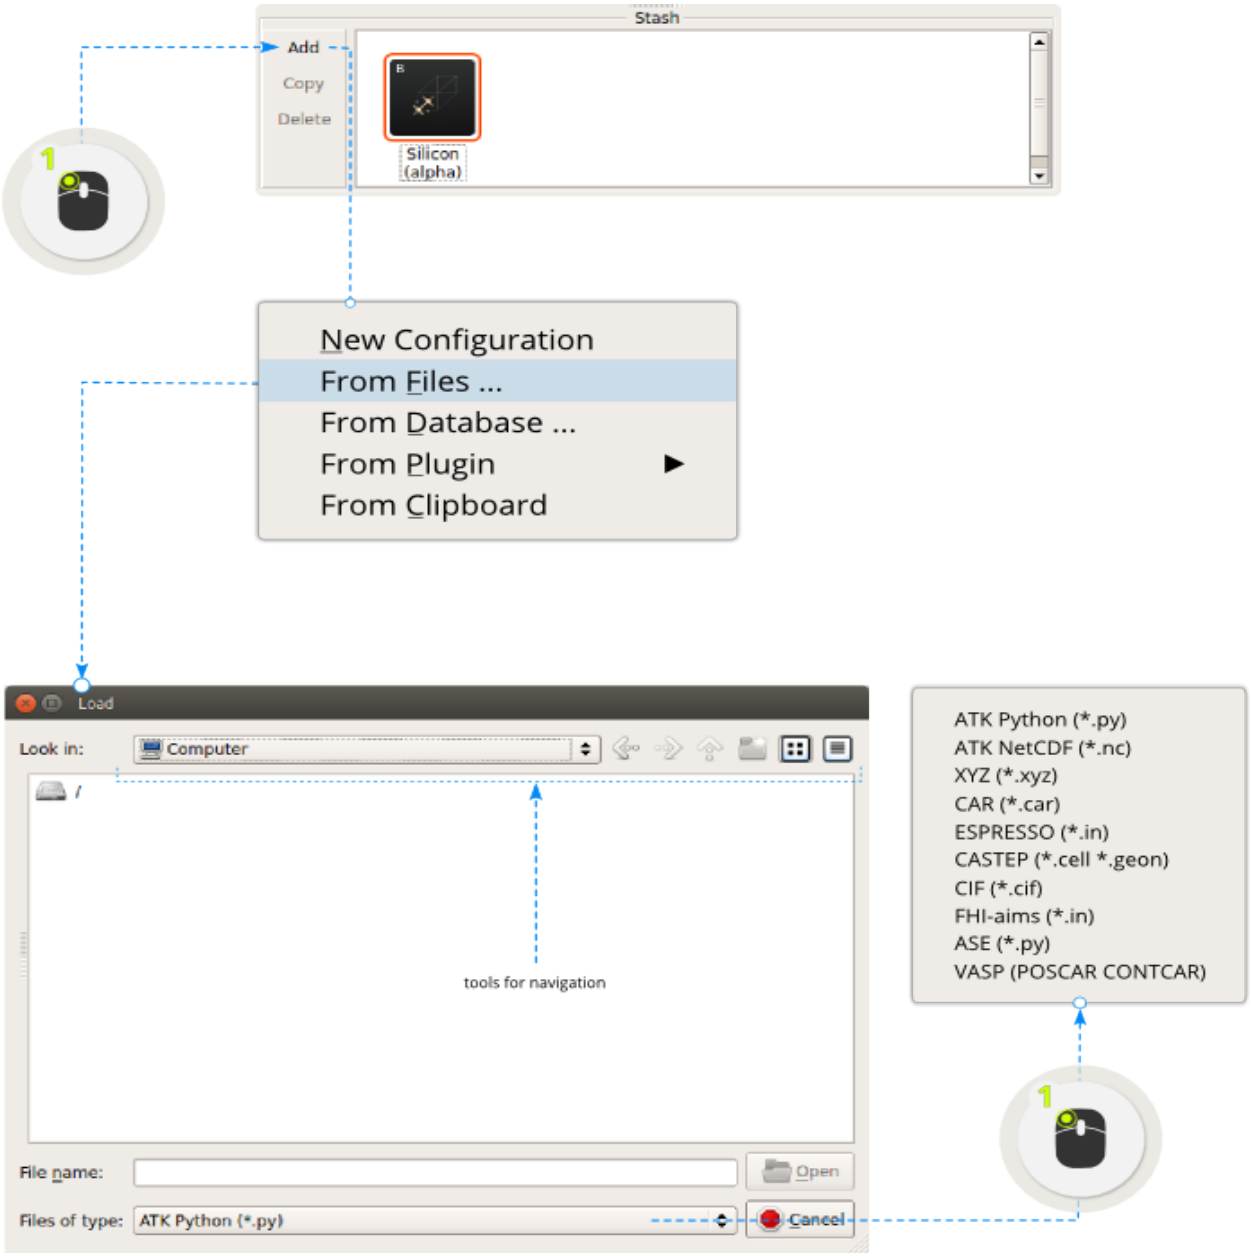
•Use the button or double click the name of the structure to add it to the **Stash**.

Add from Files

If you have files from previous **QuantumATK** projects, or from a database or some other software, it is easy to load them in **QuantumATK**:

- Use *Add* → *From Files* and load structures from the relevant files.

Remember to choose also the file type or extension of your file (see picture below).



Add from Plugins

The **QuantumATK Builder** provides a range of convenient plugins for creating structures.

•Use *Add* → *From Plugin* to find a list of helpful plugins.

The list of plugins is extendable:

•Use *Help* → *AddOn Manager* to find new plugins for **QuantumATK**.

Note: The plugins database keeps expanding, and you can even write your own (Python) plugins, and add them to the existing ones.

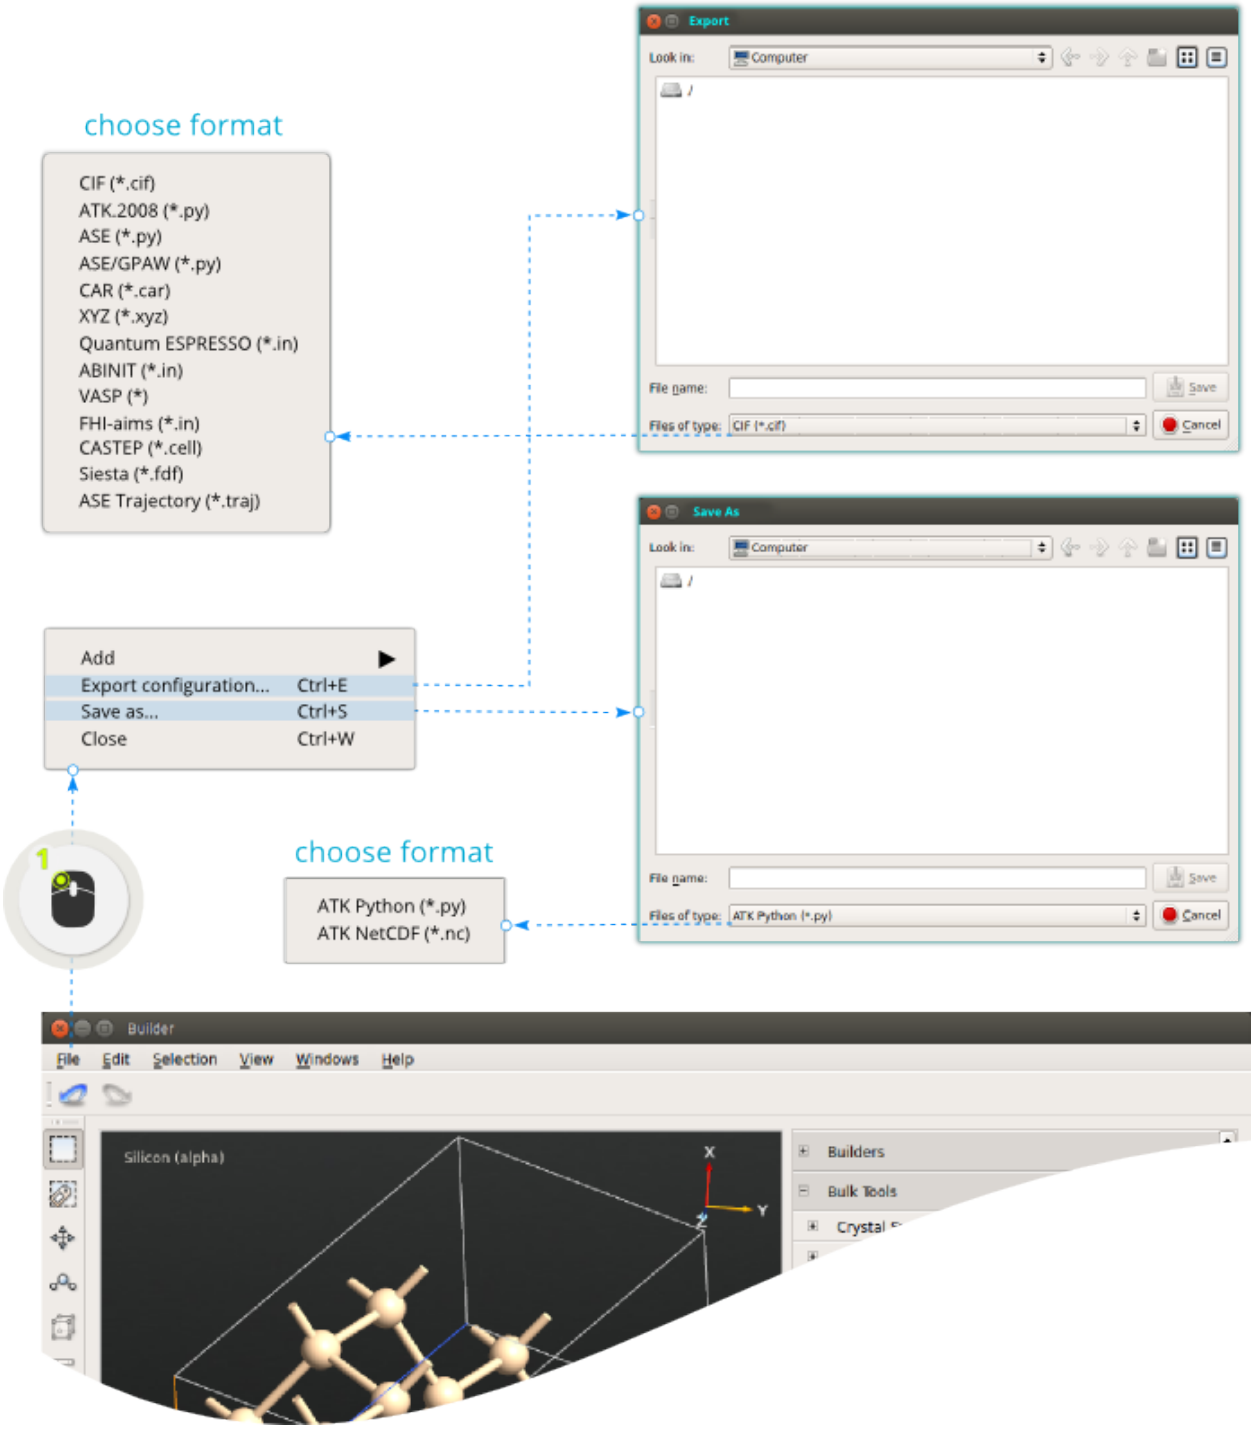
Save and Export Structures

•Save a structure by right-clicking on it and choosing *File*.

The two most important options are *Save as* and *Export configuration*. Many export formats are available, apart from the **QuantumATK** native `.nc` format:



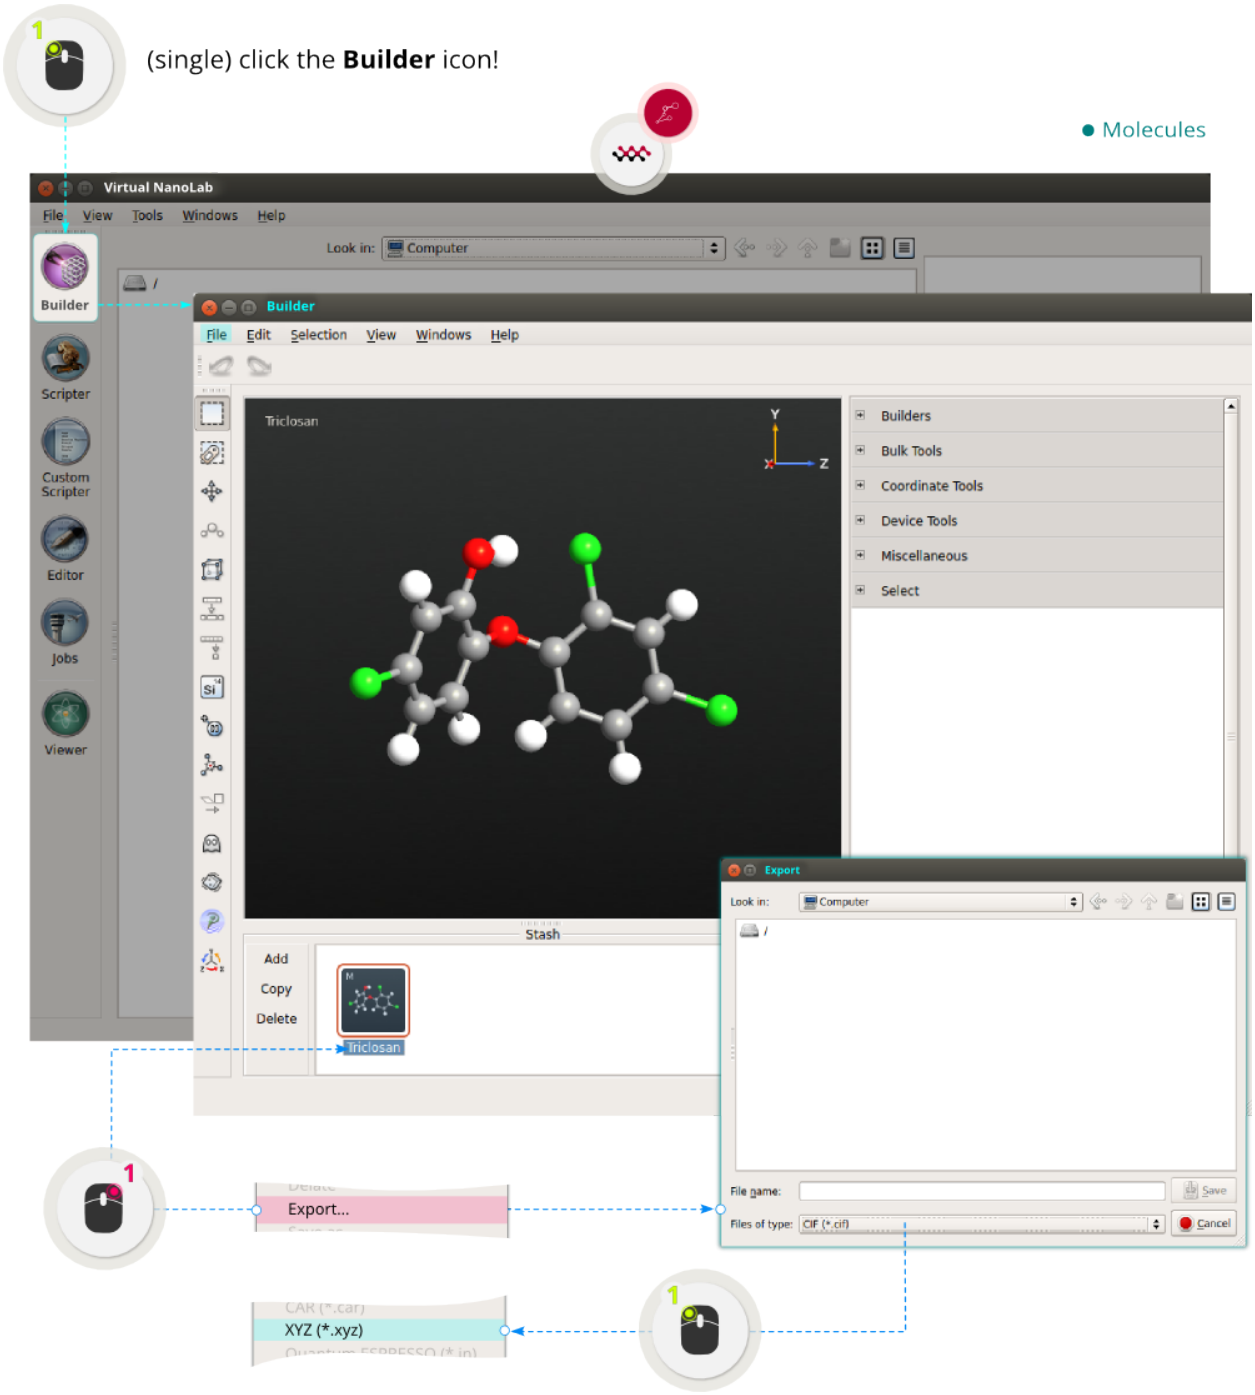
2.9.2 Export XYZ, CIF, CAR, VASP Files in QuantumATK

QuantumATK: File handling Platforms: Links: VASP, VASPfiles, *Import Files* **File types: XYZ, CIF, CAR, VASP** *In this tutorial, you will learn how to build a configuration in QuantumATK and export it for use in another program.*

Built-in export filters

Molecular Structures

For molecular structures, you can directly export the geometry in an **XYZ** file, via the menu *File→Export configuration* in the **Builder**. Choose the XYZ format under *Files of type*, enter the file name, and save the file.



(single) click the **Builder** icon!

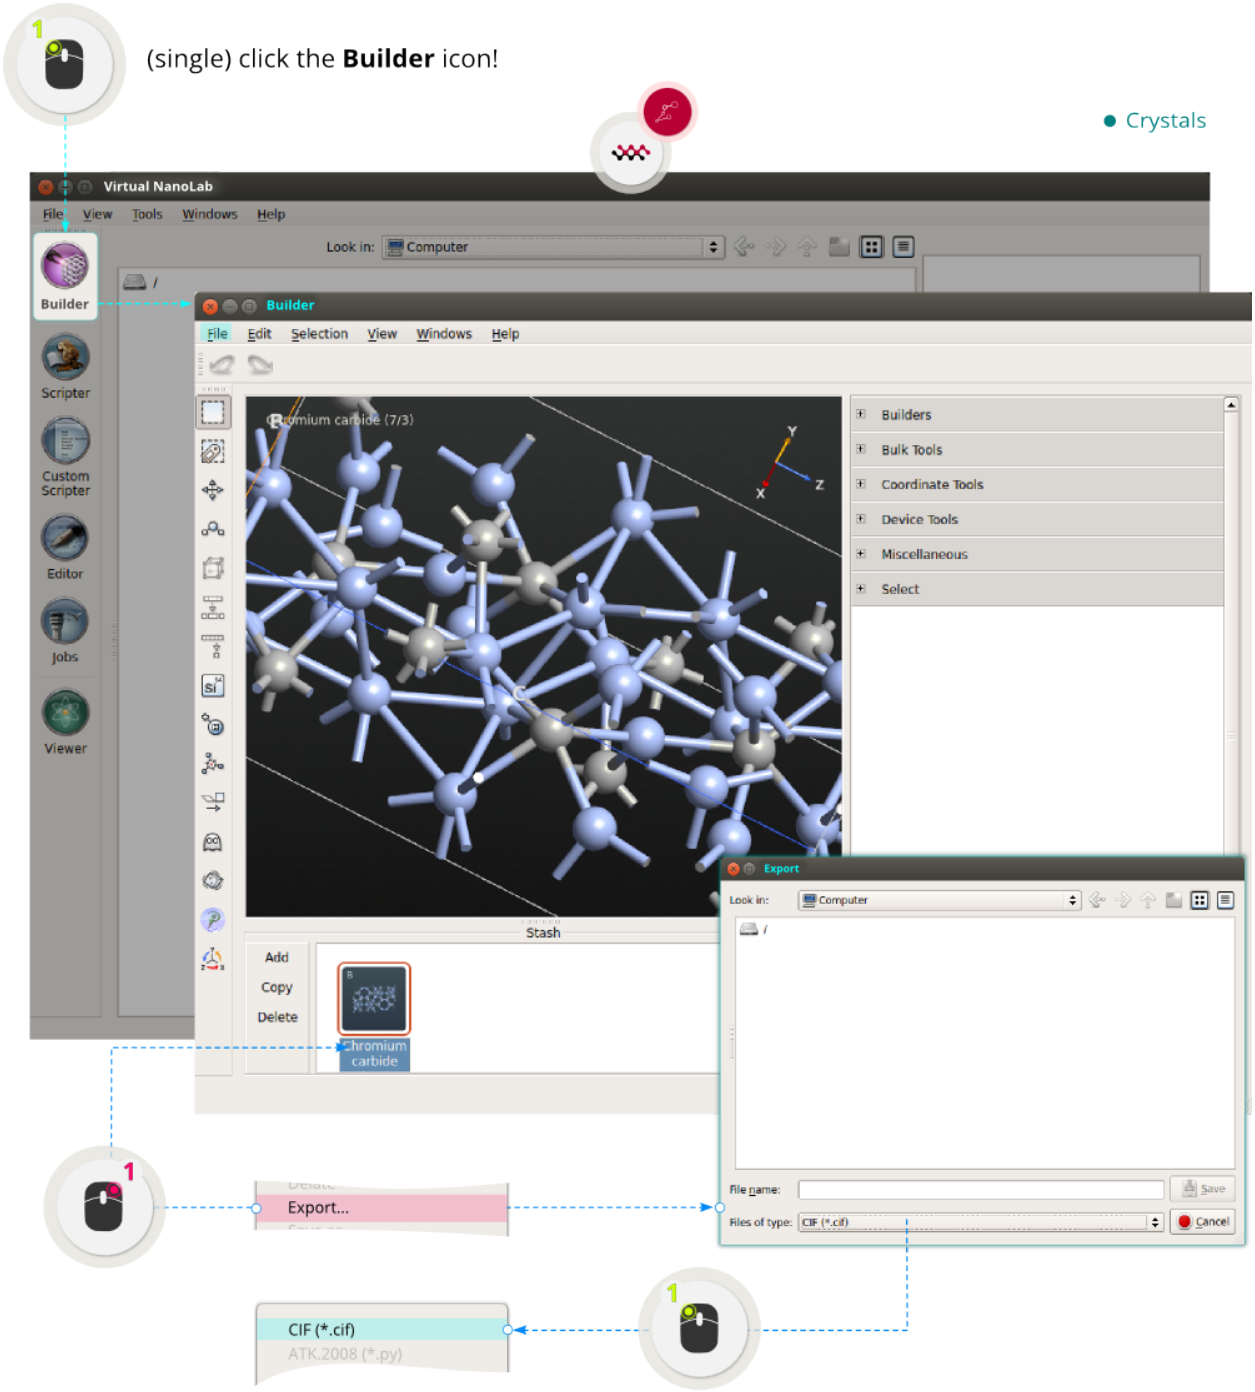
CAR (*.car)
XYZ (*.xyz)

Crystal Structures

A similar approach is possible for exporting periodic structures (crystals, nanotubes, etc) to **CIF** or **CAR** files.



Exporting from scripts

The function **nlprint** is also a convenient tool for exporting structures:

```
nlprint(configuration)
```

Include this line in a script (referring to the correct variable for the structure), and pipe the output to a file when you run it:

```
atkpython script.py > file.xyz
```

There will be a few lines in the file file.xyz that you need to remove, but the format of the coordinate list is proper XYZ. If the structure is a two-probe or bulk configuration, there will be some additional information about the unit cell too.

Note: The **XYZ** file format is a chemical file format. There is no formal standard and several variations exist, but a typical XYZ format specifies the molecule geometry by giving the number of atoms with Cartesian coordinates that will be read on the first line, a comment on the second, and the lines of atomic coordinates in the following lines. The file format is used in computational chemistry programs for importing and exporting geometries. The units are generally in Angstroms. Some variations include using atomic numbers instead of atomic symbols, or skipping the comment line. Files using the XYZ format conventionally have the **.xyz** extension.

Note: **CAR** stands for **Component Application Resource**. The CAR files contain information about the assets that are available for a software application being run on the Brew Mobile Platform. This platform is used to operate applications on a variety of mobile phones. The CAR files are compiled into a binary BAR file. This file is automatically loaded when the application is run.

The **.car** file extension is also used for AtHome Assistant files, Biosym chemical modeler input files, NeoBook Cartoon image format files, CAR Archive compressed archive files, CardMaker card files, Carnivores Ice Age resource files, Design-Your-CD data files and Railroad Tycoon 3 car properties files.

Note: **Crystallographic Information File** (**CIF**) is a standard text file format for representing crystallographic information, promulgated by the International Union of Crystallography (IUCr). CIF was developed by the IUCr Working Party on Crystallographic Information in an effort sponsored by the IUCr Commission on Crystallographic Data and the IUCr Commission on Journals. Full specifications for the format are available at the IUCr website. Many computer programs for molecular viewing are compatible with this format, including Jmol.

Note: **VASP** is a fileformat/extension used by VASP. VASP software uses a relatively large number of input and output files:

INCAR	CONTCAR	DOSCAR	XDATCAR	PCDAT	EIGENVAL
STOPCAR	POSCAR	PROOUT	TMPCAR	OSZICAR	WAVECAR
stout	IBZKPT	ELFCAR	CHG	PROCAR	CHGCAR
POTCAR	KPOINTS	LOCPOT	EXHCAR	DOSCAR	

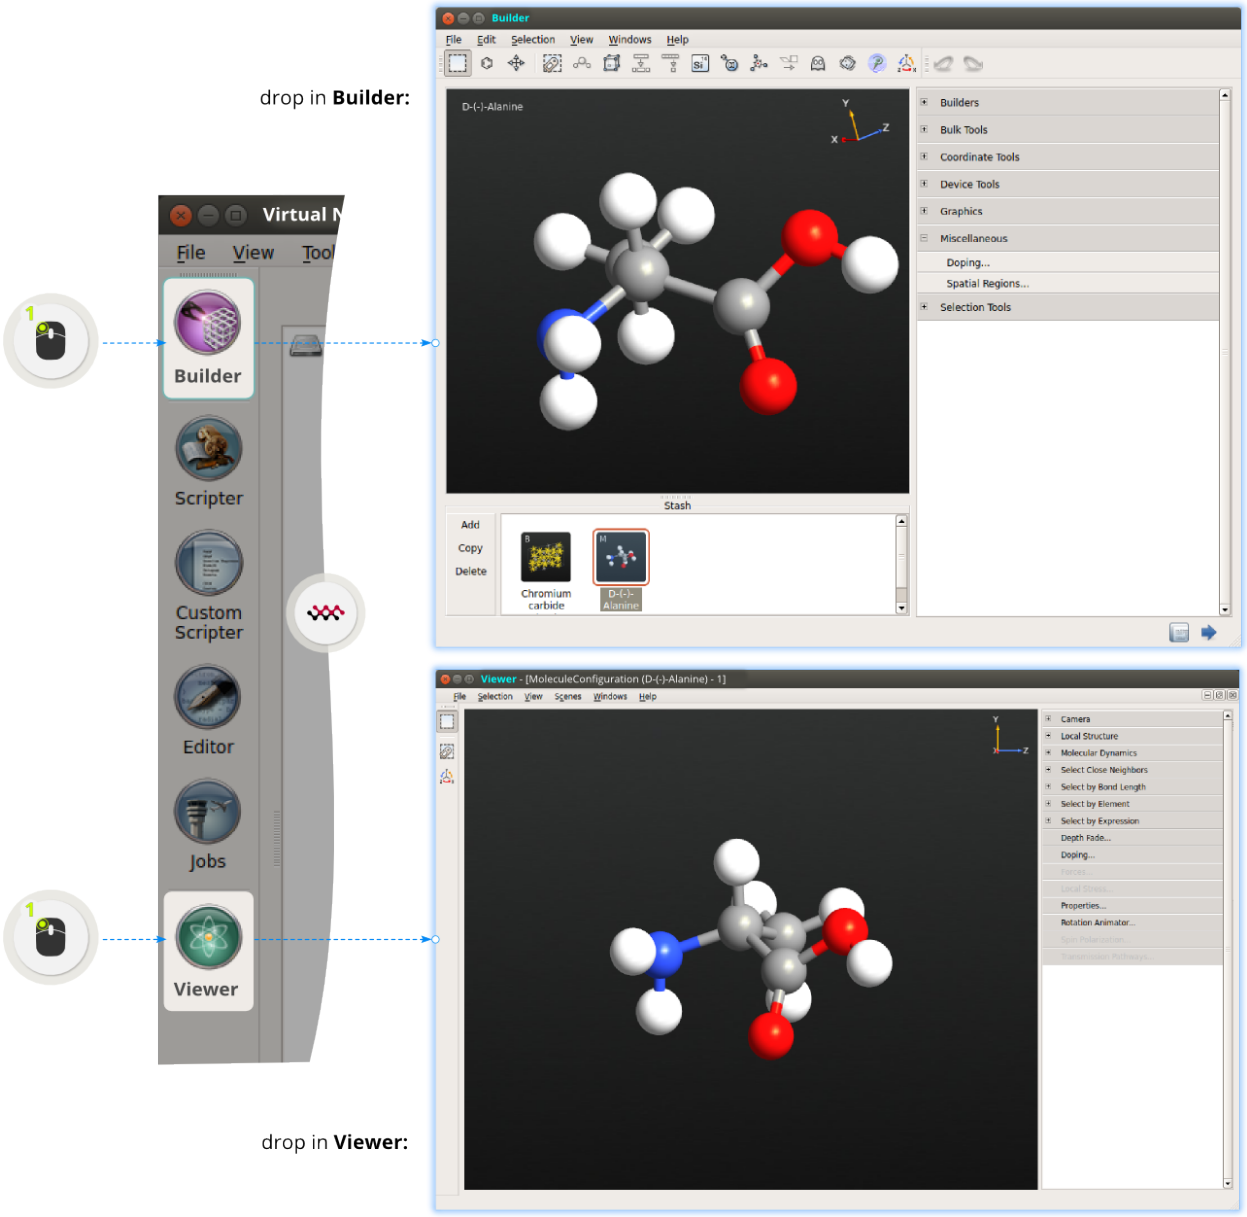
You can find more details about their content on the VASP website.

2.9.3 Import XYZ, CIF, CAR, VASP Files in QuantumATK

QuantumATK: File handling Platforms: Links: *Export Files* **File types: XYZ, CIF, CAR, VASP(POSCAR)** *In this tutorial, you will learn how to import configuration files from other programs.*

Drag and Drop

In the simplest case, all you actually have to do is to drop the file itself on one of the instruments in **QuantumATK**, typically the **Builder** (for editing the structure), or the **Viewer** (for just visualizing the structure).



Importing structures in a script

It is also possible to import and use external files directly in a script:

```
molecule = nlread('myfile.xyz')[0]
```

Note that nlread returns a list, normally only with one element, hence the [0]. The file formats are recognized by the extensions, so the same principle would apply to CIF, CAR, or POSCAR files alike. Here is another way to use the XYZ format, if you prefer to just copy/paste the coordinate list

```
h2o = MoleculeConfiguration(xyz_format=
    """3
    water
    O   0.000 0.000 0.0
    H   0.757 0.586 0.0
    H  -0.757 0.586 0.0""")
```

Note that the format must be that of a real XYZ file, with the two first lines specifying the number of atoms, and the comment/title. For more details, see the manual entry for the `MolecularConfiguration` class.

Note: The **XYZ** file format is a chemical file format. There is no formal standard and several variations exist, but a typical XYZ format specifies the molecule geometry by giving the number of atoms with Cartesian coordinates that will be read on the first line, a comment on the second, and the lines of atomic coordinates in the following lines. The file format is used in computational chemistry programs for importing and exporting geometries. The units are generally in Angstroms. Some variations include using atomic numbers instead of atomic symbols, or skipping the comment line. Files using the XYZ format conventionally have the **.xyz** extension.

Note: **CAR** stands for **Component Application Resource**. The CAR files contain information about the assets that are available for a software application being run on the Brew Mobile Platform. This platform is used to operate applications on a variety of mobile phones. The CAR files are compiled into a binary BAR file. This file is automatically loaded when the application is run.

The **.car** file extension is also used for AtHome Assistant files, Biosym chemical modeler input files, NeoBook Cartoon image format files, CAR Archive compressed archive files, CardMaker card files, Carnivores Ice Age resource files, Design-Your-CD data files and Railroad Tycoon 3 car properties files.

Note: **Crystallographic Information File** (**CIF**) is a standard text file format for representing crystallographic information, promulgated by the International Union of Crystallography (IUCr). CIF was developed by the IUCr Working Party on Crystallographic Information in an effort sponsored by the IUCr Commission on Crystallographic Data and the IUCr Commission on Journals. Full specifications for the format are available at the IUCr website. Many computer programs for molecular viewing are compatible with this format, including Jmol.

Note: **VASP** is a fileformat/extension used by VASP. VASP software uses a relatively large number of input and output files:

INCAR	CONTCAR	DOSCAR	XDATCAR	PCDAT	EIGENVAL
STOPCAR	POSCAR	PROOUT	TMPCAR	OSZICAR	WAVECAR
stout	IBZKPT	ELFCAR	CHG	PROCAR	CHGCAR
POTCAR	KPOINTS	LOCPOT	EXHCAR	DOSCAR	

You can find more details about their content at the VASP website.

2.10 Molecular builder

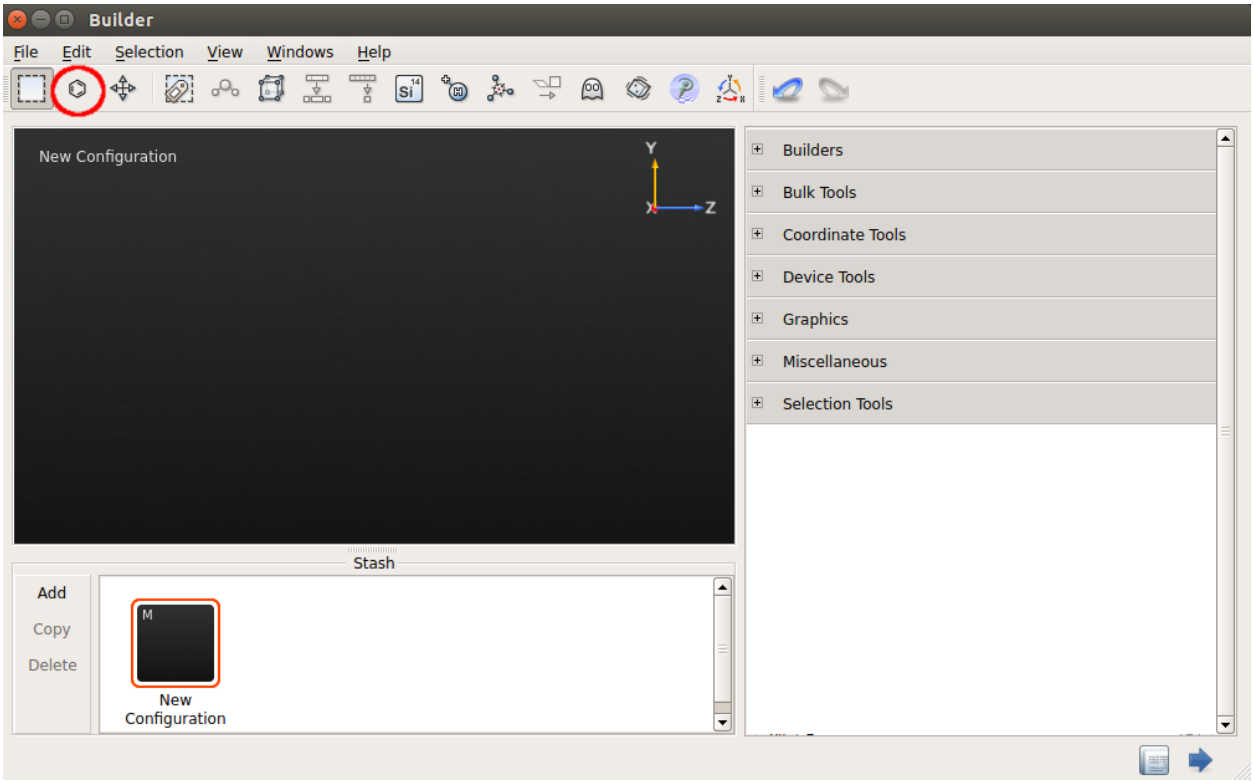
Platforms: *In this tutorial, you will learn how to use the Molecular Builder tool, which makes it easy to build complex molecular structures by combining atoms and molecular fragments. As examples of use, you will build the ethanol and caffeine molecules.*

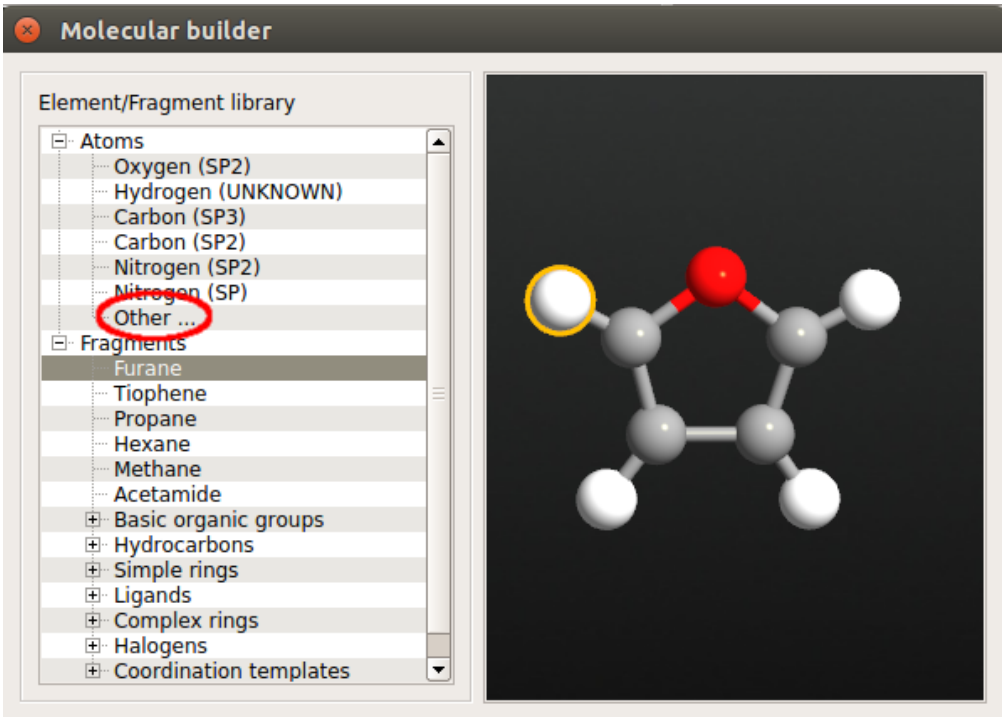
Note: The **Molecular builder** tool is selected using the icon in the top plugins bar. You need to highlight a Stash configuration before activating the tool.

2.10.1 Ethanol molecule

Create a new empty project called molecular_builder and open the Builder to get started:

1. Use *Add* → *New Configuration* to create a Stash item, and remove the hydrogen atom to create an empty configuartion.
2. Activate the **Molecular builder** by clicking . It will look like illustrated below.

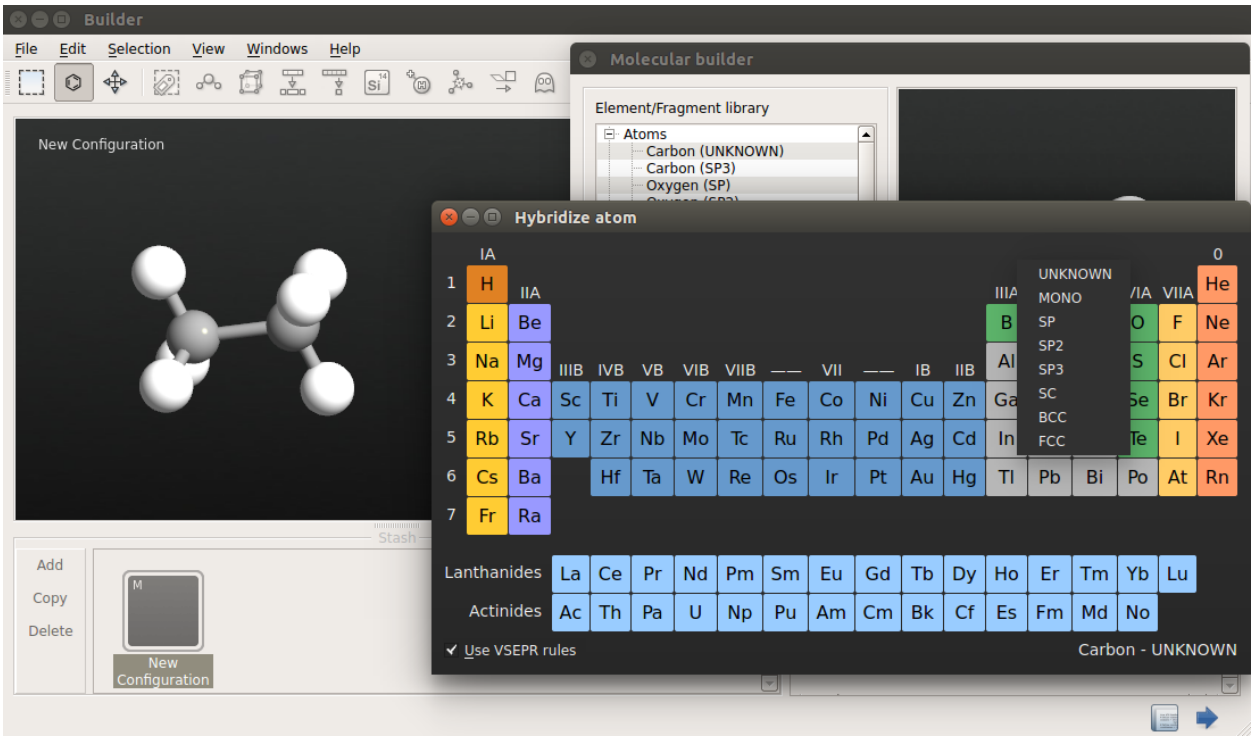




Attention: What you see is a library of elements and fragments that can be added to the current Stash configuration. The most recently used ones appear at the top of the list.

Click **Other** and a periodic table will open up. You can now select the atomic elements you need to build your molecular structure. An easy way to build ethanol is to first build ethane, and then add the hydroxyl group:

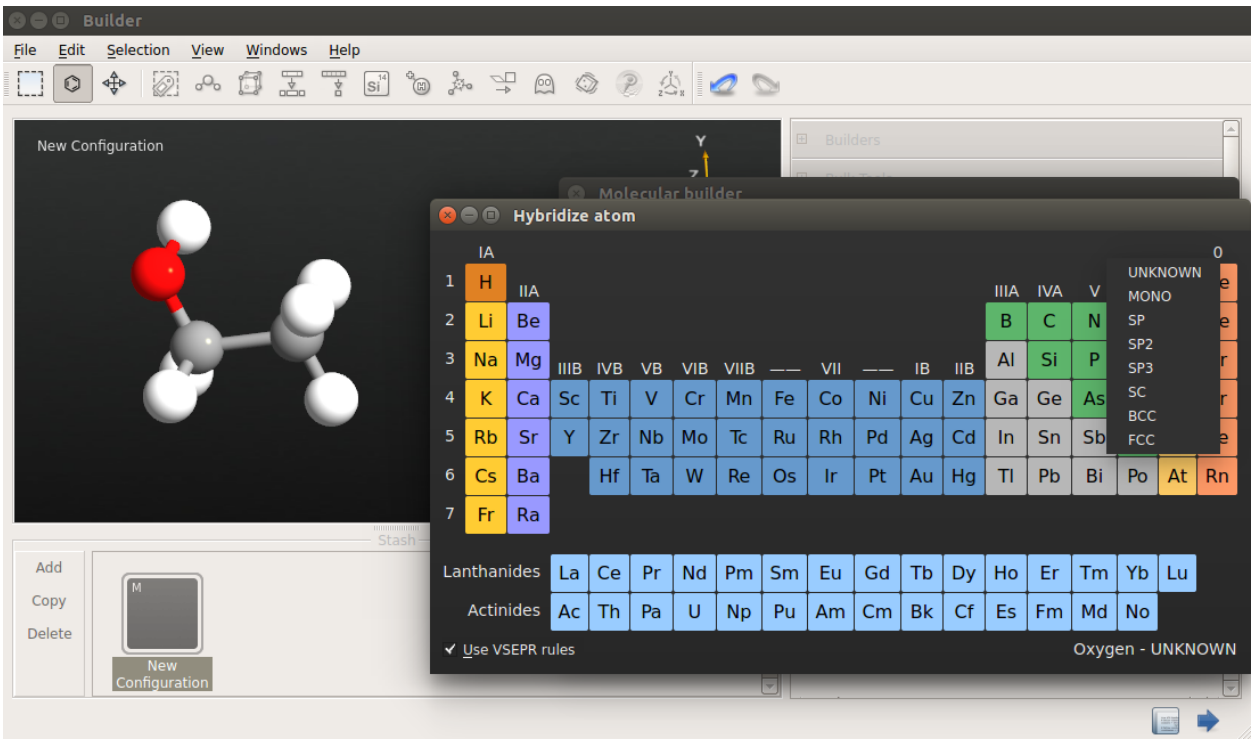
1. Click the C atom and select SP3 to select a C atom that should be sp3 bonded.
2. Click the 3D View to add the sp3 saturated carbon to the configuration. Note that this produces the methane molecule.
3. Then click on one of its hydrogen atoms to substitute that atom for another sp3 bonded carbon. You have then built ethane.



Next, add the hydroxyl group:

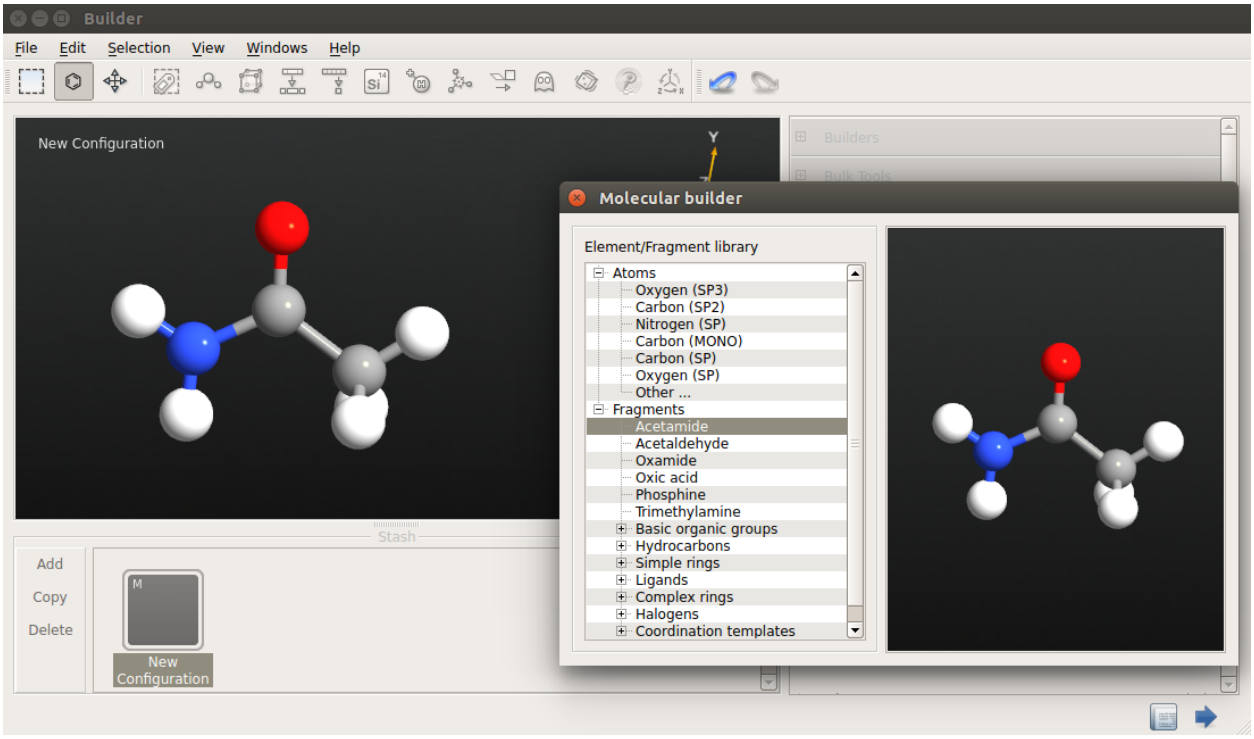
1. Select from the periodic table a sp3 O atom and make sure that the *Use VSEPR rules* option is selected. With this option we make sure that we are adding a OH group to the molecule (see more details about the *Use VSEPR rules* option below).

2. Click one of the hydrogen atoms in the 3D View to substitute it for the OH group.

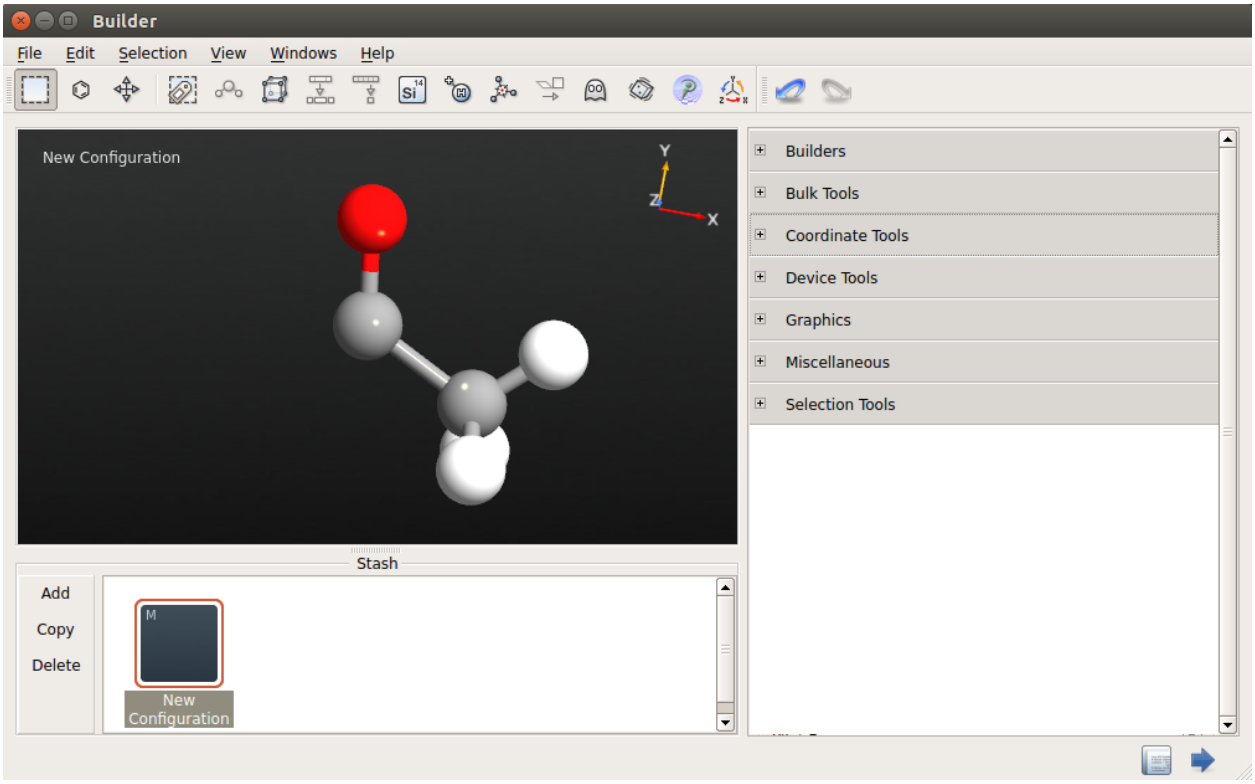


You have just built the ethanol molecule by combining atoms. You could also have built the same molecular structure by combining molecular fragments in a variety of ways. For instance, you could have added Methanol from the fragment library and then replaced one of its hydrogen atoms with the Methane fragment. Another easy alternative could be to select Acetamide fragment, remove its amine group and passivate the molecule to create sp3 O and C atoms:

1.Import Acetamide fragment from the fragment library.

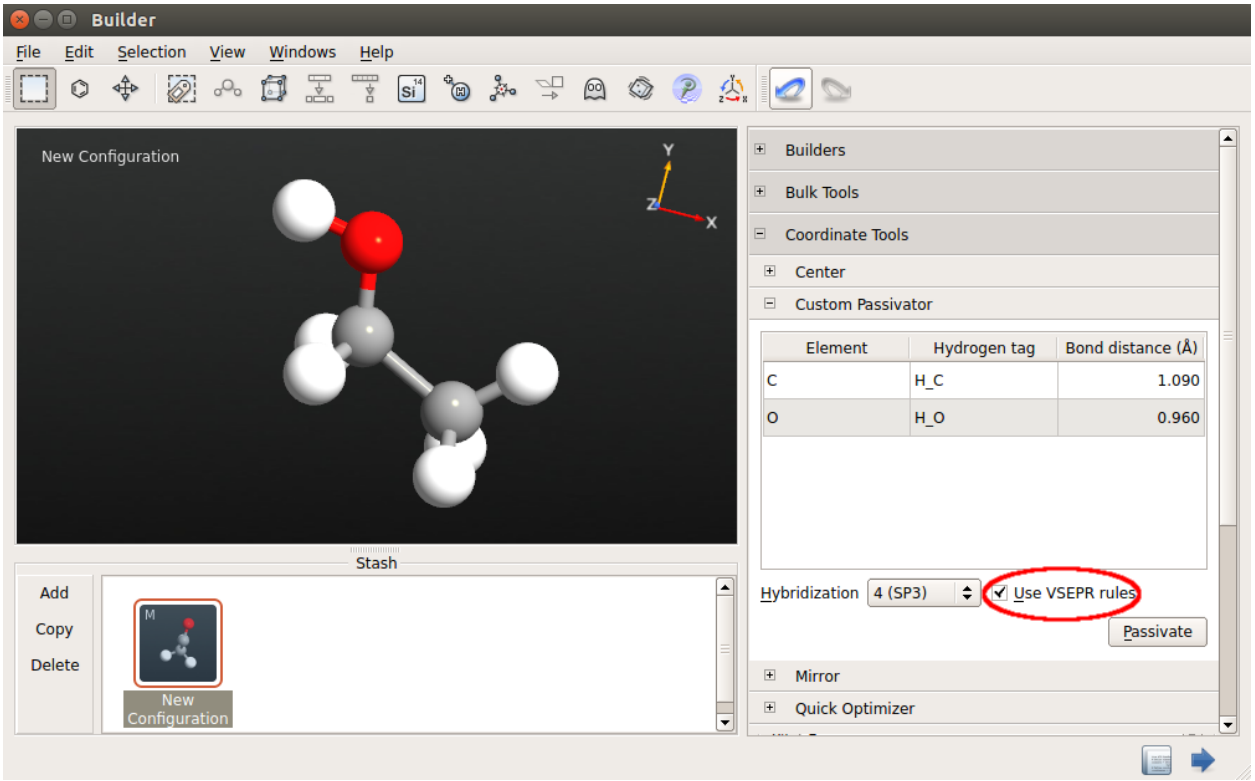


1.Select the amine moiety and remove it.



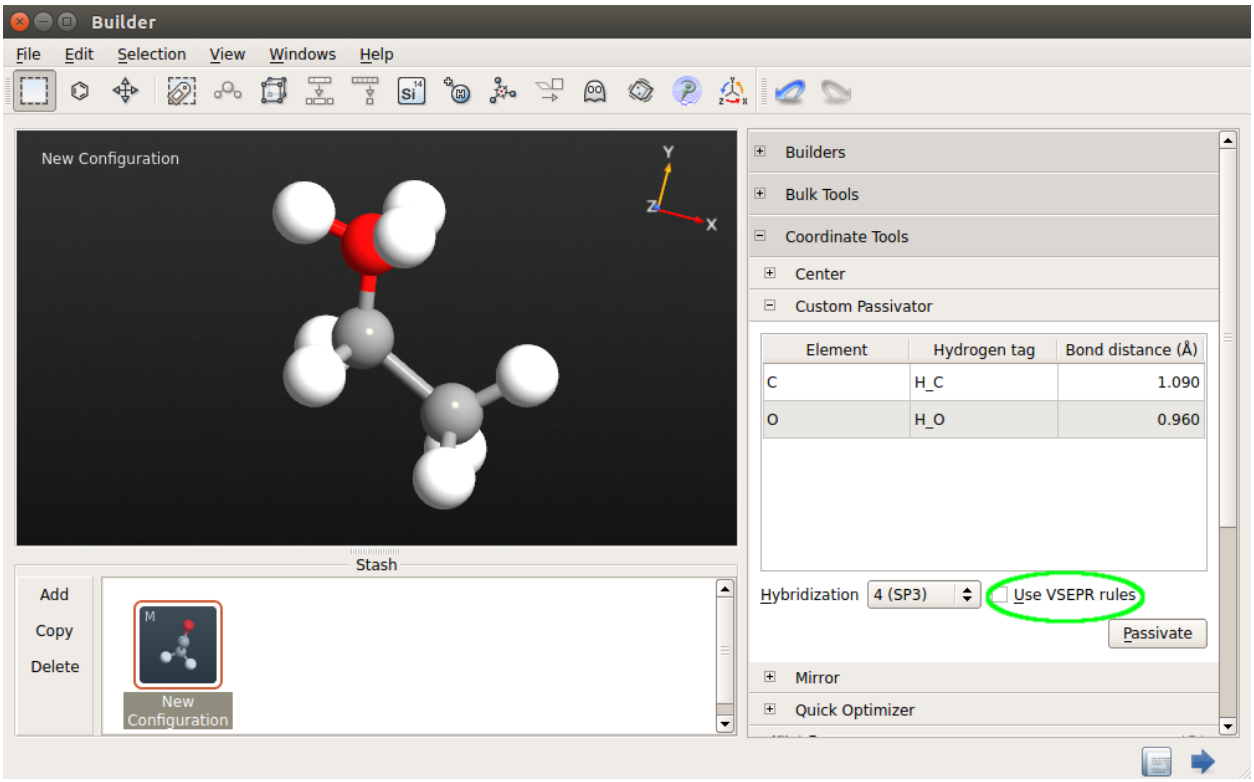
1.Go to *Coordinate Tools* → *Custom Passivator* and choose Hybridization 4(SP3).

2.Tick Use VSEPR rules to ensure that you passivate the structure following the Valence Shell Electron Pair Repulsion (VSEPR) rules, and click Passivate.



The VSEPR rule determines the bonding coordination of an atom considering the minimum repulsion between its valence electron pairs (both shared and unshared). The use of VSEPR rules ensures the passivation of the structure considering the bonding electrons and the lone pairs. Instead, if we passivate the molecule without following the VSEPR rules each atom of the molecule will be passivated with the maximum number of hydrogen atoms for the corresponding hybridisation, as the lone pairs will no be considered.

In the latter case, we get the structure shown below if we passivate the molecule without considering the VSEPR rules.



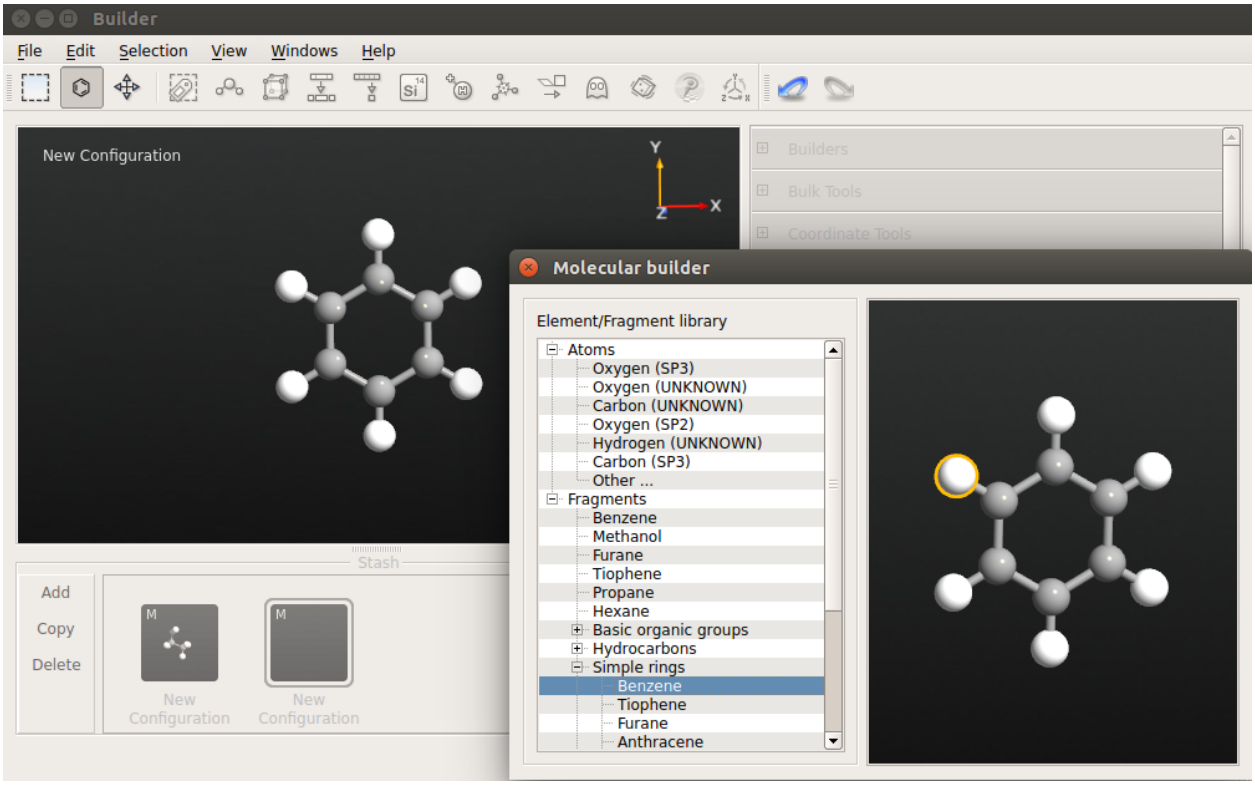
Tip: It is always a safe choice to passivate the structure considering the VSEPR rules when building neutral molecules.

Note: It is not possible to select any of the atoms in the 3D View while the Molecular builder window is active. You need to close this window first before the other Builder functionalities can be used.

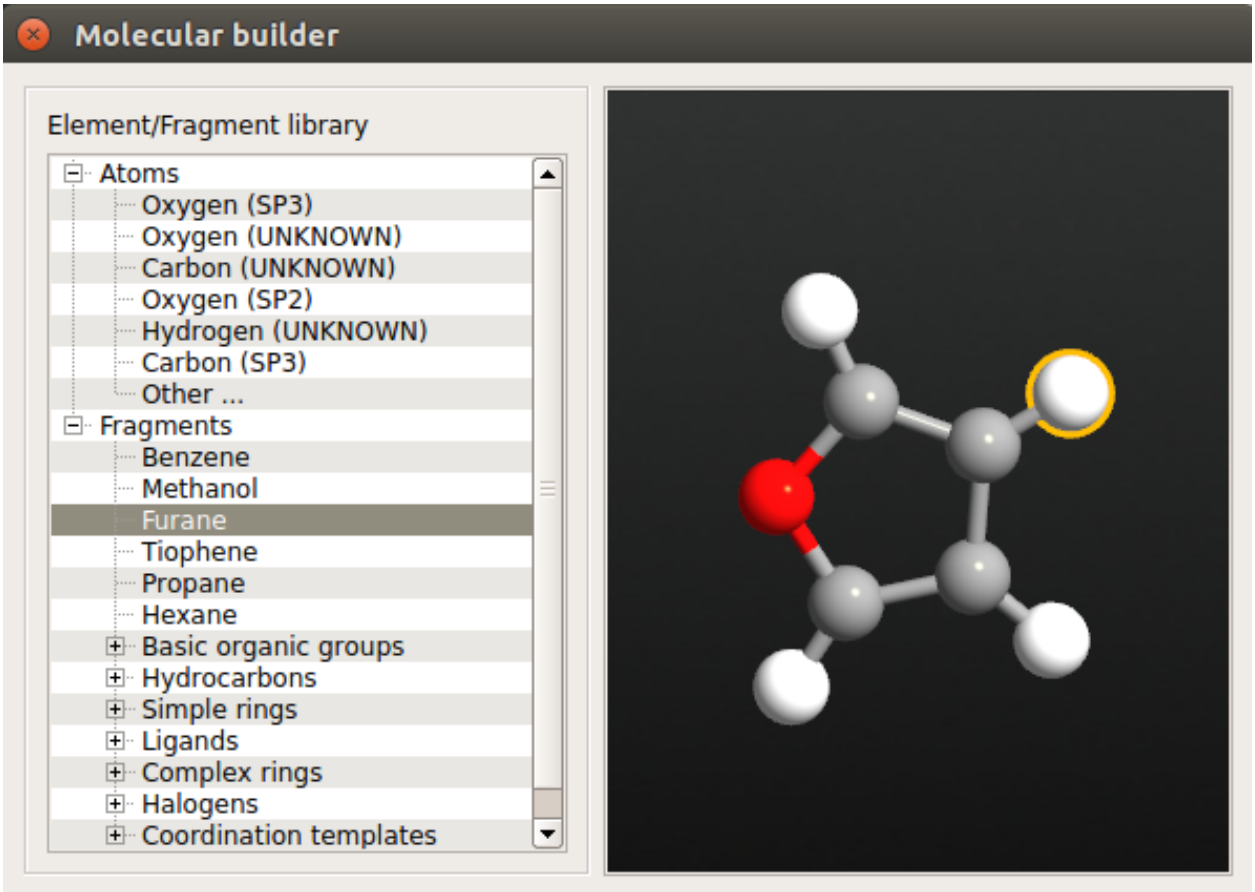
2.10.2 Caffeine molecule

It is quite easy to use the Molecular builder to build complex structures from simple fragments instead of from atoms. You will now build the caffeine molecule, also known as 1,3,7-Trimethylpurine-2,6-dione. The chemical formula is $C_8H_{10}N_4O_2$.

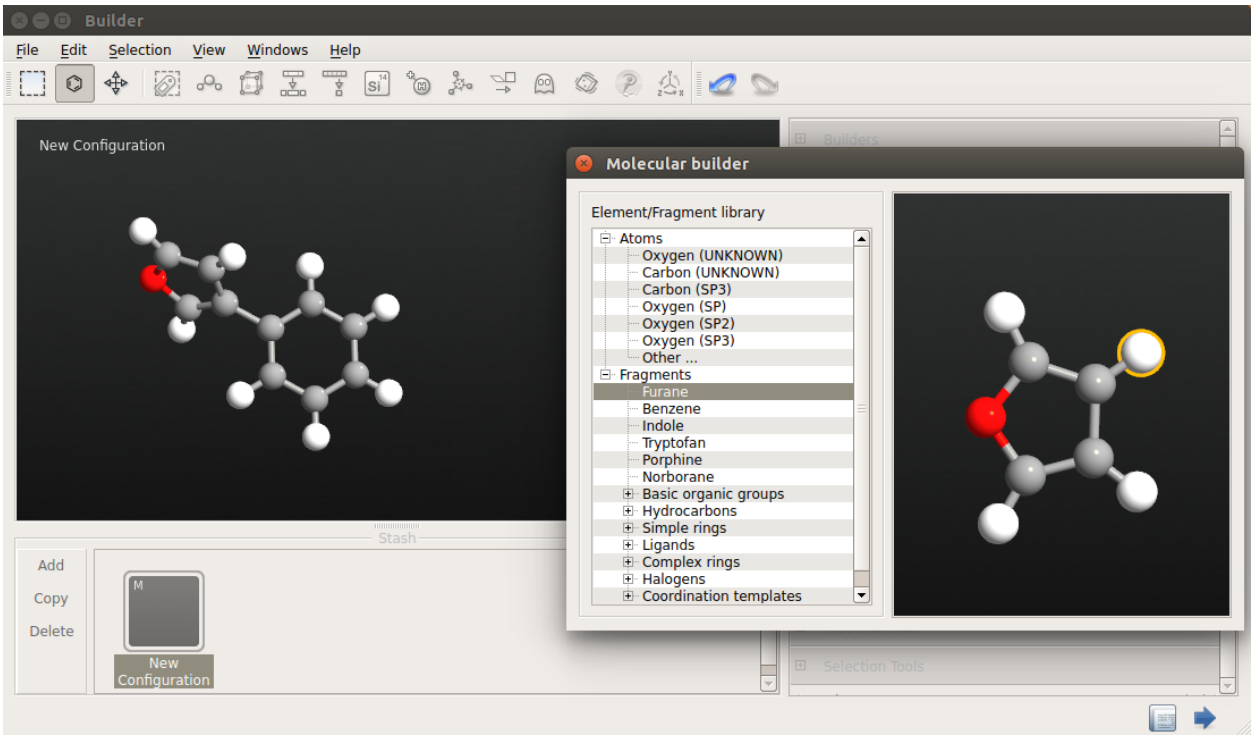
1. Add an empty configuration to the Stash and activate the Molecular builder .
2. Go to *Fragments* → *Simple rings* and select Benzene.
3. Click the 3D View to add benzene to the configuration.



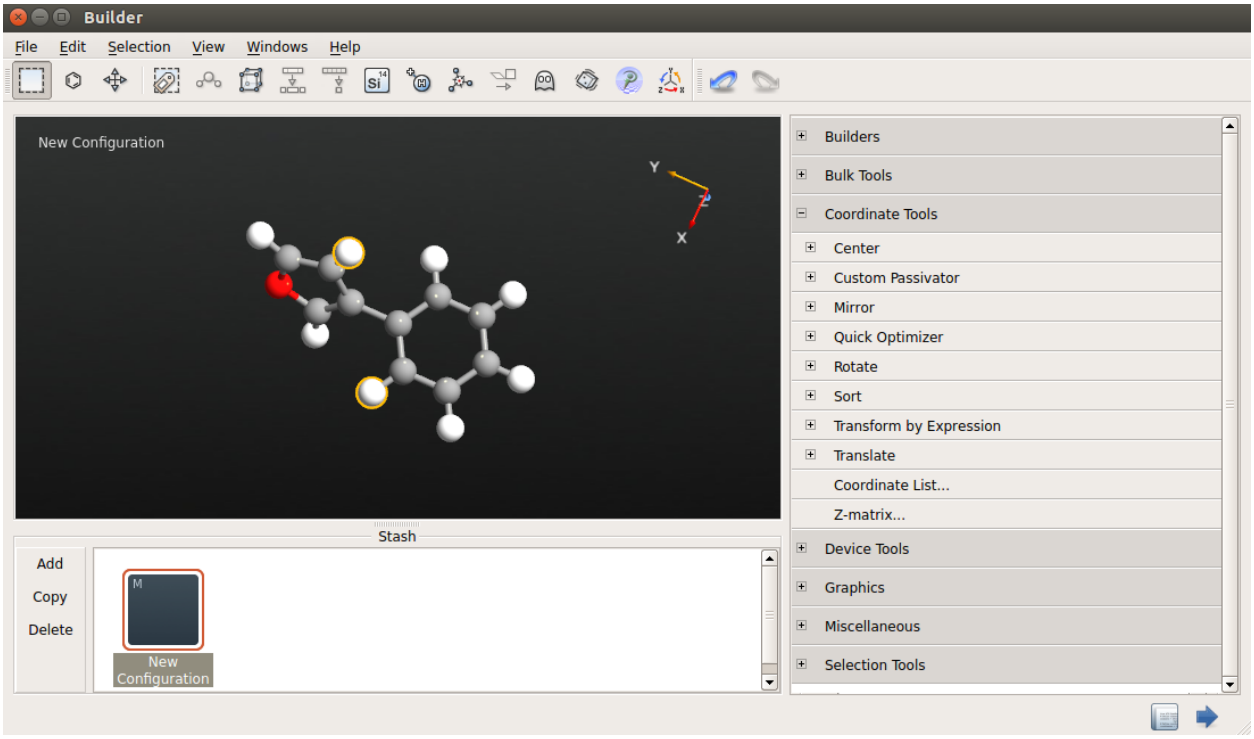
4. Select Furane from the Molecular Builder fragments library, and use mouse-click to **select** the hydrogen atom indicated below.



5. In the 3D View, add the furane fragment to the configuration by clicking one of the hydrogen atoms. Note that the furane is fused to the benzene ring exactly at the hydrogen that was selected in the Molecular builder.

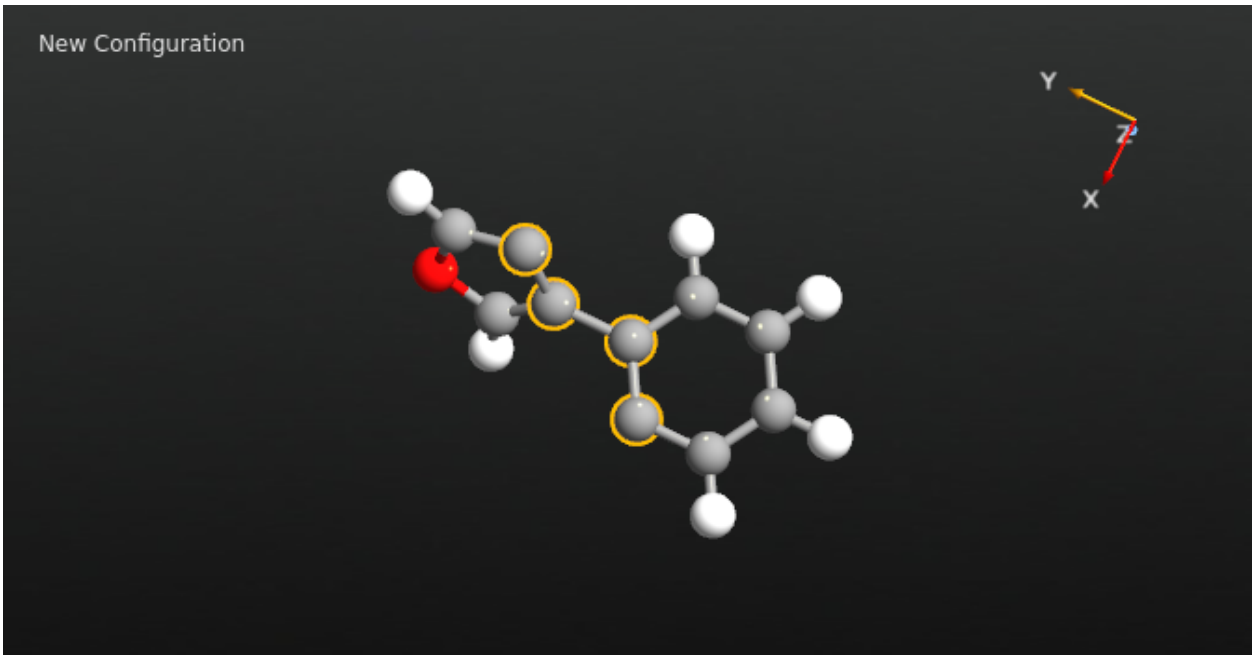


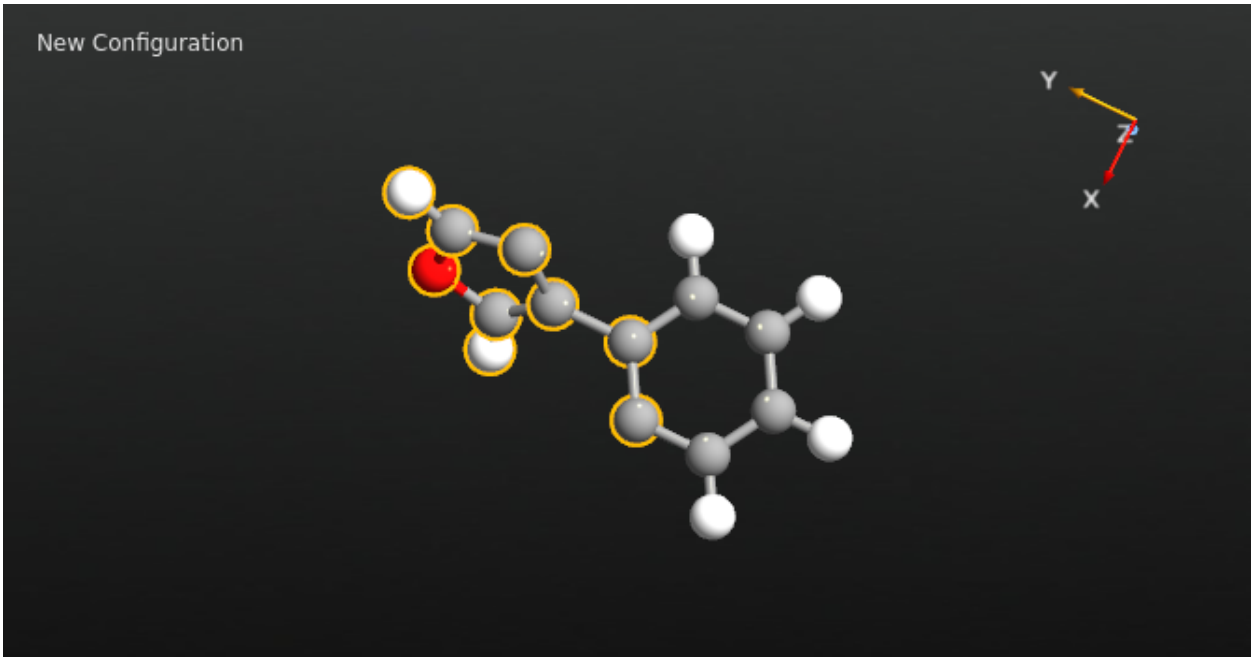
6.Select the hydrogen atoms that are highlighted below and remove them.



In order to make sure that both rings are in the same plane, you need to do a dihedral rotation using the **Z-matrix** plugin:

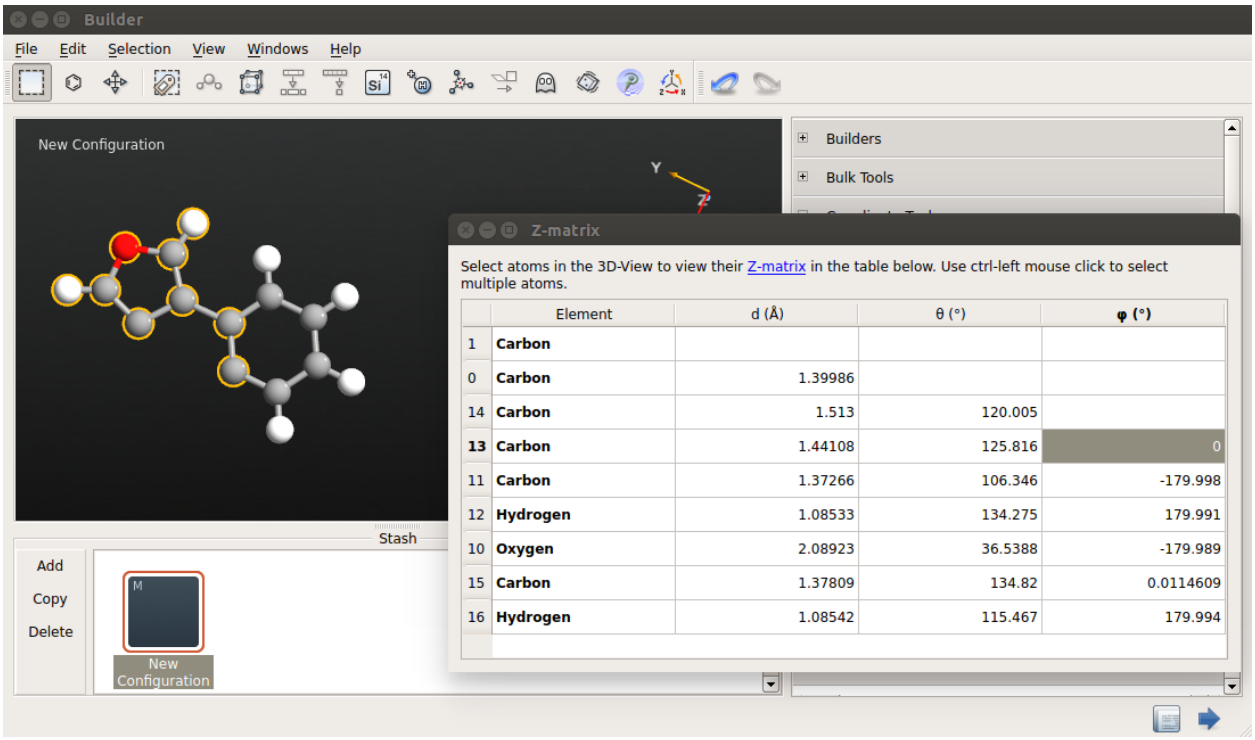
1.First select the atoms that define the dihedral angle. Once the angle is defined, you need to select the atoms that will move with the rotation; select the remaining atoms of furane moiety.





2.Go to *Coordinate Tools* → *Z-matrix* and the **Z-matrix** window will open up.

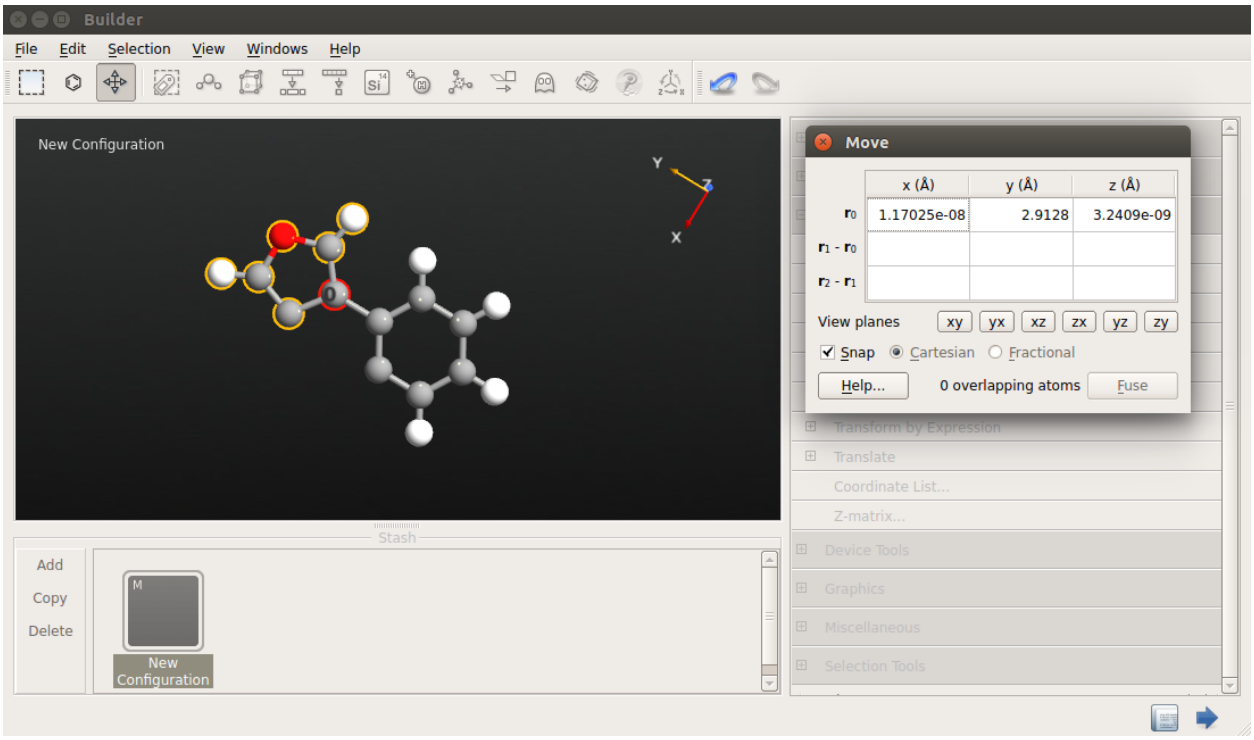
3.Set the value of the angle you want to change as shown in the next figure.



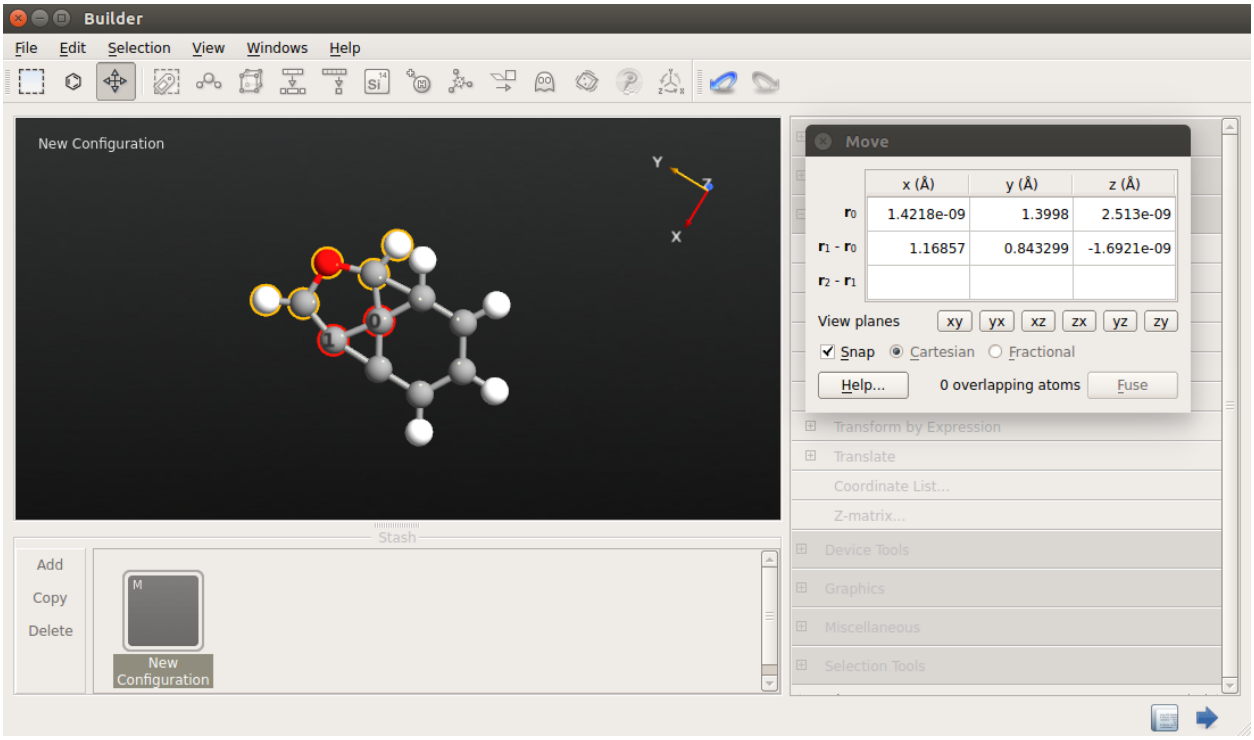
Next, you need to overlap the C atoms that link both rings and remove the overlapping atom by fusing the rings:

1.Select the atoms that will move; the atoms belonging to the furane moiety.

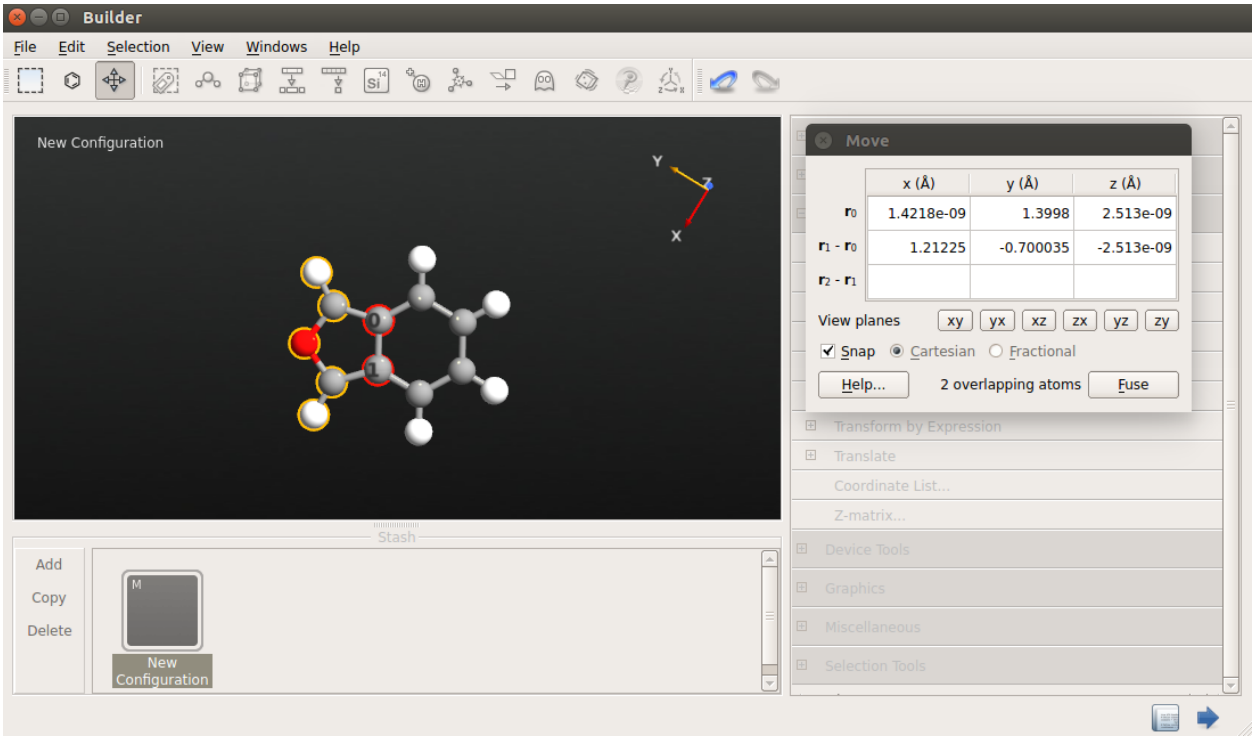
2.Select the **Move** tool and select just the atom of furane linked to benzene moiety.



3.Drag the selected atom so that it ends up on the top of the C atom of bencene linked to it and select the C atom numbered 1 in the below figure.

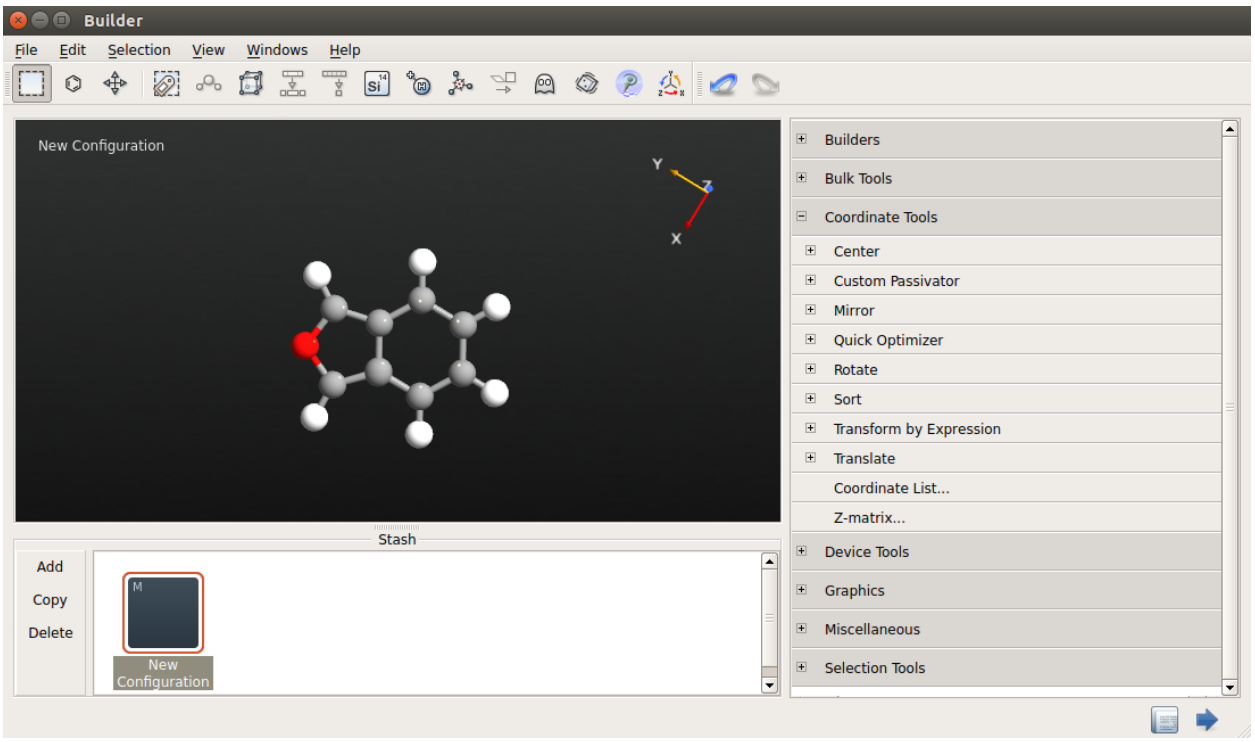


4.Drag the C atom numbered 1 so that it ends up on the top of the nearest C atom of benzene as shown in the figure below.



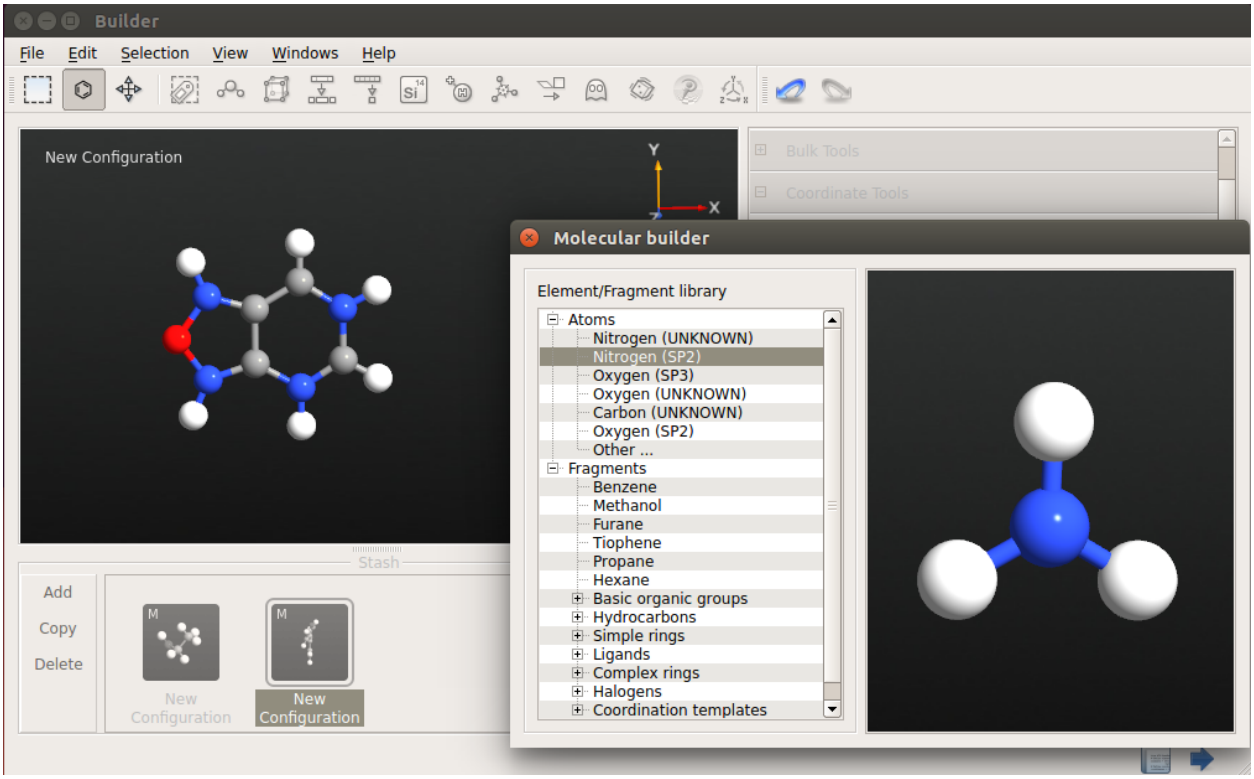
5.Click Fuse to remove the overlapping atoms.

6.Close the **Move** window and click the 3D background to deselect the atoms.

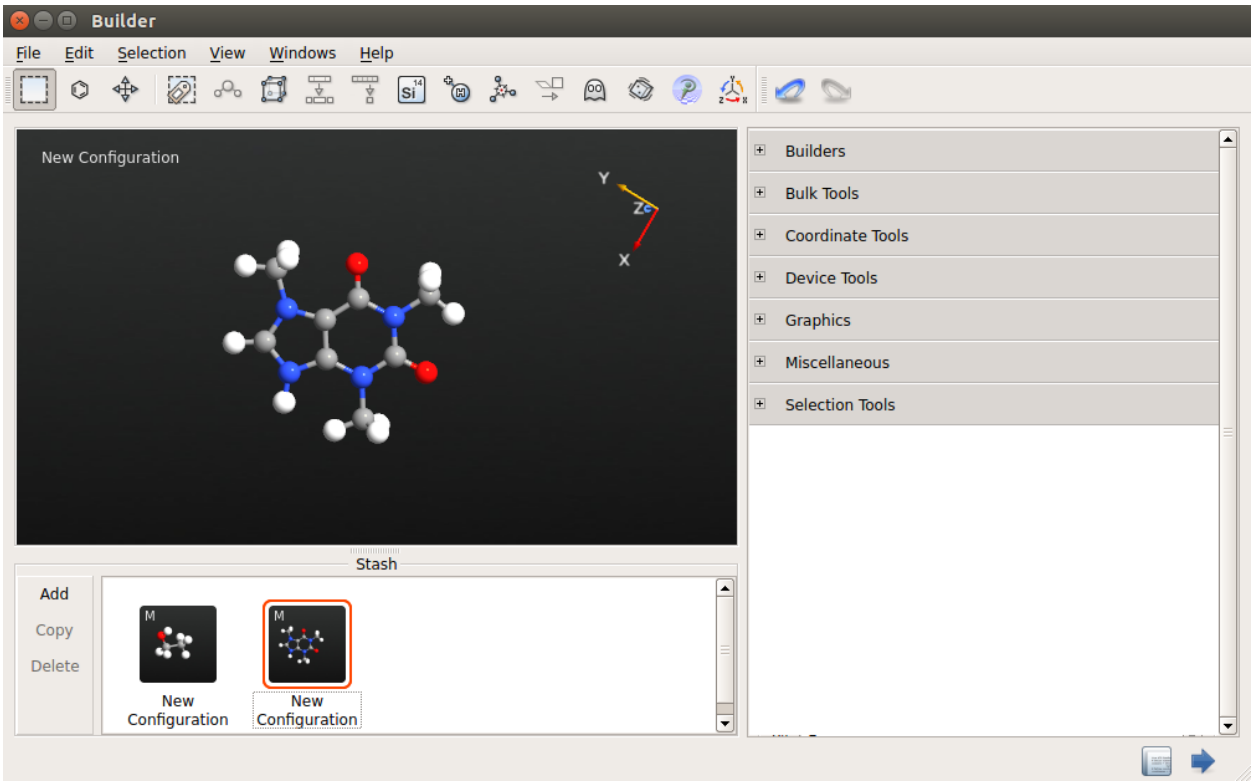


7.Go to **Molecular Builder** and slect sp2 N atom.

8.Replace the C atoms by N as shown in the next figure.



9.Follow the same steps to replace the H atoms by sp2 O atoms and Methane fragments and the oxygen atom belonging to the five-membered ring by a sp2 C atom, as shown in the next figure.



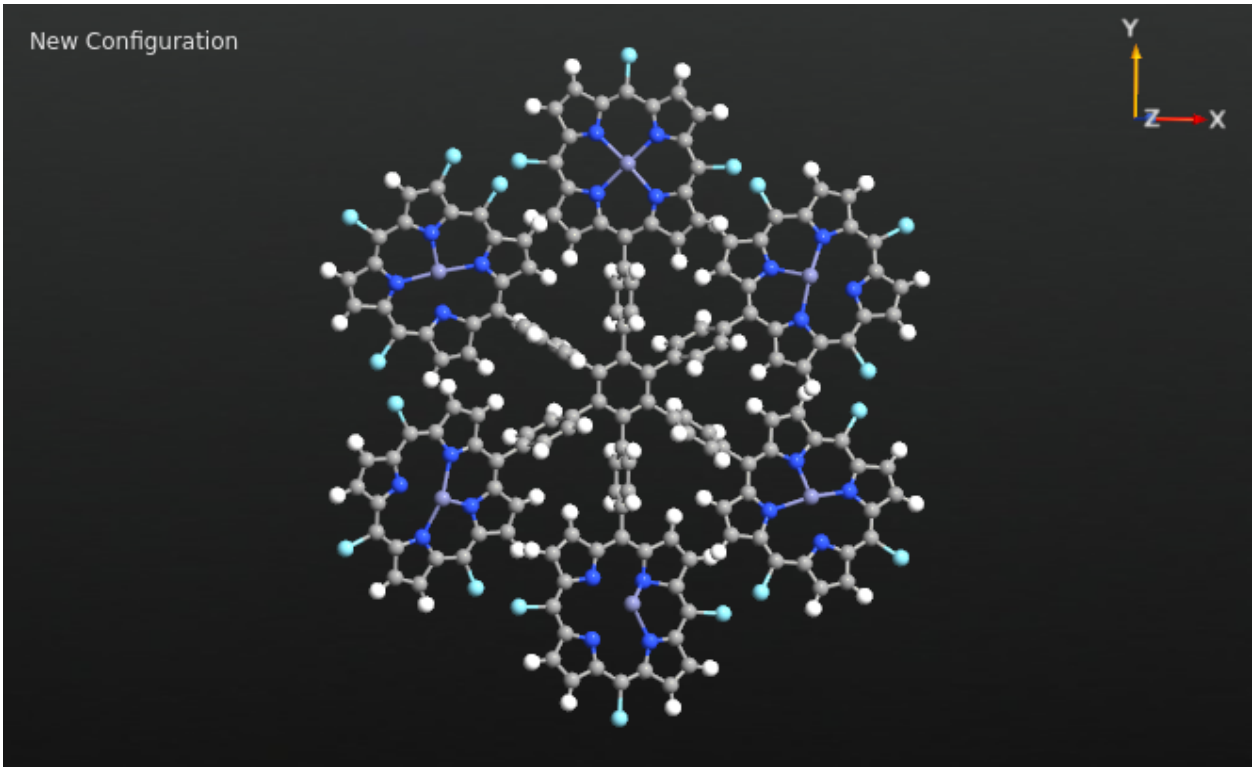
You have built the caffeine molecule! You could also have built it using Indole fragment and making the appropiate

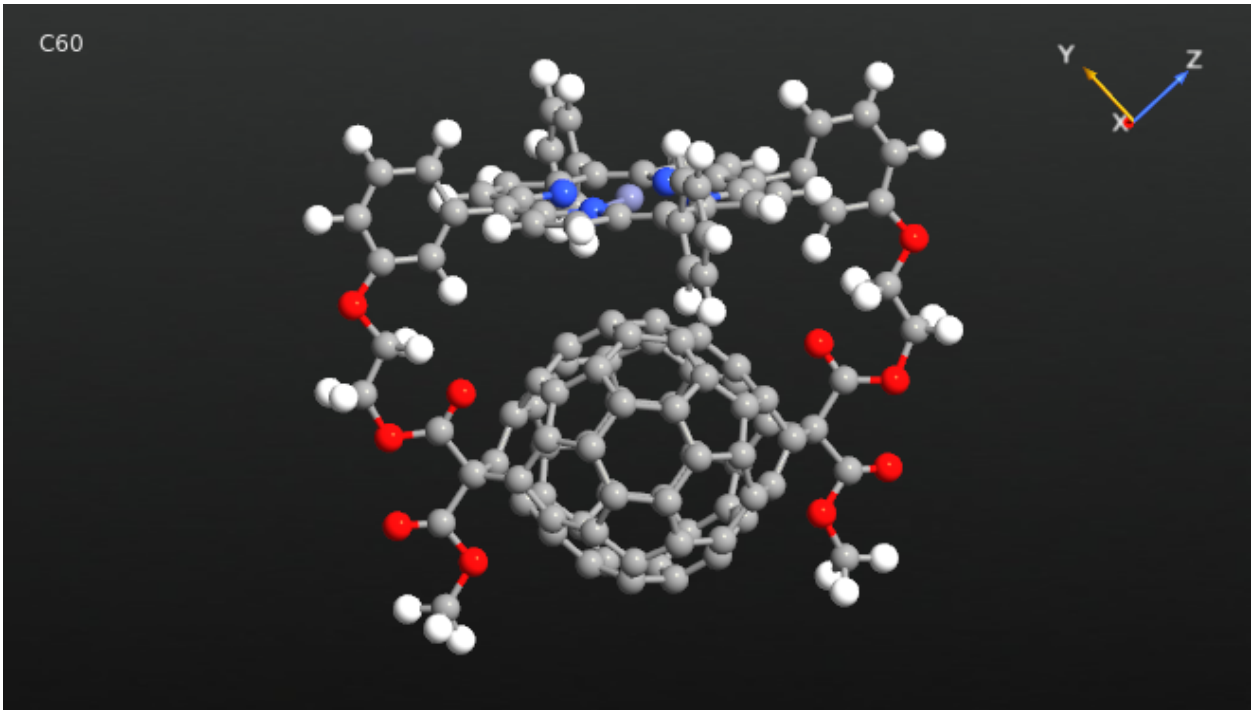
changes in the six- and five-membered rings.

2.10.3 Going further

In this tutorial you have built molecular structures starting from an empty configuration. You can also build a new structure starting from a molecular configuration that you already have or from a configuration imported from the **Database**, using *Add* → *from Database*. You can add as many structures as you want to the Stash. In order to include them in your active configuration, you just need to drag and drop them onto the 3D View.

The next two structures are easily built using the steps outlined above. The first one can be built combining benzene and porphine fragments. For the second, you need to import C60 from the **Database** and then combine it with benzene, porphine, methane and formaldehyde fragments.



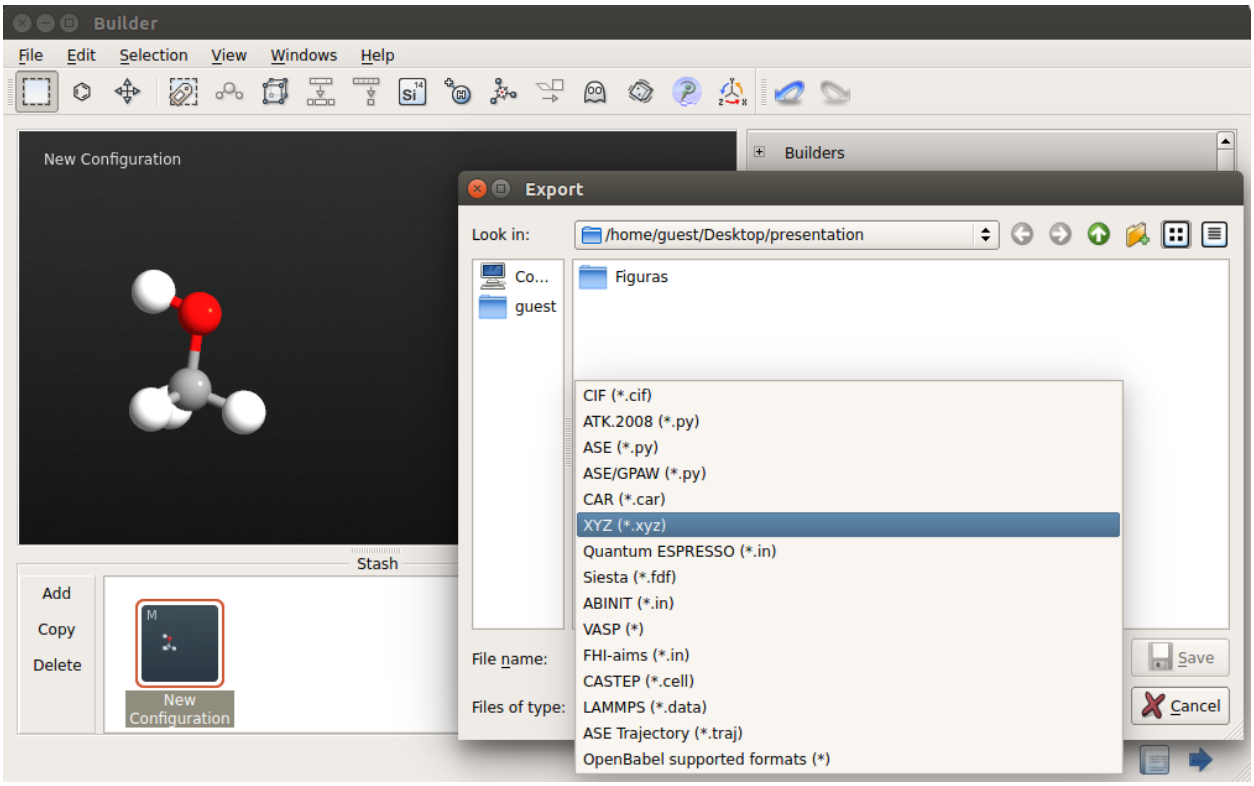


Tip: In order to link a new fragment to a fullerene molecule you will need to change the hybridisation of the carbon atom that will link to the new fragment.

Note: You can click the *Help* button in the Move window to get more details about the Move tool.

2.10.4 Export the Stash Configuration file

Once you have built your molecular structure, you can save it in different formats. You just need to go to *File* → *Export Configuration* as is shown in the next figure.



Please, note that it is also possible to export your configuration to a OpenBabel supported formats.

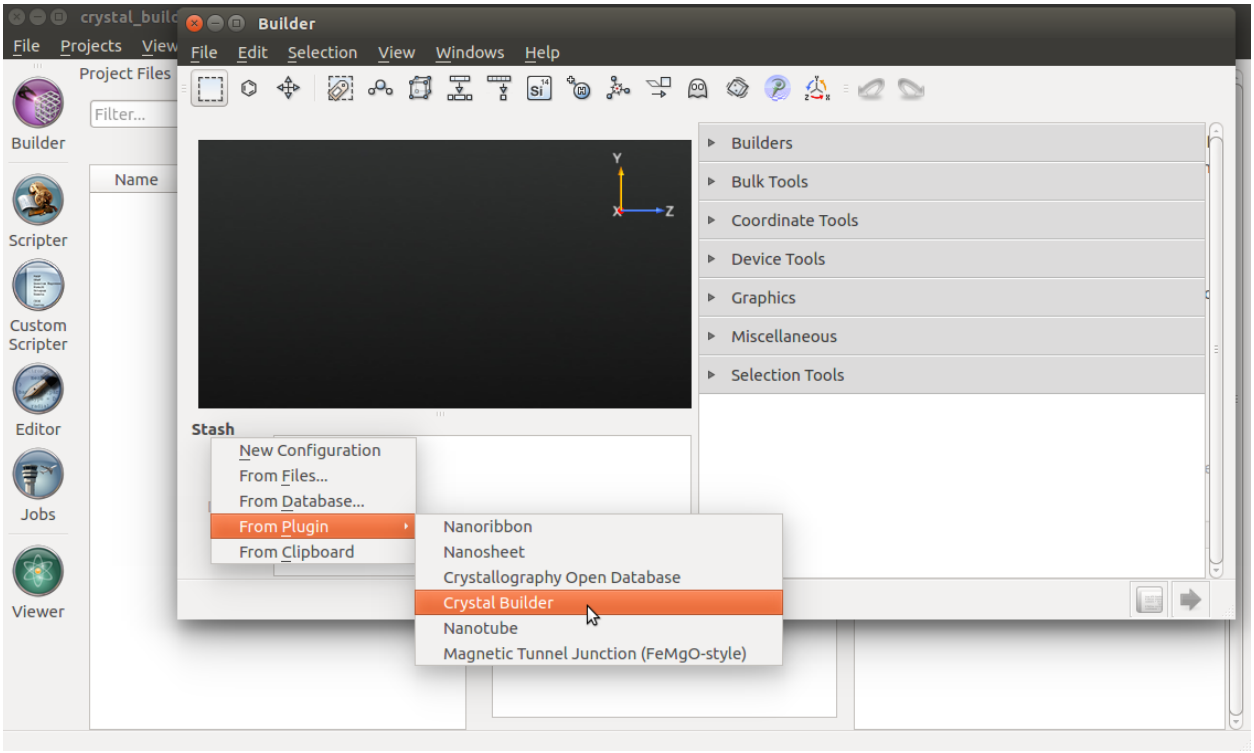
2.11 Using the Crystal Builder

Version: 2016.0

2.11.1 Introduction

QuantumATK has a tool, **Crystal Builder**, which makes it easy to create crystal structures by specifying parameters for the lattice and atom coordinates. The tool is a plugin for the QuantumATK **Builder** and can be found under

Add → *From Plugin* → *Crystal Builder*.



2.11.2 Crystal structure of black phosphorus

As an example, this tutorial focuses on phosphorene (a monolayer of black phosphorus), which is attracting attention in electronics due to its analogy with graphene (see chemistryworld and, e.g., Refs.[1],[2], and[3].)

The table below lists the relevant information about the black phosphorus crystal[4]; space group and lattice constants, and Wyckoff positions for the phosphorus atoms. Based on that information, we first construct the bulk crystal, from which phosphorene is then created.

Space group	*C m c a* (#64)
a	3.3136 Å
b	10.478 Å
c	4.3763 Å
Atom positions	
P	8f: (0, 0.10168, 0.08056)

Hint: Basics of Crystallography

•There are in total 230 space groups, which are enumerated and symbolized in crystallography. In Hermann–Mauguin notation, the 64th group is represented by *C m c a* (a new notation *C m c e* is also used). See, e.g., Ref.[5] for more

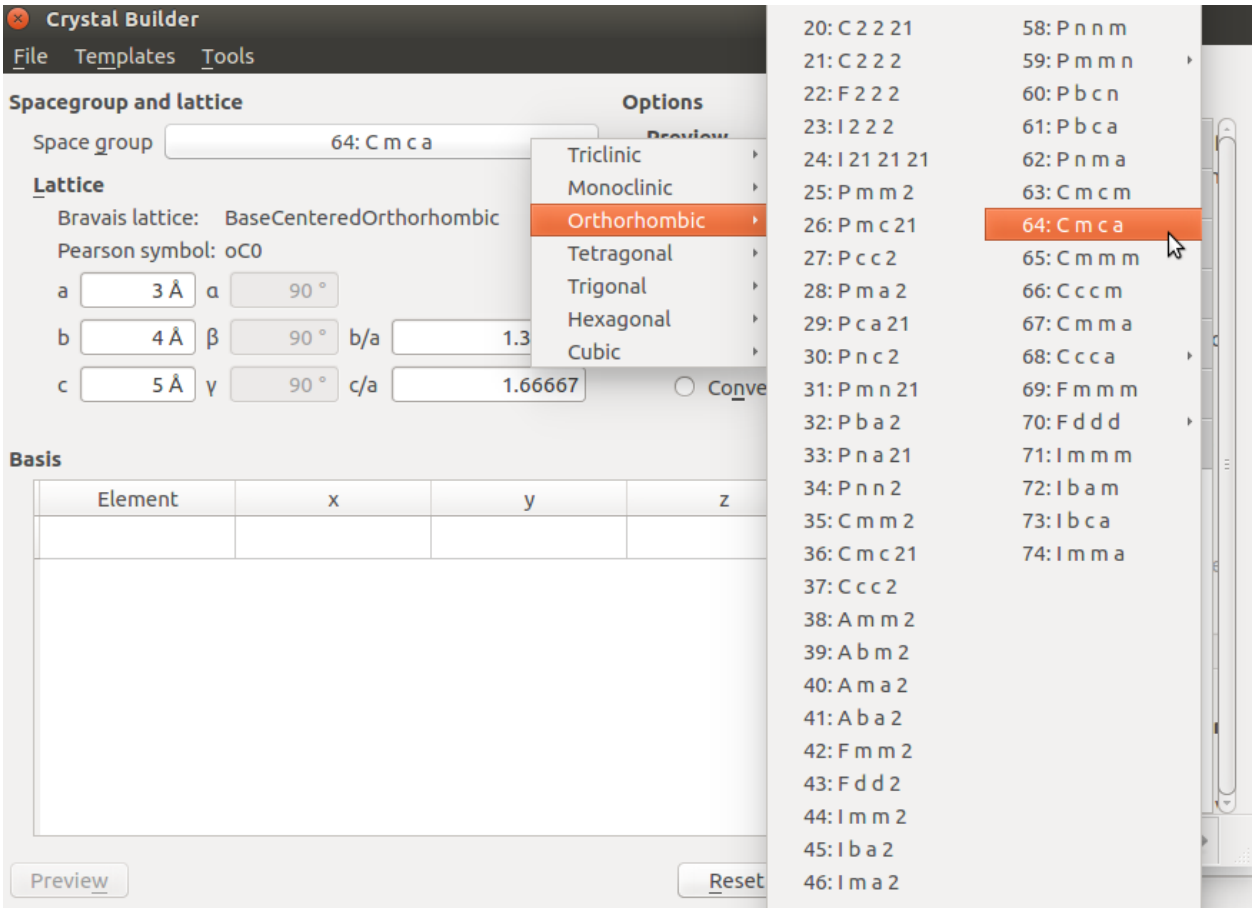
details.

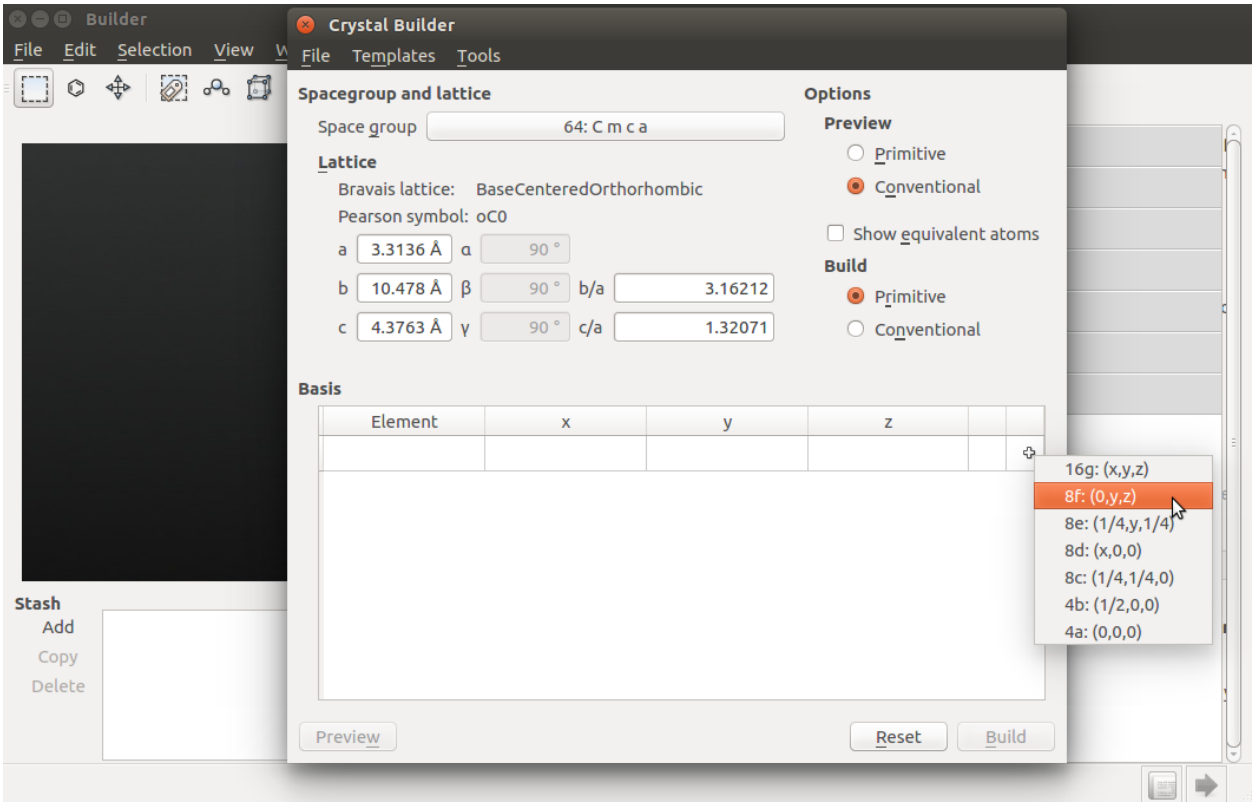
- Wyckoff positions indicate the positions that atoms are allowed to occupy in a lattice belonging to a particular space group. These are specified in fractional coordinates, e.g., (0, 0.10168, 0.08056) in the case of black phosphorus. For each space group, the Wyckoff positions are confined to certain areas in the lattice, e.g., only on the yz-plance in the case of black phosphorus, so as to give all lattice points which are transformed from one another by the symmetry operations belonging to the group.
- Wyckoff positions are denoted according to multiplicity (number of equivalent atoms in a unit cell) and Wyckoff letter (defined for each Bravais lattice). In the case of black phosphorus, the multiplicity is 8 and the Wyckoff letter is f.

Attention: The information given in the table above is enough to fully define the black phosphorus crystal. Inserting P atoms in the Wyckoff position 8f of the lattice with space group #64 yields the black phosphorus crystal.

Let us now build the bulk configuration. First, open the **Crystal Builder** plugin, and select space group 64: C m c a, which is orthorhombic:

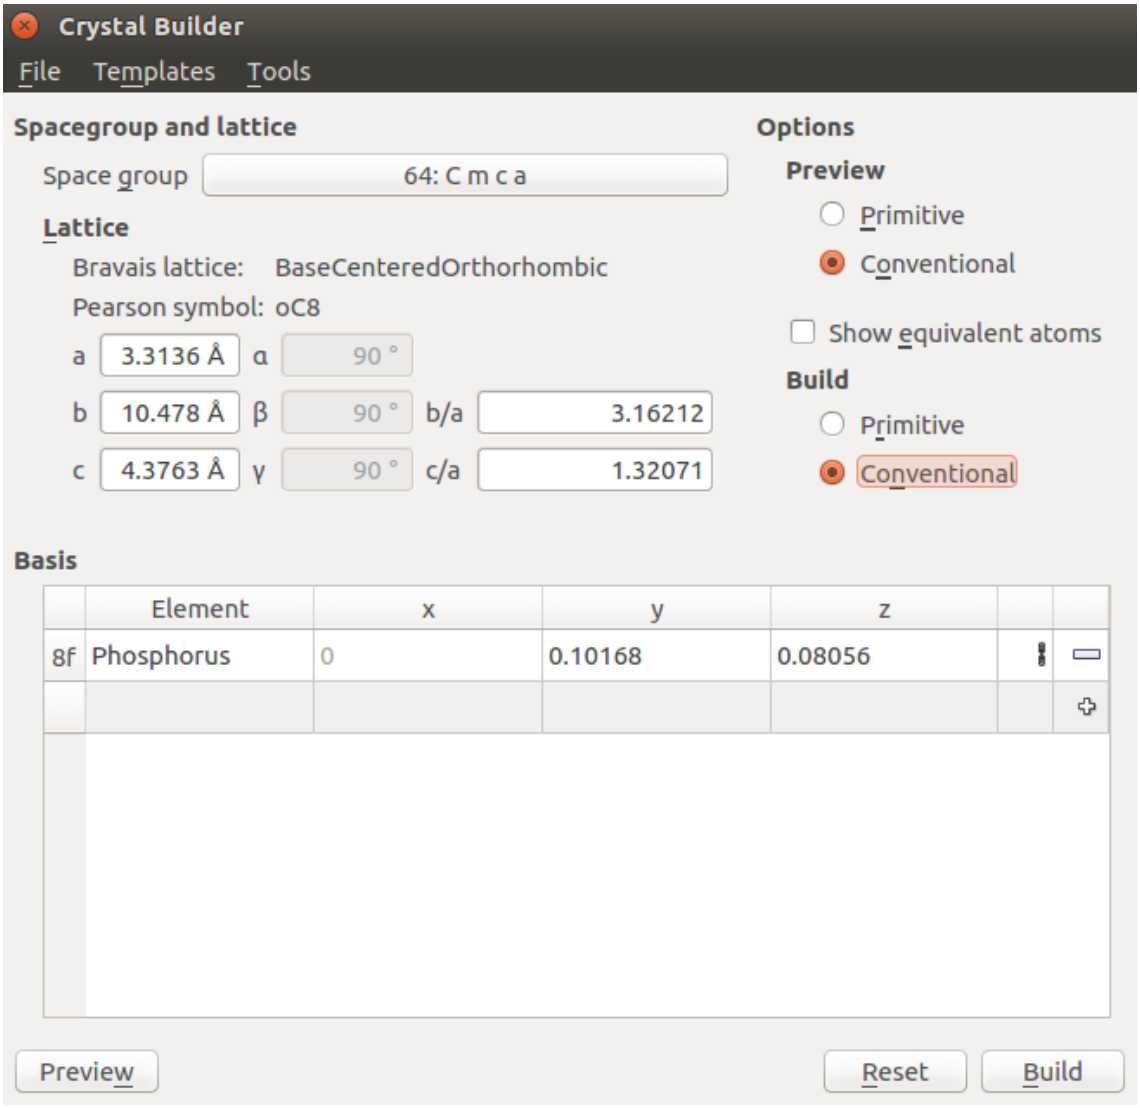


Then insert the a, b and c lattice parameters as listed in the table above, and click the + button to add one atom at the Wyckoff position *8f: (0,y,z)*.

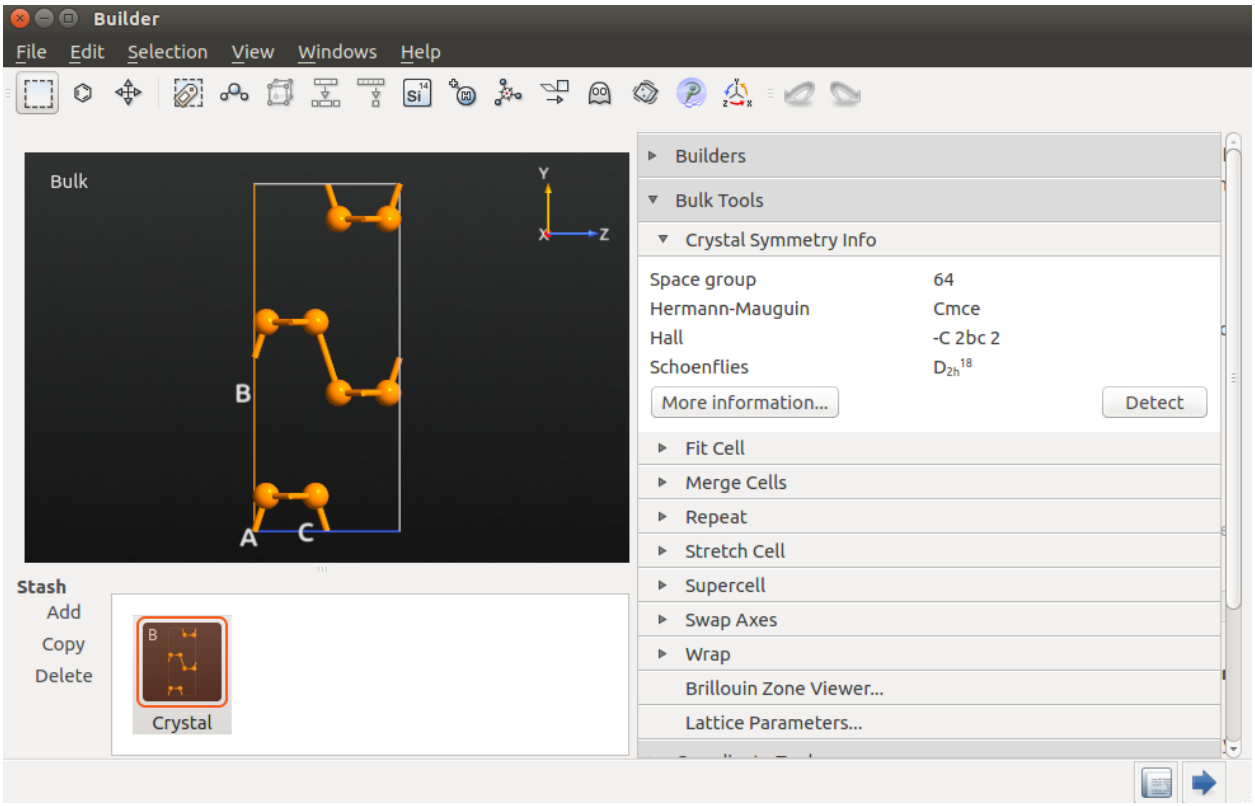


Change the newly added element from hydrogen to phosphorus, and change its y and z positions according to the table above, y=0.10168, z=0.08056 (fractional coordinates). While making these operations, you will see a preview of the structure in the Builder main window.

By default, the Crystal Builder will preview the *conventional* unit cell, but actually build the *primitive* cell. This usually has computational advantages, but in this case the conventional cell is more convenient for the subsequent manipulations needed to prepare the monolayer. Therefore, choose the conventional cell and click **Build** to create your structure.



The black phosphorus crystal is added to the Stash in the Builder, and is ready for further manipulations. Before moving on, open *Bulk Tools* → *Crystal Symmetry Info* and check the symmetry to make sure that the system is truly black phosphorus.



Tip: You can do **3D** rotations and **2D** rotations of any configuration: Simply **click and hold down the right mouse-button** and move the cursor.

•Moving the cursor **inside the Viewer window** gives you **3D** rotations.

•Moving the cursor **outside the Viewer window** gives you **2D** rotations.

•Also note that the cursor changes when you are in rotate mode:

2.11.3 Phosphorene and its bandstructure

One very interesting feature of black phosphorus is the interesting electronic properties when the material is two-dimensional. The name phosphorene was introduced by Liu *et al.* for such a 2D p-type material[Page 277, 1].

Now that you have created black phosphorus, you can easily exfoliate that bulk structure, create phosphorene, and then analyze its electronic properties.

You can find many tutorials on how to use the Builder to create and modify your system and running QuantumATK calculations. Below is a brief example of what you can do with phosphorene – the results can be compared with Ref.[Page 277, 1].

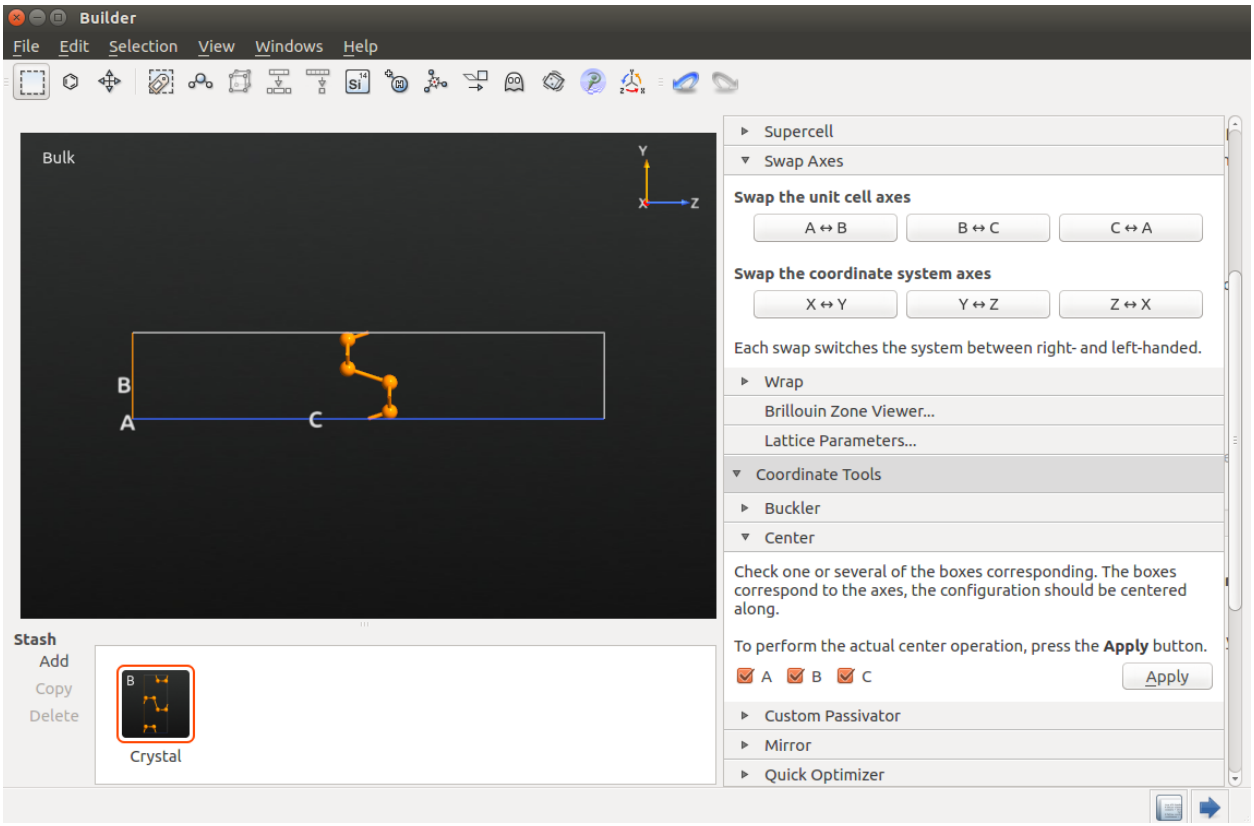
The image below shows phosphorene, created in the QuantumATK Builder by following these steps:

1. Open the *Bulk Tools* → *Swap Axes* tool and click B-C and Y-Z in order to align the phosphorene plane perpendicular to the C axis.
2. The lattice type has now been reset. You therefore need to open *Bulk Tools* → *Lattice Parameters* and select *Simple Orthorhombic* as the lattice type.

3.Delete four P atoms such that you have a monolayer.

4.Open again the *Bulk Tools* → *Lattice Parameters* tool and increase the C vector length to 24 Å. This adds a vacuum region along the non-periodic C-direction.

5.Finally, use the *Coordinate Tools* → *Center* tool to center the configuration in the unit cell.



Hint: Meanings of these manipulations

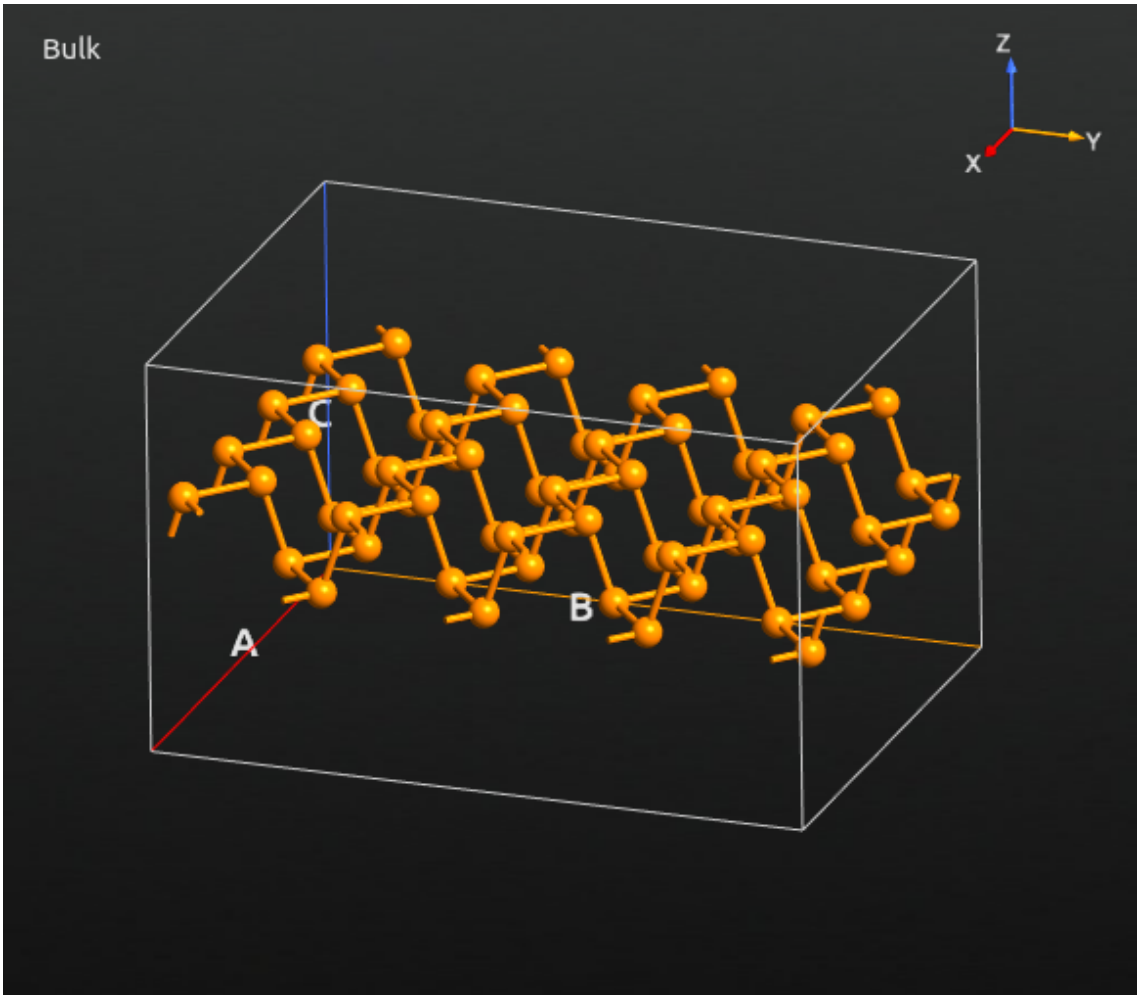
•Manipulation 1 sets each layer to be normal to the z axis, and the zigzag and armchair directions to be parallel to the x and y axes, respectively.

•Manipulation 3 ensures that each conventional unit cell contains a monolayer.

•Manipulation 4 then increases the distance to the repeated images of the monolayer along the C-direction, such that they are electronically decoupled. The configuration thereby represents a true monolayer.

•The snapshot below shows the monolayer obtained after manipulations 1–5 (the structure is repeated 3 times along A and B in order to clearly visualize the monolayer).

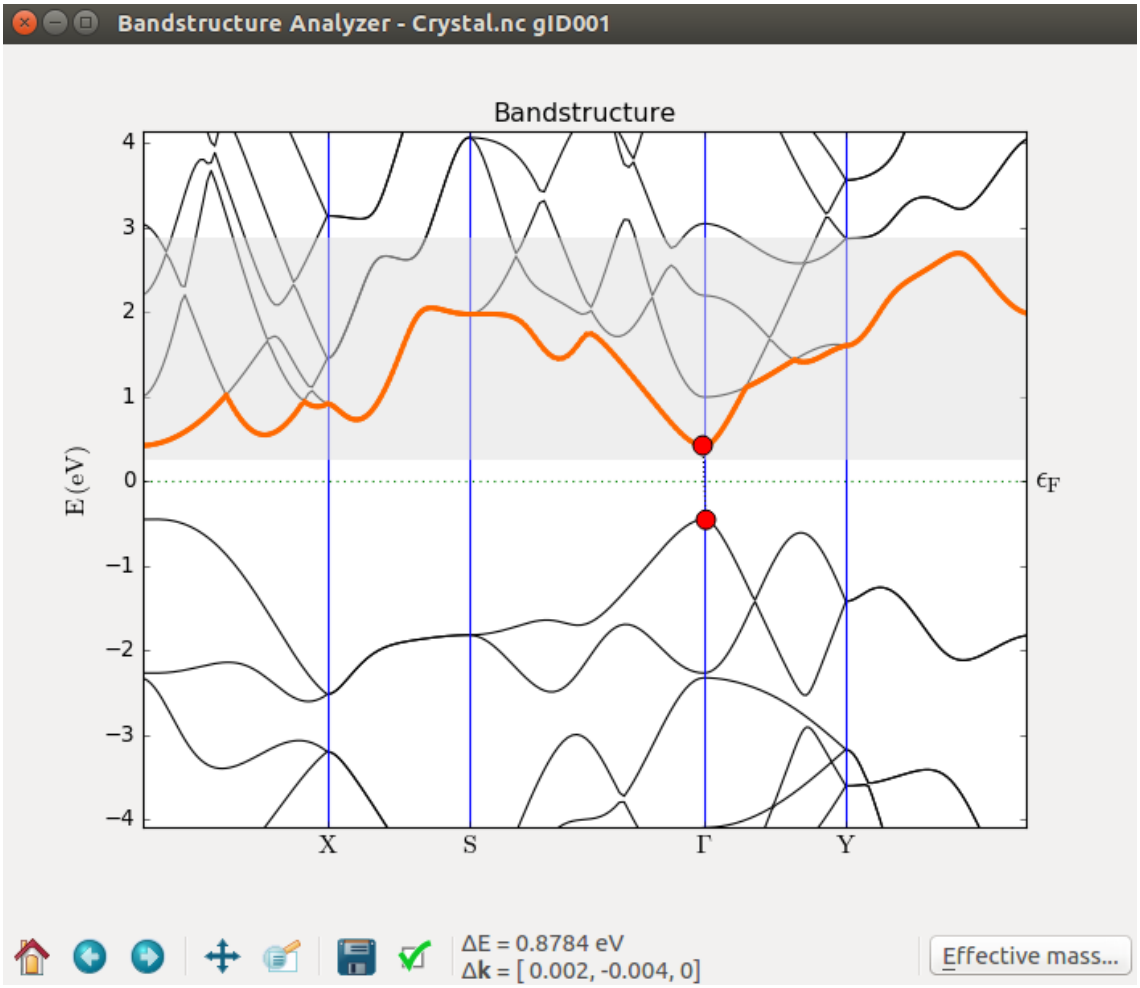
•The definition of the first Brillouin zone of the monolayer depends on the orientation of the unit cell in real space (ABC with respect to XYZ), as well as the orientation of the atoms in the cell (atom positions with respect to ABC). Manipulations 1–5 provide the same orientations as in Refs.[Page 277, 1] and[Page 277, 2], and therefore the same first Brillouin zone as in those references.



Note: You can export this configuration to a CIF file. Once you have the configuration in the **Builder** Stash, you can use the *File* → *Export Configuration* menu or simply right-click the configuration.

Bandstructure

Finally, calculate the bandstructure of phosphorene along the X–S–G–Y Brillouin zone path. The band structure along this path is shown in Refs.[Page 277, 1] and[Page 277, 2]. You should find a band gap of about 0.87 eV, in agreement with the results in these references.



The following ATK-DFT calculator parameters have been used:

•PBE exchange-correlation functional.

•Norm-conserving FHI pseudopotential.

•*DoubleZetaPolarized* basis set.

•90 Hartree density mesh cutoff energy.

•8x8x1 k-point sampling grid.

2.11.4 References

2.12 The Builder Console

The Builder Console is an expert tool in the Nanolab Builder, where you can manipulate the Builder configurations using QuantumATK scripting.

Also, Builder Plugins can expose QuantumATK commands in the console. When plugins write to the console, a visual counter is shown over the console icon.

Unfold the console by clicking the console icon in the bottom left corner of the Builder.

•*Special variables*

–*The active configuration*

–*The selected atoms*

–*The active camera*

–*The Builder Stash*

•*Console Snippets*

•*The console in Builder plugin development*

•*Questions*

2.12.1 Special variables

You can execute any valid QuantumATK command through the console. In addition the console also exposes four magic variables, which allow you to interact with the configurations in the Builder.

The active configuration

The special `configuration` variable always refers to the active configuration in the 3D window. If the current configuration is methane or CH_4, you can use QuantumATK to perform operaitons such as querying the elements list:

```
In [-]: configuration.symbols()
Out[-]: ['C', 'H', 'H', 'H']
```

You can also manipulate the current configuration, using the exposed methods:

```
In [-]: configuration.deleteAtoms([1, 2])
In [-]: configuration.shiftAtoms([0, 0, 1] * Angstrom, indices=[0, 1, 2, 3])
In [-]: configuration.findBonds()
```

Read more about the exposed methods by consulting *MoleculeConfiguration*, *BulkConfiguration*, *SurfaceConfiguration*, *DeviceConfiguration*, *NudgedElasticBand* in the reference manual.

You can also replace the current configuration by assigning to the `configuration` variable:

```
In [-]: configuration = repeat(configuration, 2, 2, 2)
In [-]: configuration = MoleculeConfiguration([Oxygen, Oxygen],
                                              [[0, 0,     0] * Angstrom,
                                               [0, 0, 1.208] * Angstrom])
```

In the Builder Console the configurations also expose their title. This is special for the Builder Console, and cannot be used in other QuantumATK scripts.

```
In [-]: configuration.title()
Out[-]: 'Methane'
```

The selected atoms

The special `selection` variable contains a list of the selected indices of the active configuration.

```
In [-]: selection
Out[-]: array([1, 2])
```

You can change the current selection by setting the selection like this:

```
In [-]: selection = [0, 1, 2, 3]
```

Note that the first element is numbered 0, the second 1 and so on. You can also select All or None of the atoms.

```
In [-]: selection = All
In [-]: selection = None
```

The active camera

The special `camera` variable allows for the manipulation of the current 3D window camera. Center the camera on the configuration, by calling:

```
In [-]: camera.center()
```

The Builder Stash

The list of configurations in the left side of the Builder is called the Builder Stash, and the console has a special `stash` variable that refers to this list of configurations.

Simply retrieve configurations in the stash by referring to their index or title:

```
In [-]: stash[0]
In [-]: stash['GaAs']
```

The latter only works if there is only one configuration titled GaAs. Note that the first element is numbered 0, the second 1 and so on.

Configurations in the stash can be overwritten by assigning different configuration, for example:

```
In [-]: stash['GaAs'] = MoleculeConfiguration([Oxygen, Oxygen],
                                              [[0, 0,   0  ],
                                               [0, 0, 1.208]] * Angstrom)
```

In the stash you can also query both for title and index:

```
In [-]: stash.title(0):
Out[-]: 'GaAs'
In [-]: stash.index('GaAs')
Out[-]: 0
```

The titles of the stash items can also be changed:

```
In [-]: stash.setTitle('GaAs', 'GalliumArsenide')
```

Configurations can be added to and deleted from `stash` by using the methods `insert`, `append`, `duplicate` and `delete`:

```
In [-]: stash.insert(2, new_configuration)  # Or using the title stash.insert('GaAs', new_
↪configuration)
In [-]: stash.append(new_configuration)
In [-]: stash.duplicate(2)                  # Or using the title stash.duplicate('GaAs')
In [-]: stash.delete(2)                     # Or using the title stash.delete('GaAs')
```

You can also switch to another active configuration. This will also update the special `configuration` variable.

```
In [-]: stash.activate(index)
```

The stash also supports iteration,

```
In [-]: for c in stash:
      :     print(c.title())
Out[-]: Methane
      : SiC
      : SiC [111]
```

You can also access the currently selected entries in the stash. Select multiple items by clicking on configurations in the Builder Stash with your mouse. Then call the `stash.selected()` method to retrieve a list of the selected configurations.

```
In [-]: stash.selected()
Out[-]: [Configuration(), ..., Configuration()]
```

An iterating over the selected titles and e.g. centering their camera.

```
In [-]: for item in stash.selected():
      :     stash.activate(item.title())
      :     camera.center()
```

2.12.2 Console Snippets

Sometimes you may wish to execute same set of commands in the Builder Console several times over. The Console snippets help you do just that without having to bother with copy-pasting preformatted commands.

Unfold the console and access the snippets by clicking on the button to the top-right of the console. The first time you do this, the following menu opens:

•configuration_info

•stash_info

•New snippet

•Open snippets folder

The first two entries are example snippets that ship with QuantumATK. Each snippet show a simple example that uses the `configuration` and the `stash` variable respectively.

Click a snippet to insert it into the console. You can also insert and execute the snippet by clicking the running man icon, or open the snippet in the snippet editor by clicking the pencil icon.

New snippets are created by clicking the `New snippet` menu entry. This opens the Snippet editor, where you can rename, edit, delete and execute (run) the snippet in the Builder Console.

Since snippets are just python scripts, they are saved in the *~/.vnl/buillder/console* subfolder. You can open the folder by clicking `Open snippets folder`.

2.12.3 The console in Builder plugin development

Note: This section discusses the development of **BuilderToolBarPlugins** or **BuilderPanelPlugins**, and only relevant if you wish to develop your own plugins.

Builder plugin developers can insert and execute commands in the Builder console.

Several native plugins already expose their QuantumATK commands in the Console. Try using either the **Repeat**, **Center** or **Passivate** Builder plugins to see how it works.

Builder plugins (`BuilderToolBarPlugin` and `BuilderPanelPlugin`) are passed a reference to the Console object in their constructor, and can access it through the `plugin.console()` method.

The Console object exposes the following API:

```
console.execute(script)
```

This writes the script to the console and executes it afterwards.

For advanced users it is also possible to append a script to the console history, and insert additional parameters into the console scope.

```
console.append(script, parameters=None)
```

The `parameters` keyword must contain a dictionary with the defined variables and their values. Note that it is not possible to overwrite the special variables, `configuration`, `selection`, `camera` and `stash`.

It is also possible to simply insert a script into the console without executing it. This can be done by invoking the `write` method on the console object.

```
console.write(script)
```

2.12.4 Questions

Do not hesitate to write questions or comments about the Builder console in the QuantumATK User Forum

2.13 AddOns

2.13.1 Creating AddOns

If you want to create an addon we strongly recommend to read the relevant tutorial: *AddOns*. There is no special restriction for addon creation in general. The Synopsys QuantumATK Team creates addons that ship with the software, but any other QuantumATK user has the option to create addons either for personal use or for wider usage (expanding QuantumATKs capabilities) after Synopsyss consent. For more details read `<installation_path>/atkpython/lib/python3.11/site-packages/AddOns/LICENSE` on Linux installations, or `<installation_path>atkpythonLibsite-packagesAddOnsLICENSE` on Windows. Also you can get more details in the above-mentioned tutorial. The tutorial just gives the general framework through some examples since, obviously, the design of an addon depends on its purpose.

2.13.2 Disabling or Uninstalling AddOns

Its quite simple! Just open the (Help >) **AddOn Manager**, choose the addon(s) you want and click the **Uninstall** button. When restarting QuantumATK these addons will have been removed.

2.13.3 Getting Addons

Some (necessary) addons are installed alongside with the QuantumATK installation on your system. Read more in section *Managing plugins using the AddOn Manager* about getting additional addons.

2.13.4 Installing AddOn

Usually, the addon installation is a straightforward operation to perform. However, you must take into account the kind of user who is using QuantumATK. Namely, there are two different kinds of users:

- **Limited access users**: They can use QuantumATK but cannot modify the installation, which is in control of a system administrator.
- **Administrators**: They have a local installation on their systems where they are local administrators, they can install and uninstall QuantumATK (or other software) themselves.

Install AddOns as limited access users

While local administrators can just run QuantumATK with admin rights and install addons, limited access users have to take an additional step since they cannot write to the main installation folder. In the *Preferences* dialog of QuantumATK, one can find the option to install addons in a separate folder, which is located in the user profile directory. After enabling this option any user can install additional addons.

Installing AddOns on the local system

We distinguish the following cases:

A. Install official addons. In this case just follow these steps (assuming you have internet connection):

- **Step 1:** Open QuantumATK and click the Help button on the toolbar.
- **Step 2:** Choose AddOn Manager - a window pops up (see above).
- **Step 3:** Choose the addon you want (directly or using the search box).
- **Step 4:** Restart QuantumATK to activate the new add-on.

B. Ready to install zip file. In this case we assume that you have already the zip folder of the addon (downloaded from our website or elsewhere) somewhere on your system and would like to install it (no internet connection is required).

- **Step 1:** Open QuantumATK and click the Help button on the toolbar.
- **Step 2:** Choose AddOn Manager - a window pops up.
- **Step 3:** Click the button Install zip/folder.
- **Step 4:** Navigate to the downloaded zip file and install it.
- **Step 5:** Restart QuantumATK to activate the new add-on.

2.13.5 Failing AddOn Installation

There are many possible reasons for this. The most common problems come usually from the following facts:

•Incorrect addon design.

•Problems with your internet connection.

•Some dependencies are missing on your system (a.e. the addon calls external binaries).

•Insufficient permission, see *Install AddOns as limited access users*.

In any case we strongly suggest to open QuantumATK from a command-line terminal in order to see the error messages in detail.

2.13.6 AddOns Location

All the addons which are installed system-wide, are located at `<installation_path>/atkpython/lib/python3.11/site-packages/AddOns` on Linux and `<installation_path>atkpythonLibsite-packagesAddOns` on Windows. If the user has enabled the option to install addons in the user profile directory, the newly installed addons will be located at `<user_profile_dir>/.quantumatk/<quantumatk_version>/AddOns`.

2.13.7 Updating AddOns

In the (Help >) **AddOns Manager** window click the **Refresh** button to make sure the *Installed* and *Latest* versions showed in the table are up to date. Then select an AddOn and click the **Update** button, or the **Update All** button to execute it on all AddOns. Then restart QuantumATK to make sure all changes are applied.

2.13.8 What Is an AddOn

An addon is a code unit that can be added to QuantumATK in order to increases and enhances its capabilities. The addons of QuantumATK are python (.py) files zipped (.zip) into unified bundles. You can find more details at *AddOns*.

2.13.9 Check Installed AddOns

You can see the installed addons either through the (Help >) **AddOns Manager** or by checking the *AddOns Location*.

```

In this introductory tutorial, you will learn how to use QuantumATK to

- Train custom MACE machine-learned force-fields (ML FFs) via Python scripts which can be used for molecular dynamics (MD), geometry optimization, and other force-field-based simulations - in this tutorial for crystal and amorphous TiSi and $TiSi_2$ structures.
- Validate the quality of the trained MACE models.
- Load a trained MACE model into QuantumATK in a workflow via the **MachineLearnedForceFieldCalculator** block.

In recent years, advancements have been made in the world of Machine Learned Force Fields (ML-FFs) with the emergence of universal foundation models. One of the current state-of-the-art potential architectures yielding a good trade-off between performance and accuracy is MACE[1] - a message-passing Neural Network (MPNN) from which prominent universal foundation model versions are preinstalled and available for use in QuantumATK. While such universal models can constitute an excellent calculator in its own right, it is trained to perform reasonably well within a very broad domain. This means that it has trained on a large amount of data, and that the model has a size that limits the inference speed. For problems within a limited application domain, it is also possible to train custom MACE models within QuantumATK. MACE models can be trained either from scratch, which can be used to balance model size and simulation speed against accuracy, or by finetuning foundation models to achieve even better accuracy in a specific application domain while building on top of previous knowledge.

The amount of data needed to train a MACE model depends on the complexity of the system and the kind of training being conducted. In general, more data is usually preferred if training from scratch. However, for fine-tuning from a foundation model on the order of 100 structures can be enough to reach good accuracy in a specific domain. In this

[1] Ilyes Batatia, DavidăPeter Kovacs, Gregor N.ăC. Simm, Christoph Ortner, and Gabor Csanyi. MACE: higher order equivariant message passing neural networks for fast and accurate force fields. In AliceăH. Oh, Alekh Agarwal, Danielle Belgrave, and Kyunghyun Cho, editors, *Advances in Neural Information Processing Systems*. 2022. URL: https://openreview.net/forum?id=YPpSngE-ZU.

tutorial, both approaches will be presented using a small dataset containing a mix of 241 crystal and amorphous structures of TiSi and $TiSi_2$. This data was used to train a Moment Tensor Potential in a different *tutorial*. The dataset is available for download: `c-am-TiSi-TrainingSets.hdf5`. It should be noted that this system is chosen for demonstration purposes. For simple systems, the accuracy advantage of MACE over MTP is not significant. Training an MTP model may be the better choice here, due to its advantages in simulation speed. MACE is in general expected to be capable of reaching higher accuracy in complex systems where more traditional ML FFs face limitations.

Note: It is in general advised to do all training of MACE models on GPUs using 1 process per GPU. It is similarly recommended to run inference with trained MACE models on GPUs to utilize the model efficiently. Instructions on how to run on GPUs can be found in the *technical notes*.

In order to train a MACE model, we utilize the *MACEFittingParameters* and *MachineLearnedForceFieldTrainer* objects. The parameters object is used to set up all training parameters, while the trainer object is used to perform the training. In the reference manual, all available parameters are listed and explained. In this tutorial, only a subset of the parameters with high impact on the model training and accuracy are included. When training from scratch, the most important parameters are the maximum L value, which controls the symmetry (equivariance) of the messages sent within the model architecture, the distance cutoff, which controls the cutoff radius up to which the local environment should be encoded for each node, and the number of channels, which controls the number of features the local environment of each node is described by.

Note: In the **Version:** X-2025.06 release, MACE model training modules are only available in scripting. Workflow Block support in the GUI is not yet included.

Training a MACE model from scratch

We first set up a script to train a small MACE model from scratch. The script is available for download: `Train_model_from_scratch.py`. The script first loads the training data to be used for training. It is important that the training data already includes energy, forces, and (if desired) stress labels, as the MACE training framework does not perform these calculations. The data should be stored in one or more *TrainingSet* objects, which are then appended to a single list. Next, the script sets up the calculator to be used for calculating the isolated atom energies for the atom types featured in the training set data. It is important that the calculator is consistent with the precalculated training data. The calculator can either be loaded from a file if saved as part of the preparation of the training data or it can simply be redefined in the training script directly using the same settings.

Thereafter, the script sets up a *MACEFittingParameters* object that defines the model and hyperparameters for the MACE training.

Finally, the script sets up the *MachineLearnedForceFieldTrainer* object that coordinates the other objects and is used to perform the training.

The script trains a single MACE model on 80% of the 241 provided structures and validates the model on the remaining 20% in each training epoch. Various parameters are set to tune the model size, train and inference speed, as well as the accuracy of the model. The 3 most important parameters introduced in the previous section are set to the following values:

- `max_l_equivariance = 0`
- `distance_cutoff = 5.0`
- `number_of_channels = 8`

Here, the `number_of_channels` parameter is set to 8, which is a very low setting. Higher values will be explored in a small screening study for this parameter later in the tutorial.

Here, the `max_l_equivariance` parameter is set to 0, which corresponds to MACE models named or referred to as small or L0 MACE models. Similarly, `max_l_equivariance = 1` corresponds to medium/L1 models and `max_l_equivariance = 2` corresponds to large/L2 models. This is the parameter that influences computational speed and accuracy of a model the most.

The remaining parameters in the script are accompanied by short explanatory comments in the script. Additional parameters exist and are described in the *MACEFittingParameters* reference manual.

The main role of the *MachineLearnedForceFieldTrainer* object is to coordinate the training process. It takes as input the training data, the calculator, and the fitting parameters. Additionally, it takes care of creating the train-test split if desired. For MACE training it is not required to have a test set. A test set can be used to calculated RMSE values for the energies, forces, and stress on data that has never been seen before at the end of the training. This is therefore different from the validation set, which is created by taking a fraction (editable in the *MACEFittingParameters*) of the training data and using it to validate the model during training. By default, the validation set is 20% of the training data and the validation is run after each training epoch.

In order to run the training, the script is loaded in the QuantumATK Editor from where a Job can be created and submitted via the Job Tool. Instructions how to run on GPUs can be found in the *technical notes*. Using a single node, with a single MPI process, and a single GPU (Nvidia A100) requested in the Job tool the training script took approximately 9 minutes to run when creating this tutorial.

Before looking into the results of the training it is also presented how finetuning of existing models can be performed.

Naive Finetuning of foundation MACE models

Finetuning a foundation model can improve accuracy of the model for a specific domain while benefitting from the general capabilities of the original model. Due to the nature of finetuning, the architecture of the model is fixed and therefore cannot be changed into a smaller or larger model. The size is tied to the foundation model. Finetuning has the advantage that general interactions between types of atoms are already mapped quite well and that for specific domains at specific levels of theory these interactions only have to be finetuned - not learned from scratch which can be a lengthy process for large amounts of data.

In QuantumATK finetuning is done by setting the `foundation_model_path` parameter in the *MACEFittingParameters* object to the path where the foundation model is located. This model can be any MACE `.model` file trained previously. In this tutorial we will use the `mace-mp-0b3-medium` model[2], one of the most recent, high quality MACE models at the time of the **Version:** X-2025.06 release, available at: mace-mp-0b3-medium.model.

Note: Finetunable foundation models are not included in the QuantumATK installation. Therefore, any universal MACE model to be finetuned must first be downloaded and then provided to the `foundation_model_path` parameter. Due to the size of the file, it may be beneficial to store the model in a location on a cluster and have the *MACEFittingParameters* reference the specific cluster location instead of copying the model from the local machine each time a job referencing the model is submitted.

The training script for finetuning the model with the TiSi and $TiSi_2$ dataset is available for download: `Train_model_with_naive_finetuning.py`. The script is similar to the one used for training from scratch. The main difference is the `foundation_model_path` parameter pointing to the location of the foundation model in the *MACEFittingParameters* object. **When running the script, ensure that the path to the foundation model is updated to the location of the model on your system or the cluster where you will run the training.**

During naive finetuning, the foundation model is trained further on new data for a specified number of epochs. While this can significantly improve accuracy within the new, limited domain, it also carries the risk that some of the general knowledge encoded in the original foundation model may be forgotten. This effect can be more pronounced if the new dataset is very different from the original training data. Attention to final model quality and the number of epochs

[2] Ilyes Batatia, Philipp Benner, Yuan Chiang, AlinăM Elena, DávidăP Kovács, Janosh Riebesell, XavierăR Advincula, Mark Asta, Matthew Avaylon, WilliamăJ Baldwin, and others. A foundation model for atomistic materials chemistry. *arXiv preprint arXiv:2401.00096*, 2023.

to train for is therefore important to balance adaptation to new data with retention of the foundation models broader capabilities.

Using a single node, with a single MPI process, and a single GPU (Nvidia A100) requested in the Job tool the training script took approximately 10 minutes to run when creating this tutorial.

Multihead Finetuning of foundation MACE models

Multihead Finetuning, or Multihead Replay Finetuning, is a more refined approach to finetuning. In this approach, a foundation model also forms the basis of the training. Contrary to the Naive Finetuning approach, not only the foundation model is used, but also the training data used to train the foundation model. In practice this results in a model training on several model heads with separate readout layers but otherwise shared model weights. The first model head is the pretrained model head, which will be retrained on a subset of the original training data. How much of the original training data is used can be customized but by default 10000 original structures are used. The other model head will be the model head for the new training data. During training, non-readout weights are trained on both sets of training data, and therefore the model will better retain knowledge about the original training data. This minimizes the risk of the model straying away from key patterns learned from the original data while still allowing the model to learn from the new training data.

Since the Multihead Finetuning approach requires both a foundation model as well as the original training data, more parameters need to be set in the *MACEFittingParameters* object. In order to activate the Multihead version, the `use_multiheads_finetuning` parameter is activated. Furthermore, the `pretrained_head_train_file` parameter is set in one of two ways. If the original model is not one of the MP MACE models, the parameter is given the path to the original training data (in xyz file format). If the model is one of the MP MACE models, the parameter is simply set to `pretrained_head_train_file='mp'`. In this case, the original training data as well as a descriptors file need to be downloaded and local/cluster paths need to be provided to the script. The data used to train the MACE MP foundation models[Page 293, 23] used in this tutorial is available at:

- https://github.com/ACEsuit/mace-foundations/releases/download/mace_mp_0b/mp_traj_combined.xyz
- https://github.com/ACEsuit/mace-foundations/releases/download/mace_mp_0b/descriptors.npy

These files, if Multihead Finetuning with a MP MACE model, have to be supplied via the `mp_data_path` and `mp_descriptors_path` parameters in the *MACEFittingParameters* object. Furthermore, the `foundation_model_path` parameter has to be set in the same way as for the Naive Finetuning.

The training script for Multihead Finetuning is available for download: `Train_model_with_multihead_finetuning.py`. The script is similar to the one used for training from scratch apart from the extra parameters described. In order to run the script, ensure that the paths to the foundation model, MP data, and the descriptors files are correct and updated to where you put the files on your machine/cluster. It is recommended to store them on the cluster where training will happen to reduce the time it takes to transfer files from the Job Tool upon submission.

Using a single node, with a single MPI process, and a single GPU (Nvidia A100) requested in the Job tool the training script took several hours to run when creating this tutorial. It may be advantageous to not run this script but wait for a multi-GPU version in the beginning of the next section also training this as well as other models in less time.

For any MACE training, the job can be monitored via its log output while running. Here, loss scores and error metrics (RMSE by default) for energy, forces, and stress are reported on the validation set after each epoch. After the end of the training, the error metrics are reported for the best trained model on the train and validation set - as determined by the model with lowest loss score. For the Multihead Finetuning, the loss and error metrics are also reported for the model head retraining on the original data. The `default` model head is associated with the new training data and the `pt_head` model head is associated with the original training data. The `train` and `valid` prefixes indicate whether the metrics are reported for the training or the validation set. As an example of the log output, the following error metrics are obtained as the Multihead Finetuning training script finalizes:

[3] Bowen Deng, Peichen Zhong, KyuJung Jun, Janosh Riebesell, Kevin Han, ChristopherăJ Bartel, and Gerbrand Ceder. Chgnet as a pretrained universal neural network potential for charge-informed atomistic modelling. *Nature Machine Intelligence*, 5(9):1031–1041, 2023.

config_type	RMSE E / meV / atom	RMSE F / meV / A	relative F RMSE %	RMSE Stress (Virials) / meV / A (A^3)
train_default	15.9	94.2	7.94	14.8
train_pt_head	71.2	77.8	5.86	9.2
valid_default	17.3	100.8	9.47	13.1
valid_pt_head	46.2	87.3	4.54	8.5

The RMSE values for the validation set are in general slightly higher than for the training set for the new model head, `_default`. In the `_pt_head` model head, the picture is a little more mixed, but the validation error for the forces, which has the largest weight, is also larger than the training error. This behaviour is expected because the model only updates its parameters based on the training data during the training. The validation set is used for monitoring the model performance during training without impacting the model parameters. The combination of train and validation error metrics indicates the overall magnitude of the model accuracy. A true measure of accuracy on completely unseen data is however necessary in order to truly assess the predictive capabilities of the model. When training a model from scratch or with Naive Finetuning, only two rows of error metrics will be reported since only one model head is trained. For this Multihead Finetuning example, four rows are obtained due to training on two model heads. For most practical purposes, mainly the `_default` head is important to obtain good error metrics for since this is the model head that will automatically be extracted to a `.qatkpt` model file for use in QuantumATK when using Multihead Finetuning.

Small study with additional models trained from scratch

In order to give a slightly more nuanced view of how changing MACE training parameters can affect accuracy and performance of a model trained from scratch, before testing the models on unseen data, a few more models will be trained from scratch with `number_of_channels` varying between 8 and 128 while keeping the `distance_cutoff` of 5 Angstrom and the `max_l_equivariance` of 0 (corresponding to small/L0 MACE models) fixed. This is all done in one training script where the various models defined using *MACEFittingParameters* objects that have been conveniently generated by calling the previous *MACEFittingParameters* object in the training series to copy its settings while only setting the parameters to be updated. In this way we can easily generate new model training parameters with increasing numbers of channels. If the models from the previous sections have not yet been trained, they can also conveniently be generated by use of this last training script, available for download here: `Train_mace_models.py`. Instead of running the training on a single process and a single GPU, we this time utilize that the implementation of MACE training in QuantumATK allows distributed training. By setting the parameter `distributed_training=True`, the training can be run on multiple GPUs (with 1 MPI process per GPU). In order to run the script, ensure that the script is updated with the path to the MACE model file to finetune from as well as the paths to the original training data files.

Tip: If using multiple GPUs it is in general recommended to use the same number of MPI processes and GPUs and no threading. The training should be kept to a single node. Running training in a distributed setup can result in potential error messages not always being easy to interpret/available. If coming across errors in distributed training, it can therefore be helpful to attempt running the training on a single process and GPU to retrieve the underlying error message.

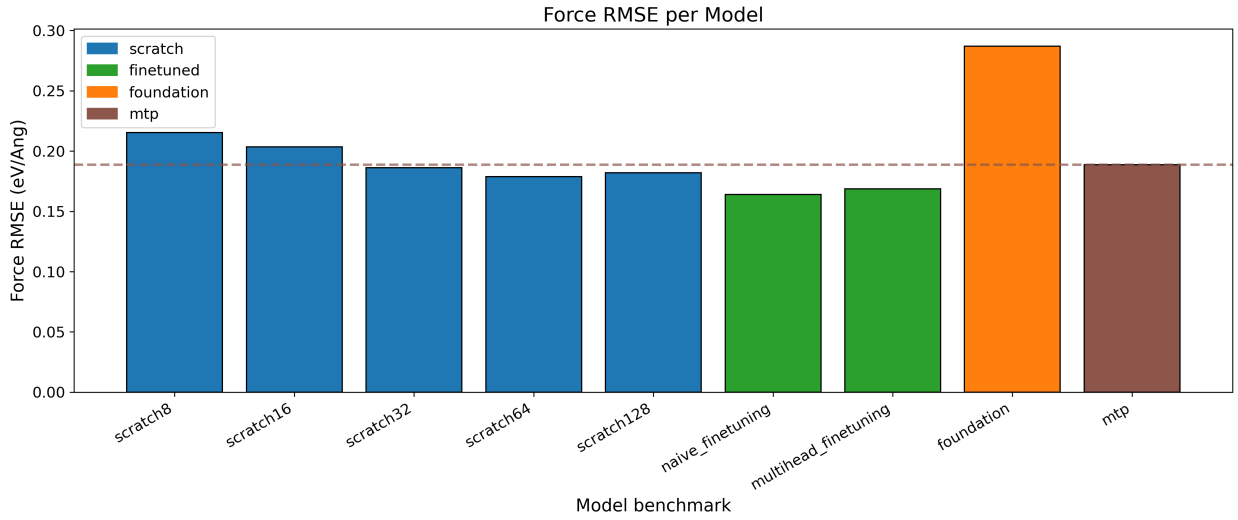
Running the script on 8 MPI processes and 8 GPUs (Nvidia A100), the training of the 7 models took approximately 2 hours in total.

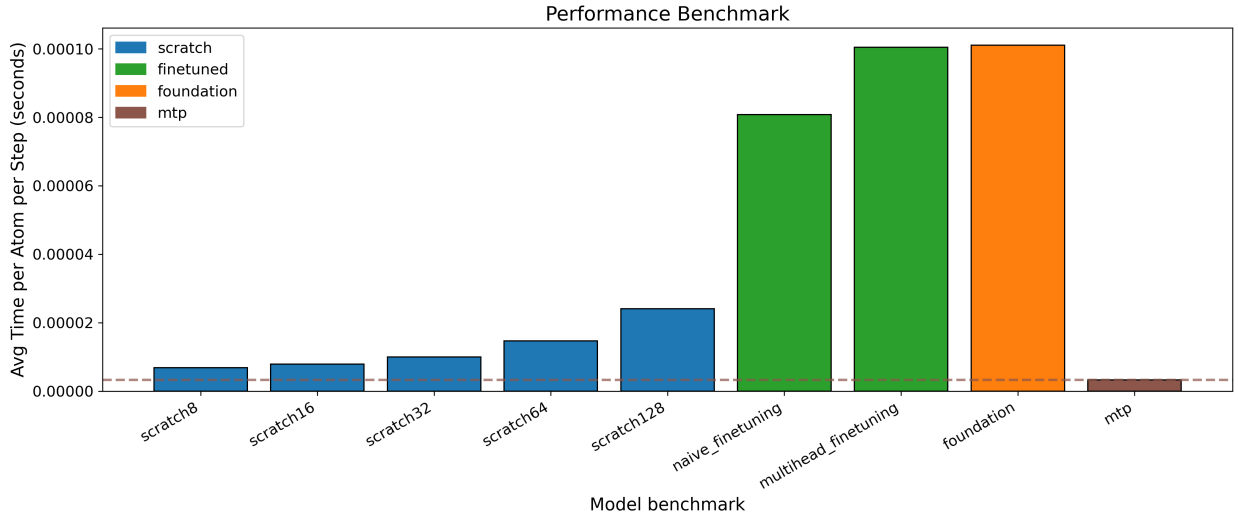
Validation of trained models

With the models trained we can now validate the models by comparing the energies and forces of the MACE models with reference DFT data for unseen data generated with Molecular Dynamics with the reference DFT calculator. This data, containing a mix of crystal and amorphous structures, is stored in the file `md_example_results.hdf5`.

With a different script, `run_benchmarks.py`, we can load the trained models and the reference data to compare the energies and forces of the MACE models with the reference DFT data, as well as run performance benchmarks of an approximately 5000-atom structure for 1000 MD steps. The output of the script is json files containing accuracy RMSE values for the energy and the force predictions as well as the performance benchmark results for the time taken per atom per step in the Molecular Dynamics simulation for each model type. On top of comparing the 7 models trained with scripts in the tutorial, benchmarks for the foundation model - included as the `TorchX_MACE_MP_0b3_medium` potential set in the **Version:** X-2025.06 release - and the MTP - trained in the related MTP *tutorial* using the same training data - are also included in the benchmarks to increase the amount of insight gained. The benchmarking script was run using a single node, with a single MPI process, and a single GPU (Nvidia A100).

The results of the benchmarks in the json files are shown in the figures below.





The two plots above provide a comparison of the different MACE models trained from scratch, the finetuned models, the foundation model, and the MTP model. The forces RMSE plot show that increasing the number of channels in the

MACE models trained from scratch leads to a consistent improvement in accuracy. Based on this plot, it is evident that the finetuned MACE models are the best performing models achieving higher accuracies than the MTP, the foundation model, and the models trained from scratch.

Note that the obtaiend accuracy (for both energy and other predicted quantities) can fluctuate depending on the initial weights. In this tutorial each model was only trained once, with a given random seed, and therefore the accuracy of the models is not guaranteed to be the best possible. In a more systematic study, one might want to run several training runs with different initial weights (by setting another `random_seed` in *MACEFittingParameters*) in order to increase the likelihood of the best possible model being created.

For a brief comparison between the train/validation errors and the test errors, we will swiftly zoom in on the forces error metrics (which have the highest weight - and therefore importance - in the loss function) of the multihead finetuned model metrics. In the error metrics table from the output log in the **Multihead Finetuning of foundation MACE models** section, the train and validation errors for the forces are 94.2 meV/Å and 100.8 meV/Å, respectively. The test error for the multihead finetuned model in the plot above is 168.6 meV/Å. This indicates that the model generalizes reasonably well to unseen data, but with a somewhat lower actual accuracy than reported on the train/validation set. The more training data is included, the more likely it is that the model will generalize well to unseen data. Similarly, the more diverse training data included, the higher the accuracy of the model is likely to become across all error metrics.

Models with higher numbers of channels (and in the case of the finetuned models which have 128 channels and a `max_l_equivariance` setting of 1 corresponding to a medium/L1 level model) achieve lower RMSE values for forces, indicating better agreement with the reference DFT data. However, this improvement comes at the cost of increased model size and slower inference, as also summarized in the performance benchmark plot where the small models trained from scratch make predictions almost as fast as the MTP while the medium sized finetuned and foundation models are orders of magnitude slower.

Focusing specifically on the two finetuned models, it is evident that the naively finetuned model is slightly faster and about as accurate as the multihead finetuned model. The speed difference comes down to the fact that the naive model only contains atom type encodings for the Ti and Si atoms. Due to not being able to find 10000 configurations to replay training with from the original training data, the multihead training included some additional atom types in the training data. Therefore, the model contains more parameters to handle additional atom types which leads to a slightly larger and slower model. As evident from the forces RMSE plot, the finetuned models are likely to perform better than models trained from scratch when trained only on a limited amount of data. The more data included in the training, the higher the likelihood will be to train models from scratch that can learn the underlying physical interactions as well as, or even better than, the finetuned versions. For large data sets, it is often an option worth exploring since, if the accuracy of the models can achieve the same levels as the finetuned models, it might just be possible to train an accurate and small (`max_l_equivariance=0`) model that is faster than models finetuned from foundation models. Due to the lower amount of training data needed and the fact that the nature of the physical interactions, to a large degree, have already been learned by the foundation models, finetuning is however often a more practical path to go to ensure creation of accurate models if performance is not of critical importance.

Since this tutorial is mainly aimed at being an introduction as to how to train MACE models in various ways, no detailed parameter study has been carried out. Similarly, it has not been ensured that models have converged. In order to conduct training with a high probability of convergence to occur, see the **General remarks** section.

Impact of important parameters

The following table summarizes the impact of key parameters on model size, inference time, and accuracy when training from scratch as well as the pros and cons of finetuning.

Parameter / Model setting	Model Size and Memory	Inference Time	Accuracy
Increasing max_l_equivariance	Higher values significantly increase model size.	Increases (can be much slower for higher values).	Generally higher, especially for complex systems. For simple systems, gains may be limited.
Increasing distance_cutoff	Increases the required amount of memory.	Increases exponentially as the local environments include more neighbour atoms.	Improves accuracy for systems with long-range interactions. For short-range systems, smaller cutoffs may suffice.
Increasing number_of_channels	More channels increase model size linearly.	Increases, but less dramatically than max_l_equivariance.	Higher number of channels generally improves accuracy, especially for forces. Diminishing returns for very high values.
Finetuning foundation models	Fixed to model architecture of foundation model used.	Similar to foundation model used.	Typically improves accuracy over training from scratch, especially with limited data.

Based on these considerations, the following general recommendations stand if choosing to train a MACE model from scratch. Note that a requirement for reaching a good model is that sufficient amounts of diverse training data is available.

- `max_l_equivariance`: Typically 0 or 1. Start with 0; optionally increase if accuracy is insufficient and sufficient training data is available.
- `distance_cutoff`: Typically 5–6 Å. Keep within a range of 4-7 Å.
- `number_of_channels`: Typically 64 or 128. Smaller numbers of channels can be tested for creating smaller models where speed-accuracy tradeoffs can be investigated.

There is no guarantee that training from scratch will yield a model that is better than finetuning a foundation model. If the training data is limited or not exhaustive enough, finetuning a foundation model is the better choice. If the training data is large and diverse enough, both approaches can be tested for the given use case. Under the right circumstances, a model trained from scratch might be able to achieve similar accuracy as a finetuned model while being smaller and faster. This is however not guaranteed and depends on the specific training data and application domain.

General remarks

The following remarks are general notes regarding training of MACE models and are not specific to the examples in this tutorial. They are included here for reference.

- Restarting is by default activated in the MACE training. This means that if a training is interrupted, it can be resumed from the last checkpoint. It however has to be resubmitted in the same job folder - this is automatically the case when using the Job Tool and using the resubmit button for a job that has timed out, or when resubmitting the same submission script from the command line. Otherwise the training will start from the beginning again due to the lack of a checkpoints folder.
- For general training of MACE models there is a rough rule of thumb for ensuring the training to be likely to converge. The number of gradient updates - given by `number_of_training_configurations * max_number_of_epochs / batch_size` - should be on the order of 200000 to ensure a good likelihood of the training to converge. For small models, this number can be lower, while for larger models it may be higher but the general rule is good to keep in mind

nonetheless. The exact number differs depending on the model architecture and the specific training but it offers a good starting point when training from scratch. For finetuning, the number of gradient updates required may be lower but as a starting point the rule of thumb can still be followed. For Multihead Finetuning, the replayed training configurations are also included in the number of training configurations for determining the number of gradient updates. Note that in any kind of training, setting the `patience` parameter to a reasonable value (relative to the `max_number_of_epochs`) can cut the training short, if the training seemingly has converged early. This is not required but can be a good practice to avoid unnecessary training time.

- In order to avoid using a lot of disk space and saving a lot of files that will not be used, it may be beneficial to not save all the checkpoints during the training as in the end only the best checkpoint from the training will be used to generate the final model. As has been done in all examples in this tutorial, this is achieved by deactivating the keep checkpoints parameter: `keep_checkpoints=False`.

- As with any kind of machine learning model, during experimentation several train-validation or, if preferred, train-validation-test splits should be screened to ensure that the model is not overfitting to the training data and that the data splitting hyperparameters (`random_seed` - both in *MACEFittingParameters* and in *MachineLearnedForceField-Trainer* if a test set is created) are set meaningfully and optimized. The random seed in the *MACEFittingParameters* also controls the random initialization of the model weights, which can have a significant impact on the final model performance. Therefore, when training from scratch, it is recommended to run the training several times with different random seeds to ensure that different initial weights are attempted as part of the model training process.

- The most important hyperparameters to screen in general have all been introduced during this tutorial. For delicate applications other hyperparameters, as documented in the *MACEFittingParameters*, can also be tuned. However, this is mainly recommended for expert-users, as it requires more profound experience.

Loading custom MACE models into QuantumATK

As part of the `validation scripts`, it has already been shown how to load a custom MACE model into QuantumATK in scripting. Custom MACE models can also be loaded from within the Workflow Builder in Nanolab to generate full workflows. Continuing with the multihead_finetuned model trained above, a TiSi configuration is loaded from a database as a BulkConfiguration.

The Set MachineLearnedForceFieldCalculator block is then selected. In the `Potential set type` dropdown menu, `MACE_potential` is selected. This updates the widget menu specifically to custom MACE models. In the `MACE filename` field, the file with the model can be selected by clicking the `...` symbol. Note that the file to choose is the file with the `.qatkpt` extension. After choosing the model file ensure to click the blue arrow in the left part of the filename field to ensure that the file has been found and is compatible. If suitable for the desired simulation, the `Float precision` can be changed to 64-bit, which is recommended, e.g. for accurate optimization, dynamical matrix calculations, NEB, or transition state optimization. This example will only set up a molecular dynamics simulation and the value is kept at 32-bit. After this, the calculator is ready to use and the widget can be closed again.

A simple MolecularDynamics block can be set up to complete the workflow. Note that the script can run on either CPU alone or also include GPU. This is automatically handled at runtime, as described in the *technical notes*, depending on available resources and licenses. If the license configuration supports it, running with GPU enabled is recommended for MACE models to ensure efficient inference.

The Workflow outlined above is available for download: `Trained_model_usage_example_with_MD.hdf5`. The workflow can be added manually to the Workflows folder within the current project and thereafter opened in the workflow menu in QuantumATK. In order to remove the error shown in the Set MachineLearnedForceFieldCalculator block, the path to the custom MACE model must be updated in the `MACE filename` field. Alternatively, the workflow can be acquired and set up in a separate QuantumATK project by downloading all the mentioned project files in a zip folder, unpacking it, and opening the folder as a project in QuantumATK with all trained models included. The zip folder can be downloaded here: `Tutorial_MACE_amorphous_and_crystal_structures_all_data.zip`

Summary

In this tutorial, it has been shown how to train MACE models from scratch, finetune foundation models, and how validating trained models on unseen data can be approached. It has also shown how to load custom MACE models into QuantumATK and use them in workflows and scripts. The tutorial has provided a brief overview of the most influential MACE training parameters and how they affect the model size, inference time, and accuracy. Furthermore, strategies for how to approach training new models with custom data as well as things that should be taken into consideration when training models for custom applications have been discussed.

Compared to MTP, MACE models can provide an even better accuracy, especially for very complex systems with many atoms, at the expense of slower simulation speed.

3.1.2 2D Database and potentials

Version: X-2025.06

In this tutorial, you will learn how to use structures from the 2D materials database integrated in QuantumATK Nanolab and how to couple them with corresponding potential sets made specifically for the structures in the database. Here, it will be exemplified with a SiO 2D-structure and a corresponding Stillinger-Weber potential[1] for which its phonon bandstructure is determined.

Importing a Structure from the 2D Materials Database

The following step-by-step protocol describes how to import a SiO 2D-structure from NanoLabs Internal Database.

1. In the **Builder** *Stash* (1), click on the *Add* button (2) and choose *From Database* (3).

2. Navigate to the *2D materials* Database tab and use the *Search* bar (1) to find the SiO (buckled) structure (2). Then click on the *Add* button (3) to add the structure to the **Builder** *Stash*.

Creating and Setting a Calculator from a 2D Potential Set

In order to set up a forcefield calculator from a potential set corresponding to the structure, the following steps are taken.

1. In the **Builder**, use the *Send content to other tools* button to send the imported buckled SiO structure to the **Workflow Builder**.

[1] Jin-Wu Jiang and Yu-Ping Zhou. Parameterization of Stillinger-Weber potential for two-dimensional atomic crystals. *arXiv preprint arXiv:1704.03147*, 2017.

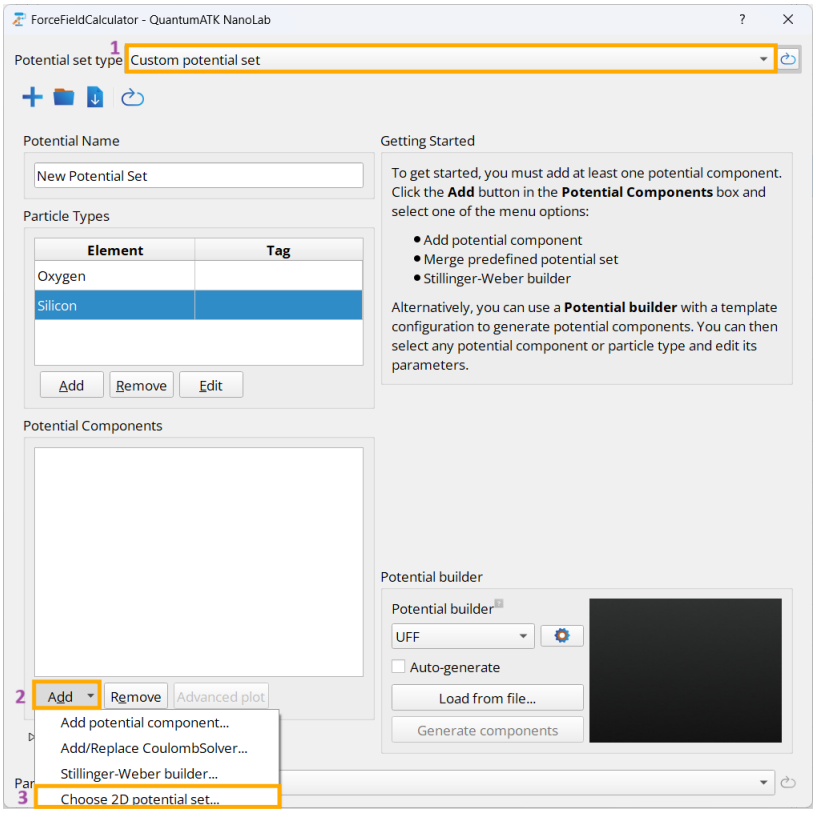
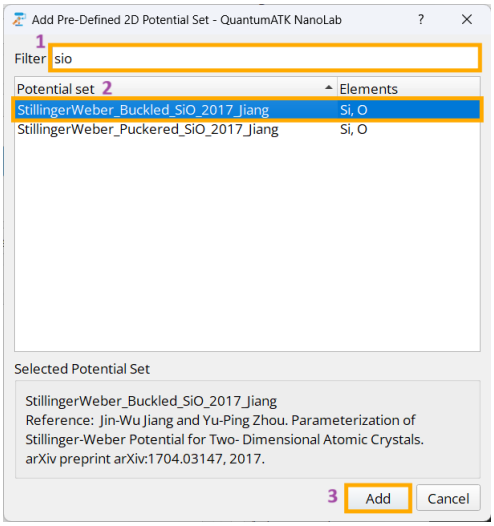
2.Go to the *Block Catalog* → *QuantumATK* tab → *Calculators* category on the right hand panel and drag-and-drop the *SetForceFieldCalculator* block to the middle *Workflow Area* → *Build* tab.

3.Double-click on the *SetForceFieldCalculator* block and change the *Potential set type* from *Pre-defined potential set* to *Custom potential set* (1). In the *Custom potential set* menu, click the *Add* button under *Potential Components* (2) and click the *Choose 2D potential set* option (3) to open a menu for choosing a predefined 2D potential set.



4.Use the *Filter* bar (1) to search for the Stillinger-Weber potential set corresponding to the buckled SiO structure. Marking the potential set (2) and clicking on the *Add* button (3) adds the potential set to the calculator of the SetForceFieldCalculator block.

Note: Most 2D potential sets require specific tags to be present on the structure. These tags are automatically attached on the corresponding structure in the 2D materials database. If a different or a custom structure is used, where one or more tags are missing on the structure, the forcefield calculator block will throw an error highlighting the tag requirement that is not fulfilled. It is possible to circumvent this error by clicking the checkbox field *Ignore 2D tags error* that will appear in the *Custom potential set* menu. This allows the potential set to be scripted for visual inspection. It should be noted that the script will still not be able to complete any calculations with this setting selected, as long as any tag remain missing.



Phonon Bandstructure calculation

Now that a calculator based on the appropriate potential set has been attached to the 2D structure, any desired calculation can follow. In this example workflow, we will calculate the phonon bandstructure. This usually requires a geometry optimization with a tight tolerance for accurate results. The forcefield-structure pair is however already optimized to within an even tighter tolerance than we will use here. Nevertheless, an optimzation step is included for completeness.

1. In the **Workflow Builder**, add an *Optimization and Dynamics* → *OptimizeGeometry* block. Set the *Force tolerance* to 0.001 eV/Å in the menu.

2. Add an *Analysis* → *PhononBandstructure* block. This will automatically add a required *DynamicalMatrix* input block. These blocks will not be discussed in more detail here - see *DynamicalMatrix* and *PhononBandstructure* documentation or related tutorials for more information.

Analyzing Results

Once the calculation has finished, the results can be analyzed.

1. Go to the **Data View** tool.

2. Since the optimization converged after the first step, no additional optimization steps were taken. This can be confirmed by inspecting the original and optimized lattice constants in text representation. In *Data Sources* select the file `BuckledSio_2017_results.hdf5` (or equivalent if a different destination filename has been used) and then in *Data View* window select both *BulkConfiguration_0* (initial geometry) and *optgeom* (optimized geometry), followed by a right-click to *Open All with Text Representation*. As expected we find the that lattice constants of the 2D buckled SiO remained at values of a=2.815 Å and c=25.000 Å.

3. Right-click on the phonon bandstructure *PhononBandstructure_0* in *Data View* and choose to *Open with Phonon Bandstructure Analyzer*. This will display the phonon bandstructure for the simple 2D unit cell.

3.1.3 Moment Tensor Potential (MTP) Training for Crystal and Amorphous Structures

Version: W-2024.09-SP1

Downloads

c-am-TiSi-MTP-training.hdf5 MTP_TiSi_basis400_final.mtp c-TiSi-DFT-EOS.hdf5 c-TiSi-MTP-EOS.hdf5 am-TiSi-MTP-validation.hdf5 c-am-TiSi-MTP-training-validation-results.zip

In this introductory tutorial, you will learn how to use QuantumATK to

- Set-up a workflow for training a machine-learned force field (ML FF), MTP, for crystal and amorphous TiSi and $TiSi_2$ structures, which can be used for molecular dynamics (MD), geometry optimization, and other force-field-based simulations.
- Analyze the MTP training results.
- Validate the quality of the trained MTP.

Unlike many empirical potentials with physical functional forms, ML FFs such as MTPs are not highly transferable and must be trained with the target application in mind. For example, an MTP trained for bulk structures will not describe accurately free surfaces or nanoparticles of that material without the addition of such structures to the training set. However, the outlined training protocol can be easily adapted or extended to train an accurate MTP for different geometries, stoichiometries, element composition and other materials by explicitly including relevant training data for such structures.

Prerequisites

•Tutorial *Geometry Optimization*

•Tutorial *Molecular Dynamics Simulations for Generating Amorphous Structures*

Overview of the MTP Training Workflow

ML FFs are trained to predict *ab initio*, i.e., DFT, potential energy surfaces (PES) and vastly improve the accuracy of classical dynamics simulations while keeping the computational cost at the level of empirical force fields. To train a ML FF, one first needs to calculate training data (energy, forces, stress) for generated training configurations (typically, of relatively small sizes) with the reference DFT calculator and then fit an MTP to that DFT training data. Simulations with trained ML FFs can reach the high accuracy, long simulation times and large system sizes that capture the complexity of realistic systems, e.g., amorphous and alloy materials, and processes, e.g., diffusion, crystallization or deposition.

QuantumATK implemented Moment Tensor Potentials (MTPs)[1] as they provide high performance for a given accuracy when compared to other ML FFs models in the literature[2]. MTP advantages include:

•Very fast and supports large scale simulations.

•Allows training to multi-element-materials.

•Systematically improvable.

Tip:

1.Since the MTP is trained to match the DFT reference calculator results, the accuracy of the final MTP is tied to this choice. Thus, it is important to choose the reference calculator that gives a good description of the system and application you want to study.

2.Learn more about ML FFs and their benefits here: Glossary page on What are Machine-Learned Force Fields

---

MTP training for crystal and amorphous structures in QuantumATK is structured into three stages:

1.**Crystal Training Data** - generates crystal training configurations with random displacements and calculates training data (energy, forces, stress) with the reference calculator DFT. Crystal training data forms the bulk of the training set, giving a fundamental description of the material in question. It will also be used to fit an initial MTP in the 2nd MTP training stage.

2.**Amorphous Active Learning** - fits an initial MTP to the crystal training data, which is then used to run iterative Active learning geometry optimization and MD simulations to identify relevant configurations which are not represented in the initial training set. This workflow actively adds extrapolating amorphous configurations, incl. DFT data, to the training data set. The combined amorphous + crystal training data is then used in the 3rd stage to fit an ensemble of MTP models.

3.**Final MTP Fitting** - generates an ensemble of MTP models and selects the best fitted MTP that gives lowest and comparable training and testing errors with respect to the reference DFT method.

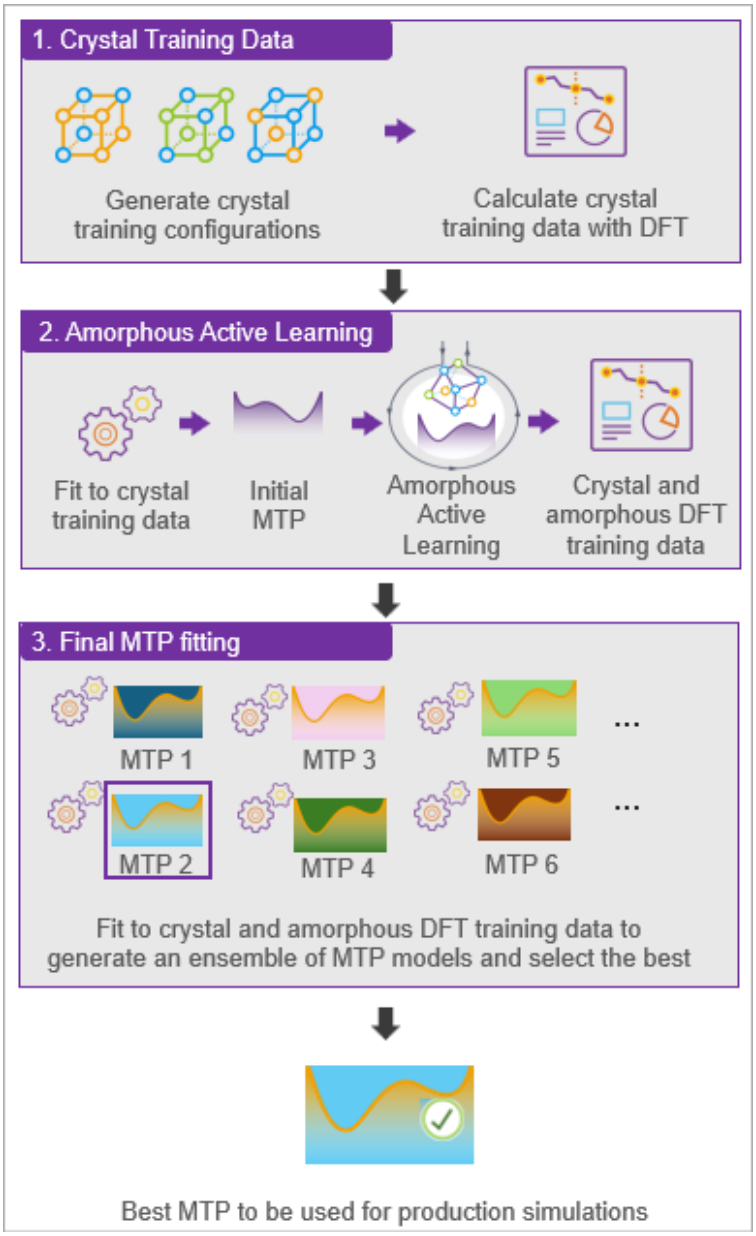
[2] Yunxing Zuo, Chi Chen, Xiangguo Li, Zhi Deng, Yiming Chen, Jörg Behler, Gábor Csányi, AlexanderăV. Shapeev, AidanăP. Thompson, MitchellăA. Wood, and ShyueăPing Ong. Performance and Cost Assessment of Machine Learning Interatomic Potentials. *The Journal of Physical Chemistry A*, 124(4):731–745, 2020. URL: https://doi.org/10.1021/acs.jpca.9b08723, arXiv:https://doi.org/10.1021/acs.jpca.9b08723, doi:10.1021/acs.jpca.9b08723.

The chosen MTP can then be used in production simulations, such as MD, geometry optimization, and other force-field-based simulations.



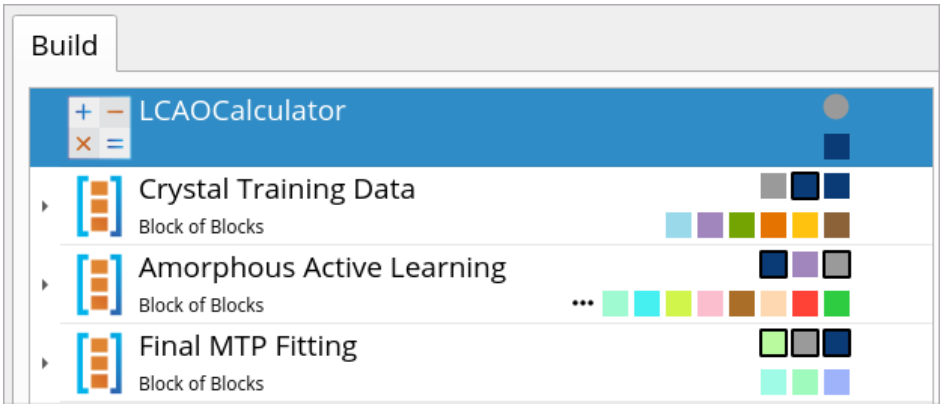
1.Download the ready-to-use MTP training workflow `c-am-TiSi-MTP-training.hdf5` and open it in the **Workflow Builder**.

2.The workflow consists of three aforementioned stages (each contained in a so-called *Blocks of Blocks*) and is applicable to any crystal and amorphous material:

1.**Crystal Training Data**

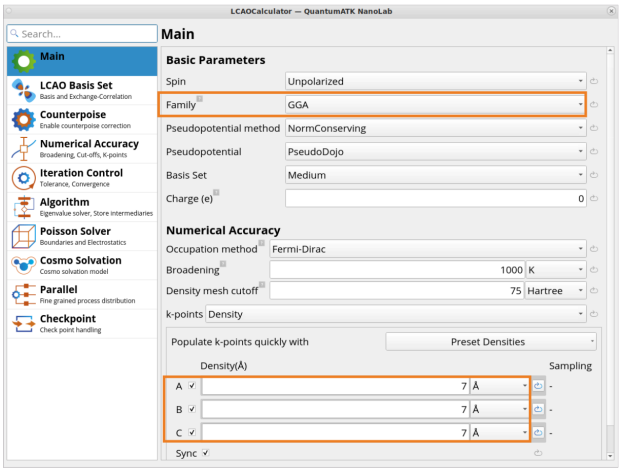
2.**Amorphous Active Learning**

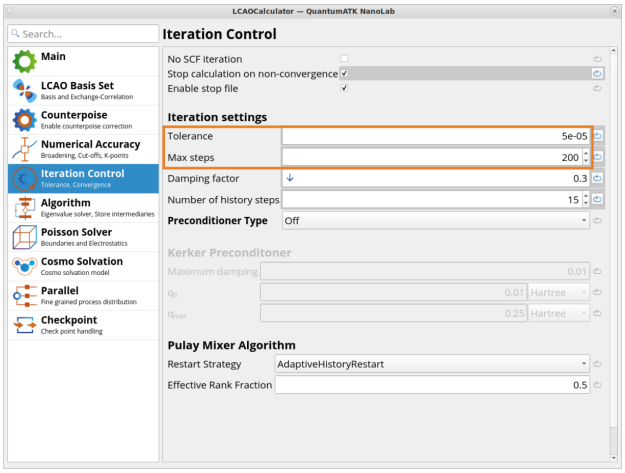
3.**Final MTP Fitting**



3.The **LCAOCalculator** block placed above the three *Blocks of Blocks* is used for defining a reference DFT-LCAO calculator (using the PBE xc-functional) that is used to calculate training data (energy, forces and stress) throughout the MTP training simulations.

- Under the *Main* tab, the *k-point density* is increased from the default *medium* to *high*, i.e., from *4Å x 4Å x 4Å* to *7Å x 7Å x 7Å*, to reduce the impact of sampling discontinuities when slightly changing the cell size during random displacements of the structure.
- Under the *Iteration Control* tab, the SCF *Tolerance* is decreased from the default *1e-04* to *5e-05* to reduce the noise in energy, forces, stress, and the *Max steps* for SCF is increased from default *100* to *200* so that SCF also converges even if the configuration needs more steps due to the tighter tolerance.
- Under the *Algorithm* tab → *Parameters*, the default *Optimize diagonalization for memory* is switched to *Optimize diagonalization for speed*.

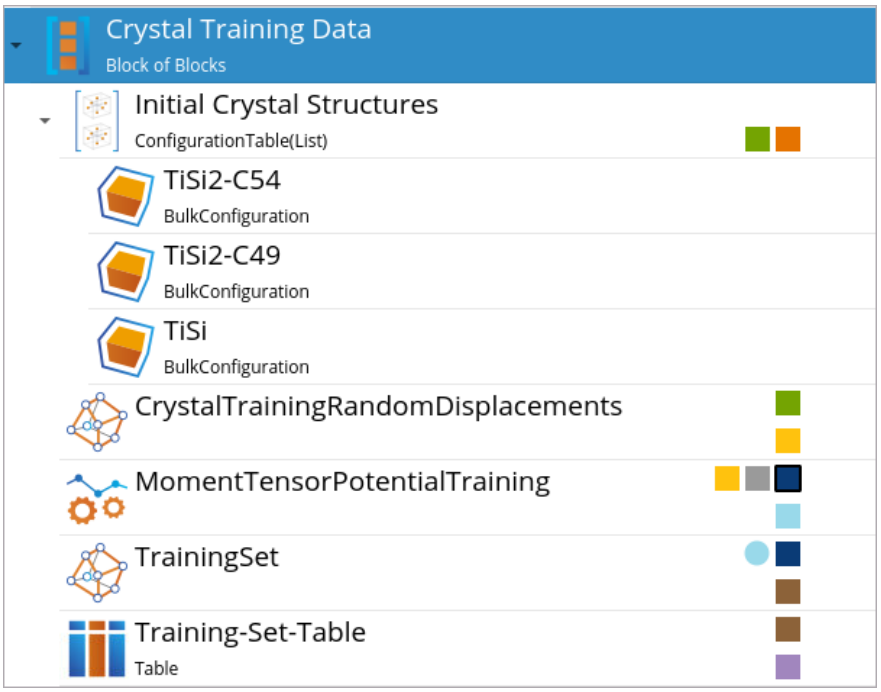




We will now go through the three stages step-by-step, explain the settings, and provide tips and recommendations.

Crystal Training Data

We will begin with the 1st stage of the MTP training workflow - **Crystal Training Data**. This includes generation of crystal training configurations, i.e., repeated and randomly displaced crystal structures of different phases of titanium silicide using the *crystalTrainingRandomDisplacements* protocol, and calculation of training data with DFT for these displaced configurations.

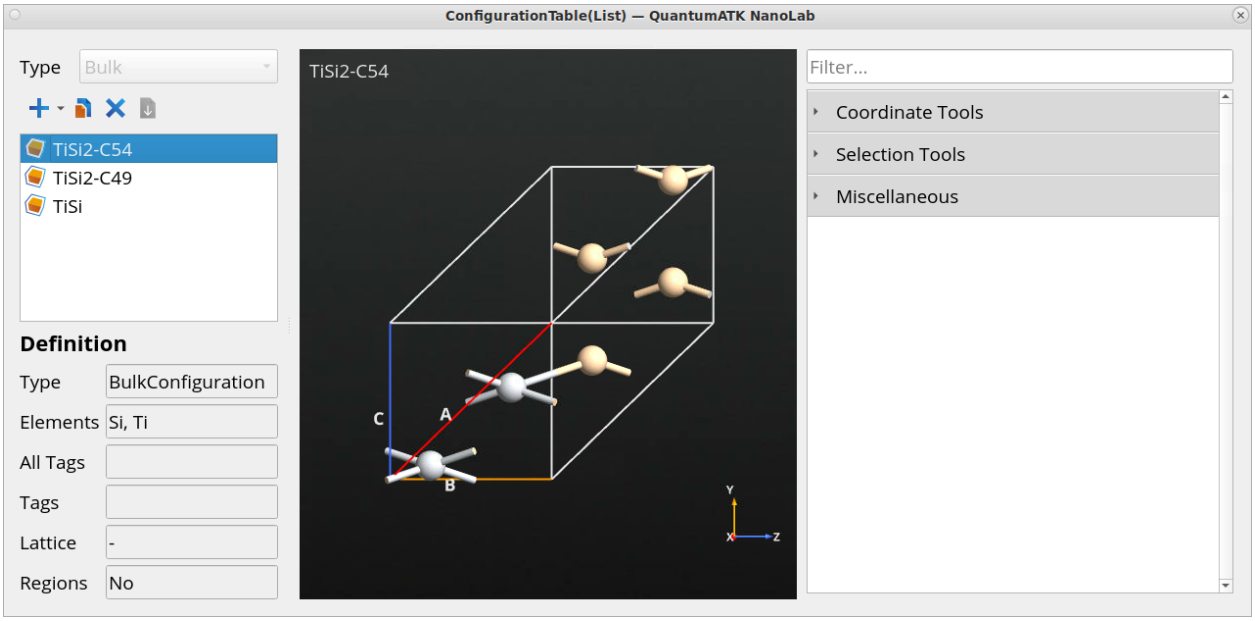


1. The **Initial Crystal Structures** *ConfigurationTable(List)* block contains three crystal structures of titanium silicide, with two different stoichiometries, which we will include in the MTP training: TiSi, $TiSi_2$-C54 and $TiSi_2$-C49. These structures will be used for generating randomly displaced structures - the training configurations.

Note: The required input for the **Initial Crystal Structures** depends on the application of the final trained MTP. If you intend to use the trained MTP for simulating other stoichiometries and crystal phases than TiSi, $TiSi_2$-C54 and $TiSi_2$-C49, then you should include structures with these other stoichiometries and crystal phases as well, to ensure accurate simulations for those materials.

Tip:

1. Crystal structures can be imported from the *NanoLabs Internal Database* in the **Builder** or from the *Materials Project* database in the **Databases**.
2. It is recommended to optimize the geometry of crystal structures with the reference (DFT) calculator before using them for the MTP training.



2. The **CrystalTrainingRandomDisplacements** block sets parameters for randomly displacing configurations around the equilibrium of the provided crystal structures of titanium silicide.

- *System sizes:* Define the target sizes for the supercells in which the atoms will be displaced. It is recommended to use at least 2 different sizes (in this case, *20* and *50*), so that the MTP model can better learn the system-size dependence of the total energy.
- *Target sample size:* Set the minimum for how many displaced configurations should be generated. Note that depending on various input choices, the final number of training configurations can be significantly higher. Here, we choose *200* (default).
- *Base / max atomic rattling amplitudes:* Define by what magnitude the atoms are displaced. Should be chosen so most displaced configurations have max. atomic forces below 5 eV / Ang, and that the max. atomic forces peaks are between 20 – 40 eV / Ang. The default values (*0.15 Å/ 0.4 Å*) work well for most materials, but for pure metals larger values can be chosen (e.g. *0.25 Å / 0.55 Å*).
- *Include strain:* Should be enabled (by default), unless not needed for a specific application.

3. The **MomentTensorPotentialTraining** block sets parameters for calculating DFT training data (energy, forces, stress) for the randomly displaced configurations.

- Only the parameters in purple boxes, i.e., related to the calculation of the DFT training data, are used. The remaining parameters are related to the MTP fitting, which we do not carry out in this stage.
- *Number of processes per task*: Specify how many MPI processes should be used for each DFT calculation (default - *all available processes*). Since the DFT calculations are mostly independent from each other, multiple DFT calculations can be done at the same time. For example, when submitting a calculation on 40 MPI processes, number of processes per task could be *8*, thus resulting in 5 DFT calculations running at the same time. This can speed up the entire calculation, but will use more memory.
- *LCAOCalculator* and *MomentTensorPotentialTraining* blocks must be connected, so that the defined *LCAOCalculator* is used to calculate training data.

4. The **TrainingSet** block exports the generated training data with DFT as a *TrainingSet* object.

- *Sample size*: Keep this at *All configurations* (default) to include all configurations from the *CrystalTrainingRandomDisplacements* block in the dataset.

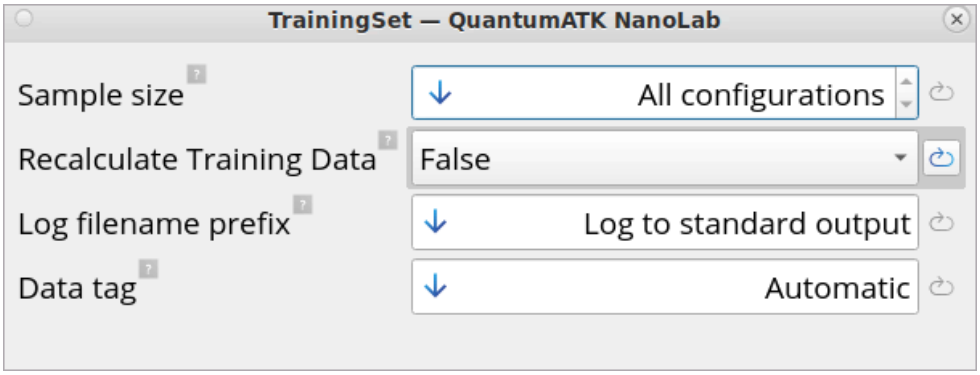
•*Recalculate Training Data*: Changed to *False*, because the DFT data has already been calculated. Only if the same configurations are used with a different reference calculator, should this parameter be set to *True*.



Note: In case of training an MTP model for the use of crystal applications only, one could take the *TrainingSet* generated above and directly move to the 3rd stage - **Final MTP Fitting**. The resulting MTP would be able to describe the trained crystal phases up to medium temperatures (i.e., well below the melting point where the crystal is still stable). Crystal properties, such as lattice constants, elastic moduli, or phonons, are typically described very well using this training data.

Amorphous Active Learning

In the 1st stage of the MTP training we generated crystal training data for the initial MTP fitting. In the 2nd stage, **Amorphous Active Learning**, we will include training data for amorphous configurations. Here, it is not so straightforward to identify all relevant amorphous configurations beforehand, thus we will employ the *ActiveLearningSimulation* approach for on-the-fly improvement of training dataset by actively adding extrapolating amorphous training configurations from dynamic simulations, such as geometry optimization and melt-quench MD.

Note:

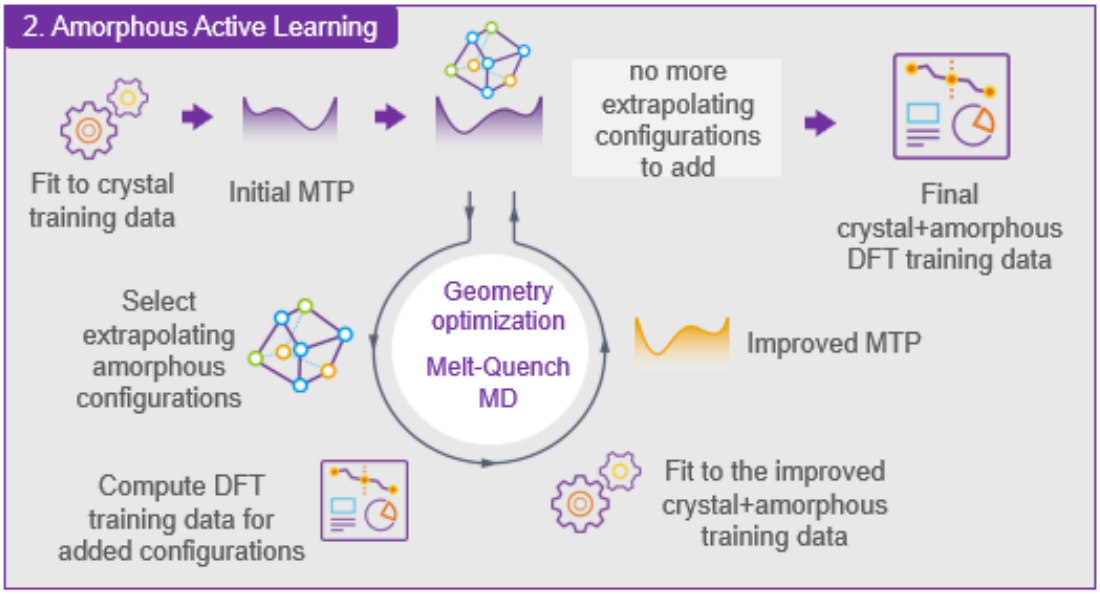
1. Active learning is a strategy for iteratively finding and selecting new atomic configurations for which the MTP has the highest uncertainty, i.e., highest prediction errors (so-called *extrapolating configurations*). These configurations are most likely to improve the MTPs accuracy when added to the training data set. Since Active learning targets specific configuration spaces instead of randomly sampling configurations, it reduces the need for expensive DFT training data calculations, which leads to efficient and fast training.
2. It is recommended to include Active learning when training an MTP for amorphous systems, interfaces, surface processes, and systems at high temperatures.
3. In addition to geometry optimization and MD, methods such as NEB, AKMC and TFMC can also detect extrapolating configurations and add them to the training data set.

During **Amorphous Active learning**, first, one fits an initial MTP to the crystal training data and then iteratively repeats the flow below until there are no more extrapolating configurations to add, as also shown in the figure below:

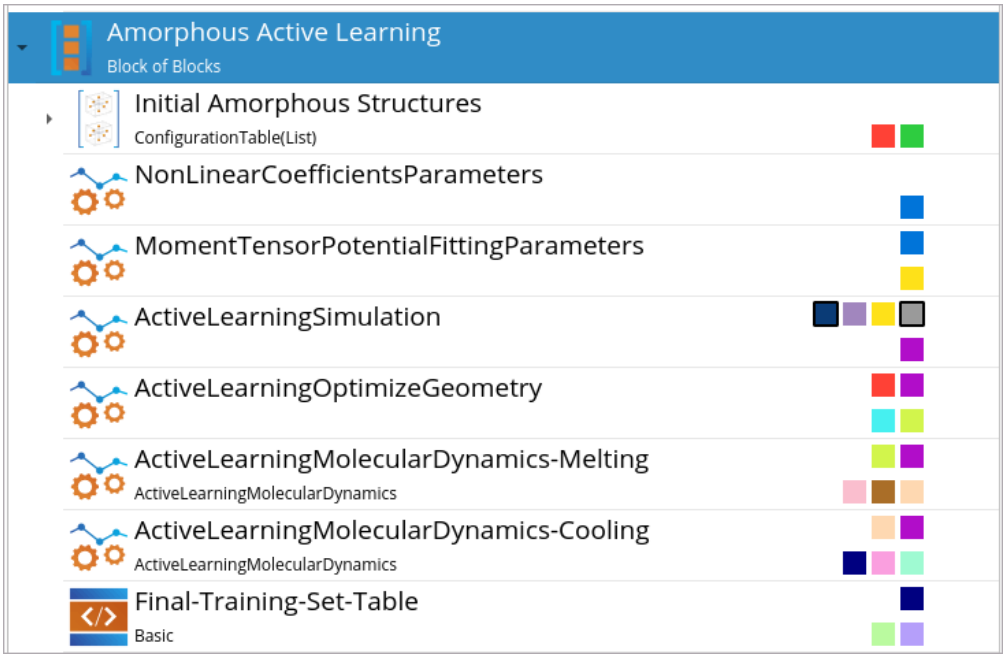
•Perform geometry optimization and MD melt-quench (melting/cooling) simulations with the current MTP to find additional extrapolating amorphous training configurations.

•Calculate DFT training data for these added training configurations.

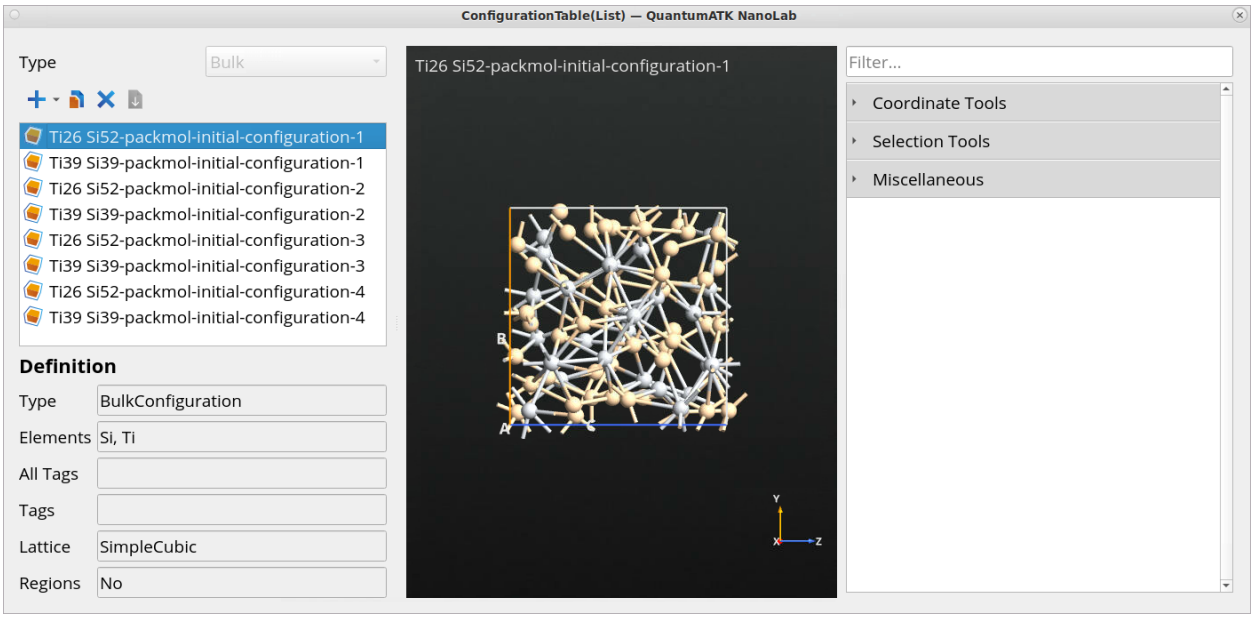
•Fit a preliminary MTP to the improved training data.



The actual workflow for the **Amorphous Active Learning** stage in the **Workflow Builder** looks like this:



1. The **Initial Amorphous Structures** *ConfigurationTable(List)* block contains initial amorphous structures of titanium silicide, where each of them will be used as a starting point for *Active learningGeometryOptimization* and *Active-LearningMolecularDynamics* simulations. Since we have eight initial amorphous $Ti_{39}Si_{39}$ and $Ti_{26}Si_{52}$ structures, QuantumATK will perform eight Active learning geometry optimization and eight subsequent Active learning MD melt-quench simulations.



Tip: Initial amorphous configurations can be generated using *Packmol* in the **Builder** as showcased in the tutorial *Molecular Dynamics Simulations for Generating Amorphous Structures* or can be generated on-the-fly using the *AmorphousPrebuilder* block in the **Workflow Builder**.

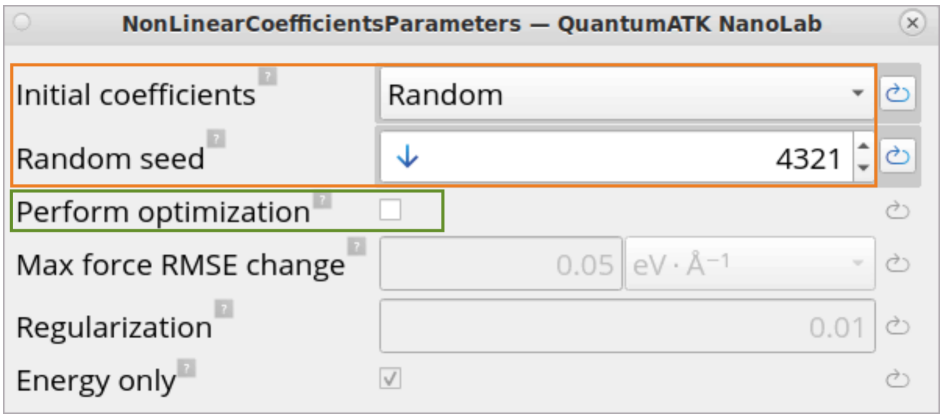
Now lets set up the generation of MTP fitting parameters that will be fitted to the training set data by minimizing the error (energy, forces and stresses) with respect to the reference DFT calculator.

2. The **NonLinearCoefficientsParameters** block contains settings for randomly generating non-linear coefficients for the radial functions for each element pair (see *NonLinearCoefficientsParameters* for more info), that will be used in the next step - calculation of MTP fitting parameters (see *MomentTensorPotentialFittingParameters* for more info).

- *Initial coefficients*: Set to *Random* to use random values for initial non-linear coefficients.
- *Random seed*: Set to an arbitrary number, but use the same number for different Active learning runs. This way consistent results are achieved between different Active learning runs.
- *Perform optimization*: recommend to keep it unchecked in the *Amorphous Active Learning* stage as non-linear MTP training (optimizing non-linear coefficients) usually does not give much improvement in accuracy and it will increase the calculation time.

3. The **MomentTensorPotentialFittingParameters** block contains settings for MTP fitting using the non-linear coefficients generated in the previous step.

- *Basis size*: Use *400* basis function in this example. Generally, it is recommended to use either *Predefined Basis Small* (default), or between *300 – 800* basis functions. More basis functions usually provide a better accuracy (lower training error), but the simulation can become less stable, especially in out-of-equilibrium situations, e.g., at high temperatures or energies.
- *Outer cutoff radii*: Set to *4.5 Ang* in this example. This value specifies the range of the atomic environments. Typically values between *4-5 Ang* are recommended. Similar to basis size, larger values can increase accuracy, whereas smaller values can provide more stability.
- *MTP filename*: One should always specify a filename with `.mtp` extension. This is where the trained MTP parameters are stored.



•*Forces cap*: Specify this value in order to exclude configurations with very large forces, i.e., above the *Force cap*, from the training. For Active learning it is always recommended to set this to a relatively large value, e.g. *500 eV / Ang*, to include closer atom distances with larger forces in order to make sure the repulsive behavior is predicted correctly in such situations. Increasing the *Forces cap* (within some limit) makes the simulation more stable, but less accurate. Thus, while setting the *Forces cap*, one needs to balance between simulation stability and accuracy.

Note: Within the MTP framework, the total energy of a configuration is computed as the sum of energy contributions from atomic environments. Atomic environments are defined as the representation of the immediate chemical environment of each atom in the system within a cutoff radius. Moment tensors include the radial, angular, and many-body distribution of atoms within a cutoff sphere. Their contractions into scalar basis functions provide an invariant representation of atomic environments (structure) as input for MTP training[Page 305, 1].

Now lets set up Active learning simulation parameters.

4. The **ActiveLearningSimulation** block contains settings for running Active learning simulations. MTP fitting parameters from the previous step and the initial training data from the crystal training are used as an input.

•*Candidate/ Retrain Threshold*: These are numerical measures governing how much configurations can differ from the training set before they are considered to be extrapolating. If the current configuration has an extrapolation grade higher than the candidate threshold (default *1*), it will be kept as a possible candidate to be included in the next training. If the value is larger than the retrain threshold (default *3*), the current simulation will be stopped, extrapolating configurations will be added to the training data set, and then Active learning will be re-started now using an improved MTP fitted to the extended training data set.

•*Limit candidates*: Set to *100*. Limit the number of recorded candidates for each simulation. This can be beneficial in case the simulation moves between candidate and retrain threshold for a long period and many candidates are registered. In that case the candidates are typically very correlated and not all of them are needed. The limited candidates are then taken from the raw list of candidates at a regular interval, before a structural filter extracts the most different configurations and adds them to the training set.

•*Max. Iterations*: The maximum number of re-training iterations, i.e., how many times the simulation will start again with a new MTP. Stick to the default value. It can be increased if more iterations are expected.

•*Extrapolation grade algorithm*: Select which algorithm is used to calculate the extrapolation grade. Unless there is only a single element in the simulation, we always recommend to set this to *QueryByCommitteeForces*.

•*LCAOCalculator* and *ActiveLearningSimulation* blocks must be connected, so that the defined *LCAOCalculator* is used to calculate training data during Active learning.

5. The **ActiveLearningOptimizeGeometry** block contains settings for performing Active learning geometry optimization. All initial amorphous configurations from the *Initial Amorphous Structures ConfigurationTable(List)* block will be used as a starting point for the *ActiveLearningOptimizeGeometry*. The optimizations will be run independently and

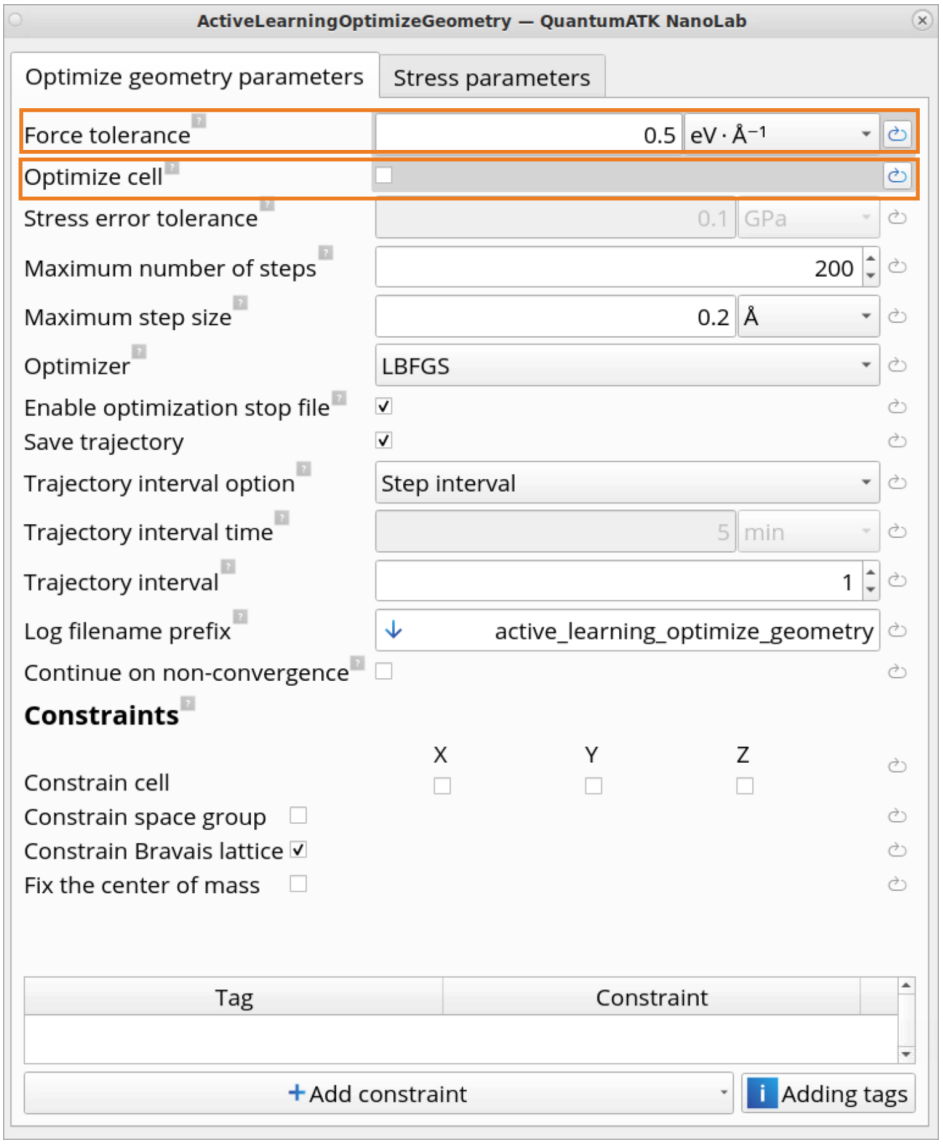
in parallel (as much as the parallel settings allow that, otherwise sequentially). The DFT calculations and training are done collectively, using the combined extrapolating candidate configurations selected from all optimizations.

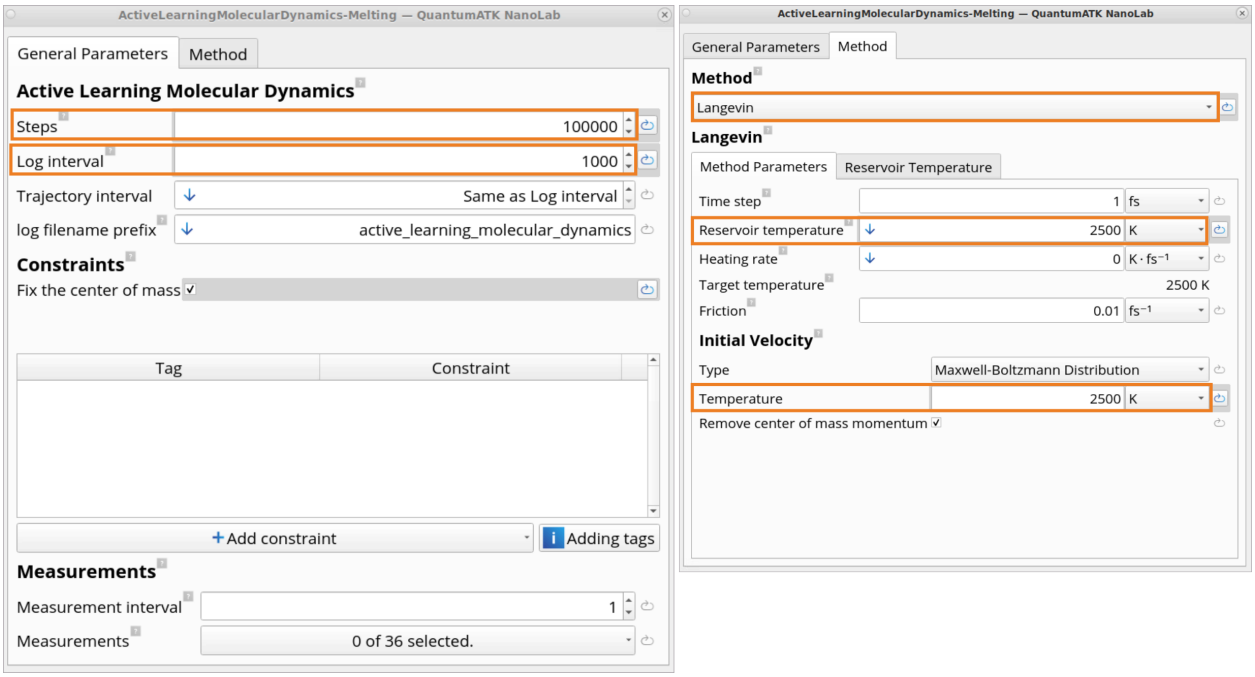
- *Force tolerance*: set a bit higher than the default, i.e., to *0.5 eV / Ang*, as this part should primarily do a quick pre-optimization to avoid large forces in the active learning MD part.
- *Optimize cell*: this is disabled to make the optimization more robust.



The combined crystal training + amorphous geometry optimization training data is used to train an improved MTP, which is then used for subsequent Active learning melt-quench MD simulations.

6. The **ActiveLearningMolecularDynamics-Melting** block contains settings for performing Active learning MD melting simulations. Here, we want to run MD at relatively high temperatures to melt the disordered configurations and sample many different relevant atomic environments.

- *Steps*: set to *100 000* MD steps and set *Log interval* to *1000* MD steps.
- *Method*: set to *Langevin*.
- *Reservoir temperature* and *Temperature of initial velocities* is set to *2500 K* to melt the disordered configurations.



Tip: One can also use a different thermostat type than *Langevin*, however, to ensure the simulation is relatively robust one should pick a robust thermostat, like Berendsen or Bussi-Donadio-Parrinello. At such high temperatures, it is recommended to run NVT simulations, whereas NPT simulations should primarily be run at lower temperatures.

Note:

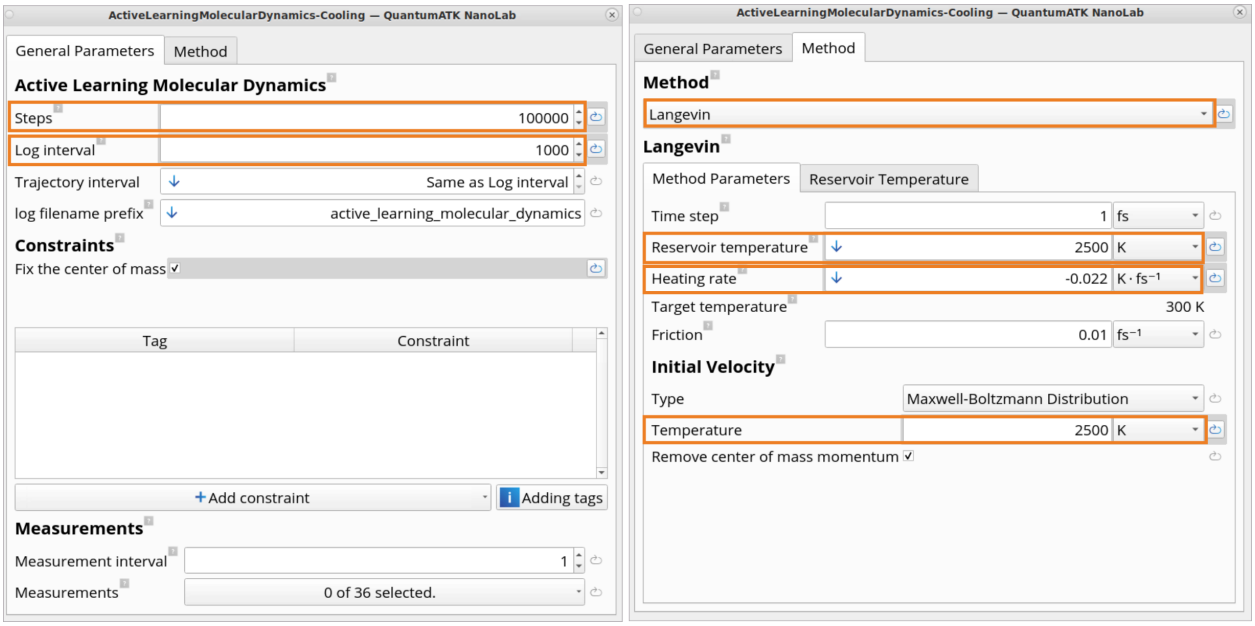
- The chosen **Active learning MD temperature** should reflect a physical process (e.g., chemical reactions, phase transitions, or material properties) that occur within a specific temperature range and that you want to simulate in production simulations with a trained MTP.
- The temperature should not be too low as it would miss configurations relevant at high temperatures (e.g., disordered amorphous structures).
- The temperature should also not be too unphysically high, as in that case the system may visit configurations that are physically unrealistic, or not representative of the systems true equilibrium state. In addition, due to too high temperature, the system may also fail to properly sample the configuration space by jumping over energy barriers rather than exploring the free energy surface in a smooth, gradual manner.
- To sum it up, too low or too high temperature could result in the reduced accuracy of Active learning and thus the trained MTP.

The combined crystal training + amorphous geometry optimization + amorphous MD melting training data is used to train a further improved MTP, which is then used in subsequent Active learning MD cooling simulations.

7. The **ActiveLearningMolecularDynamics-Cooling** block contains settings for performing Active learning MD cooling simulations - to simulate cooling the liquid configuration to room temperature.

- *Steps*: set to *100 000* MD steps and set *Log interval* to *1000* MD steps.
- *Method*: set to *Langevin*.

•*Reservoir temperature* and *Temperature of initial velocities* is set to *2500 K*, but now we specify a negative heating rate of *-2200/100 000 K/fs* to decrease the temperature from *2500 K* to *300 K* during the 100 ps of MD.

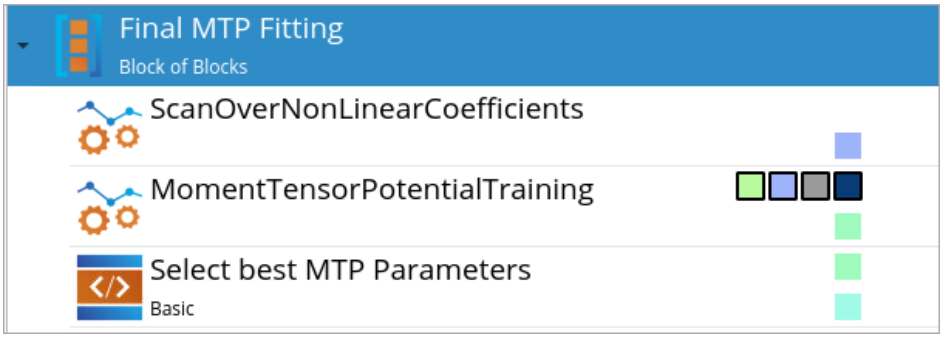


8. The **Final-Training-Set-Table** block picks up the *Training-Set-Table* containing the combined data from crystal displacements and Active learning and exposes it under a more obvious name, so that it can easily be used in the following **Final training** stage.

Final MTP Fitting

In the 2nd *Amorphous Active Learning* stage we did preliminary MTP fittings to generate amorphous training data for titanium silicide on-the-fly. For this, we used only one set of initial non-linear MTP coefficients. In the 3rd stage, **Final MTP Fitting**, we will fit an ensemble of MTP models to the crystal+amorphous training data and select the best fitted MTP. We will scan over 30 different initial guesses of non-linear MTP coefficients to generate different fitted MTPs based on these initial guesses. We then select the one which gives the lowest, and comparable, training and testing errors with respect to DFT. This can then be used in production simulations.

The actual workflow for the **Final MTP Fitting** stage in the **Workflow Builder** looks like this:



1. The **ScanOverNonLinearCoefficients** block contains settings for scanning over different initial guesses of non-linear MTP coefficients and obtaining MTP fitting parameters for these different initial guesses. *scanOverNonLinearCoeffi-*

cients is essentially an outer loop over *NonLinearCoefficientsParameters* + *MomentTensorPotentialFittingParameters* that loops over different random seeds.

•*Number of initial guesses*: Defines how many different initial values should be considered. The default value of *30* is usually sufficient. Increasing the number means a better chance of finding the best possible MTP at a cost of an approximately a linear increase in the calculation time.

•*Basis size*: Use *400* basis functions for this example (same as in active learning). Generally, it is recommended to use either *Predefined-Small*, or between *300 – 800* basis functions. More basis functions usually provide a better accuracy (lower training error), but the simulation can become less stable, especially in out-of-equilibrium situations, e.g., at high temperatures or energies. For calculations which require a high accuracy, but not stable MD, it can be meaningful to increase the number of basis functions beyond this range. In rare cases, mainly for calculations which require a very high accuracy, such as precise phonon calculations or defect energies, it can be meaningful to increase the number of basis functions to as much as 5000.

•*Cutoff radii*: Inner and tapering cutoff radii rarely need to be changed from their defaults. The outer cutoff radius should be set to the same as in Active learning (*4.5 Å*), as the extrapolation behavior will depend on this choice.

•*MTP filename suffix*: Specify the filename, where the MTP parameters are written to. The different fits will create files such as `0_mtp_filename_suffix.mtp`, `1_mtp_filename_suffix.mtp`, etc.

•*Forces cap*: Specify this value in order to exclude configurations with large forces. In this stage it does not have to be as large as for Active learning, we recommend *100 -200 eV / Ang* for most cases, unless the application explicitly requires to be able to deal with very large forces (e.g. impact of high-energy ions). We choose *200* here, so that some large forces are included to train the MTP to be able to deal with close atoms, that might occur during the melting MD simulations.

•*Perform optimization*: Run a separate, local optimization of the non-linear coefficients. This takes much longer, and in most cases it gives very little improvement in accuracy, therefore it is recommended to have it disabled (default).

Tip:

•*ScanningOverNonLinearCoefficients* is kind of a non-linear MTP optimization, but a crude one in that one just tests many initial guesses and then picks the best one (without the explicit local optimization of non-linear coefficients). For systems that do not have too many elements it works well.

•If the number of elements becomes larger (5+ different elements), it can be beneficial to use the particle-swarm-optimization (PSO) method *ParticleSwarmOptimizationParameters* to optimize the non-linear parameters instead of scanning over different initial guesses. This will take longer, but provides a more systematic optimization and often results in a better accuracy for complex systems. Since we only have 2 elements in the system we use here, we will not use PSO in this tutorial.

2.The **MomentTensorPotentialTraining** block contains settings for taking care of running and analyzing the MTP fitting runs based on 30 different sets of MTP fitting parameters. See *MomentTensorPotentialTraining* to learn more.

•*Train test split*: Set it to *0.9* to use 90 % of the calculated reference data for training and 10 % for testing. The split is done randomly. Specify an arbitrary number for the random seed to make it deterministic and reproducible, e.g., if one wants to change other hyperparameters like a cutoff radii or a basis size later and compare the results.

•*Committee size*: Number of committee models to train and store using the same data and hyperparameters for the MTP MD uncertainty predictions. This can be set to a small number (we recommend 6). The committee model can then be used in MD simulations to obtain an estimate of the energy and forces error during the production simulations with a trained MTP, using the *MolecularDynamicsErrorPredictionHook*.

•Ensure that the *MomentTensorPotentialTraining* block is linked to the *Training-Set-Table*, *ScanOverNonLinearCoefficients* and *LCAOCalculator* blocks.

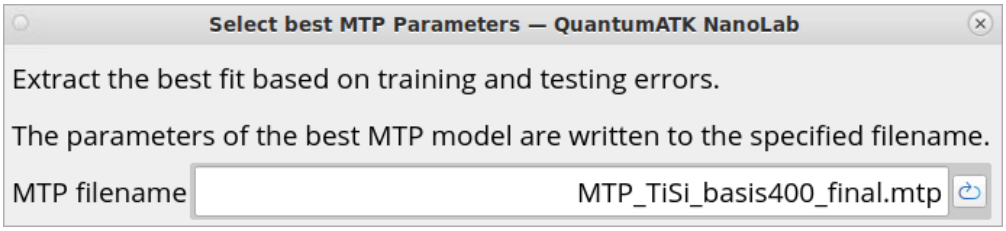
•We use random numbers to initialize the coefficients for the MTP training, randomly displacing crystal configurations and training-test set splitting. Therefore, reproducibility of the results to the numerical accuracy is only ensured if you use the same **Random seed** while re-running the MTP training simulation.

•Many different sets of MTP parameters could result in similar results as there could be many degenerate minima in the hyper-parameter surface. Thus it is not a cause for concern if you get different sets of MTP fitting parameters with similar accuracy.

3.The **Select best MTP Parameters** block is for selecting the best fitted MTP from 30 generated MTPs based on training and testing errors.

•*MTP filename*: The parameters for the best fit are written to this file. It should have the extension `.mtp`. This mtp file is what you will use for setting up production simulations with the trained MTP.



Submitting the MTP Training Calculation

The MTP training set-up is now finished and you are ready to submit this job.

1.Change the *Workflow* name and *Filename* as needed (e.g., `c-am-TiSi-MTP-training-results.hdf5`).

2.Click on the *Send content to other tools* button and choose *Jobs as a script* to send the workflow to the **Jobs** tool to submit this job on a local machine or a remote cluster. It is recommended to use MPI parallelization for MTP training simulations, as both training data calculations with DFT and MTP fitting benefit from MPI parallelization.

3.This also generates a Python script `c-am-TiSi-MTP-training-results.py`, based on this workflow. It can be opened and edited with the **Editor** tool and then sent to the **Jobs** tool, if you need to make manual changes.

4.Estimate of the MTP training run-time: in our test it took 5 hours on the 40-core machine.

Analyzing MTP Training Results

Once the MTP training calculation has finished, we are ready to analyze the results.

Download the following output files if needed: `c-am-TiSi-MTP-training-results.log`, `c-am-TiSi-MTP-training-results.hdf5`, `c-am-TiSi-MTP-training-results_4.hdf5`, `active_learning_molecular_dynamics.4.log` and open them in the **Data View**.

1.`c-am-TiSi-MTP-training-results.log`: The main `.log` file contains a lot of information about the progress of the overall simulation, while the DFT training data, Active learning geometry optimization and MD log outputs are written to separate files. The most important parts of the `c-am-TiSi-MTP-training-results.log` file are:

•**Completion of Active learning** geometry optimization and melt-quench MD simulations, reporting the number of added extrapolating amorphous training configurations. For titanium silicide, 14, 8 and 0 extrapolating amorphous configurations were added during Active learning geometry optimization, MD melting and cooling phases, respectively.

```

```

- **MTP training report** at the end of the `.log` file. This displays the size of the training set (216 configurations 90% of all training configurations) and testing set (25 configurations 10% of all training configurations) for each fit. It also shows a list with all the training and testing RSME errors and r^2 values for energy, forces, and stress for all 30 fits with respect to the reference DFT calculator. In this case, each fit corresponds to a different initial guess for the non-linear coefficients. One can inspect the errors manually and select the best fitted MTP with lowest RMSE errors.

- **Best MTP fit**, reported by QuantumATK based on the automatic analysis of all the errors. In this case, QuantumATK reports the MTP fit number 19 to be the best, corresponding to the lowest overall training and testing errors. The best fitted MTP is written to `MTP_TiSi_basis400_final.mtp`, which can then be used for validation and production simulations. All the 30 fitted MTPs are written to files `0,...,29_MTP_TiSi_final_basis400.mtp`.

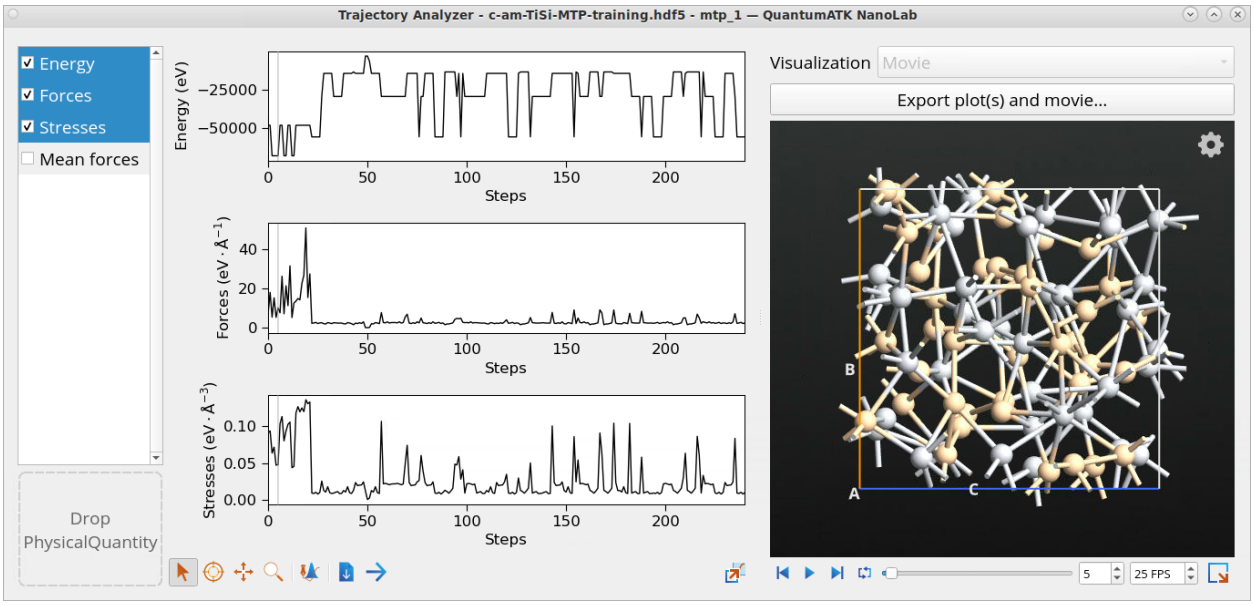
Best fit at index 19.
Copying the best parameters to file MTP_TiSi_basis400_final.mtp.
```

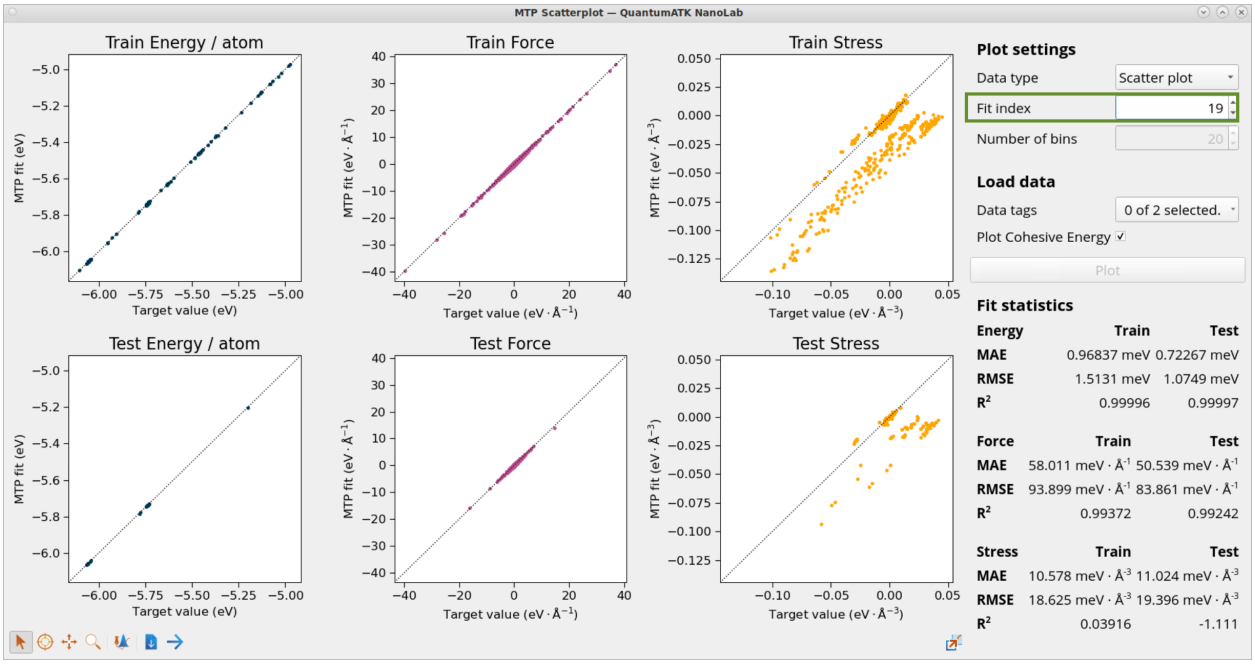
Note: r^2 values, coefficient of determination, indicate how good the MTP is at predicting the trained properties in the dataset, with values closer to 1 being better. Looking at the log-file, we can see that all of the trained MTPs have an r^2 value of over 0.99999999 indicating that they are all accurate within the configurational space sampled in the training data set, thus not helping much in choosing the most accurate fitted MTP. Therefore, to find the best MTP fit, one has to look for an MTP fit with lowest training and testing RMSE errors.

2. `c-am-TiSi-MTP-training-results.hdf5`: The main `.hdf5` file can be used to inspect crystal and amorphous training data, as well as training and testing errors for all 30 fits.

- **Amorphous and crystal training configurations**, along with DFT calculated energy, forces and stresses. Right-click on the *mtp_1* object to open it with the *Movie tool*. The total number of training configurations for titanium silicide is 241 from which 22 are amorphous configurations from the **Amorphous Active Learning** stage (in the beginning of the set) and 219 are crystal configurations from the **Crystal Training Data** stage.



•**MTP fitting analysis** to graphically inspect MAE, RMSE and r^2 values for all 30 MTP fits. Right-click on the *mtp_1* object to open it with the *MTP Analyzer*. Click on *Fit index* to choose a fit, e.g., 19 (19 is the best fit in this case), and then click *Plot*. The *MTP Analyzer* produces a scatterplot of MTP predicted values vs. the reference DFT values for energy, forces, and stress, for each of the training and testing datasets.



The above scatter plot compares the MTP predicted data (y-axis) and reference DFT data (x-axis). The energy, forces and stress values are compared for both training and test sets and indicates high accuracy of the trained MTP: the data points for energy and forces lie along the 45 degree line and for stress there are minor deviations, but overall good correlation.

Note: We recommend to look at the training configurations to aid potential debugging. In case your production simulations with the trained MTP give unexpected results, check if the training data set includes all the important

configurations that needs to be included.

3.Look at `c-am-TiSi-MTP-training-results_x.hdf5`, `active_learning_molecular_dynamics.x.log` and `active_learning_geometry_optimization.x.log` to inspect Active learning geometry optimization and melt-quench MD trajectories. Since we started from 8 different initial amorphous configurations, we have 8 different `.hdf5/.log` files, where x=0-7.

•Each `.hdf5` file contains an *alopt*, *md* and *md_2* objects, which can opened with the *Movie tool*

•The *alopt* object is for inspecting the Active learning geometry optimization trajectory along with the calculated energy and forces.

•The *md* object is for the Active learning MD melting trajectory along with the calculated temperature, energy, pressure, extrapolation grade, etc. every 10 MD steps.

•The *md_2* object is for the Active learning MD cooling trajectory along with the calculated temperature, energy, pressure, extrapolation grade, etc. every 10 MD steps.

•Open, e.g., the *md* object from the `c-am-TiSi-MTP-training-results_4.hdf5` with the *Movie Tool* and `active_learning_molecular_dynamics.4.log` with *Text Representation* to inspect MD trajectory during the Active learning MD melting phase.

•The extrapolation grade becomes 1.73 at step 30850 and 2.80 at step 30860. As these are larger than the candidate threshold of 1, but smaller than the retrain threshold of 3, these extrapolating configurations are kept as candidates to be included in the next training and the simulation proceeds.

•When the extrapolation grade becomes 18.3 at step 30870, thus larger than the retrain threshold, the current simulation will be stopped, extrapolating configurations will be added to the training data set, and then Active learning MD will be re-started now using an improved MTP fitted to the extended training data set.

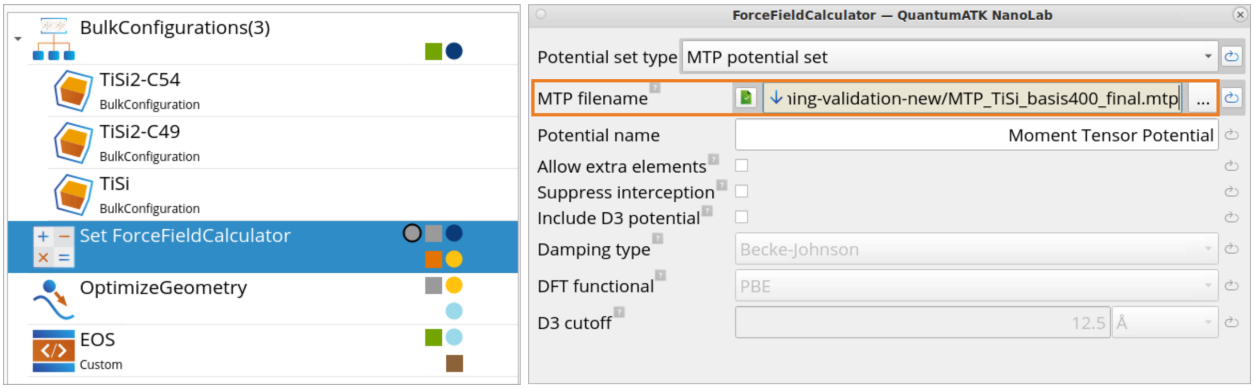
Note: As shown in this tutorial, Active learning targets PES areas where the model is uncertain and selects the extrapolating amorphous configurations (22 in this case), for which to calculate DFT training data, thus minimizing the number of expensive DFT calculations needed. Randomly sampling PES using MD alone would require much longer simulation time scales, which would then become computationally unfeasible if DFT is used for each MD step.

MTP Validation for Crystals

To validate the trained MTP for crystals, one can use the trained MTP to calculate lattice constants and equation-of-state (EOS) for the relevant crystal phases of titanium silicide, TiSi, $TiSi_2$-C54 and $TiSi_2$-C49 and compare with the corresponding DFT results.

1.Download `c-TiSi-DFT-EOS.hdf5` and `c-TiSi-MTP-EOS.hdf5` workflow files for DFT and MTP, respectively, and open them in the **Workflow Builder**.

2.In the *Set ForceFieldCalculator* block, specify the location and name of the final trained MTP, `MTP_TiSi_basis400_final.mtp`, which will be used for the validation.



Run the workflows, and once the calculations of optimizing lattice constants and obtaining EOS are finished, we are ready to analyze the results.

3. Download `c-TiSi-DFT-EOS-results.hdf5` / `c-TiSi-MTP-EOS-results.hdf5` and then in the *Data View* window select the *optgeom*, *optgeom_1* and *optgeom_2*, which contain optimized geometries of the three different crystal phases.

4. Right-click on *optgeom*, *optgeom_1* and *optgeom_2* objects to *Open All with Text Representation*. Inspect and compare lattice constants of optimized geometries obtained with the trained MTP and DFT. MTP gives good agreement with DFT results (within 1-2%) for all crystal phases, as shown in the table below.

```
# Item:     1
# Location: c-TiSi-MTP-EOS.hdf5
# Name:     optgeom
# Type:     BulkConfiguration
+-------------------------------------------------------------+
| Bulk Bravais lattice                                        |
+-------------------------------------------------------------+
Type:
FaceCenteredOrthorhombic

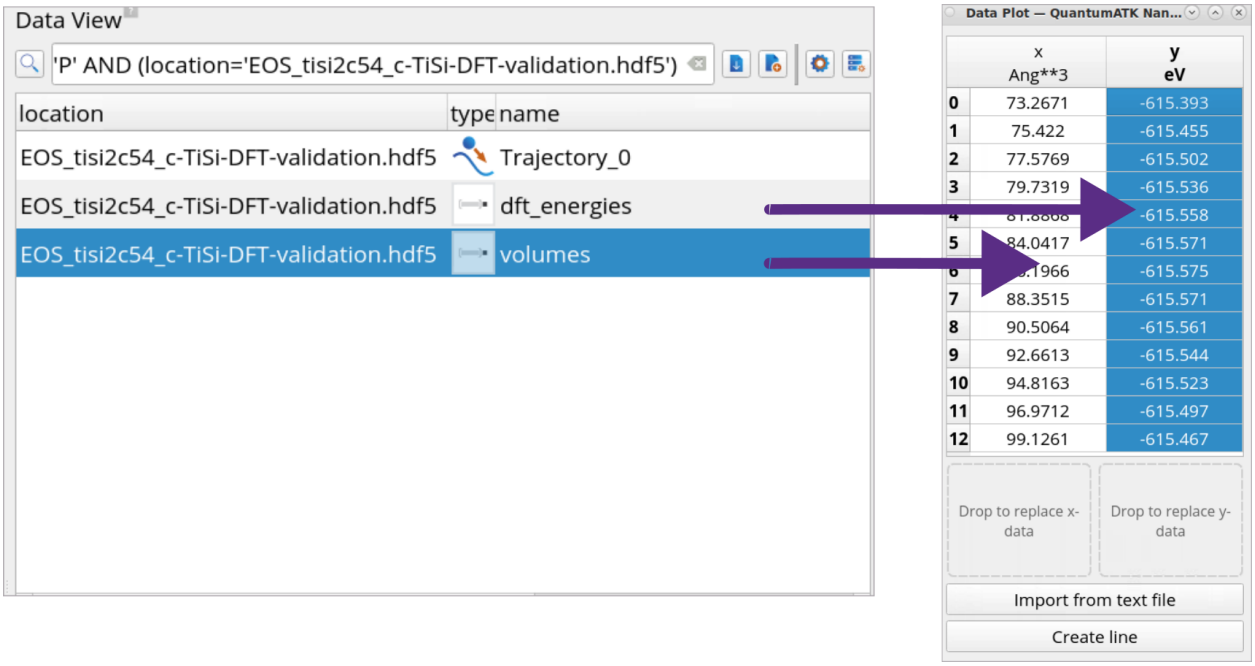
Lattice constants:
a =      4.779122 Ang
b =      8.162575 Ang
c =      8.694788 Ang
```

Lattice constants with MTP vs. DFT

	TiSi		$TiSi_2$-C54		$TiSi_2$-C49	
	MTP	DFT	MTP	DFT	MTP	DFT
a	4.779 Å	4.829 Å	3.524 Å	3.558 Å	3.657 Å	3.647 Å
b	8.163 Å	8.306 Å	13.298 Å	13.644 Å	4.955 Å	5.025 Å
c	8.695 Å	8.595 Å	3.604 Å	3.591 Å	6.419 Å	6.562 Å

5. Calculated EOS (energy as a function of volume) are saved in these files `EOS_tisi2c49_c-TiSi-MTP-validation.hdf5`, `EOS_tisi2c54_c-TiSi-MTP-validation.hdf5`, `EOS_tisi_c-TiSi-MTP-validation.hdf5` for MTP and in these files `EOS_tisi2c49_c-TiSi-DFT-validation.hdf5`, `EOS_tisi2c54_c-TiSi-DFT-validation.hdf5`, `EOS_tisi_c-TiSi-DFT-validation.hdf5` for DFT.

6. In **Data View**, find the *Data Plot* tool under *Supplementary tools*, and then drag-and-drop *volumes* and *dft_energies* from the *Data View* panel to the *Data Plot* tool *x* and *y* drop areas, respectively.



7. Click *Create line* to plot EOS for each crystal phase with DFT and MTP.
8. Repeat the steps 6 and 7 for each crystal phase with DFT and MTP for a total of 6 plots.
9. Drag-and-drop the handle from one plot to another to combine the plots into one.
10. Combined plots for $TiSi_2$-C54 and $TiSi_2$-C49 show that the trained MTP reproduces the DFT trend, so that the $TiSi_2$-C49 crystal phase is lower in energy than the $TiSi_2$-C54 crystal phase at the minimum.

MTP Validation for Amorphous

To validate the trained MTP for amorphous structures, one can use the trained MTP to run some short melt-quench MD simulations (50 ps melting and 50 ps cooling) on, e.g., $Ti_{26}Si_{52}$, take some ~10 snapshots from each and recalculate these with DFT and calculate the energy, forces and stress RMSE between MTP and DFT.

1. Download `am-TiSi-MTP-validation.hdf5` workflow and open it in the **Workflow Builder**.
2. In the *Set ForceFieldCalculator* block, specify the location and name of the final trained MTP, `MTP_TiSi_basis400_final.mtp`, which will be used for the validation.

   Run the workflow and once the calculation is finished, we are ready to analyze the results.
3. Open the `am-TiSi-MTP-validation-results.log` and at the end of the file inspect the calculated energy, forces and stress RMSE between MTP and DFT. Small RMSE values shown in the figure below indicate a good accuracy of the trained MTP.

```
+-------------------------------------------------+
| Energy RMSE: 0.0172973844972 eV                 |
| Forces RMSE: 0.231592088227 eV/Ang              |
| Stress RMSE: 0.0238206661876 eV/Ang**3          |
+-------------------------------------------------+
```

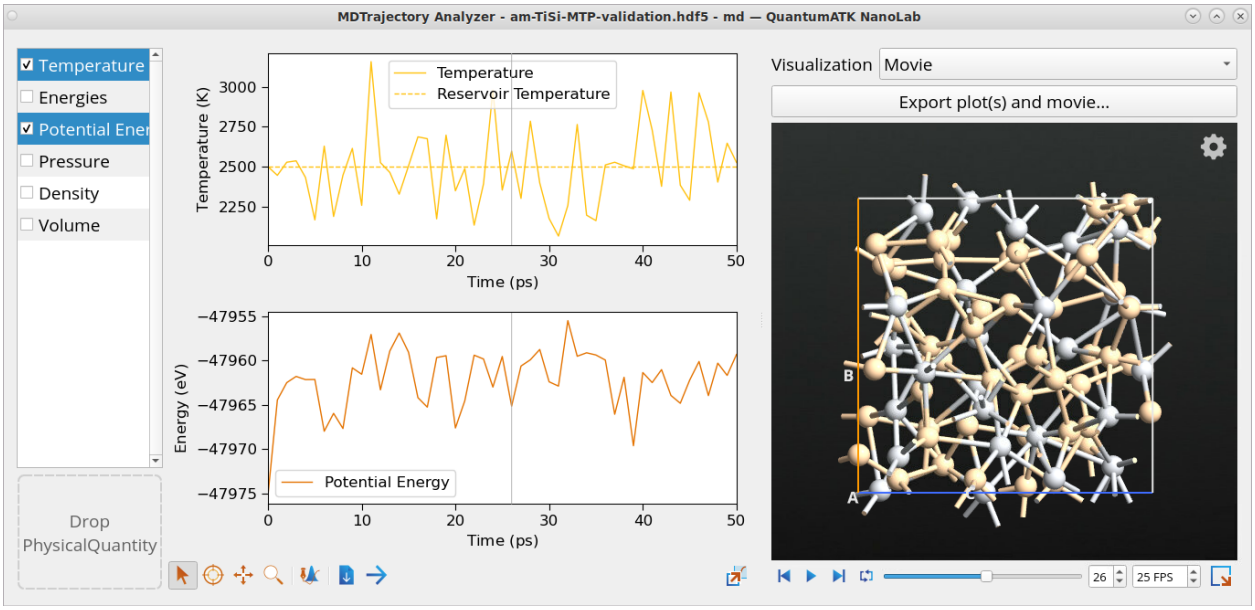
4.Open the *md* and *md_2* objects from `am-TiSi-MTP-validation-results.hdf5` using the *Movie Tool* to inspect MD trajectories from the 50 ps MD melting and from 50 ps cooling simulations, respectively.



Note: It is recommended to check the MD trajectories with the trained MTP to ensure that the trajectories look as expected and appear physical. In this case, check that the amorphous configuration does not crystallize during the cooling part of the simulation. In case of unexpected crystallization, one can consider increasing the size (number of atoms) of the amorphous training configurations and/or add additional amorphous configurations from Active learning to the training data set.

Summary and Outlook

In this introductory tutorial, you have learnt how to set up and analyze MTP training and MTP quality validation calculations for crystal and amorphous materials. In order to adapt the introduced MTP training protocol for different geometries (surfaces, interfaces, nanoparticles), stoichiometries, element composition and other materials, you need to explicitly include relevant training data for such structures.

Depending on the intended MTP application, consider also validating these properties against the reference DFT values:

- Elastic constants, bulk modulus, phonon bandstructure.
- RDF and ADF for amorphous structures (it requires some long DFT-MD simulations, which is expensive).
- Experimental properties that are relevant for the application, if available, but note that since the MTP is trained to reproduce DFT results it can only be as accurate as the underlying DFT model.

MRAM builder Basic QuantumATK Tutorial ATK Reference Manual Vampire

This video tutorial will introduce the QuantumATK interface to the Vampire code and use it to calculate the free layer stability factor in a STT-MRAM magnetic tunnel junction structure. The stability factor is obtained from atomistic spin dynamics simulations using Vampire with input parameters obtained from density functional theory (DFT).

Introduction

Spin transfer torque magnetic random access memory (STT-MRAM) is currently being used as standalone and embedded MRAM in modern technology nodes. Further enhancement of the application of STT-MRAM as last level cache requires optimization of the performance and scalability of the magnetic tunnel junction (MTJ) stacks comprising the reference and free magnetic layers as well as additional tunnel barrier and capping layers. The main parameters to optimize in a STT-MRAM are

•**Reading**. This is determined by the tunneling magneto resistance (TMR), which can be calculated using DFT-NEGF in QuantumATK.

•**Writing**. The writing operation depends on multiple parameters such as spin transfer torque, magnetic moment of the free layer, and Gilbert damping. These quantities can also be studied with QuantumATK.

•**Storage**. The storage is characterized by the stability factor $\Delta = \frac{\Delta E}{k_B T}$, where ΔE is the anisotropy energy at the operating temperature T. This is the topic for this tutorial.

Engineering the MTJ to co-optimize the three main requirements of reading, writing, and storage is an active area of research and development.

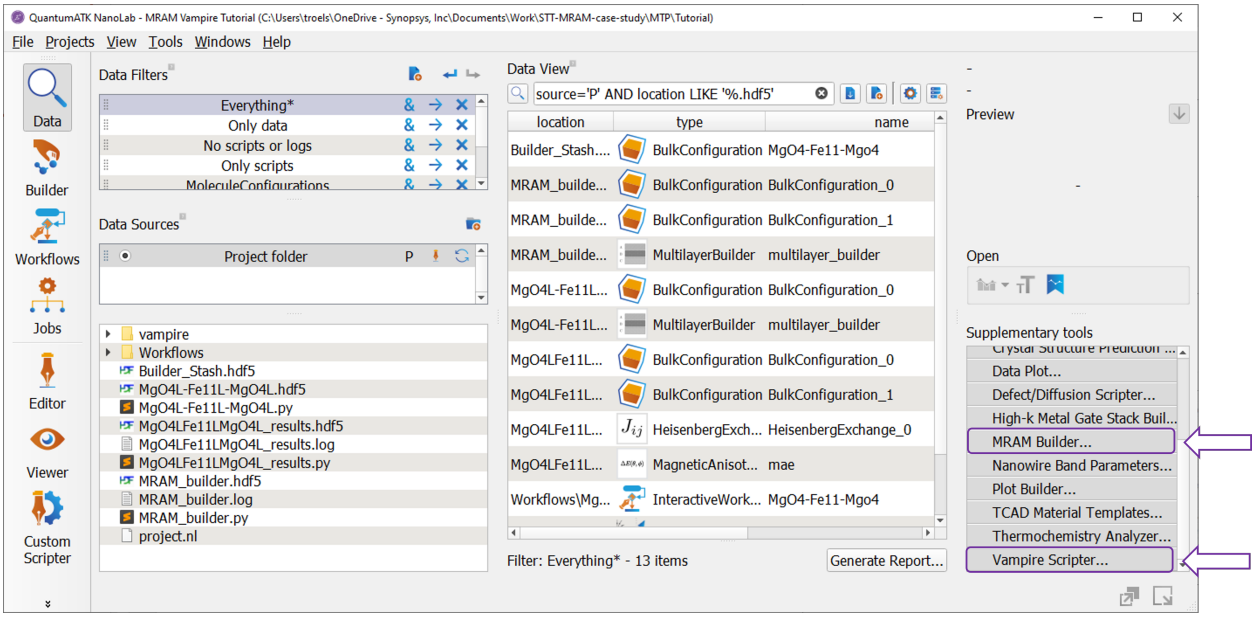
In this video tutorial we demonstrate a work-flow for calculating the stability factor based on atomistic calculations. Below we summarize the main steps in the work flow, but leave the details to the video.

Workflow for calculating the free layer stability in a STT-MRAM MTJ structure

In the tutorial we adopt the following workflow

- Setup the structure using the **MRAM Builder** and perform structural relaxation with machine-learned forcefield of the moment tensor potential (MTP) type.
- Calculate Heisenberg exchange coupling parameters and uniaxial anisotropy energies with the *HeisenbergExchange* and *MagneticAnisotropyEnergy* objects using DFT.
- Setup and run Vampire simulations using the **Vampire Scripter** and analyze the results.

The figure below shows where to find the **MRAM builder** used for building the MTJ structure, and the **Vampire Scripter** used for setting up the Vampire simulations.



Vampire

The Vampire simulation tool enables you to perform a range of different atomistic spin dynamics simulations. Common to them all is the basic description of the spin Hamiltonian of the system. While parameterizations of the spin Hamiltonian exist for bulk materials, it is important to note that several of these parameters change significantly in nano-structured systems and in particular at interfaces between different materials. It it thus advantageous to couple DFT calculated parameters with the Vampire simulations.

Spin Hamiltonian

The starting point for atomistic spin dynamics simulations performed in Vampire is the spin Hamiltonian

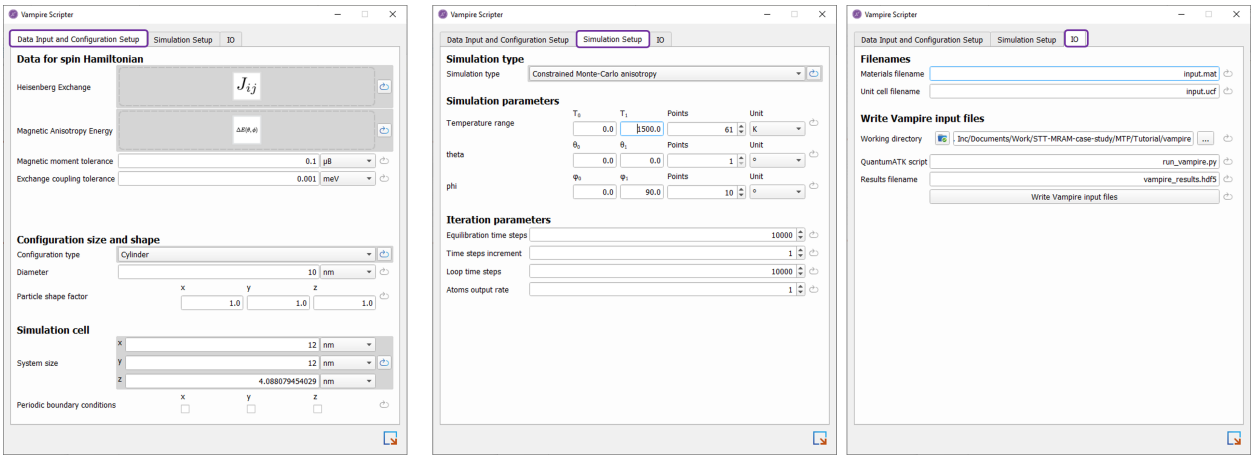
$$H = -\sum_{i<j} J_{ij}\,\mathbf{S}_i \cdot \mathbf{S}_j - \sum_i k_i (\mathbf{S}_i \cdot \mathbf{e}_z)^2 - \sum_i \mu_i\,\mathbf{B}_{app} \cdot \mathbf{S}_i$$

where J_{ij} are the Heisenberg exchange coupling parameters that can be calculated in QuantumATK using the *HeisenbergExchange* analysis object. The spin vector $\mathbf{S}_i$ is a normalized vector with the local spin moment direction on atom i, and k_i is the uniaxial anisotropy energy for atom i, which can be calculated in QuantumATK using the *MagneticAnisotropyEnergy* study object, and $\mathbf{e}_z$ is a unit vector along the z-direction. B_{app} is an externally applied field and μ_i is the local spin moment of atom i.

More information can be found on the Vampire home page and in refs.[1] and[2]. Please cite these papers appropriately if using Vampire in scientific publications.

Vampire scripter

When opening the **Vampire Scripter**, you need to drag-and-drop a *HeisenbergExchange* onto the first tab in the scripter. This is always required. For magnetic anisotropy energy calculation, you should also provide a *MagneticAnisotropyEnergy* object since this is responsible for the uniaxial anisotropy constant giving rise to to the anisotropy energy. The first tab is also where you specify the configuration size and shape as well as the simulation cell.



In the second tab you specify the simulation type and various parameters, while in the third tab you specify filenames and where to run the simulation.

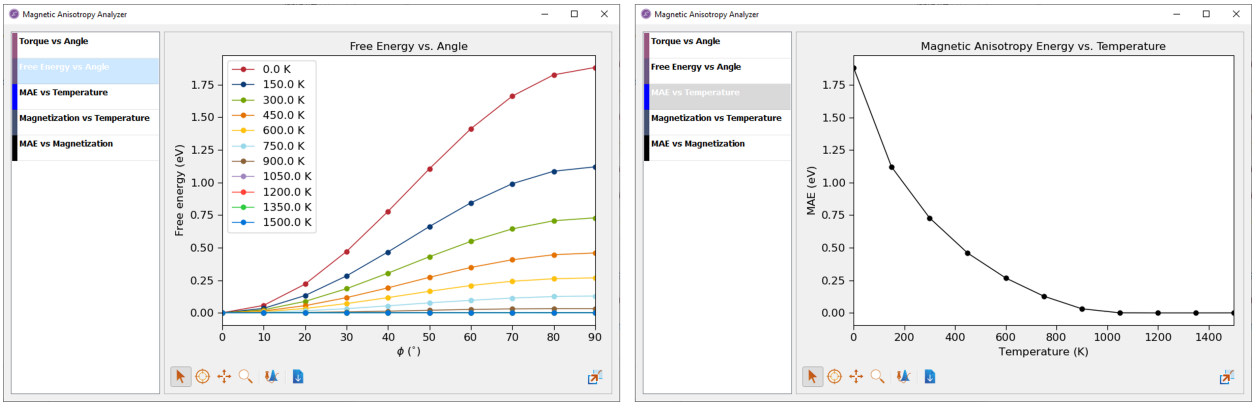
[2] P.ăAsselin, R.ăF.ăL. Evans, J.ăBarker, R.ăW. Chantrell, R.ăYanes, O.ăChubykalo-Fesenko, D.ăHinzke, and U.ăNowak. Constrained Monte Carlo method and calculation of the temperature dependence of magnetic anisotropy. *Phys. Rev. B*, 82:054415, Aug 2010. URL: https://link.aps.org/doi/10.1103/PhysRevB.82.054415, doi:10.1103/PhysRevB.82.054415.

Anisotropy energy

Using the constrained monte-carlo (CMC) anisotropy method in Vampire[Page 333, 2], it is possible to calculate the anisotropy energy $\Delta E(T)$, as shown in the tutorial. This differs from the uniaxial anisotropy energy, ΔE_0, obtained from the *MagneticAnisotropyEnergy* study object by being evaluated at a finite temperature, whereas ΔE_0 is a zero-temperature result. Also, the $\Delta E(T)$ obtained from the Vampire simulation is obtained from the large cylindrical structure, whereas the ΔE_0 from the *MagneticAnisotropyEnergy* study object is obtained from the unit cell. There is thus an area factor difference such that at 0 K we thus expect $\Delta E(0K)/\Delta E_0 \approx \pi R^2/A_{uc}$, where A_{uc} is the unit cell area.



The figure shows two of the analysis tabs in the the **Magnetic Anisotropy Analyzer** used for visualizing and analyzing the result of the Vampire CMC anisotropy simulation. From the MAE value at 300 K $\Delta E(300K) = 0.729\,\mathrm{eV}$ we manually obtain the magnetic stability factor for the 10 nm diameter cylinder

$$\Delta_{10nm} = \frac{\Delta E(T)}{k_B T} = \frac{0.729eV}{0.0258} = 28$$

For 10 years of retention, one typically requires $\Delta = 60$. Assuming that ΔE is proportional to the area, this would require a cylinder with a diameter of

$$\frac{\Delta = 60}{\Delta_{10nm}} = \frac{\pi D}{\pi(10\,\mathrm{nm})^2} \Rightarrow D = 10\,\mathrm{nm}\sqrt{\frac{60}{28}} \approx 15\,\mathrm{nm}$$

3.1.5 Generating A Magnetoresistive RAM (MRAM) Stack using the MRAM-Builder

Version: U-2022.12

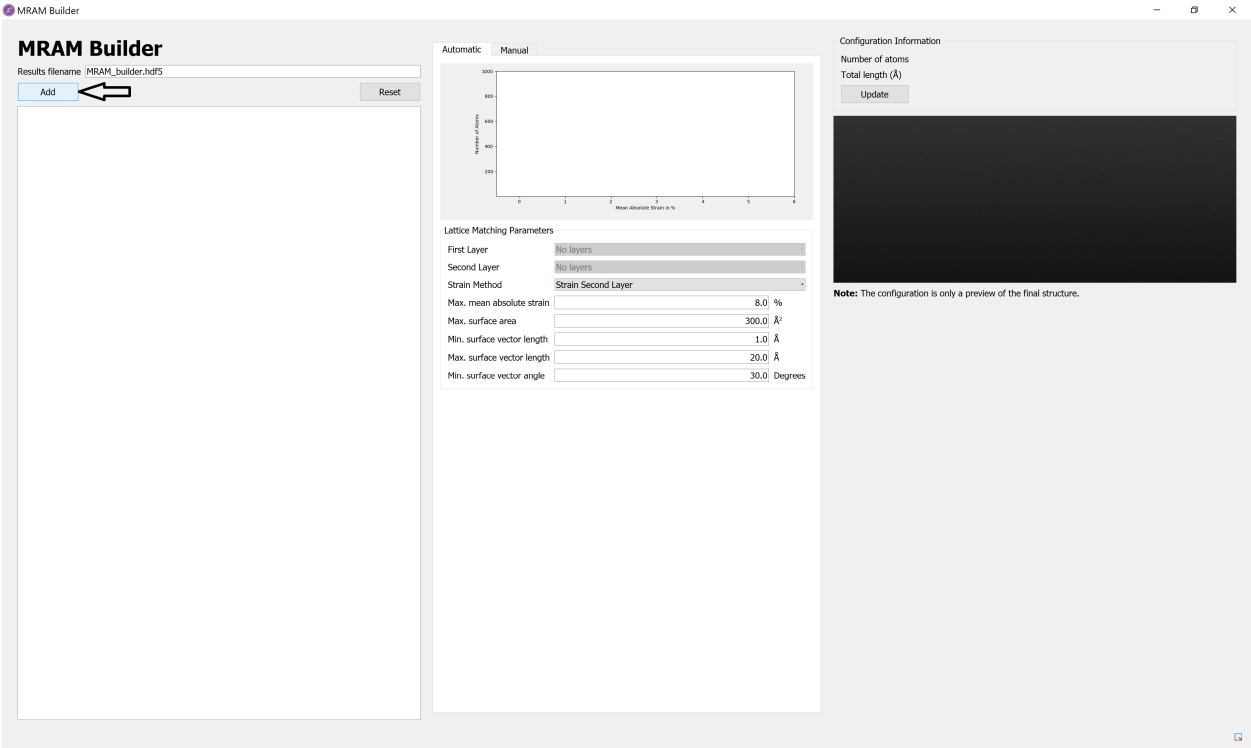
Introduction

Magnetoresistive RAM has become of increased interest for memory technology in the recent years. This device uses magnetic states to store information. It writes and reads electronically, hence enables to integrate in semiconductor chips. Understanding the configuration at the atomic level will help to engineer different properties i.e. *MagneticAnisotropyEnergy* (MAE). To understand the correlation between changes in the atomic structure and stack composition, it is often needed to create multiple configurations. However constructing such configurations at DFT level is very time consuming. Here we use moment tensor potential (MTP) which is a machine learned interatomic potential, to construct such configurations. Machine learned interatomic potentials (MLIPs) have emerged popular in recent years since they can provide ab initio level of accuracy within a realistic timescale, even for relatively complex materials. More information about the MTP can be found here .

Workflow to generate the MgO-FeCo-MgO MRAM structure

We begin by setting up the atomic structure of a MgO-FeCo-MgO structure. Start by opening the **MRAM Builder**. The MRAM Builder can be found in the **Nanolab**. In the MRAM Builder do the following (see image below):

•Press the **Add** icon. This will add new layers.

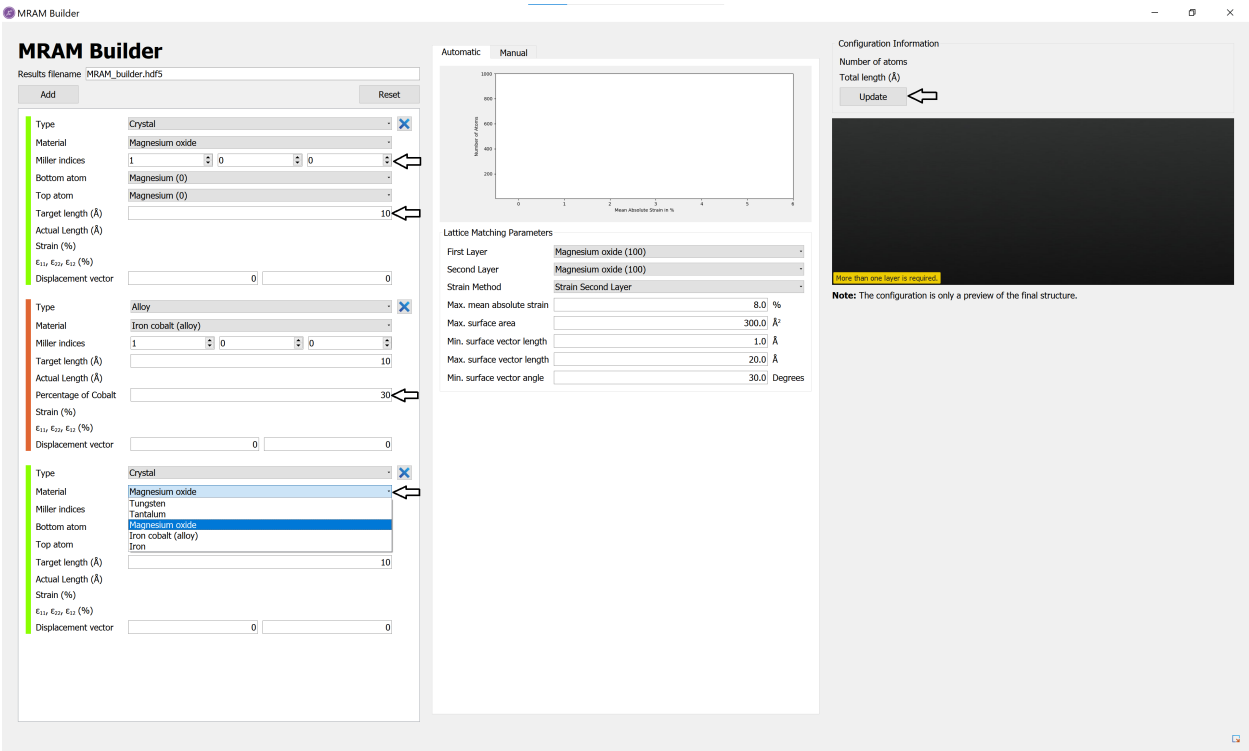


In the layers you can do the following changes (see image below):

•You can change the **material**, **miller indices** and the **thickness** of the layer.

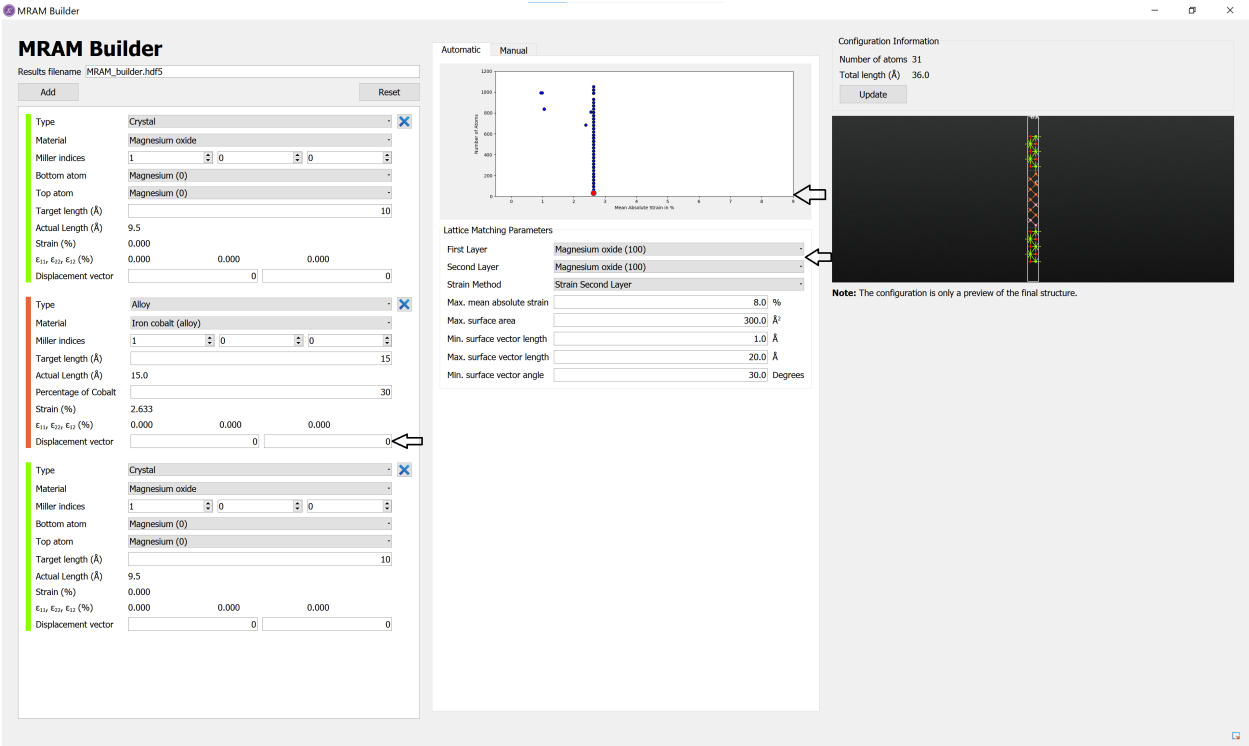
•If the material type is alloy then you can select the **percentage of Cobalt**.

•After the changes you need to click **Update**. This will create multiple stack candidates with different ratio of strain vs. number of atoms.



Next you can do the following steps:

- you can select the configuration based on mean average strain and number of atoms from the **mean average strain vs number of atoms** plot.
- You can also change the **Displacement vector** with the mouse wheel or arrow keys to move a certain layer laterally in the AB-plane. This can be used to control the interface alignment, e.g. which atoms above each other. This will help to create a better initial configuration to obtain configurations with less defects.
- You can modify the strain method as well as the layer that you want to strain from **Lattice Matching Parameters**.



Send the calculation to the **Job Manager** using the icon and run the calculation. If needed some modification in the script, you can generate a script using the **Send-to** button and run the calculation.

Note:

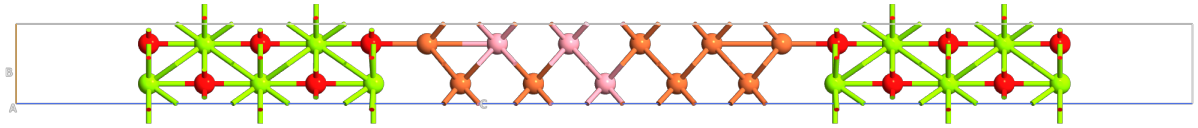
- The builder for this type of stack is primarily designed to work with *CrystalLayer* and *AlloyLayer* types. Pre-trained MTP models for Fe-MgO, FeCo-MgO, Ta-Fe, Ta-FeCo, W-Fe, W-FeCo interfaces and FeCo alloy are provided in the MRAM builder. Other interfaces can be used in scripting, if a suitable interface calculator is specified. This could be a DFT calculator, a force-field calculator, or a user-trained MTP model.
- The `relaxation_length` and `interaction_length` can be tuned according to the need of the interface. If the layer thickness is less than the `relaxation_length` then the optimization will not be done for the interface. By default, interfaces are not annealed, but this can be activated if needed.

Tip:

- To run the MultilayerBuilder efficiently in parallel we recommend using the OpenMP parallelization.
- If you have multiple alloy layers in the stack, you should provide different values for the `random_seed` parameter in *AlloyLayer*. This will ensure that all the alloy layers in the stack are different.
- If you increase the thickness of the layer from the default values, increasing the `relaxation_length` and `interaction_length` parameters in the script can help to achieve better configuration. For more details on these parameters please check the *MultilayerBuilder* study object.

The final MRAM stack configuration can be accessed using the `configuration()` method in *MultilayerBuilder*. A MgO-FeCo-MgO MRAM stack obtained from such calculation is shown below. Download the provided script (`MRAM_builder_example.py`) to generate such a configuration. This configuration is now ready for further DFT

calculation for different electronic and magnetic properties. One can also use it as a starting configuration to manually add defects or dopant atoms in the Builder to investigate their effect on the magnetic properties.



3.1.6 Generating A High-k Metal Gate Stack Using the HKMG-Builder

Version: U-2022.12

Introduction

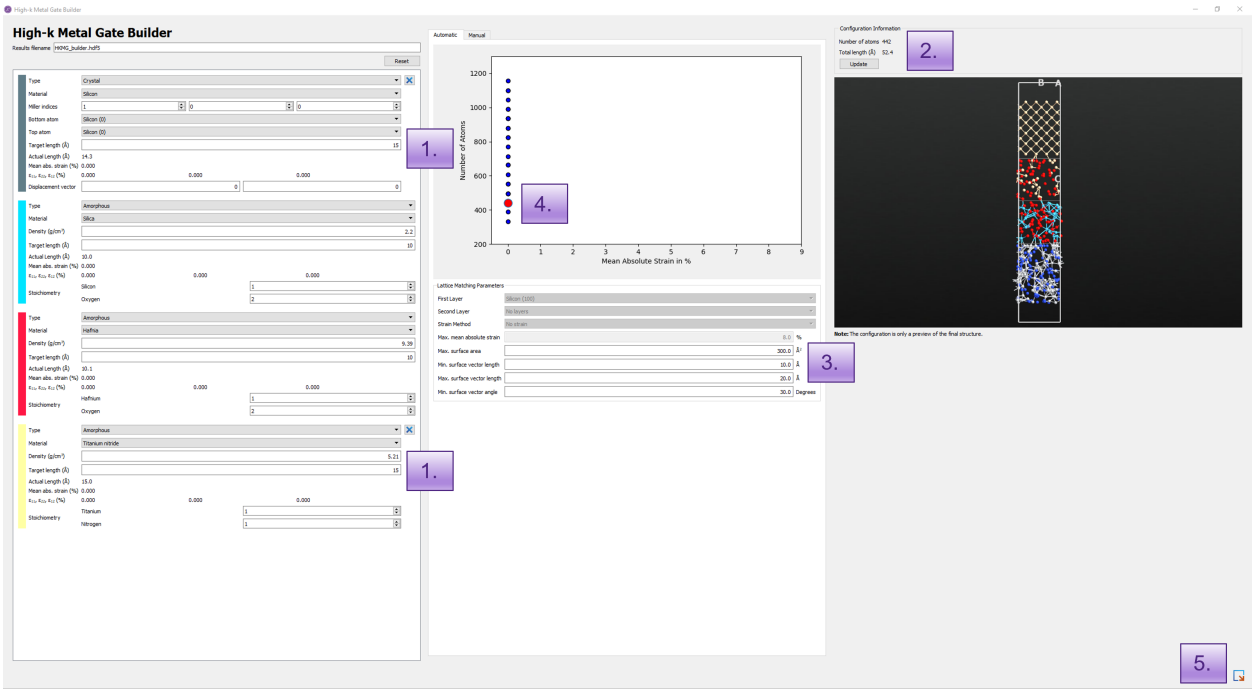
HKMG stacks are complex device building blocks used in transistor gates in modern logic applications. They consist of layers of different materials in different states (e.g. crystalline, poly-crystalline, amorphous). Understanding these stacks at the atomic level will help to tune electronic and structural properties. However, constructing and structurally optimizing such stacks at the DFT level requires considerable computational resources. Instead, we use moment tensor potentials (MTP) which are machine learned force fields (ML-FFs). ML-FFs have become popular in recent years since they can provide *ab-initio* level of accuracy within a realistic timescale. More information about MTP can be found here.

Workflow

Step 1: Prepare the script using the builder

Open the **High-k Metal Gate Stack Builder** found in the *Supplementary tools* section of **NanoLab**.

The builder is pre-populated with a four-layer stack consisting of the semiconductor substrate, an insulating oxide, the high-k material and finally a metallic layer. Different choices of materials are available and all layers can be selected either as crystalline or amorphous. In the case of amorphous layers, the stoichiometry may be specified. For this tutorial, the default settings will not be changed except for the lengths of the outer layers which are considered to be bulk-like. The builder produces a script which will generate the actual HKMG-stack when run. To obtain the script, follow the steps below.



1.Change the target length of silicon and titanium nitride to 15 Å.

2.Click *Update* to show the stack preview.

3.Increase the min. surface vector length to 10 Å to filter out small unit cells.

4.Select the third stack from the bottom of the size-strain plot. This stack has a square base.

5.Generate the script by clicking on and sending to the **Editor** or download it here: `HKMG_builder_original.py`.

Tip:

•The displacement of the layers in the AB plane can be adjusted by clicking into the **Displacement vector** field and using the mouse wheel or arrow keys. The updated interface will be shown in the preview after pressing enter. This is particularly useful for aligning atoms in crystal-crystal interfaces and reducing defects.

Step 2: Get candidate structures by running the script

The generated script has to be run in order to build the final stack structure. As an alternative, the preview structure can be sent to the **Builder** to be inspected and manually modified. However, especially for amorphous layers, it is strongly recommended to refine the initial structure using the *MultilayerBuilder*, which will take care of optimizing interfaces and properly annealing amorphous layers.

Tip:

•To run the MultilayerBuilder efficiently we recommend using OpenMP parallelization.

•For layers of a certain thickness it might be advisable to change the *relaxation_length* and *interaction_length* arguments for better results.

Since generating the amorphous layers is a stochastic procedure, it is not guaranteed that the result of a single script run will yield a stack with satisfactory properties. In the following we will therefore build several candidate stacks by repeating the layer set-up and the *MultilayerBuilder* run in a loop using different random seeds. Take a look at the modified script (`HKMG_builder_loop.py`) and optionally change the sample size or the random seed. Then run the script. This step might take several hours on a multi-core workstation.

Note: Validated, ready-to-use MTPs are provided for all material and interface combinations available in the builder. However, user generated potentials can be substituted in the script.

Step 3: Select a high-quality stack from the set of candidates

Now that we have a set of initial candidate structure from step 2, we can proceed to select the best stack configuration. The most important quality criteria to consider are unphysical bonding patterns and various forms of (coordination-) defects formed in particular at the interfaces.

Download the provided script (`selectHKMGconfigurations.py`) which first checks for too close atoms. Then, it passivates dangling Si-bonds at the Si-SiO_2 interface by inserting additional hydrogen and oxygen atoms. Finally it filters out stacks with undesired structural patterns, such as O-O bonds, as well as clearly over- and under-coordinated atoms. Run the script in the same folder containing the builder output to receive a list of low-defect stacks ranked by the number of added saturating hydrogen atoms.

3.1.7 How to select the right calculator

A calculator is the engine that performs the atomic simulations, defining how we describe the interactions of the electronic system. It both represents a level of theory (full quantum mechanical approach, semi empirical approach, or classical approach) and algorithmic settings.

In this tutorial, you will receive a brief overview of the different calculators and learn to select the calculator that best fits your needs in *QuantumATK NanoLab*.

Table of Contents

- *The Calculator types*
- *The DFT Calculators (LCAO and Plane Wave)*
- *The Semi Empirical Calculator*
- *The Force Field Calculator*

The Calculator types

When setting up a calculation in the *Workflows* tool ( ) you must select a calculator to perform the atomic scale modelling.

	Quantum Mechanical (DFT) Calculators
DFT: LCAO *DFT: Plane Wave*	The two quantum mechanical calculators both model the electronic properties within the framework of density functional theory (DFT). These DFT calculators provide the most accurate results, but require the largest computational resources. It is recommended to use these when the accuracy of the results is of foremost concern.
	Semi Empirical Calculator
Semi Empirical	The semi empirical calculator is also based on DFT, but it approximates the electron-electron interactions, using experimental data. Due to these approximations the semi empirical calculator is orders of magnitudes faster than the quantum mechanical calculators, but the accuracy is correspondingly reduced. The semi empirical calculator is often used when qualitative results will suffice, or when a DFT calculator cannot be used.
	The Classical Calculator
Force Field	The force field calculator, is based on classical mechanics and estimate the forces between atoms using a range of element-pair specific potentials. The force field calculator is the fastest calculator, orders of magnitudes faster than the semi empirical calculator, and is often the calculator of choice when dealing with huge systems (many thousands of atoms) or when modelling the full dynamic evolution of the system on longer time frames (molecular dynamics).

The DFT Calculators (LCAO and Plane Wave)

Both the plane wave calculator and the LCAO calculator solve the time independent Kohn–Sham equations. The main difference is that the LCAO calculator employs numerical LCAO (**L**inear **C**ombination of **A**tomic **O**rbitals) basis sets, while the plane wave calculator employs a PW (**P**lane **W**ave) basis set.

Neither of the two DFT calculators require any system specific input, and can in general be expected to produce results of similar quality, independent of the system. A basis set is required for each element species in the system under investigation (for plane wave, the basis set is only used for initialization and projections). Nearly all basis set provide support for all elements, with only a few exceptions.

The Plane Wave Calculator

The plane wave bases incorporate the periodicity of the bulk system into the basis set, which allows a higher accuracy to be obtained. The plane wave calculator is the state of the art calculator, though it is often slow and can only be applied to bulk systems. *Introducing the QuantumATK plane-wave DFT calculator*

See *DFT: Plane Wave* for more details.

The plane wave calculator is suitable for treating system sizes on the order of hundreds of atoms.

The LCAO Calculator

In general, it is recommended to use the LCAO calculator, which can work with both molecules and bulk systems. In most cases, an accuracy close to the plane wave calculator can be achieved at significantly reduced computational effort. The accuracy of the LCAO calculator can be improved even more by using a larger basis set, at the cost of longer computation times. See *DFT: LCAO* for more details.

The LCAO calculator is suitable for treating system sizes on the order of thousands of atoms.

Note: Computational effort for the DFT calculators depends heavily on the exchange correlation functional and calculator settings.

The Semi Empirical Calculator

The semi empirical calculator requires a parameter set.

QuantumATK NanoLab includes a selection of parameter sets designed for a range of purposes. However, each parameter set is only constructed for a subset of elements on the periodic table. Thus, it may be that there is no parameter set which provides support for all elements in the system under investigation.

The semi empirical calculator is suitable for treating system sizes on the order of thousands of atoms.

The is the calculator of choice when performing large scale NEGF calculations (*NEGF: Device Calculators*, see *Transport calculations with QuantumATK*)

See *Semi Empirical* for more details.

The Force Field Calculator

The force field calculator requires a potential set, comprised of potential components, which defines the types of atomic interactions to be modeled between different atomic element pairs. Consequentially, the potential set must include support for all elements in the system under investigation.

QuantumATK NanoLab includes a selection of potential sets designed for a range of purposes (See *Force Field* for more details.). However, each potential set is only constructed for a subset of elements on the periodic table. Thus, it may be that there is no potential set which provides support for all elements in the system under investigation. In such a case, there is an advance feature to create a custom potential set, which must be manually configured to handle all relevant atomic interactions between all relevant atomic element pairs.

The force field calculator is suitable for treating system sizes on the order of tens of thousands of atoms.

See *Force Field* for more details.

Bonding and non-bonding potential sets

Roughly speaking, potential sets come in two flavors: rigid and flexible.

Rigid potential sets do not handle molecular bonding, and are thus geared towards modelling non-reactive interactions such as angle-strain (represented by harmonic potentials) or dispersion (represented by van der Waals potentials).

To model chemical reactions, a flexible potential set should be used instead. Flexible potential sets can model the formation and breaking of bonds, allowing the calculator to reproduce reaction chemistry without explicit quantum mechanical considerations.

Machine Learned Potentials

MTPs (**M**oment **T**ensor **P**otentials) are machine-learned potentials that allow dynamics modelling of arbitrary materials systems. The accuracy of the results, as well as what scenarios can be modeled, are dependent on the training data used to produce the MTP. MTPs are suitable to use when large systems (e.g., amorphous materials or multi-layer stacks) need to modeled with near-*ab initio* accuracy.

3.1.8 Using Thermochemistry Analyzer to Compare Chemical Reactions

Version: T-2022.03

Downloads & Links

IdealGasThermoChemistry CrystalThermoChemistry

In this tutorial, we will learn how to use the *Thermochemistry Analyzer* GUI for computing and comparing free energies of chemical reactions. This tool can be used to quickly set up thermochemical calculations of molecules and bulk/surface configurations, import computed thermochemistry data into a database and plot free energy change of reactions.

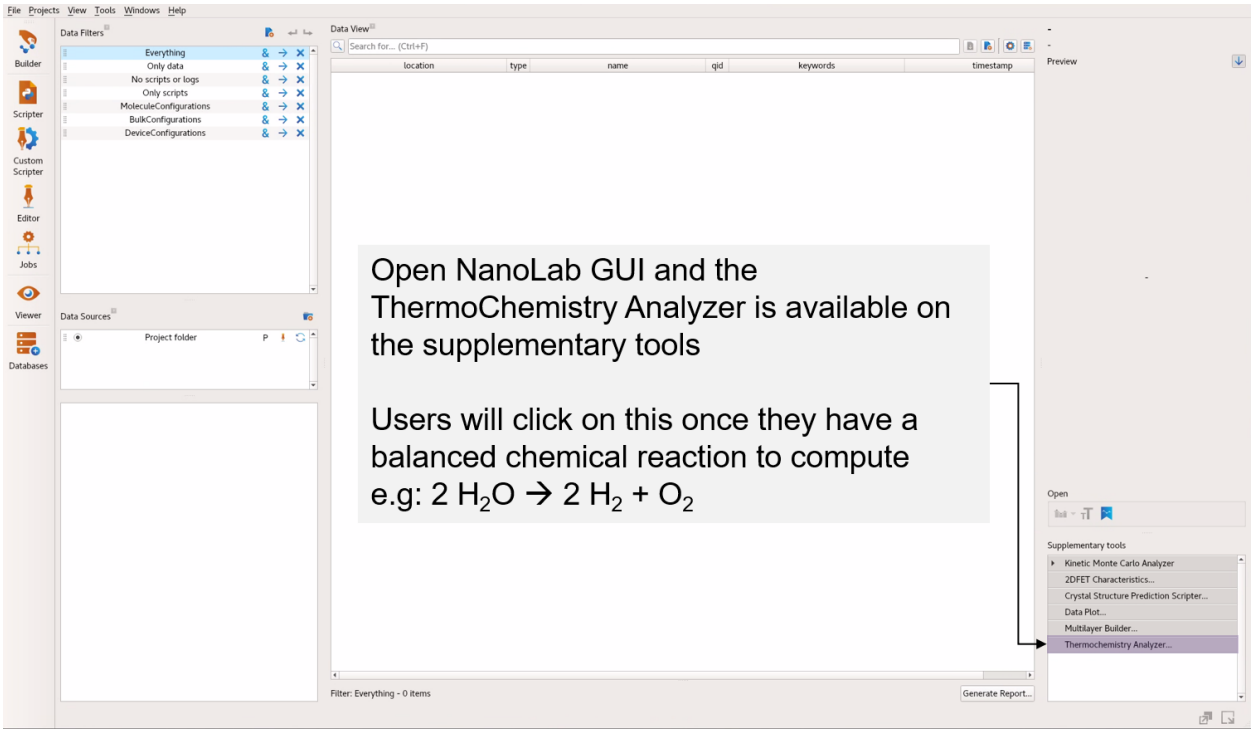
Background

In any process under study, several chemical reactions take place at the same time and some of them may compete with each other. It is interesting to find out which reaction is more dominant under a given process condition. One way to find the dominant reaction from a group of reactions is to compare their reaction free energies. Free energy (G) of a chemical species indicates the total energy available to it to diffuse, vibrate and react with other species in a medium. Free energies of molecules can be computed under the ideal gas approximation while the free energy of bulk/surface systems can be computed under the quasi-harmonic approximation. A reaction constitutes reactants and products, each of which includes 1 or more species. A reaction free energy (G) is then the difference between the combined free energies of the product species and that of the reactant species. The more negative G is, the more favorable a reaction becomes at that condition and vice-versa. It is to be noted that the G changes with process variables like temperature, pressure and concentration.

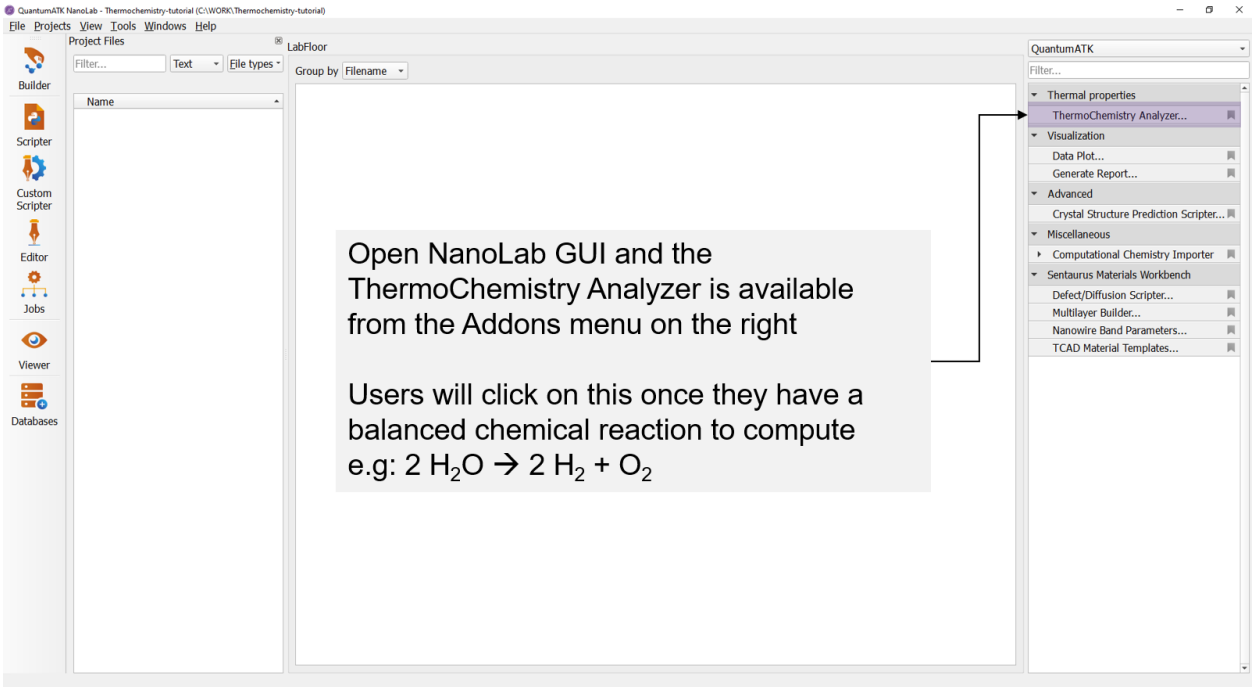
In **QuantumATK**, the *Thermochemistry Analyzer* GUI provides a one-stop-solution to compute the free energies of the participating species in a reaction using Density Functional Theory (DFT) and, ultimately, compare Gs of several reactions. The *Thermochemistry analyzer* comes with a *Thermochemistry Database* to store and extend user-generated thermochemical data of different species so the user can compare reactions whenever they want without having to compute/import the thermochemical data every single time.

Getting started

Open the **QuantumATK** GUI, NanoLab, and click *Thermochemistry Analyzer* from the supplementary tools menu on the right.

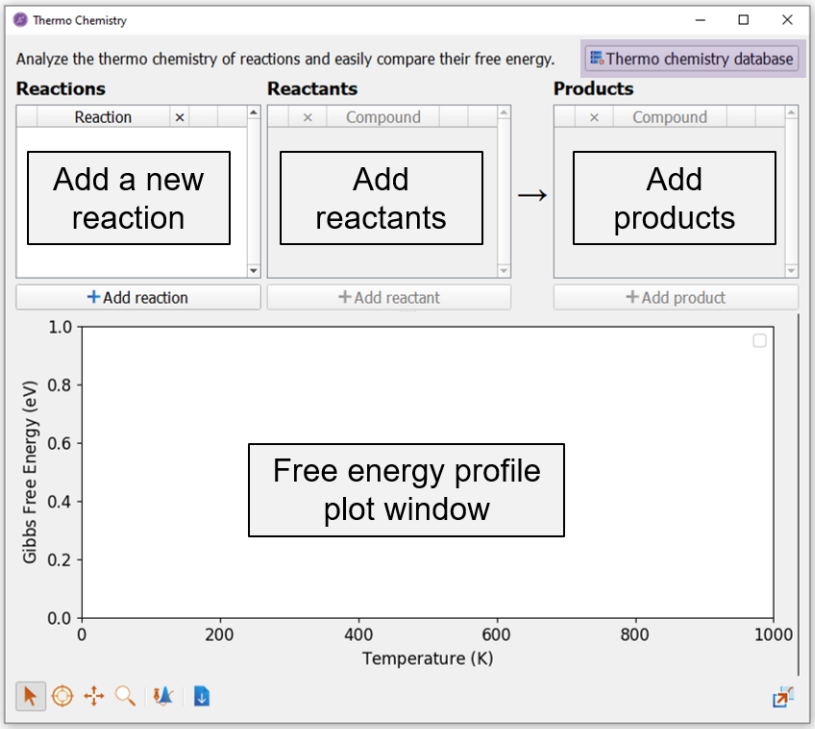


In the S release, it is found in the Addons section to the right.



Understanding the Thermochemistry Analyzer GUI

The GUI of *Thermochemistry Analyzer* is illustrated in the below image.

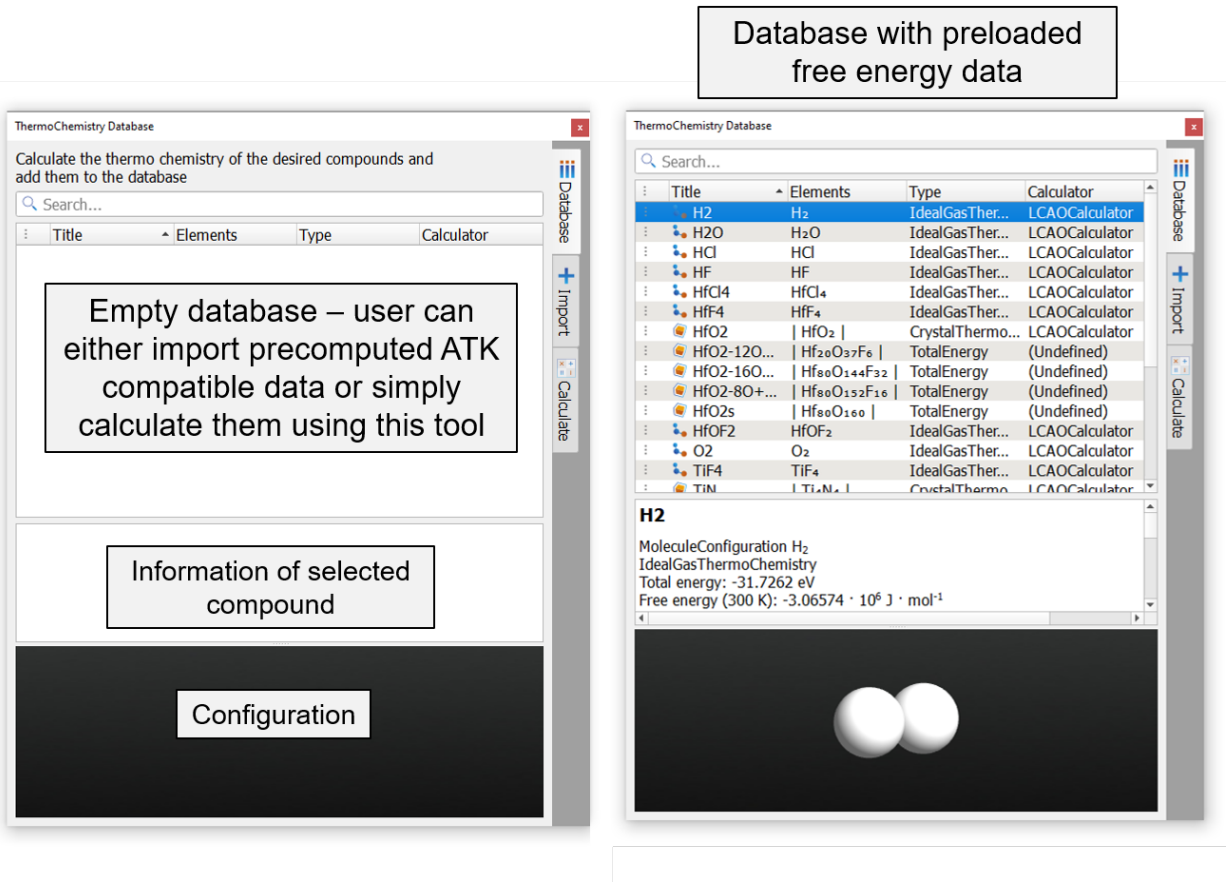


The GUI window has two main regions. The top region is for reaction input, in which the user can add a new reaction by clicking the *Add reaction* button. The next step is to add the reactant and product species of that reaction one-by-one by clicking the *Add reactant* and the *Add product* buttons.

The bottom region is a plot window, which will be updated with curves plotting the free energy of the reaction as a function of temperature. The free energy curves will appear as soon as the user adds the first reactant/product species from the *Thermochemistry Database* and updates automatically as the other reactant and product species are added.

Access to the *Thermochemistry database* is allowed by pressing the button at the top right corner of this GUI window highlighted in purple in the above image.

The below image shows an illustration of the *Thermochemistry Database*.



Thermochemistry Database GUI contains three sub-windows titled Database, Import and Calculate.

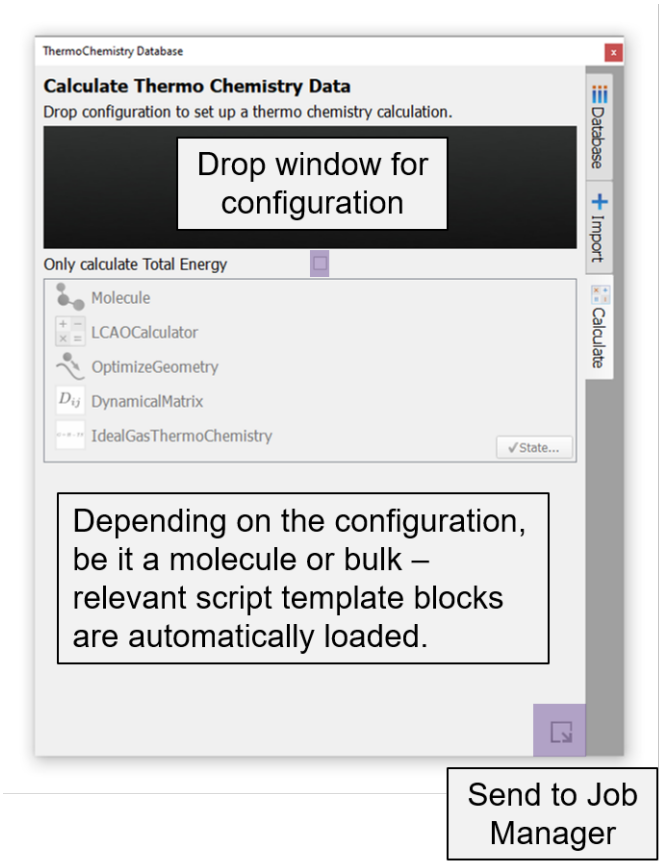
Database: A place to store thermochemistry data

The thermochemistry data of molecules and bulk/surface models are listed in this sub-window. The data is locally stored in .vnl/databases/thermochemistry. User can copy precomputed ATK compatible database entries to the above folder directly. However, we provide precomputed data for a few molecules, bulk material and surface geometries that will appear as shown in the above image.

The database gives the following information of the species: its user defined name, chemical formula, type of data (ideal gas thermochemistry, crystal thermochemistry or total energy) and the type of calculator used. On selecting any of the entry in the database, its geometry will be shown in the configuration window at the bottom and the settings used to compute its electronic structure will be printed in the text box above it.

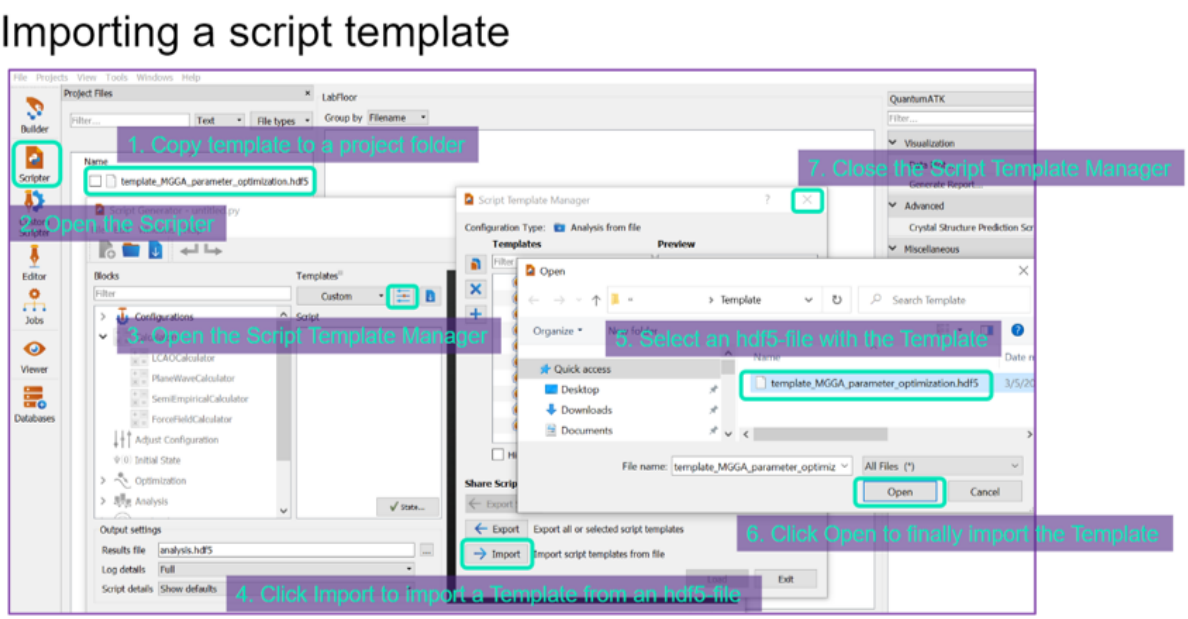
Calculate: Setup free energy calculation of a molecule or bulk configuration

Free energy calculation of a species can be set up using this sub-window.



Here, the user will drag and drop a configuration on to the drop window. Depending on the configuration, molecule or bulk, a corresponding script template to compute free energy will be loaded. This template typically contains by default the *Configuration*, *LCAOCalculator* with PBE XC functional and Pseudo-Dojo high basis set, *OptimizeGeometry* block, *DynamicalMatrix* and *IdealGasThermoChemistry* for molecule configuration (read *Notes*) or *CrystalThermoChemistry* for bulk configuration (read *Notes*). The user can edit the DFT calculator settings, constraints and tolerance for the geometry optimization and dynamical matrix. The default settings are verified to reproduce free energies reported in JANAF tables for several molecules. The user can select the *Only calculate Total Energy* option to replace the DynamicalMatrix and ThermoChemistry blocks in the scripter with a TotalEnergy object. The job can be submitted to a cluster or local computer via JobManager directly from this sub-window.

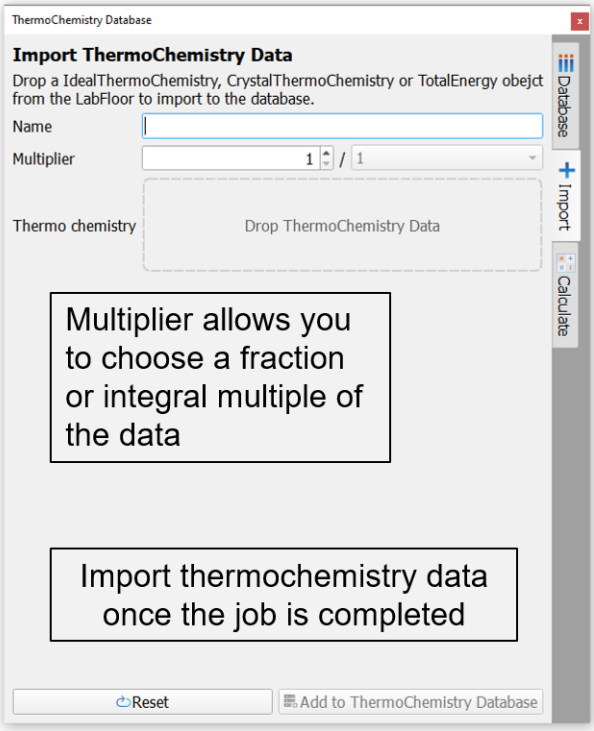
Alternatively, these calculations can also be set up in script generator using the following templates `bulk_LCAO_thermochemistry_template.hdf5`, `molecule_LCAO_thermochemistry_template.hdf5` and `surface_LCAO_thermochemistry_template.hdf5` for bulk, molecule and surface configurations, respectively. When templates are used, the calculator can also be changed. But be careful not to compute free energy using data computed using different calculators. These templates can be loaded to the script generator following the below graphic.



The resulting ThermoChemistry objects from these calculations can be imported to the *Thermochemistry Database* using the next sub-window.

Import

Once the calculations are finished and loaded on the LabFloor, the free energy/total energy data objects can be imported to the thermochemistry database in this tab in 3 simple steps.



(I)Type a suitable name for the configuration (this is the name used in the reaction equation).

(II)Drop the thermochemistry object on to the drop field and choose a multiplier (fraction or integer). For example, if a bulk configuration has 4 stoichiometric units of the compound, then the user can choose 1/4th of the thermochemistry data to correspond to one stoichiometric unit of the material.

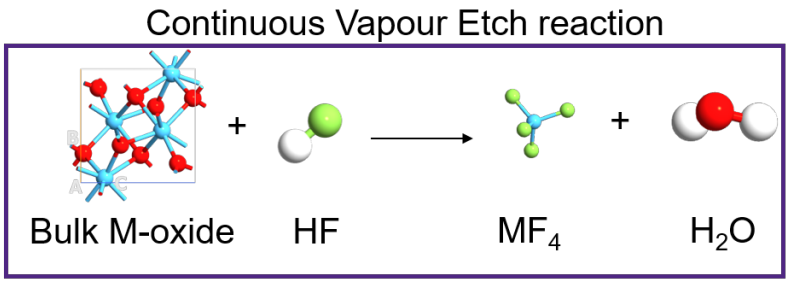
(III)Finally, click *Add To ThermoChemistry Database* button. The entry will appear in the *Thermochemistry Database*.

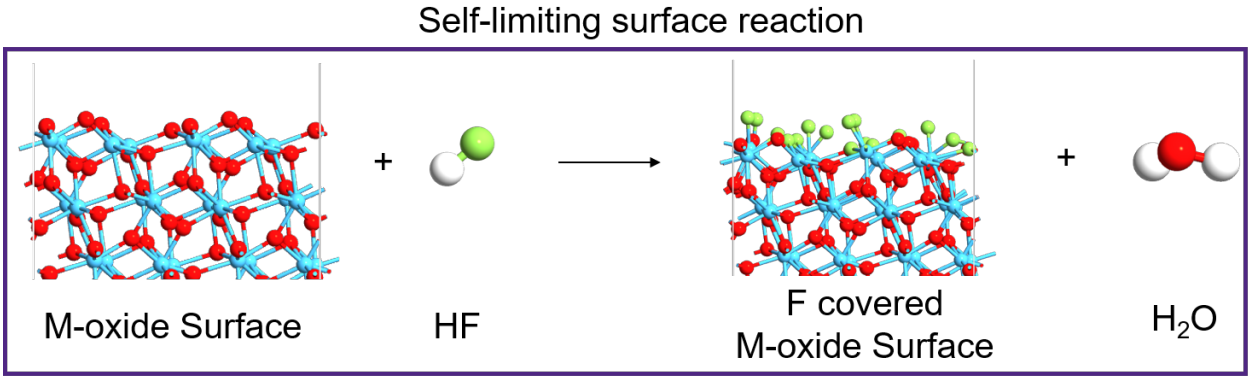
Example: Temperature Window for Thermal Atomic Layer Etching of HfO_2 and ZrO_2

To demonstrate the *Thermochemistry Analyzer*, we will try to reproduce the free energy curves published by Mullins *et al.*[1] in which hydrogen fluoride (HF) gas interacts with either the bulk or surface of HfO_2 and ZrO_2 . We use the same geometries as the ones used in the publication and they are preloaded in the *thermochemistry database* along with their free energy data computed using **QuantumATK** as explained above. For surface geometries, we only use the total energy with the assumption that the free energy contributions from the reactant and product surfaces effectively cancel each other.

For the first reaction, let us consider etching of HfO_2 bulk using HF. The reaction is HfO_2 + HF -> HfF_4 + H_2 O . The below video shows how this can be done using the *Thermochemistry Analyzer* GUI in **Quantum ATK**.

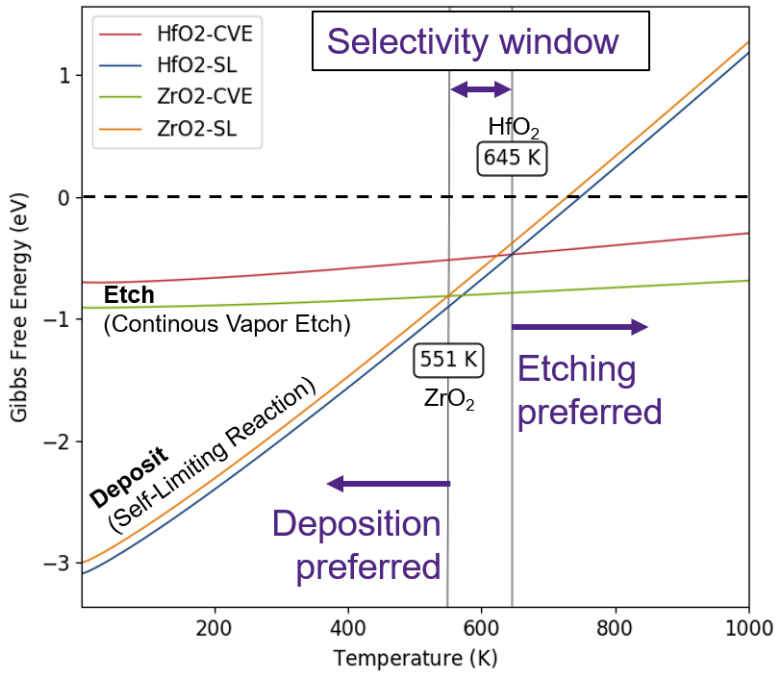
We follow the same procedure and add corresponding reactions for HF interaction with HfO_2 surface, ZrO_2 bulk and ZrO_2 surface and the resulting free energy plot is shown below. We used the data entries from the thermochemistry database titled HfO2s and ZrO2s for the bare HfO_2 and ZrO_2 surface models, respectively and used HfO2-8O+16F and ZrO2-8O+16F for the fluorinated HfO_2 and ZrO_2 surface models, respectively. The reactions studied are described in the image below.





The bulk to gas reaction is termed as continuous vapour etching (CVE) reaction and the surface to surface reaction is termed as self-limiting (SL) reaction.

[1] Rita Mullins, Suresh KondatiăNatarajan, SimonăD Elliott, and Michael Nolan. Self-Limiting Temperature Window for Thermal Atomic Layer Etching of HfO2 and ZrO2 Based on the Atomic-Scale Mechanism. *Chemistry of Materials*, 32(8):3414–3426, 2020.



The free energy profiles (G vs T) of CVE and SL reactions of a material will intersect at some temperature at which both reactions are equally probable. The reaction that has the lowest G value is more favourable at other temperatures. The crossover temperature for HfO_2 and ZrO_2 are found to be 645 K and 551 K, respectively. The corresponding values in the reference paper are 657 K and 534 K, obtained using PAW based plane wave code.

Below 551 K, HF passivates both HfO_2 and ZrO_2 surfaces and starts etching both materials beyond 645 K, of course subject to kinetic barriers. Between 551 K and 645 K, there is a selectivity window where HF passivates HfO_2 but etches ZrO_2 . Please keep in mind that this is only a thermodynamic study and kinetics could still make the reactions difficult to proceed at these temperatures. Nevertheless, they help immensely to screen reactant chemicals and specific reactions for indepth kinetic analysis.

General Uses

Apart from applications to process development, *thermochemistry analyzer* can be used for any general *ab initio* thermodynamic studies such as finding stable phases, reaction paths, gas-sensing of materials and so on. Since total energy objects can be stored in the database, one can also use it to compute and compare binding/adsorption/desorption energies.

3.1.9 Electronic Properties of Phase Change Material $Ge_2Sb_2Te_5$

Version: T-2022.03

In this tutorial, we will investigate electronic properties of $Ge_2Sb_2Te_5$, a phase change material used in non-volatile memory technology, using Density Functional Theory (DFT) calculations. Please follow the tutorial introduction_quantumatk1 to familiarize yourself with the use of scripter to set up calculations. Only the final scripts will be provided in this tutorial.

Geometry

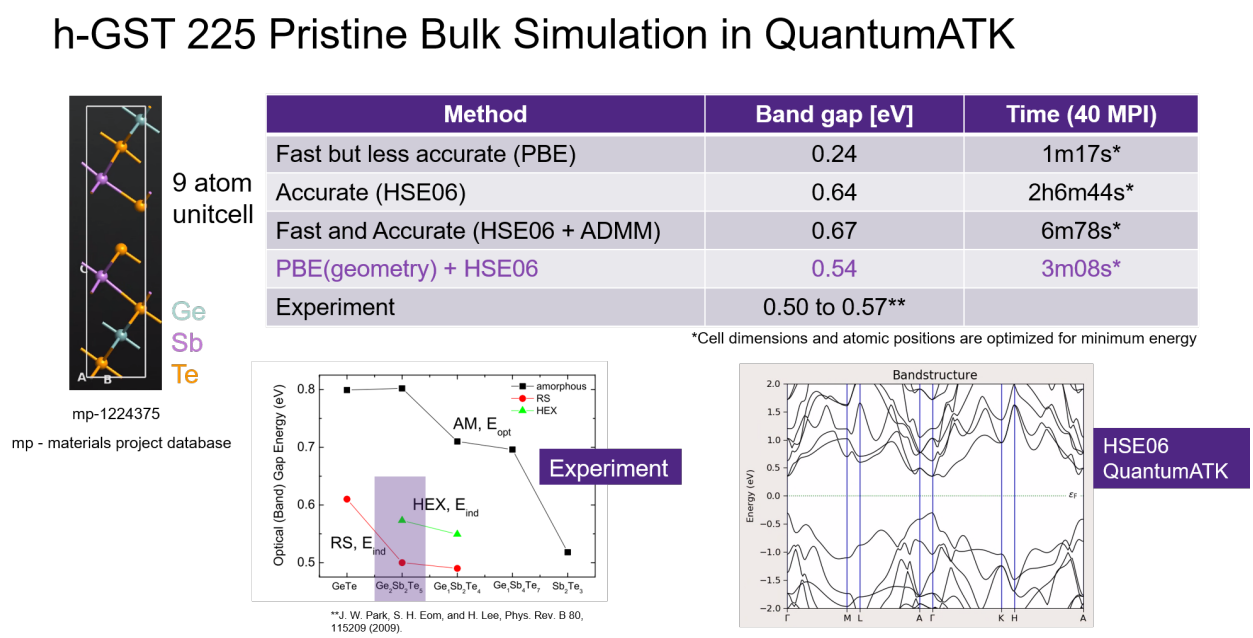
For this tutorial, let us first download the unitcell configuration of $Ge_2Sb_2Te_5$, in a trigonal crystal system with hexagonal lattice symmetry, from the materials project database (mp-1224375) using the Database Tool available in the NanoLab. For reference, the geometry can also be downloaded from here `GST-geometry.py`.

Bandgap Calculation

As the first property, let us compute the bandgap of $Ge_2Sb_2Te_5$ and compare to literature data. To do that, the unit cell geometry will be optimized with space group constraint for minimum energy first and then its BandStructure will be computed. Additionally, we will compare the default GGA (PBE XC functional) results to more accurate HSE06 calculations using the PseudoDojo LCAO basis sets. To be exact, 4 different calculation settings will be used as follows:

- PBE functional based geometry relaxation and BandStructure calculation(`PBE.py`)
- HSE06 hybrid functional based geometry relaxation and BandStructure calculation(`HSE.py`)
- HSE06 hybrid functional with ADMM basis set for both geometry relaxation and BandStructure calculation(`HSE-ADMM.py`)
- PBE functional based geometry relaxation followed by HSE06 hybrid XC functional based BandStructure calculation(`PBE-HSE.py`)

The bandgap can be quickly viewed from the BandStructure object preview window or from the BandStructure Analyzer object. The corresponding results of the above calculations (using 40 MPI processes in 1 node) are given in the below image.



Experimental bandgap of hexagonal $Ge_2Sb_2Te_5$ is known to be between 0.50 and 0.57 eV[1]. PBE only calculation is the fastest but the bandgap is underestimated to 0.24 eV only. Standard HSE06 calculation took over 2 hours and gave a bandgap of 0.64 eV. Inclusion of ADMM basis sets accelerated the HSE06 calculation to completion within 7 minutes

[1] Jun-Woo Park, SeungăHwan Eom, Hosun Lee, JuarezăLF DaăSilva, Youn-Seon Kang, Tae-Yon Lee, and YoonăHo Khang. Optical properties of pseudobinary GeTe, Ge2Sb2Te5, GeSb2Te4, GeSb4Te7, and Sb2Te3 from ellipsometry and density functional theory. *Physical Review B*, 80(11):115209, 2009.

and produced a similar bandgap. However, HSE06 based bandstructure calculation on PBE optimized geometry gave a better bandgap value of 0.54 eV while taking only about 3 minutes.

Lattice Parameters

Lattice parameters of the $Ge_2Sb_2Te_5$ unitcell after geometry optimization using the PBE and HSE06 functionals are given in the below image.

	a / c [Å]	
Method	**QuantumATK**	**Literature**
PBE	4.31 / 17.17	
HSE06	4.27 / 17.28	
Experiment		4.25 / 17.27*

*J. Appl. Phys., 92, 7, 1 (2002)

Both PBE and HSE06 optimized geometries have lattice parameters within 0.1 Å of the experimental values[2].

Cohesive Energies

Cohesive energies of the $Ge_2Sb_2Te_5$ is computed using PBE and HSE06 methods using E_{bulk} - ($2*E_{Ge} + 2*E_{Sb} + 5*E_{Te}$) and the results are shown below. Here, E_{bulk} is the total energy of bulk system and E_{Ge}, E_{Sb} and E_{Te} are atomic reference energies of Ge, Sb and Te, respectively.

	Cohesive Energy (eV/atom)	
Method	**QuantumATK**	**Literature**
PBE	-3.71	-3.75*
HSE06	-4.37	-

*Phys. Rev. B 84, 085130 (2011)

Ref. Ge, Se, Te energies are for isolated atoms

	Cohesive Energy (eV/atom)	
Method	**QuantumATK**	**Literature**
PBE	-0.124	-0.103*
HSE06	-0.119	-

*https://materialsproject.org/materials/mp-1224375/

Ref. Ge, Se, Te energies are for respective monocrystalline

Te : mp-19
Sb : mp-104
Ge : mp-32

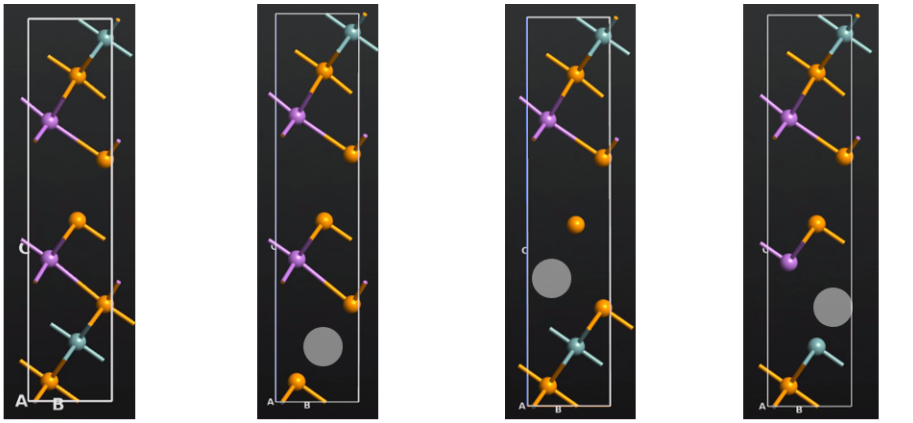
In the above results, two different sets of reference energy values are used for the elemental contributions. First set of cohesive energies (top of the picture) are computed using total energies of isolated Ge, Sb and Te atoms as reference

[2] BJăKooi and JăThăM DeăHosson. Electron diffraction and high-resolution transmission electron microscopy of the high temperature crystal structures of GexSb2Te3+x (x= 1,2,3) phase change material. *Journal of applied physics*, 92(7):3584–3590, 2002.

and match well with literature[3]. The following scripts are used for the above reference calculations (Ge (`HSE`, `PBE`), Sb (`HSE`, `PBE`), Te (`HSE`, `PBE`)). For the second set, total energies per atom in homogeneous bulk systems are used. The corresponding scripts are attached here (`Ge`, `Sb`, `Te`). Reference cohesive energy is calculated using the data from materials project database using the following IDs (GST:mp-1224375, Ge:mp-32, Sb:mp-104, Te:mp-19). From the above image, we find that our calculations agree reasonably with the published calculated reference values within 4 meV/atom for isolated atom reference and within 20 meV/atom for bulk reference. Note that the literature reference uses a different basis set and calculator settings.

Neutral Vacancy Formation Energies

In this section, we compute the formation energies of neutral vacancies within a unitcell of $Ge_2Sb_2Te_5$ using PBE XC functional and compare to literature results[4]. The formation energy of a single neutral vacancy is obtained as $E_{\text{pristine GST}}$ - ($E_{\text{GST with vacancy}}$ + $E_{\text{bulk reference}}$), where $E_{\text{bulk reference}}$ is the energy of the removed atom in its bulk state.



QuantumATK [eV]	0.59	1.29	1.22
Reference [eV]	0.96	1.60	1.20

We perform three vacancy calculations by removing either one Ge, one Sb or one Te atom from the unitcell geometry as highlighted in the above image and replacing them with a ghost atom. A ghost atom is used to include the basis functions for that removed atom in the calculation. The corresponding scripts are given here (`Ge-vacancy`, `Sb-vacancy`, `Te-vacancy`). As can be seen from the above image, the formation energy of Ge vacancy is the lowest followed by Te and Sb. This ordering is similar to the literature results with some discrepancies in the absolute values. This could be attributed to the different lattice parameters and basis sets (reference: plane wave basis and PAW, QuantumATK: LCAO and PseudoDojo medium) used in the literature reference and in our calculations.

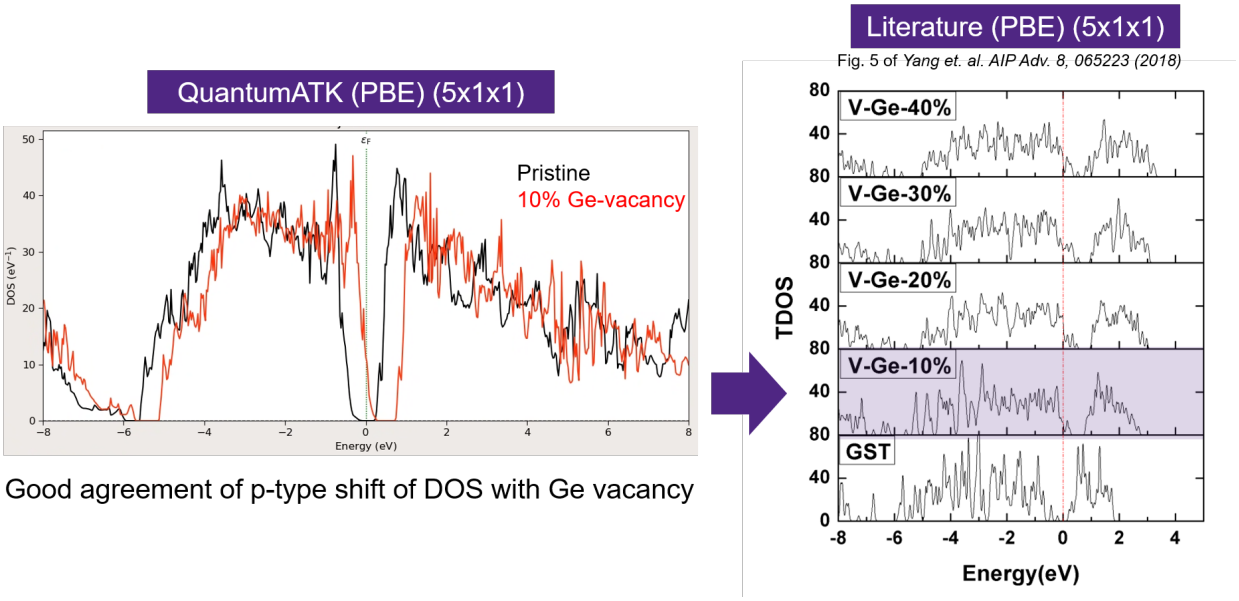
Total DOS With and Without Ge Vacancy

In this section we compare the total density of states from the GST (5x1x1) supercell with and without a Ge vacancy and compare the results to literature[Page 353, 4]. The scripts used for this calculation can be downloaded from these links (`Pristine`, `VGe`).



Good agreement of p-type shift of DOS with Ge vacancy

The above plot shows the DOS comparison and a clear p-type shift is observed on including 10% Ge vacancy. This observation is in good qualitative agreement with the reference.

3.1.10 STM simulations of tunneling anisotropic magneto resistance (TAMR)

Version: S-2021.06

In this tutorial you will learn how to use the *LocalDensityOfStates* analysis object for simulating STM measurements of surfaces. In particular we will be studying the tunneling anisotropic magneto resistance (TAMR) which is a measure of the difference in STM current and conductance depending on the magnetization direction of the substrate.

Introduction

Scanning tunneling spectroscopy is an experimental technique which uses a scanning tunneling microscope (STM) to probe the local density of electronic states (LDOS) of surfaces and materials on surfaces at the atomic scale. A scanning tunneling spectrum is obtained by placing the STM tip above a particular place on the sample. With the height of the tip fixed, the electron tunneling current is measured as a function of electron energy by varying the voltage between the tip and the sample. The conductance, dI/dV, obtained from such a measurement is proportional to the local electron density of states (LDOS) at the position of the tip.

TAMR

The resistance (inverse of conductance) of a tunneling junction involving just a single ferromagnetic layer may depend on the magnetization direction relative to the crystallographic axes. This effect is called tunneling anisotropic magnetoresistance (TAMR) and has been observed in several STM experiments[1,2]. The TAMR is caused by spin-orbit coupling, which results in an anisotropy of the density of states in and above the surface layer. The TAMR is potentially interesting for spintronics applications as it requires only one magnetic layer as opposed to traditional magnetic tunneling junctions involving both a reference and free magnetic layer.

This tutorial is inspired by the experimental and theoretical works in[Page 355, 1,2] which studies the TAMR of an iron bilayer on a W(110) surface, 2LFe/W(110), as schematically illustrated Fig. 3.1 below.

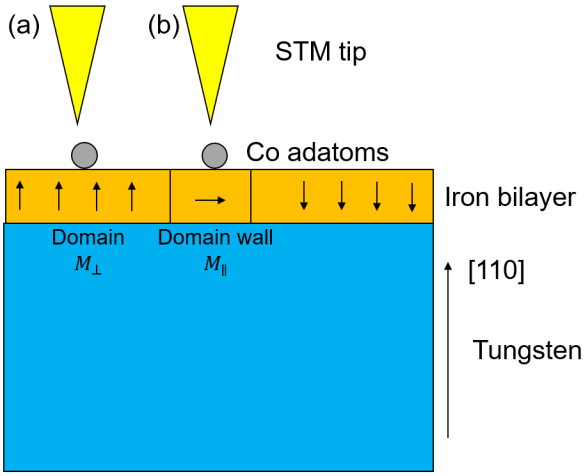

Fig. 3.1: Schematic illustration of the experiments. An iron bilayer is deposited on W(110). The Fe bilayer forms magnetic domains with the magnetization perpendicular to the interface. The magnetic domains are separated by domain walls in which the magnetization is parallel with the interface plane. By positioning the STM tip either over the domain (a) or over the domain wall (b) it is possible to measure the TAMR effect.

This surface can be prepared in such a way that finite domains of out of plane magnetizations are formed. Within the domain wall the magnetization will be in-plane. By measuring with STM the conductance over a domain you get the

[1] N.ăNeel, S.ăSchroder, N.ăRuppelt, P.ăFerriani, J.ăKroger, R.ăBerndt, and S.ăHeinze. Tunneling Anisotropic Magnetoresistance at the Single-Atom Limit. *Phys. Rev. Lett.*, 110:037202, Jan 2013. URL: https://link.aps.org/doi/10.1103/PhysRevLett.110.037202, doi:10.1103/PhysRevLett.110.037202.

[2] Johannes Schöneberg, Paolo Ferriani, Stefan Heinze, Alexander Weismann, and Richard Berndt. Tunneling anisotropic magnetoresistance via molecular $\ensuremath \pi $ orbitals of Pb dimers. *Phys. Rev. B*, 97:041114, Jan 2018. URL: https://link.aps.org/doi/10.1103/PhysRevB.97.041114, doi:10.1103/PhysRevB.97.041114.

out of plane component $(dI/dV)_\perp$ while the same measurement over a domain wall you get the in-plane component $(dI/dV)_\parallel$. The TAMR is then found as

$$TAMR = \frac{(dI/dV)_\perp - (dI/dV)_\parallel}{(dI/dV)_\perp}$$

The main experimental results from[1] are shown in the figure below. Panel (a) shows the measured dI/dV over a Co adatom on a 2LFe/W(110) surface for both in- and out of plane magnetization and panel (b) shows the TAMR as function of sample voltage.

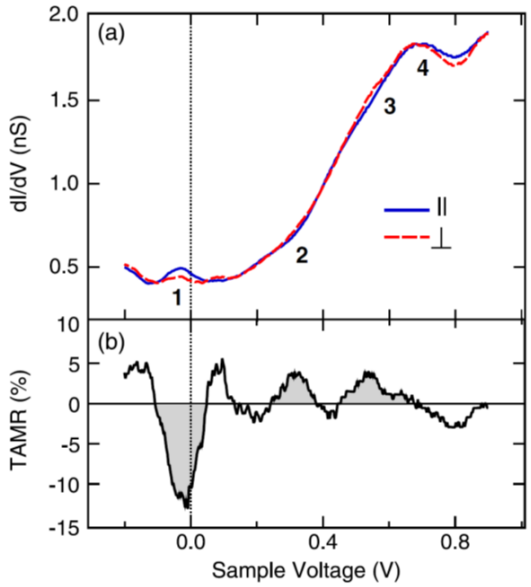

Fig. 3.2: Experimental results. (a) dI/dV spectra obtained on Co adatoms on domains (red dashed line) and on domain walls (blue solid line) of an Fe double-layer film on W(110). (b) TAMR determined from the spectra in (a). From[Page 355, 1].

Tersoff-Hamann approximation of simulated STM

The *LocalDensityOfStates* can be used to simulate scanning tunneling microscopy (STM) images within the Tersoff-Hamann approximation[3] assuming that the tip wave function has s-orbital character and is non-magnetic. When simulating an STM image, the `energy` can be interpreted as the bias difference applied between the tip and the surface and the *LocalDensityOfStates* represents the STM dI/dV measurement.

Since the local density of states $n(E,r) = A\frac{dI}{dV}|_{V=V_s}$ with $E = e \cdot V_s$ where V_s is the sample voltage, we can simulate the TAMR as

$$TAMR = \frac{n_\perp(E,r) - n_\parallel(E,r)}{n_\perp(E,r)} \tag{3.1}$$

Likewise, the current measured in an STM with an applied bias of V_s and with the tip at zero bias can be approximated as the partial electron density originating from eigenstates in the energy interval $[0; e \cdot V_s]$.

[3] J.ăTersoff and D.ăR. Hamann. Theory of the scanning tunneling microscopy. *Phys. Rev. B*, 31:805, 1985. doi:10.1103/PhysRevB.31.805.

Setting up the 2LFe/W(110) structure

We will start by setting up the structure for the calculations.

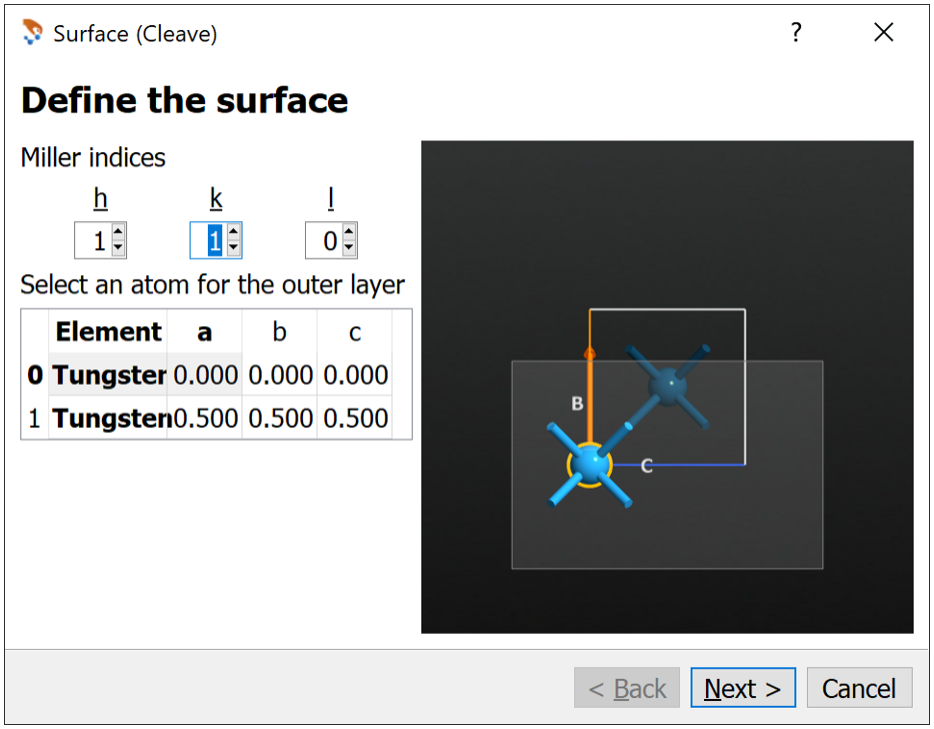
Structure

Open the **Builder** and

•Add a Wolfram/Tungsten bulk configuration from the database (search for *Wolfram*).

•Make a (110) surface using the **Surface (Cleave)** under **Builders** in the right column.

•On the first page set *h=1*, *k=1*, *l=0* . Press *Next*.



•On the second page simply press *Next* using all default values.

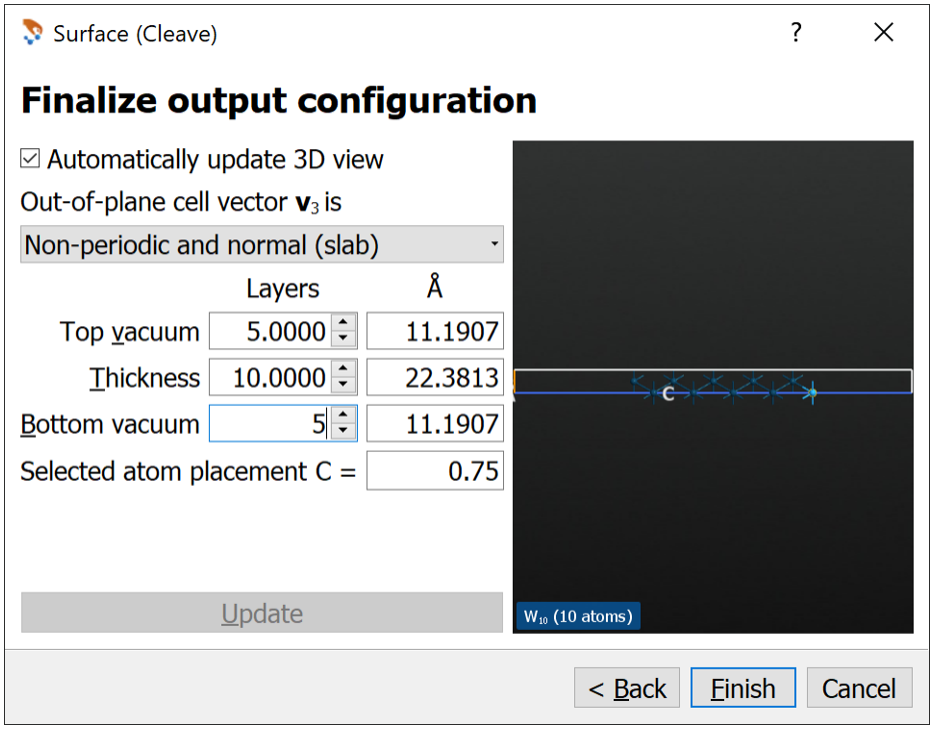
•On the third page apply the changes (see image below)

–From the combo box choose *Non-periodic and normal (slab)*

–Set the **Top** and **Bottom** vacuum to *5 layers*

–Set the **Thickness** to *10 layers*

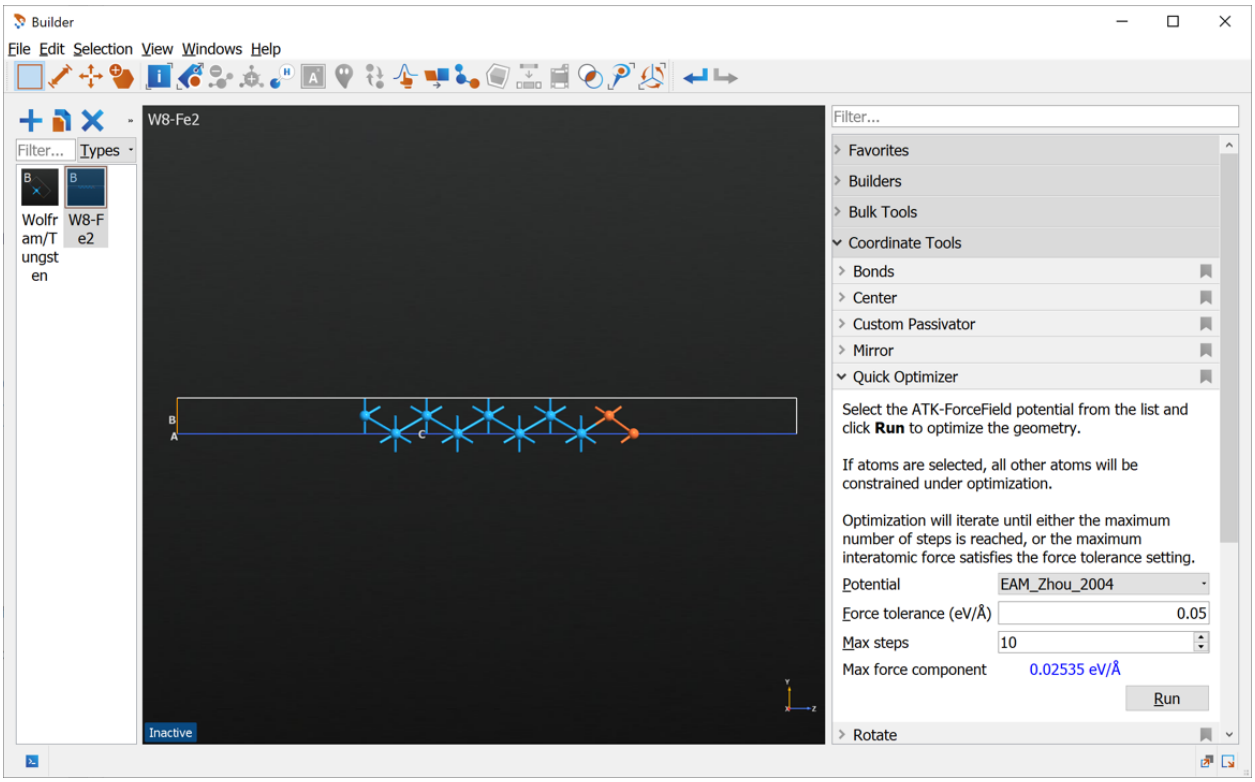
–Press *Finish*.



•Change the two rightmost **W** atoms to **Fe**.

•Rename the structure to `W8-Fe2` (press `F2`).

We can make an initial optimization of the structure using the **Quick Optimizer** (see image below). Run the optimization, which only takes a few seconds.



Send the structure to the **Script Generator** using the icon.

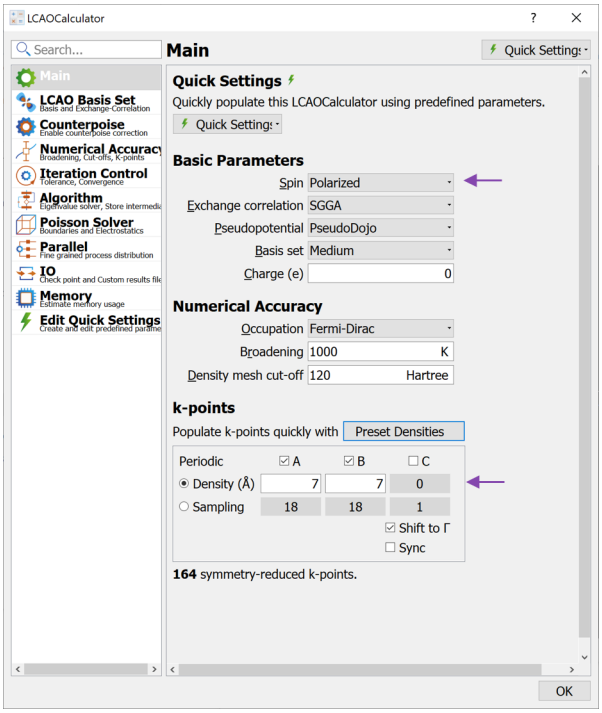
Tip: The **Quick Optimizer** is an easy way to do an initial optimization of the structure to make it more reasonable before proceeding with the main calculations. It is fast because it uses a ForceField, and will automatically suggest the possibilities from the internal QuantumATK database. However, not all structures will be supported by an appropriate ForceField.

Structural relaxation

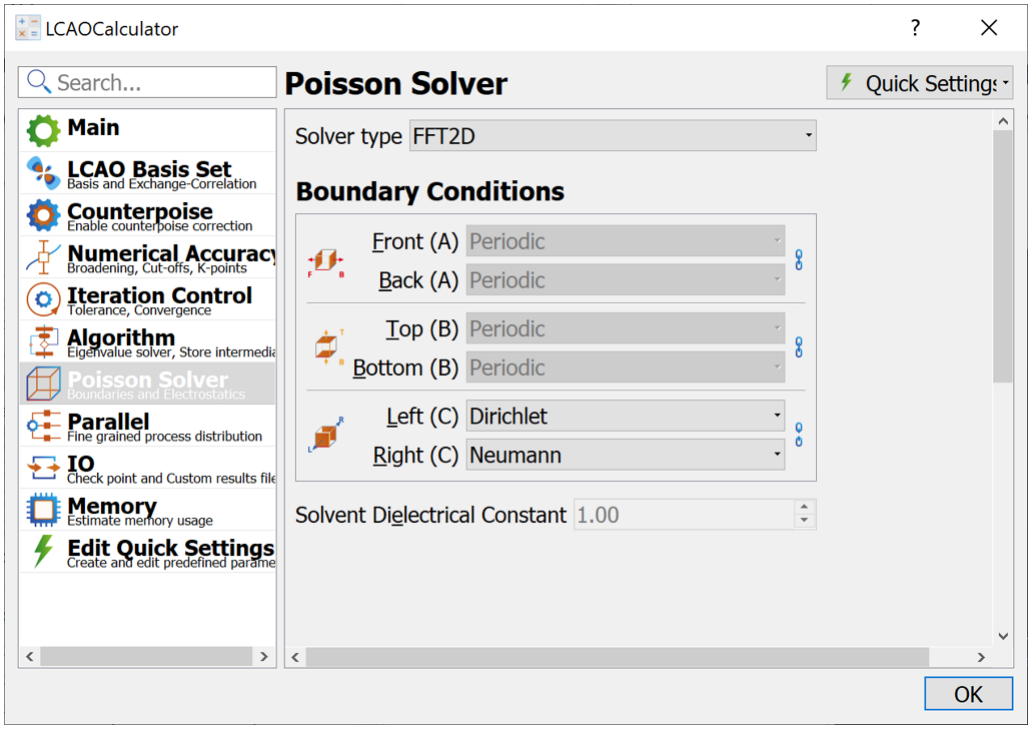
Although the structure has been relaxed using the **Quick Optimizer**, we will still perform a geometry optimization using a DFT calculator. The geometry optimization will be performed using a *spin-polarized* calculator, while the subsequent analysis will be performed with *spin-orbit coupling* included.

Now do the following:

- Add an **LCAOCalculator** to the script, open the **LCAOCalculator** widget and apply the changes on the main page
  - Change **Spin** to *Polarized*
  - Increase the **k-point density** to *7* (select from the *Preset Densities*).



- Go to the **Poisson Solver** page and apply the changes (see image below)
  - Change the **solver type** to *FFT2D*
  - Change the **boundary conditions** in the *C-direction* to *Dirichlet* and *Neumann*. (Click the chain-symbol to the right of the combo boxes to allow for different boundary conditions.)



•Close the **LCAOCalculator** widget.

Note: The reason for modifying the Poisson solver boundary conditions is to allow for a dipole shift across the W/Fe interface. At any interface between two materials a certain charge transfer will occur, which will give rise to a surface dipole. Using periodic boundary conditions in the C-direction will result in a electrostatic potential with a certain slope in the vacuum region, effectively acting as an external electric field. By using the combination of *Dirichlet* and *Neumann* boundary conditions, the electrostatic potential will be flat in the vacuum regions, but have different values on each side of the slab. Try to add an `ElectrostaticPotential` or `ElectrostaticDifferencePotential` analysis to the script and inspect the results after the calculation using the **Grid 1D Projector**.

•Now add an **OptimizeGeometry** to the script and use the default settings.

Finally change the name of the **Results file** to `W8-Fe2-polarized.hdf5` and run the calculation. The relaxed structure can also be downloaded here `W8_Fe2_relaxed_configuration.py`.

Local Density of States calculations

Having relaxed the atomic coordinates we are now ready to study the TAMR effect by calculating the local density of states (LDOS). The LDOS contains the DOS at a given energy projected onto a real-space position $n(E, r)$.

Send the relaxed configuration to the **Script Generator** and go through the following steps:

•Add an **LCAOCalculator** and open the widget.

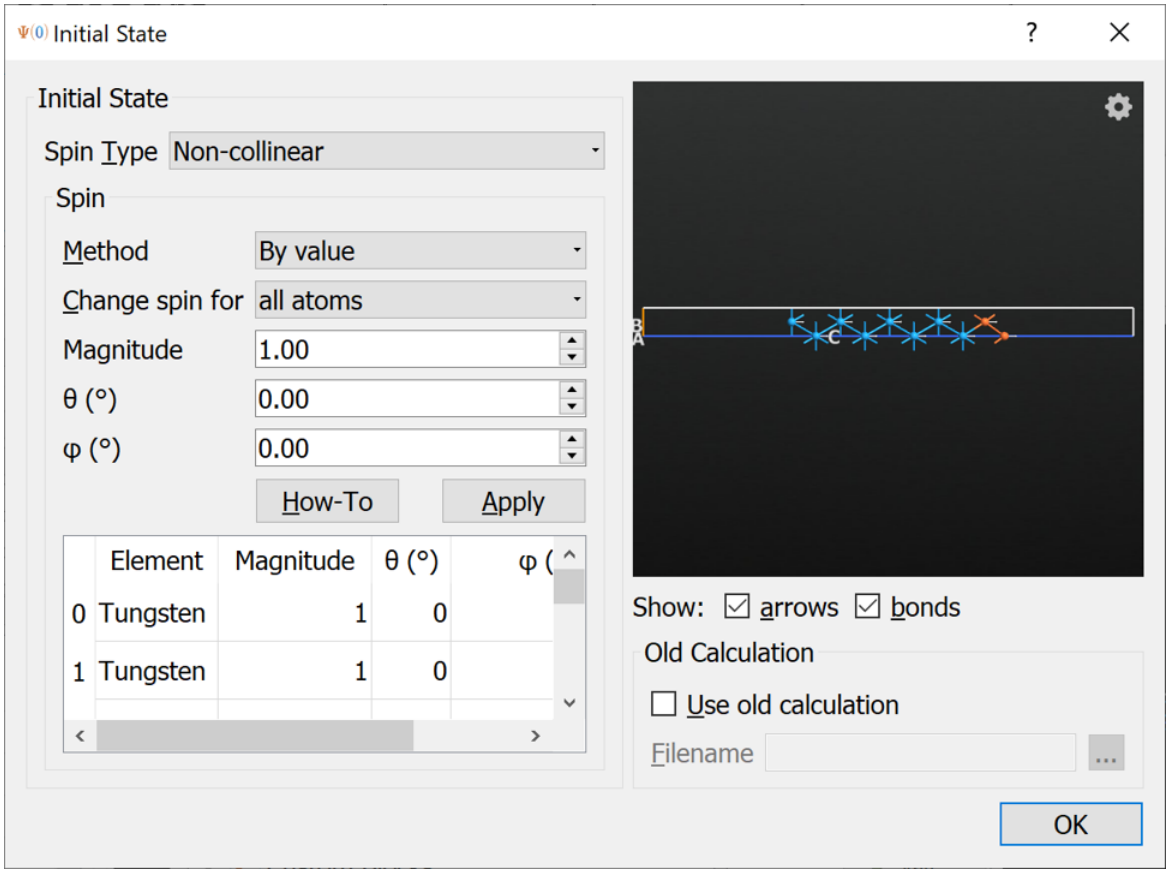
–Change **Spin** to *Noncollinear Spin-Orbit*

–Increase the **k-point density** to *7* (select from the *Preset Densities*).

–Modify the **Poisson Solver** as described above.

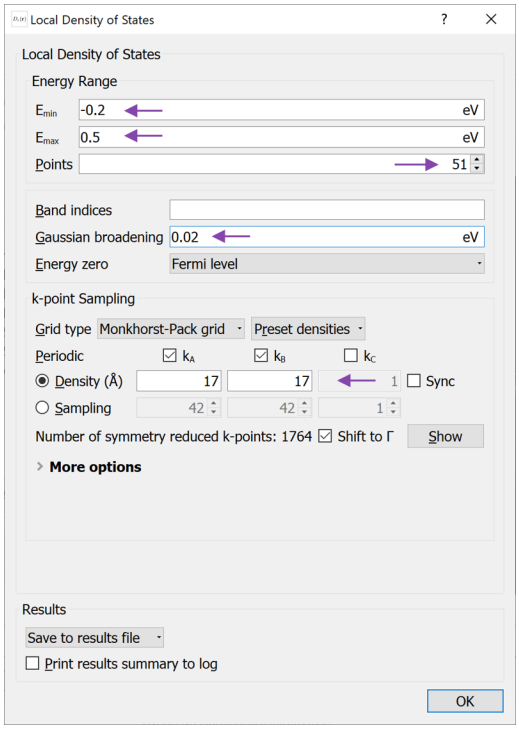
–Close the **LCAOCalculator**

•Add an **Initial State** block to the script and open it. In the **InitialState** widget you can change the initial spin orientation, when changing the **Spin Type** to *Non-collinear* (see below). For global spin rotations applied to all atoms the initial spin orientation will usually be kept during the self-consistent calculation. For now you can leave the angles at the default values of $\theta = 0°$ and $\phi = 0°$, which corresponds to the out-of-plane magnetization.



Tip: The spin vectors are shown in the 3D window, allowing easy inspection of the initial spin state.

•Add a **LocalDensityOfStates** object and open it to apply the changes indicated in the figure below



•Add a $\mathrm{Tr}(\rho S)$ **MullikenPopulation** object to the script.

•Finally change the **Results file** to `W8-Fe2-theta-0-phi-0.hdf5`. Send the job to **Job Manager** and run the calculation. The calculation takes around 30 minutes when run on a single node with 16 processes.

Note: `LocalDensityOfStates` objects can take up a lot of memory, since a real-space grid object is stored for every energy point. In order to reduce the memory of the calculation as well as of the stored `.hdf5` file, the number of energy points can be lowered. It is also possible to modify the density of real-space grid points. In order to do the latter, you must send the script to the **Editor** and add the line `density_mesh_cutoff=20*Hartree` to the **LocalDensityOfStates** object as shown below.

```
# ------------------------------------------------------------
# Local Density Of States
# ------------------------------------------------------------
kpoints = KpointDensity(
    density_a=17.0*Angstrom,
    density_c=0.0*Angstrom,
    force_timereversal=False,
    )

local_density_of_states = LocalDensityOfStates(
    configuration=bulk_configuration,
    kpoints=kpoints,
    energies=numpy.linspace(-0.2, 0.5, 51)*eV,
    band_indices=All,
    energy_zero_parameter=FermiLevel,
    spectrum_method=GaussianBroadening(0.02*eV),
    density_mesh_cutoff=20*Hartree,              # <--- Added line
```

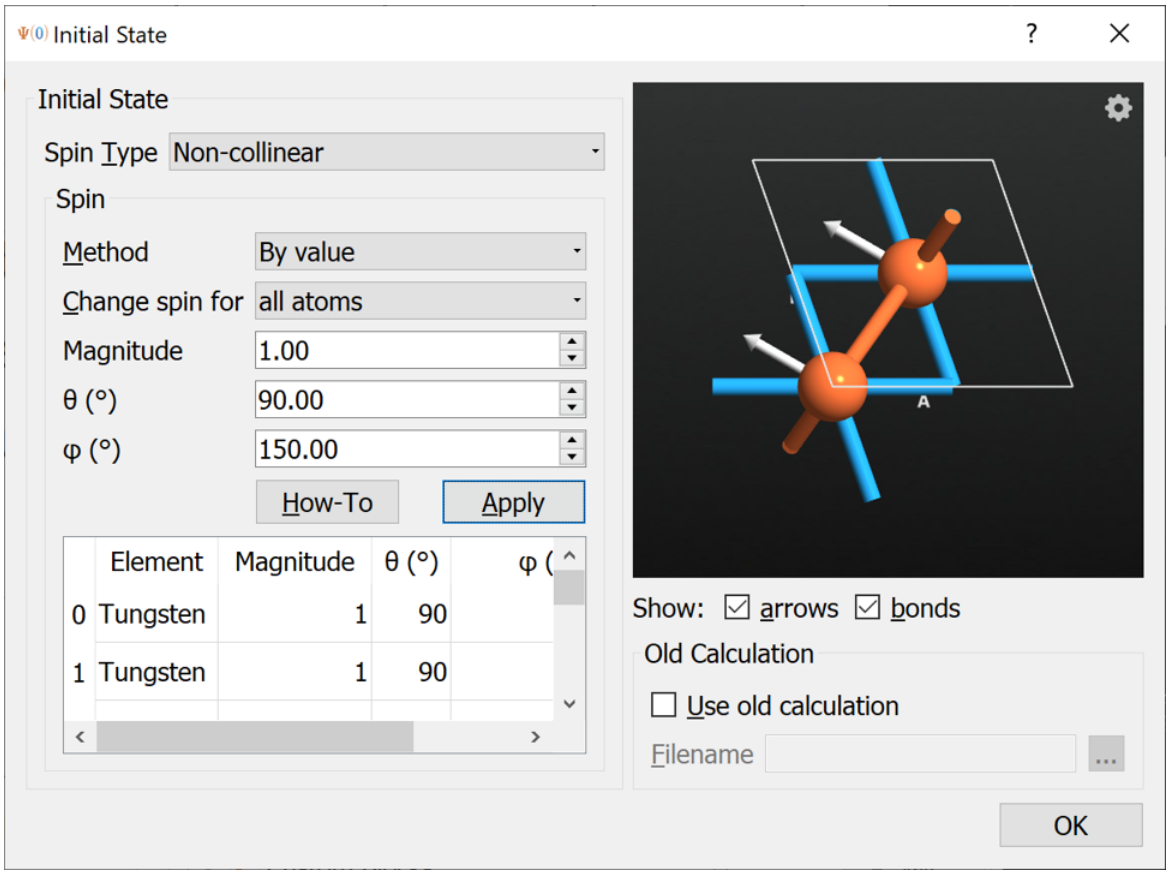
(continues on next page)

(continued from previous page)

```
    )
```

Now we will change the initial spin to simulate the in-plane magnetization.

•Open the **Initial State** widget again and change the angles to $\theta = 90°$ and $\phi = 150°$, which is the orientation with the lowest energy (try for yourself to scan over ϕ angles and calculate the total energy at each.) Press **Apply** to rotate the angles. The spin orientation should now look as below:



Close the **InitialState** widget and change the **Results file** to `W8-Fe2-theta-90-phi-150.hdf5` and run the calculation.

When both calculations have finished, we are ready to analyze the results.

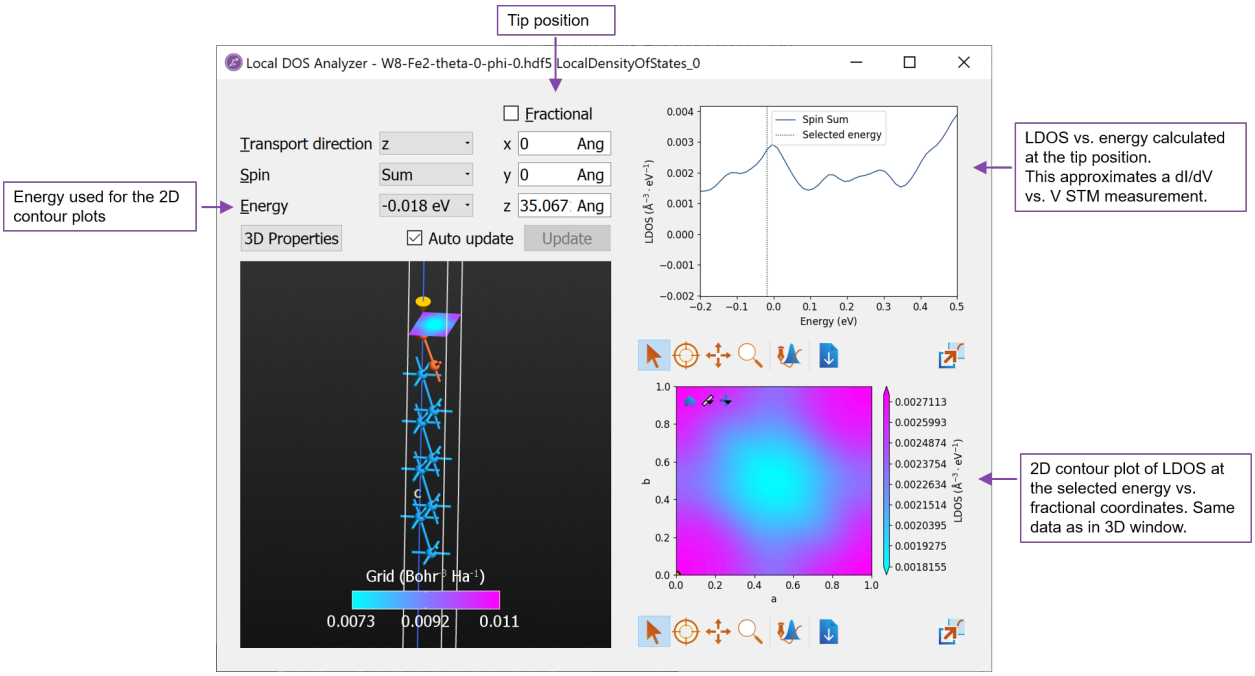
Analyzing the results

Once the calculation has finished we are ready to analyze the results. Before analyzing the **LDOS** calculations, take a look at the calculated **MullikenPopulations** using the **Viewer**. Verify that the spins on the iron atoms are pointing in the expected directions - out of plane (in the z-direction) for the `W8-Fe2-theta-0-phi-0.hdf5` file and in-plane for the `W8-Fe2-theta-90-phi-150.hdf5` file.

LDOS analysis

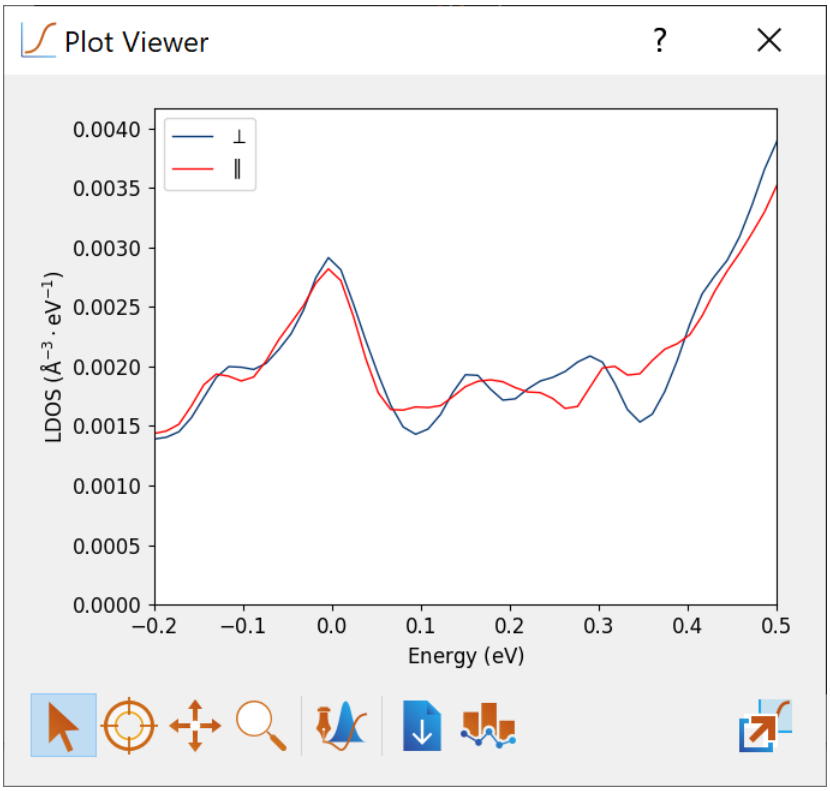
Mark the $D_\epsilon(\mathbf{r})$ **LocalDensityOfStates** object in the file `W8-Fe2-theta-0-phi-0.hdf5` and open it with the **Local DOS Analyzer**. The analyzer should appear as shown below. In the STM-like analyzer, you can adjust the tip position using both fractional- and Cartesian coordinates. When the tip position is changed, the LDOS vs. energy plot (upper right) will be updated. Change the tip position to 2 Å above the surface Fe atom at *(0, 0, 35.067)* Å. Try also to change the energy and see how the contour plot changes. The contour plot in the 3D window with the atomic structure contains the same data as the contour plot in the lower right plot.

Right click on the line in the upper right plot and choose **Edit item** and change the label *Spin Sum* to `$\perp$`, which QuantumATK will automatically parse and show as the symbol.

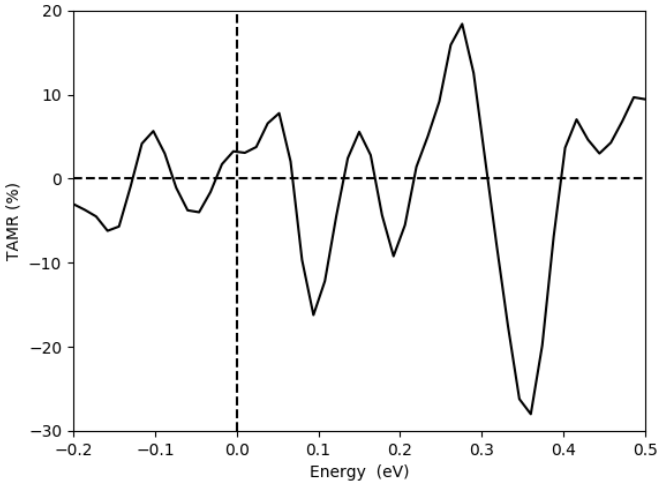


Now open the **LocalDensityOfStates** object from the file `W8-Fe2-theta-90-phi-150.hdf5` containing the in-plane magnetization. Apply the same setting for the tip position as above and edit the line in the upper right plot and change the label to `$\parallel$`. Also change the color and/or line style, such that it is different from the default setting.

Now drag one of the LDOS vs. energy plots onto the other and select *Overlay with shared axes* to obtain a plot like below. It is evident that the LDOS is different for the two magnetization directions and that there is a TAMR effect.



In order to quantify the TAMR effect, download and run the script `calculateTAMR.py`. The script calculates the LDOS vs. energy 2 Å above the surface Fe atom as we just did in the analyzer above. Then it calculates the TAMR using equation (3.1) above and produces the figure shown below. In qualitative agreement with the experimental findings[Page 355, 1] the TAMR is oscillating as a function of energy (bias voltage in an STM experiment). The magnitude of the calculated TAMR of $\sim \pm 20$



Co adatom on 2LFe/W(110)

In order to get a more direct comparison to the experiments from[Page 355, 1] shown in Fig. 3.2 at the top, we here present results for a Co adatom positioned on the 2LFe/W(110) slab. The calculations have been performed in the same way as described above. Try for yourself to add a Co atom and relax the structure using the **Quick Optimizer** in the **Builder** by going through the following steps:

- In the **Builder**, repeat the 2LFe/W(110) structure two times in the A- and B directions.
- Add a Co atom in a bridge position between two surface Fe atoms.
- Relax the configuration using the **Quick Optimizer**.
- Send the configuration to the **Script Generator** and setup the spin-orbit and **LocalDensityOfStates** calculations as described above.

A final script is also given here: `W8_Fe2_Co.py`. The script loops over the (θ, ϕ) angles and performs the self-consistent spin-orbit calculation and LDOS calculation for both angle pairs $(0, 0)$ and $(90, 150)$. Run either the scripts you have made yourself or the one given here.

When the calculations are finished (the calculation takes several hours when running on a single node with 16 cores) the results can be analyzed and plotted with the script `calculateTAMR-Co-adatom.py` to give a figure like the one shown below, on the right. The calculated LDOS and TAMR share many similarities with the experimental results in Fig. 3.3 (left part):

- The overall shape of the dI/dV and LDOS plots agree with a small peak close to the Fermi energy and a larger peak around 0.6 eV.
- Both the calculated and measured TAMR shows a clear dip around the Fermi energy and an oscillating behavior of the TAMR. The oscillation in the calculated TAMR are, however, more rabid than in the experiments.

A potential cause of the differences between experimental and calculated data is the tip distance to the Co adatom. Due to the localized basis set used in the QuantumATK calculations, the LDOS needs to be calculated relatively close to the surface - here 2 Å above the Co atom. It is very likely that the experimental distance is somewhat larger. Also, the calculated results are obtained with a supercell which is a 2x2 repetition of the unit cell. It is likely that this is too small a supercell to match the experimental conditions.

COSMICS project

TAMR effects are studied in the COSMICS project founded by the European Unions Horizon 2020 research and innovation program under Grant Agreement No. 766726. More information about the COSMICS project can be found here: http://cosmics-h2020.eu/

3.1.11 Bulk Magnetic Anisotropy Energy

Version: S-2021.06

In this tutorial you will learn how to use the *MagneticAnisotropyEnergy* study object to calculate the magneto-crystalline anisotropy (MCA) energy of bulk FePt in the $L1_0$ phase.

The result of the *MagneticAnisotropyEnergy* will be compared with self-consistent total energy calculations including spin-orbit coupling, and you will learn about the most important numerical parameters to converge, when performing MCA calculations.

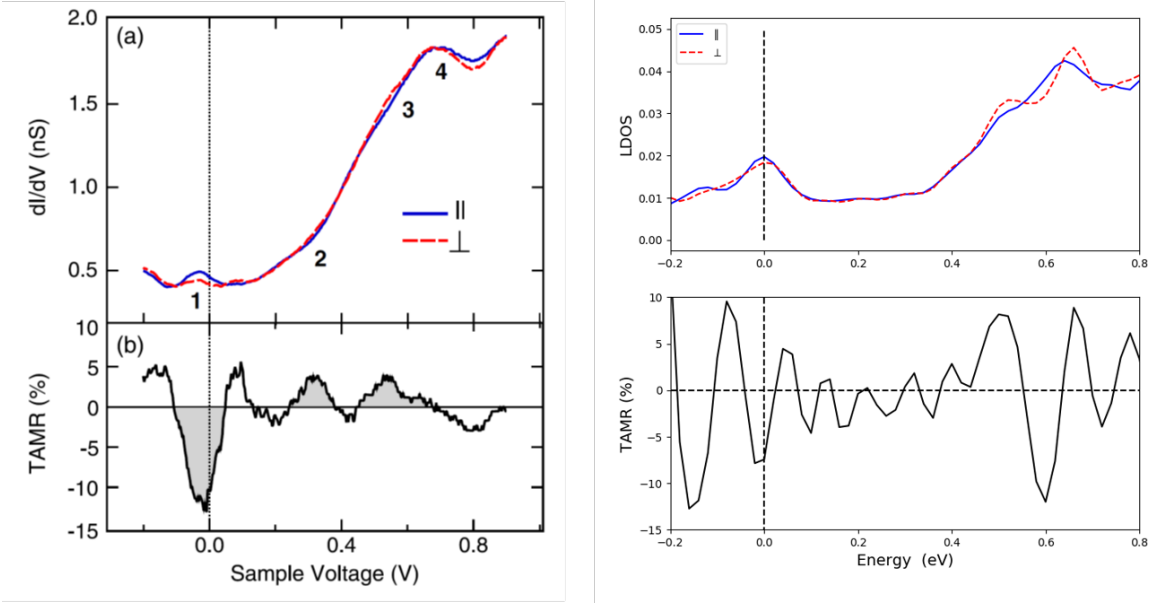

Fig. 3.3: Experimental results (left). (a) dI/dV spectra obtained on Co adatoms on domains (red dashed line) and on domain walls (blue solid line) of an Fe double-layer film on W(110). (b) TAMR determined from the spectra in (a). From[Page 355, 1]. The right part of the figure shows the data calculated with QuantumATK.

Introduction

The magnetic anisotropy energy (MAE) is the energy difference between two magnetization directions. Different physical mechanisms can contribute to the MAE, but here we are concerned with the magnetocrystalline anisotropy (MCA). Another important contribution is the shape-anisotropy, which occurs if the magnetic material has a non-spherical shape.

The origin of the MCA is the spin-orbit coupling and it is characterized by the dependence of the energy of a magnetic system on the orientation of the magnetization with respect to the crystallographic structure of the material. The axis (or plane) corresponding to the minimum of energy is the so-called easy axis (plane).

The MAE is of central interest for both fundamental and practical reasons, with STT-MRAM being one of the most important technological examples.

STT-MRAM

Spin-transfer torque magnetic random access memory (STT-MRAM) enables higher densities, low power consumption and reduced cost compared to regular MRAM devices. The main advantage of STT-MRAM over regular MRAM is the ability to scale the STT-MRAM chips to achieve higher densities at a lower cost.

One of the key requirements of an STT-MRAM device is of course to be able to store information. This requires that the energy-barrier between the 1 and 0 states is large enough to not allow switching due to thermal fluctuations. The MCA is a key element in determining the energy barrier and thus the thermal stability of a STT-MRAM memory unit.

Theory

The magnetic anisotropy energy is defined as the energy difference between two spin orientations:

$$MAE = E(\theta_1, \phi_1) - E(\theta_0, \phi_0),$$

where the spin orientation is described by the two spherical angles θ and ϕ. The MAE can be calculated directly from self-consistent calculations including spin-orbit coupling. This can, however, be computationally quite demanding since spin-orbit calculations can some-times be difficult to converge at the desired accuracy.

Force theorem

In the *MagneticAnisotropyEnergy* study object we calculate the MAE using the force theorem, which allows you to evaluate the energy difference using non-self consistent band energies[1]:

$$MAE = \sum_i f_i(\theta_1, \phi_1)\epsilon_i(\theta_1, \phi_1) - \sum_i f_i(\theta_0, \phi_0)\epsilon_i(\theta_0, \phi_0),$$

where $f_i(\theta, \phi)$ is the occupation factor for band i (including both band and k-point index) with the spin orientation (θ, ϕ) and $\epsilon_i(\theta, \phi)$ is the corresponding band energy.

The use of the force theorem (FT) has been validated in several papers, e.g.[2],[3] against self-consistent calculations of total energies. Using the FT has several advantages over the self-consistent approach:

[1] G.ăH.ăO. Daalderop, P.ăJ. Kelly, and M.ăF.ăH. Schuurmans. First-principles calculation of the magnetocrystalline anisotropy energy of iron, cobalt, and nickel. *Phys. Rev. B*, 41:11919, 1990. doi:10.1103/PhysRevB.41.11919.

[2] Piotr Blonski and Jurgen Hafner. Density-functional theory of the magnetic anisotropy of nanostructures: an assessment of different approximations. *Journal of Physics: Condensed Matter*, 21(42):426001, 2009. URL: http://stacks.iop.org/0953-8984/21/i=42/a=426001.

[3] M.ăBlanco-Rey, J.I. Cerda, and A.ăArnau. Validity of perturbative methods to treat the spin–orbit interaction: application to magnetocrystalline anisotropy. *New J. Phys.*, 21:073054, 2019. URL: https://iopscience.iop.org/article/10.1088/1367-2630/ab3060.

•It is usually faster since the self-consistent solution of the spin-orbit calculation is computationally significantly more demanding than the polarized one.

•Often it is harder to achieve good convergence for a spin-orbit calculation than for a polarized one.

•Using the FT approach allows for projection analysis since each band energy has an associated eigenvector that can be projected onto atomic sites or individual orbitals (see the :ref:ťmae_bulk_analyze_resultsť section). The projection analysis is often helpful in understanding the physics behind the calculated MAE. An example could be the difference between surface/interface atoms and bulk atoms in the contribution to the MAE in a metallic slab[4].

Note: About the naming: In this tutorial, the name magnetic anisotropy energy (MAE) will be used somewhat interchangeably with the name magnetocrystalline anisotropy (MCA). A third name, which is often used, is perpendicular magnetic anisotropy (PMA) and refers to an interface plane, often with a magnetic tunnel junction in mind - see also *Magnetic Anisotropy Energy of Fe-MgO-Fe MTJ structure*. In the literature, the MAE will sometimes include the so-called shape anisotropy as well, which accounts for the (classical) dipole-dipole interaction between magnetic moments[Page 368, 1].

MAE of FePt

$L1_0$ FePt has been studied in a number of scientific papers and is one of the materials with the largest known MCA. In this tutorial we will use the structure from[Page 368, 3]. It is well-known that even small structural difference can have a big impact on the MCA. In order to have a direct comparison to the calculated values in[Page 368, 3] we will not perform any structural relaxation.

Structure

The structure of the FePt cell is shown below.

```
# ------------------------------------------------------------
# Bulk Configuration
# ------------------------------------------------------------

# Set up lattice
lattice = SimpleTetragonal(2.722*Angstrom, 3.71281*Angstrom)

# Define elements
elements = [Platinum, Iron]

# Define coordinates
fractional_coordinates = [[ 0.5,  0.5,  0.5],
                          [ 0. ,  0. ,  0. ]]

# Set up configuration
bulk_configuration = BulkConfiguration(
    bravais_lattice=lattice,
    elements=elements,
    fractional_coordinates=fractional_coordinates
    )
```

[4] K.ăBairagi, A.ăBellec, V.ăRepain, C.ăChacon, Y.ăGirard, Y.ăGarreau, J.ăLagoute, S.ăRousset, R.ăBreitwieser, Yu-Cheng Hu, YenăCheng Chao, WoeiăWu Pai, D.ăLi, A.ăSmogunov, and C.ăBarreteau. Tuning the Magnetic Anisotropy at a Molecule-Metal Interface. *Phys. Rev. Lett.*, 114:247203, 2015. URL: https://link.aps.org/doi/10.1103/PhysRevLett.114.247203.

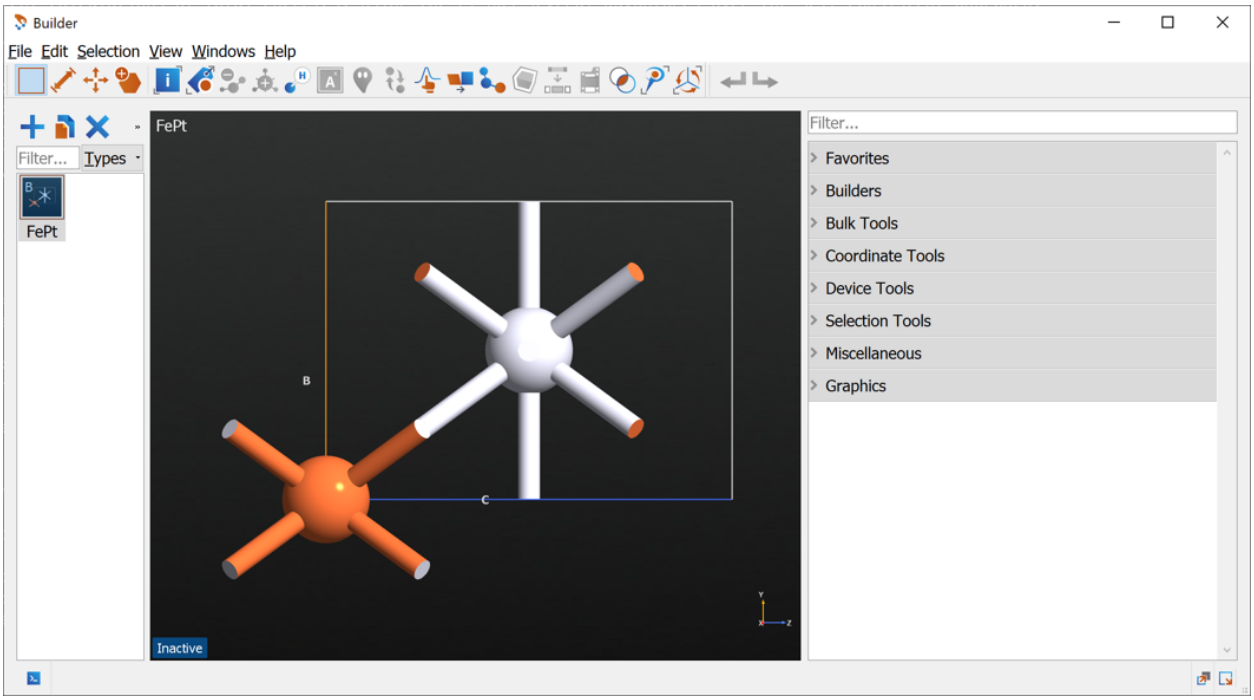
Copy the python script with the bulk configuration and paste it into the **Builder**:

1.Press the **Add** icon

2.Select **From Clipboard**

3.Press `F2` and rename the structure to FePt.

The structure should look like this:



Send the structure to the **Script Generator** using the icon.

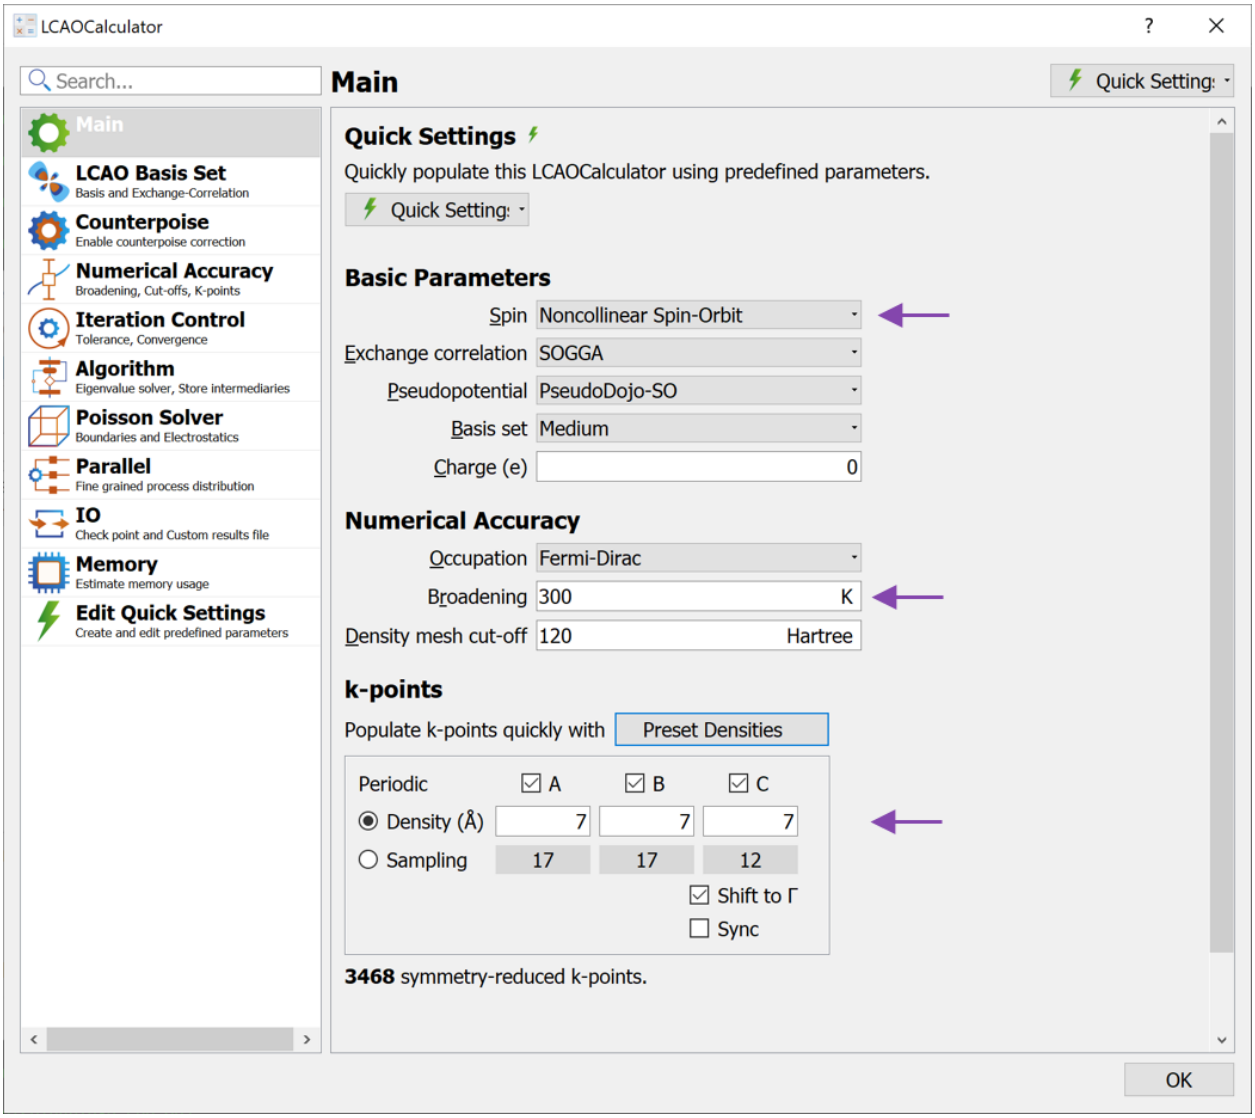
Setup MagneticAnisotropyEnergy calculation

MCA values are small quantities, most often below 1 meV/atom. This puts strong requirements on the numerical settings and a careful convergence study is recommended for any use of *MagneticAnisotropyEnergy*.

In the *Convergence of results* section we will go into more details about convergence studies. For now we will setup a calculator with reasonably well-converged settings resulting in calculated MCA values converged within ~ 0.2 meV.

In the **Script Generator** add an **LCAOCalculator**. Open the calculator block and apply the following changes (see image below):

- Change the **Spin** to *Noncollinear Spin-Orbit*
- Change the **Broadening** to *300 K*
- Finally increase the **k-point density** to *7 Å* (select from the **Preset Densities** combo box)



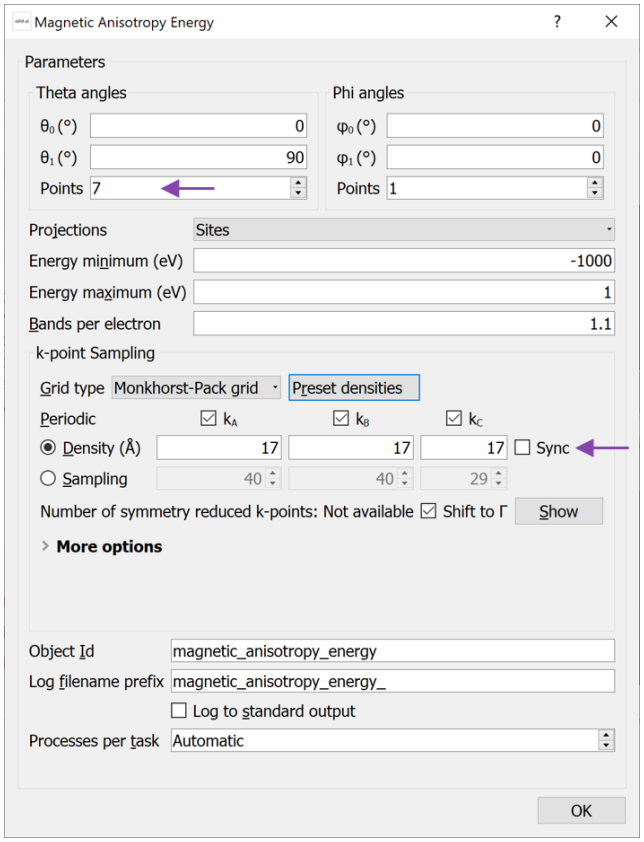
Close the calculator widget and add a **MagneticAnisotropyEnergy** block, located under the **Study object** category. Open the **MagneticAnisotropyEnergy** block to change the settings (see image below):

- Increase the number of **Theta angle points** to *7*.

  If you are only interested in the energy difference between the out-of plane, $\theta = 0$, and in-plane, $\theta = 90$, configurations it suffice to just have two Theta angle points. For tutorial purposes we add more angles to inspect the behavior of $MAE(\theta)$.

- Increase the **k-point density** to *17 Å* (select from the **Preset densities** combo box)

- Leave the **Projections** to *Sites*, but notice that you can also project on *Sites and Shells* or *Sites and Orbitals*. These options can be useful for analysis of the MAE at e.g. interfaces, and will be addressed in a different tutorial.



Close the **MagneticAnisotropyEnergy** widget. You are now ready to submit the calculations. Note that due to the rather high k-point sampling in both the **LCAOCalculator** and in the **MagneticAnisotropyEnergy** object, the calculation is somewhat computationally demanding and should preferably be run with several MPI processes.

Send the calculation to the **Job Manager** using the icon and run the calculation. The calculation can take up to several hours, depending on the available computational resources. On a single node with 24 cores, it takes around 10 minutes with QuantumATK R-2020.09-SP1.

Note: A **MagneticAnisotropyEnergy** object can only be calculated when the calculator has **Spin** set to *Noncollinear Spin-Orbit*.

Analyze results

Once the calculation is done, we can inspect the result by either using **Text Representation** or the dedicated **MAE Analyzer**:

- Find the **Text Representation** button in the right-hand panel. This will show a summary of the calculations as shown here:

```
# Title: FePt.hdf5 - magnetic_anisotropy_energy
# Type:  MagneticAnisotropyEnergy
+-------------------------------------------------------------------------------+
| MagneticAnisotropyEnergy Report                                               |
+-------------------------------------------------------------------------------+
```

(continues on next page)

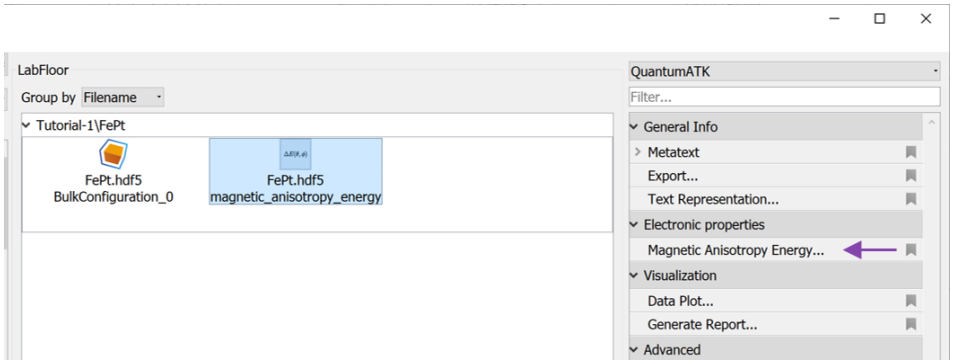
(continued from previous page)

```
+-------------------------------------------------------------------------------+
| Calculated angles (Degrees)                                                   |
+-------------------------------------------------------------------------------+
| (theta, phi) = (   0.00,    0.00)                                             |
| (theta, phi) = (  15.00,    0.00)                                             |
| (theta, phi) = (  30.00,    0.00)                                             |
| (theta, phi) = (  45.00,    0.00)                                             |
| (theta, phi) = (  60.00,    0.00)                                             |
| (theta, phi) = (  75.00,    0.00)                                             |
| (theta, phi) = (  90.00,    0.00)                                             |
|                                                                               |
+-------------------------------------------------------------------------------+
| Total magnetic anisotropy energy (MAE)                                        |
+-------------------------------------------------------------------------------+
| MAE = E(theta_1,   phi_1) - E(theta_0,   phi_0)                               |
| MAE = E(  90.00,    0.00) - E(   0.00,    0.00)                               |
| MAE =  2.3823 meV                                                             |
+-------------------------------------------------------------------------------+
```

The bottom of the output shows the final MAE calculated as the energy difference between the first and last angles. The positive MAE value means that the $\theta = 0°$ spin direction has a a lower energy than the $\theta = 90°$ direction.

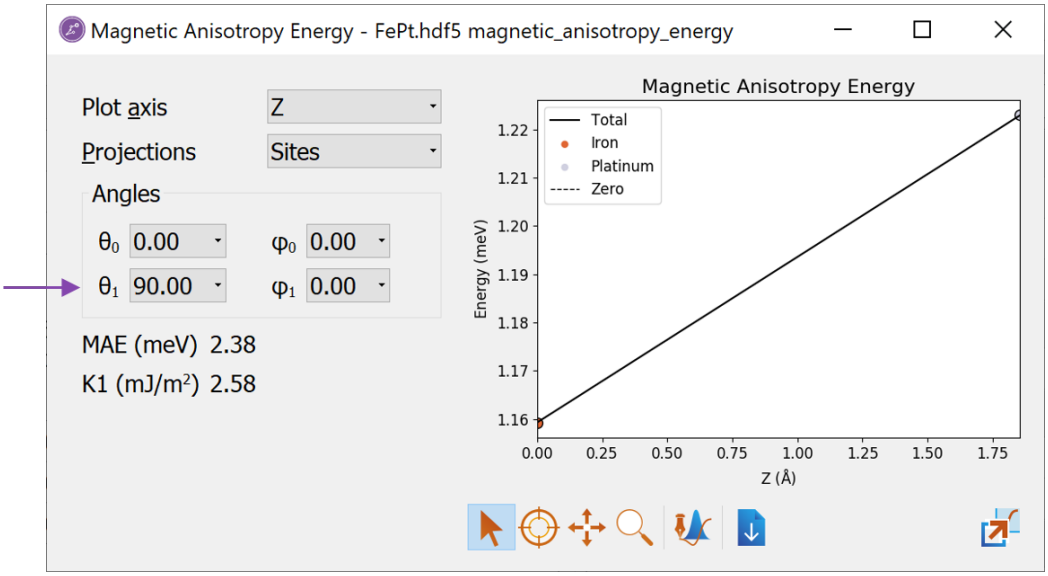
The calculated MCA values of 2.3 meV is slightly smaller than the values reported in[Page 368, 3] ranging from 2.59 meV for self-consistent total energies calculated with VASP to 2.93 meV calculated with Siesta. As will be shown in *Convergence of results*, the results ontained so far are not completely converged with respect to k-point sampling. Using higher k-point sampling, the QuantumATK values are 2.5 meV and are thus in very close agreement with the self-consistent results of VASP.

•The result of a MagneticAnisotropyEnergy calculation can also be analyzed with the Magnetic Anisotropy Energy analyzer. Mark the calculated MagneticAnisotropyEnergy on the **LabFloor** and open the analyzer.



The analyzer shows the contribution to the MAE from different projections, in this case for each atom. It shows the Fe and Pt atoms contribute more or less equally to the total MAE.

The calculated angles can be selected in the **Angles** combo boxes. Selecting $\theta_0 = 0$ and $\theta_1 = 90$ will result in the largest values.



In the lower left, the **total MAE** is shown in units of meV. Just below is shown the **K1** value, which here is defined as $K1 = MAE/(2 \cdot A)$ where A is the cross section area. This quantity is mainly relevant when studying interfaces, where **K1** is the surface anisotropy energy density. More details about this can be found in the tutorial *Magnetic Anisotropy Energy of Fe-MgO-Fe MTJ structure*.

MCA vs. angle

The dependence of the MCA value on the θ angle can be shown with a small python script.

```
import pylab

filename = 'FePt.hdf5'

# Load the MAE object
magnetic_anisotropy_energy = nlread(filename, MagneticAnisotropyEnergy)[0]

# Get the calculated angles
theta_angles = magnetic_anisotropy_energy.thetaAngles()

# Get the calculated MAE values
mae_values = [magnetic_anisotropy_energy.magneticAnisotropyEnergy(
    theta_0=0*Degrees, theta_1=theta).inUnitsOf(meV)
    for theta in theta_angles]

# Get the total MAE
k = mae_values[-1]

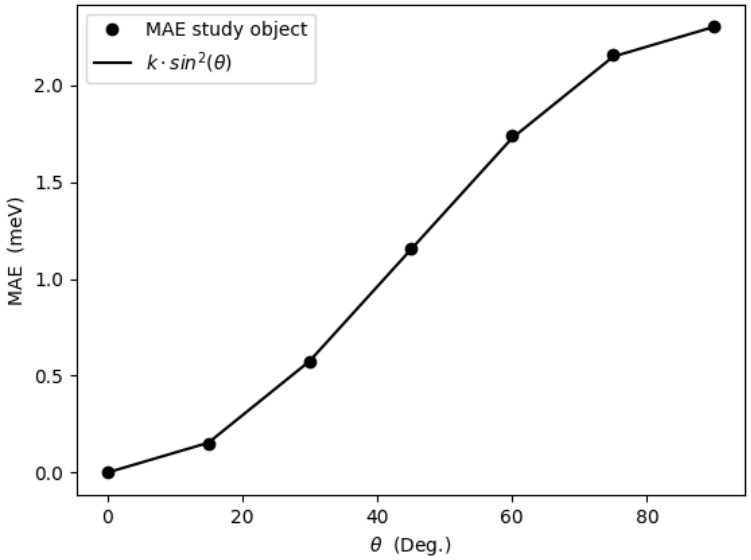
# Plot the results
pylab.figure()
pylab.plot(theta_angles, mae_values, 'ko', label='MAE study object')
pylab.plot(theta_angles, k*numpy.sin(theta_angles)**2, 'k-', label='$k\\cdot sin^2(\\
↪theta)$')
pylab.xlabel('$\\theta$  (Deg.)')
pylab.ylabel('MAE  (meV)')
```

(continues on next page)

(continued from previous page)

```
pylab.legend(loc=0)
pylab.show()
```

Run the script to produce the figure below. In the script, the MAE values are extracted for different theta angles and plotted. The plot shows that the MAE follows a $k \cdot \sin^2(\theta)$ dependence in agreement with several previous studies, where k is the maximum MCA (MAE) value.



TotalEnergy calculations

As mentioned above, the MAE calculated with the *MagneticAnisotropyEnergy* study object is calculated using the force theorem (FT), where the spin-orbit calculation is performed non-self-consistently from a polarized calculation.

It is also possible to directly calculate the MAE from total energy differences of self-consistent spin-orbit calculation as will be shown below. It can often speedup the calculation by first performing a relatively inexpensive spin-polarized calculation and use this as an initial state for the more expensive Noncollinear Spin-Orbit calculation.

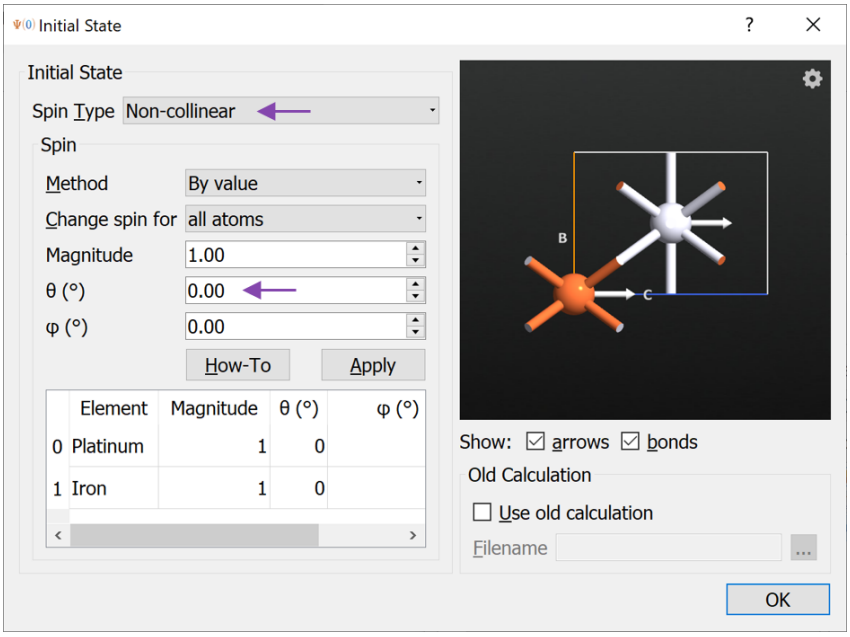
We will now show how to setup a Noncollinear Spin-Orbit with the spins rotated in a particular direction. After that we will use a slightly modified python script to loop over different spin-directions.

•Go back to the **Script Generator** and delete the **MagneticAnisotropyEnergy** block.

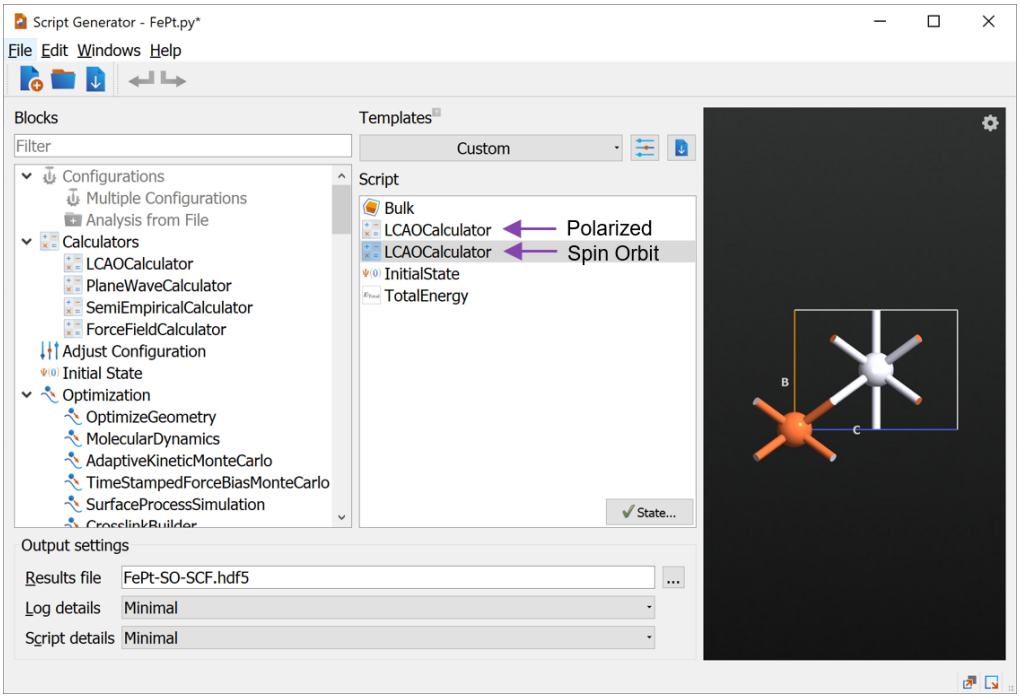
•Add another **LCAOCalculator** block to the script and apply the same settings as above.

•Open the first **LCAOCalculator** block and change the **Spin** to *Polarized*.

•Add an **InitialState** block and open it. Change the **Spin Type** to *Non-collinear*. Now you can change the spin direction of some or all atoms by modifying the θ and ϕ angles and press **Apply**. More instructions on how to setup advanced spin structures and use the widget are available if you press the **How-To** button.



•Close the InitialState widget and add a E_{Total} **TotalEnergy** analysis to the script. The script should now look as in the figure below.



Below we provide a script that loops over initial state angles. In order to understand this script, we first take a look at the current script and learn how to modify it. Send the script to the **Editor** and apply the following changes (see image below):

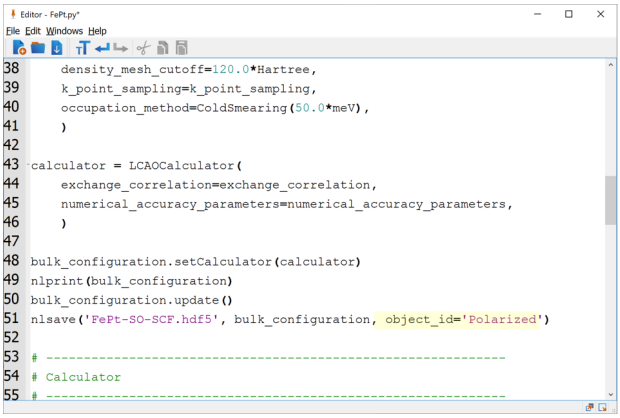
•Add `object_id='Polarized'` to the `nlsave` command in line 51.

•Add the line

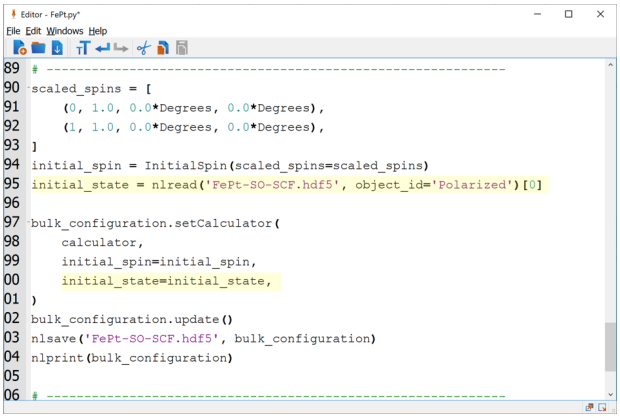
```
initial_state = nlread('FePt-SO-SCF.hdf5', object_id='Polarized')[0]
```

after the definition of `initial_spin` on line 95.

- When setting the calculator, add `initial_state=initial_state` to the setCalculator function.



```
38      density_mesh_cutoff=120.0*Hartree,
39      k_point_sampling=k_point_sampling,
40      occupation_method=ColdSmearing(50.0*meV),
41      )
42
43  calculator = LCAOCalculator(
44      exchange_correlation=exchange_correlation,
45      numerical_accuracy_parameters=numerical_accuracy_parameters,
46      )
47
48  bulk_configuration.setCalculator(calculator)
49  nlprint(bulk_configuration)
50  bulk_configuration.update()
51  nlsave('FePt-SO-SCF.hdf5', bulk_configuration, object_id='Polarized')
52
53  # ------------------------------------------------------------
54  # Calculator
55  # ------------------------------------------------------------
```



```
89  # ------------------------------------------------------------
90  scaled_spins = [
91      (0, 1.0, 0.0*Degrees, 0.0*Degrees),
92      (1, 1.0, 0.0*Degrees, 0.0*Degrees),
93  ]
94  initial_spin = InitialSpin(scaled_spins=scaled_spins)
95  initial_state = nlread('FePt-SO-SCF.hdf5', object_id='Polarized')[0]
96
97  bulk_configuration.setCalculator(
98      calculator,
99      initial_spin=initial_spin,
00      initial_state=initial_state,
01  )
02  bulk_configuration.update()
03  nlsave('FePt-SO-SCF.hdf5', bulk_configuration)
04  nlprint(bulk_configuration)
05
06  # ------------------------------------------------------------
```

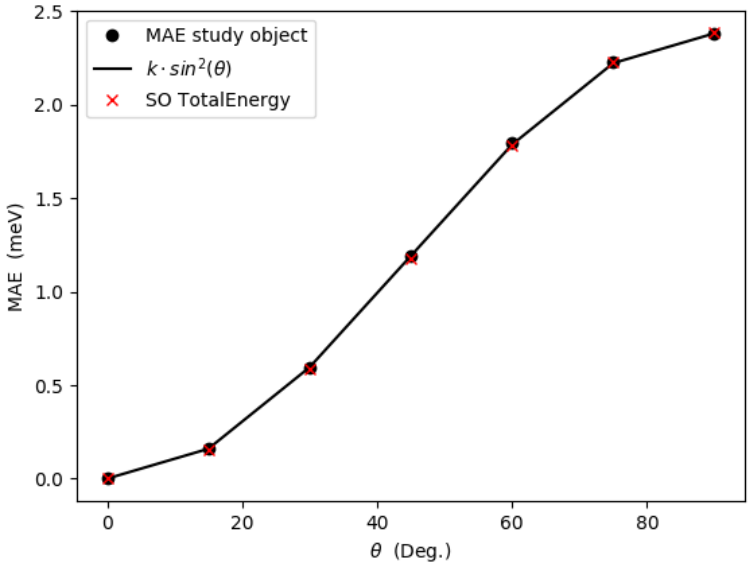
The script you now have, will first perform a spin-polarized calculation and save the result. After that, a spin-orbit calculation is performed using the polarized calculation as the initial state and with the spins rotated by the specified angles. This procedure can be done for several angles and is most easily done by inserting a *for loop* over angles. This is done in the script `FePt.py`, where the angles are setup to be the same as used in the **MagneticAnisotropyEnergy** object above. Download the script and save it to your working directory and submit the calculation with the **Job Manager**.

On a single node with 24 cores the calculation takes around 10 minutes, i.e. approximately the same time of the **MagneticAnisotropyEnergy** object. However, for larger structures with more atoms, it can be expected that the self-consistent calculations are significantly more time consuming than the *MagneticAnisotropyEnergy* study object.

Compare FT and TotalEnergy results

When the calculation is done we are ready to compare the FT results from the **MagneticAnisotropyEnergy** object with the self-consistent total energies just calculated.

Download and run the script `FePt-SO-SCF-loop-over-angles.py` to obtain the plot shown below.



It is obvious from the plot that the FT results matches very well with the self-consistent total energies. This finding is in agreement with already published results[Page 368, 3],[5].

You have now learned how to perform MAE calculation using (i) the *MagneticAnisotropyEnergy* study object which uses the force theorem and non-selfconsistent spin-orbit calculations and (ii) from total energy differences of self-consistent spin-orbit calculations with different spin orientations. The two approaches are seen to give very similar results, but using the *MagneticAnisotropyEnergy* study object allows for more analysis, such as atom- or orbital contributions to the MAE. More examples of this are provided in the tutorial *Magnetic Anisotropy Energy of Fe-MgO-Fe MTJ structure*.

Convergence of results

As mentioned above, the MAE values are very small quantities on the order of 1 meV/atom. As has been noticed in several papers, e.g.[Page 368, 3],[5], it often requires a very high k-point sampling to converge the MAE values. In this section we investigate the convergence behavior of the most important numerical parameters. These are parameters on the **LCAOCalculator**:

•K-point sampling

•Density mesh cutoff

•Basis set

•Occupation function broadening

Tip: For more information on these parameters, you can see the relevant technical notes and manual pages:

•*NumericalAccuracyParameters*

•*Pseudopotentials and basis sets available in QuantumATK*

•*Occupation Methods*

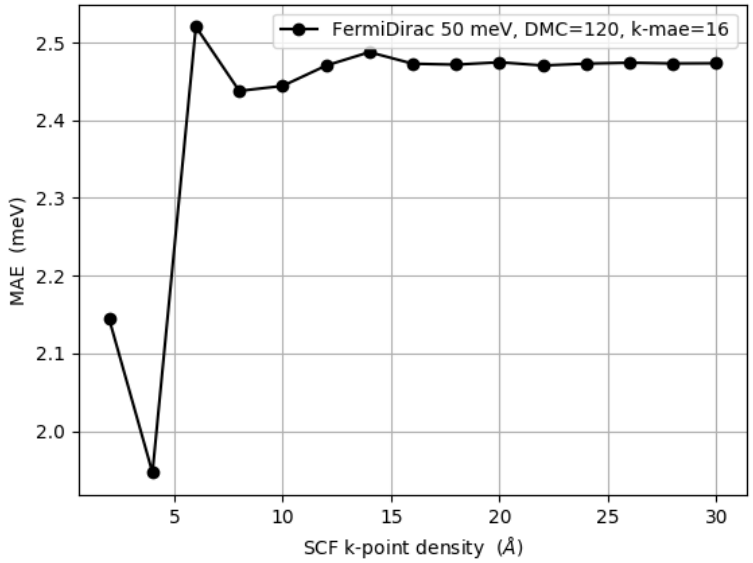
For the **MagneticAnisotropyEnergy** object the main parameter to converge is

•K-point sampling in the **MagneticAnisotropyEnergy** used for the force theorem (band energies) calculation.

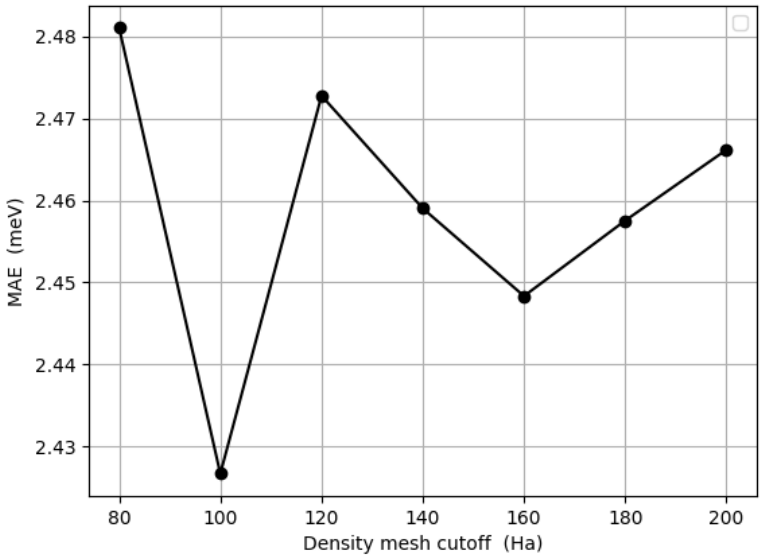
Convergence studies are easily performed in **QuantumATK** by setting up a calculation with the **Script Generator** and sending the script to the **Editor** where loops over the convergence parameters can be setup. In this section we will focus on the result of such calculations with the aim of bringing awareness to the importance of checking for convergence. All calculations in this section have been performed with the occupation function in the `FermiDirac` (default) with a broadening of 50 meV (corresponding to 580 Kelvin).

We begin with the parameters on the **LCAOCalculator**. In the figure below we show the calculated MAE as function of *k-point density*. We emphasize that the default of 4 Å in the calculator is not enough in this case. The value of 7 Å used in the above calculation is reasonably well converged, although for fully converged results a k-point density > 15 Å is required. The data have been obtained with a density mesh cutoff of 120 Hartree and a k-point density in the **MagneticAnisotropyEnergy** object of 16 Å.

[5] L.ăLeăLaurent, C.ăBarreteau, and T.ăMarkussen. Magnetocrystalline anisotropy of Fe, Co, and Ni slabs from density functional theory and tight-binding models. *Phys. Rev. B*, 100:174426, Nov 2019. URL: https://link.aps.org/doi/10.1103/PhysRevB.100.174426, doi:10.1103/PhysRevB.100.174426.



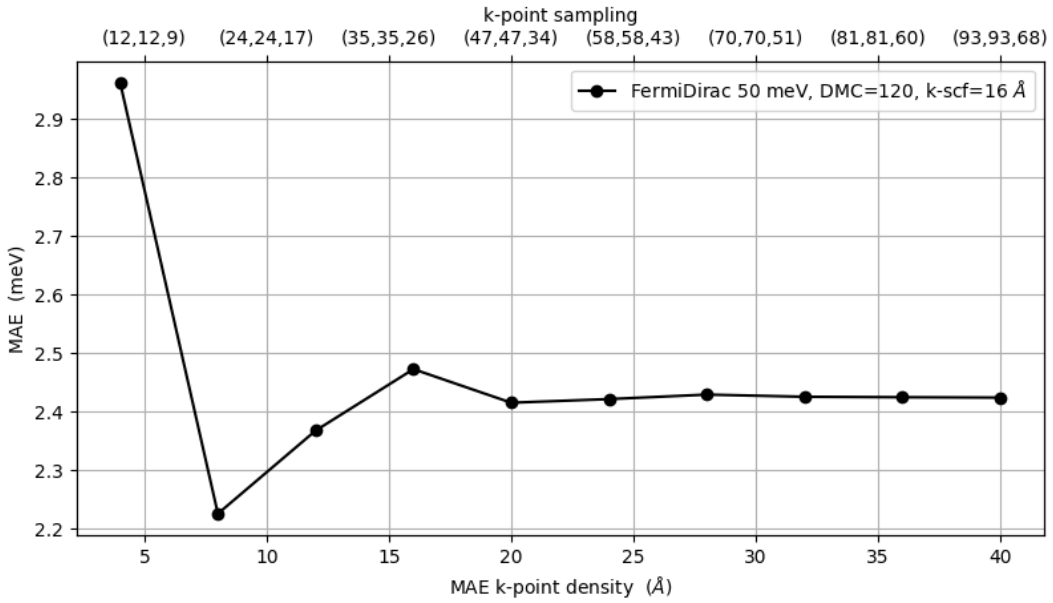
The figure below show dependence of the MAE on the *density mesh cutoff*. Although the data might not look fully converged, we note that the absolute variation is much smaller than in the figure above. The default value of 120 Hartree seems to be converged to no more than an 0.05 meV error. The data for this figure have been obtained with a k-point density of 16 Å in both the **LCAOCalculator** and in the **MagneticAnisotropyEnergy** object.



Another numerical parameter to check for convergence is the LCAO *basis set size*. The table below show the MAE results obtained with *Medium, High, and Ultra basis sets*. We observe that the calculated MAE value are almost the same for all LCAO basis set sizes with variations less than 0.1 meV indicating that the Medium basis used above is sufficient.

LCAO Basis set		
Medium	High	Ultra
2.55 meV	2.49 meV	2.57 meV

We next address the convergence of the MAE values with respect to the *k-point sampling* in the **MagneticAnisotropyEnergy** object. The figure below show results obtained with a density mesh cutoff of 120 Hartree and a k-point density of 16 Å in the **LCAOCalculator**. We see that the k-point density of 17 Å used above is reasonably well converged and above 20 Å, the results are essentially constant.

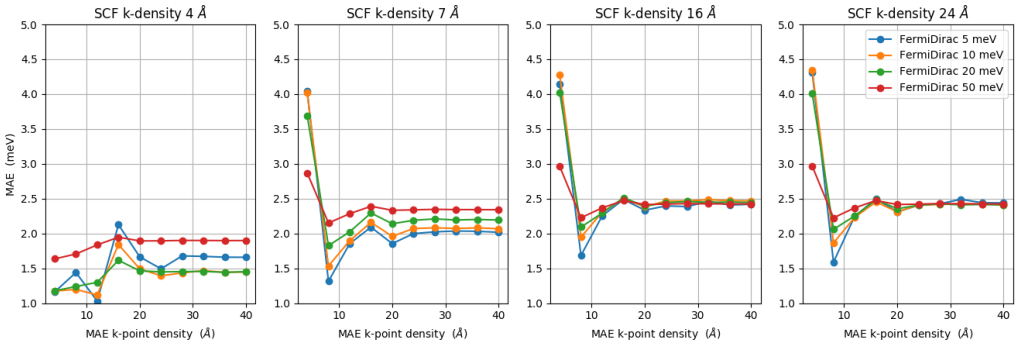


We finally consider the convergence of the broadening used in the occupation method, in this case the *Fermi-Dirac* occupation function. The main reasoning for using a finite broadening in the occupation function is to be able to use a lower k-point sampling. This is illustrated in the figure below. The figure shows four subplots. The data in each subplot has been calculated with a constant k-point density in the self-consistency (SCF) loop and the non-self-consistent spin-orbit calculation. This k-point density is shown in the title of each sub-plot. In a particular sub-plot, we show the MAE vs. k-point density used in the **MagneticAnisotropyEnergy** (MAE) object for four different occupation function broadenings: 5, 10, 20, and 50 meV.

We first observe that for high enough SCF k-point densities (16 Å or 24 Å), and sufficiently high MAE k-point density (> 10 Å), all curves are essentially on top of each other, showing that the value of the occupation function broadening is less important. However, for an intermediate SCF k-point density of 7 Å, we see that the curve for 50 meV broadening is closer to the converged MAE value of 2.5 meV than the curves with lower broadening.

At the lowest SCF k-point density of 4 Å (left-most plot) we see that none of the curves reaches the converged value of 2.5 meV.

Important: Convergence of SCF k-point density and occupation function broadening goes hand in hand. When changing the occupation function broadening, the required k-point sampling also changes.



COSMICS project

The **MagneticAnisotropyEnergy** study object has been developed within the project COSMICS founded by the European Unions Horizon 2020 research and innovation program under Grant Agreement No. 766726. Details about the object can be found here *MagneticAnisotropyEnergy*. Application of the *MagneticAnisotropyEnergy* object to metallic slabs and comparison with QuantumEspresson and tight-binding calculations are presented in ref[5].

More information about the COSMICS project can be found here: http://cosmics-h2020.eu/

3.1.12 Magnetic Anisotropy Energy of Fe-MgO-Fe MTJ structure

Version: S-2021.06

In this tutorial you will learn how to use the *MagneticAnisotropyEnergy* study object to calculate the perpendicular magnetic anisotropy (PMA) energy of a Fe-MgO-Fe magnetic tunnel junction (MTJ) structure.

You will learn how to analyze site- and orbital projected magnetic anisotropy energy (MAE) values and compare the results to `OrbitalMoment` based calculations.

The MAE is of central interest for both fundamental and practical reasons, with STT-MRAM being one of the most important technological examples.

Note: This tutorial builds on the introductory MAE tutorial treating a bulk system: *Bulk Magnetic Anisotropy Energy*, and it is assumed that the reader is familiar with its contents. If you are not already familiar with MAE calculations in QuantumATK, we suggest you go through that tutorial before continuing here.

–*COSMICS project*

Introduction

One of the key requirements of an STT-MRAM device is to be able to store information. This requires a sufficiently high energy-barrier between the 1 and 0 states of the system, such that a switch does not happen due to random thermal fluctuations. The MAE is a key element in determining the energy barrier and thus the thermal stability of a STT-MRAM memory unit. The stability factor is given by[1]:

$$\Delta = \frac{H_K M_S V}{2 k_B T}$$

where H_K is the anisotropy field, M_S is the saturation magnetization, V is the cell volume, k_B is the Boltzmann constant and T is the temperature.

When the magnetization direction is perpendicular to the interfaces of different materials, the cell design is called PP (perpendicular to plane) and is the design in focus for this tutorial[Page 382, 1].

For PP cells, H_K is determined by the PMA which has three main contributions: (i) contribution from the bulk of the magnetic material, bulk PMA, (ii) contribution from the interfaces and surfaces, interfacial PMA (iPMA), and (iii) from the shape anisotropy. Bulk Fe in the BCC phase has vanishing bulk PMA, while the iPMA can be substantial and is the focus of this tutorial.

In this tutorial we will calculate the PMA using the *MagneticAnisotropyEnergy* study object, which uses the force theorem to evaluate the energy difference between two magnetization directions. More information about the force theorem and validation of its use can be found in the reference manual: *MagneticAnisotropyEnergy* and in the tutorial: *Bulk Magnetic Anisotropy Energy*.

Fe-MgO-Fe MTJ structure

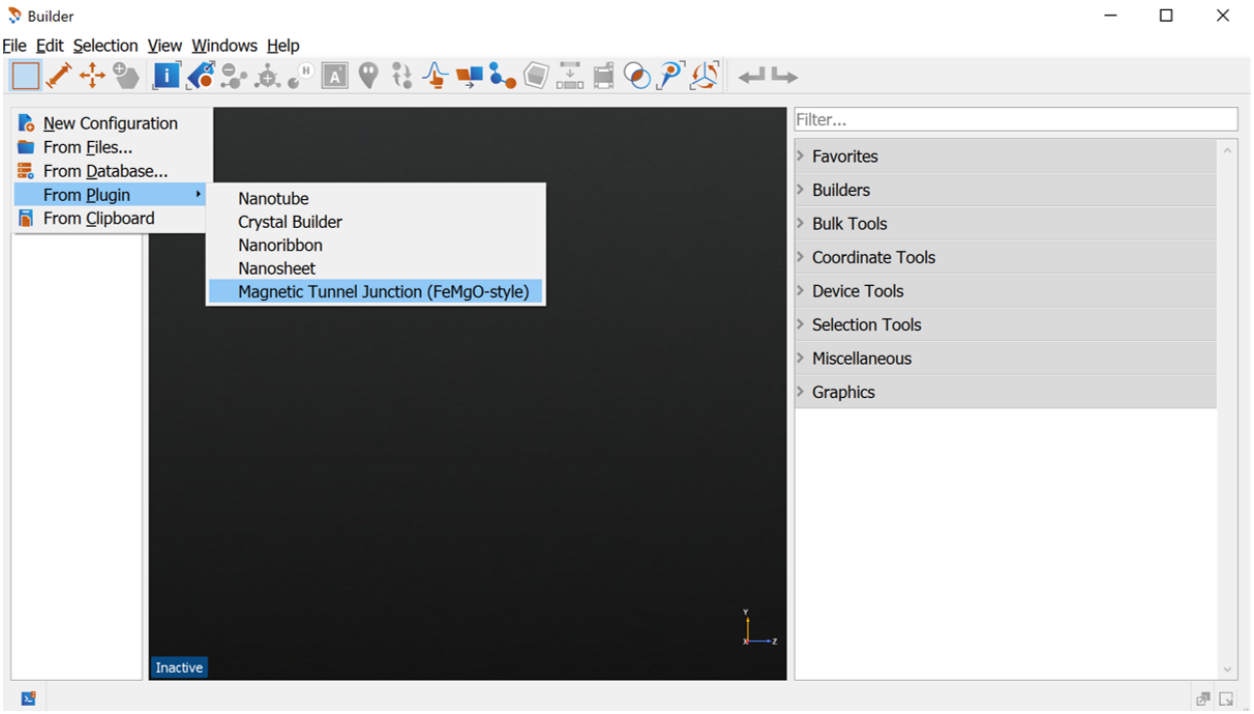
We begin by setting up the atomic structure of a Fe-MgO-Fe structure. Start by opening the **Builder**. In the Builder do the following (see image below):

•Press the **Add** icon

•Select **From Plugin**

•Select **Magnetic Tunnel Junction (FeMgO-style)**

[1] AăV Khvalkovskiy, DăApalkov, SăWatts, RăChepulskii, RăS Beach, AăOng, XăTang, AăDriskill-Smith, WăH Butler, PăB Visscher, DăLottis, EăChen, VăNikitin, and MăKrounbi. Basic principles of STT-MRAM cell operation in memory arrays. *Journal of Physics D: Applied Physics*, 46(7):074001, feb 2013. URL: https://doi.org/10.1088/0022-3727/46/7/074001, doi:10.1088/0022-3727/46/7/074001.



In the **Magnetic Tunnel Junction Builder** apply the following changes (see image below)

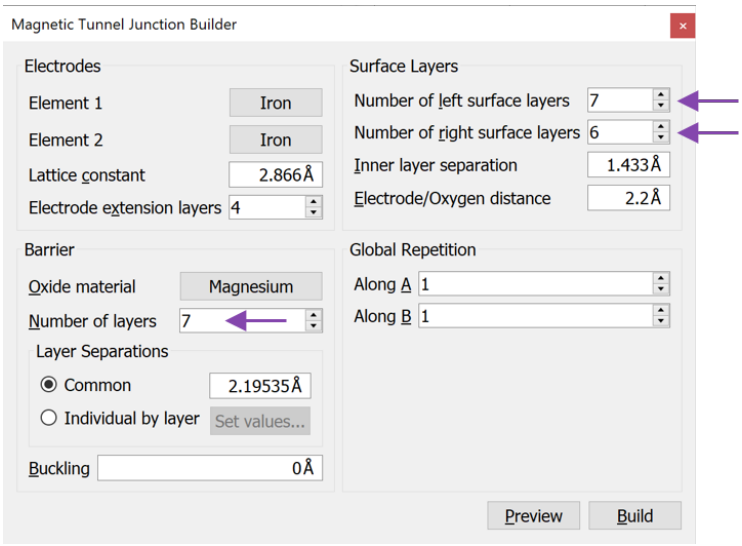
•For the **Barrier** set the **Number of layers** to *7*

•**For the Surface Layers:**

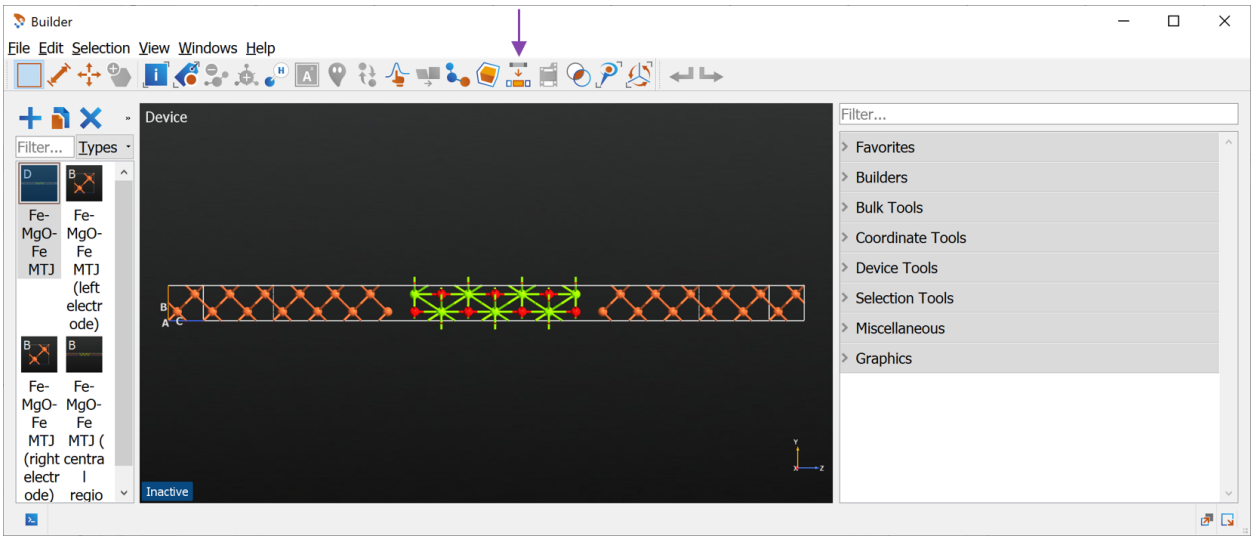
–Set **Number of left surface layers** to *7*

–Set **Number of right surface layers** to *6*

•Press **Build**

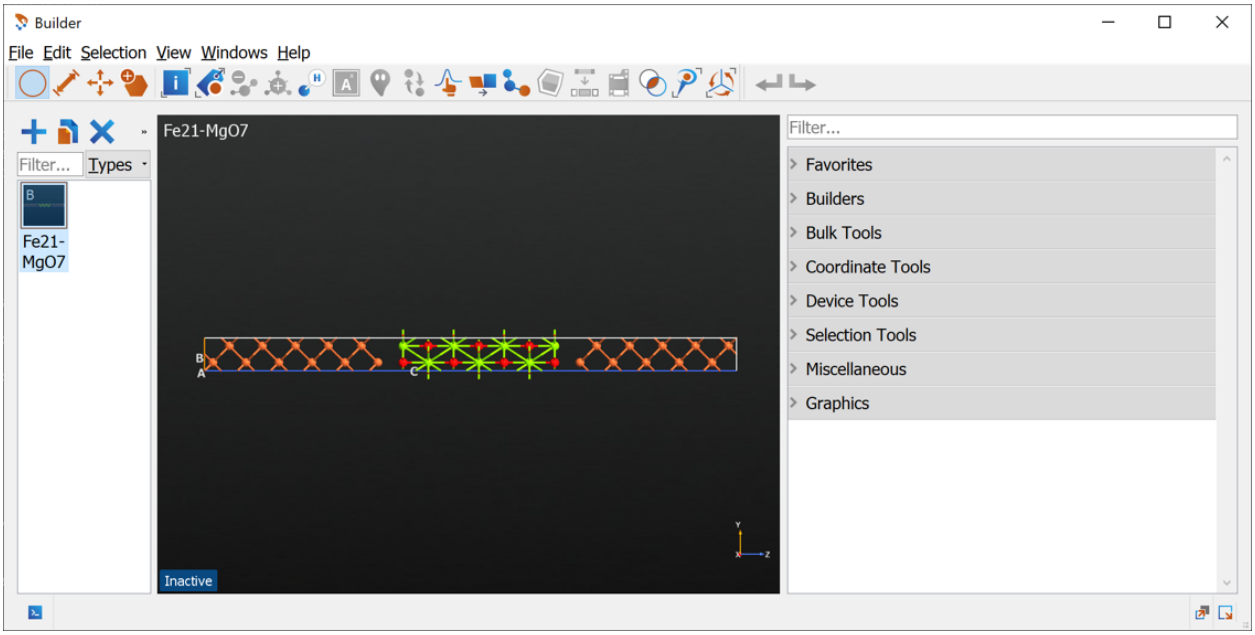


You now have a **DeviceConfiguration** in the Builder. Split the device into electrodes and central region using the button indicated in the figure below.



Once the device has been split, you can delete the original device structure as well as the electrodes. Finally rename the remaining central region to *Fe21-MgO7* (press `F2`), indicating that the structure has 21 Fe layers and 7 MgO layers. Your builder should now look as below.

Note: The although we setup the MTJ structure with 6 and 7 surface layers, we ended up with a bulk configuration of 21 layers. The reason is that we have also included the 4 electrode extension layers on both sides. The total number of layers is thus the sum of left and right surface layers and the electrode extension layers, $6 + 7 + 4 + 4 = 21$.



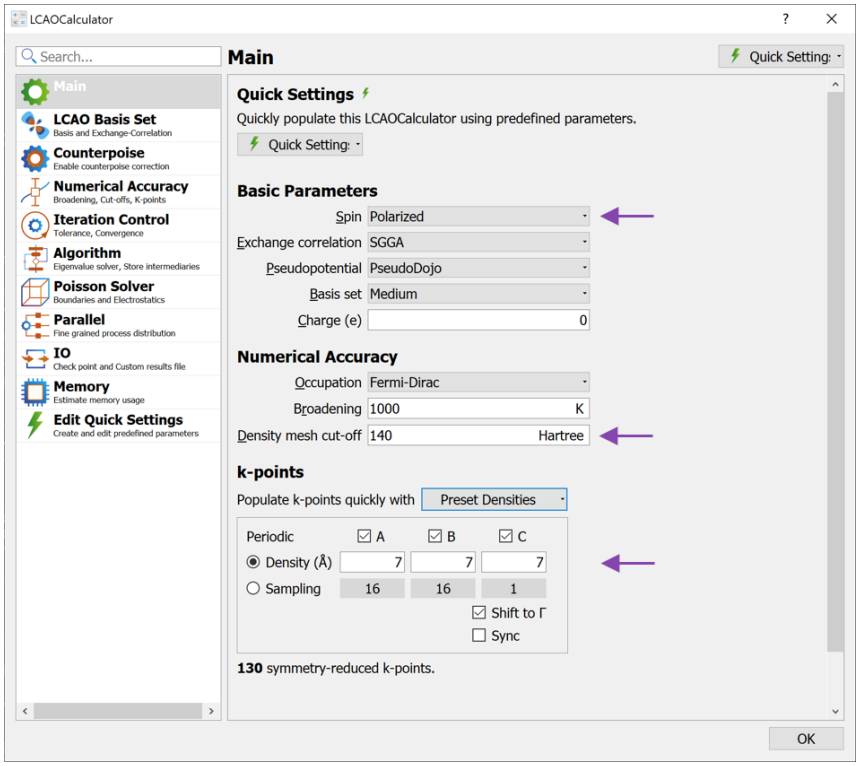
Send the structure to the **Script Generator** using the **Send-to** button.

Structural relaxation

The next step will be to relax the structure. In the **Script Generator** do the following:

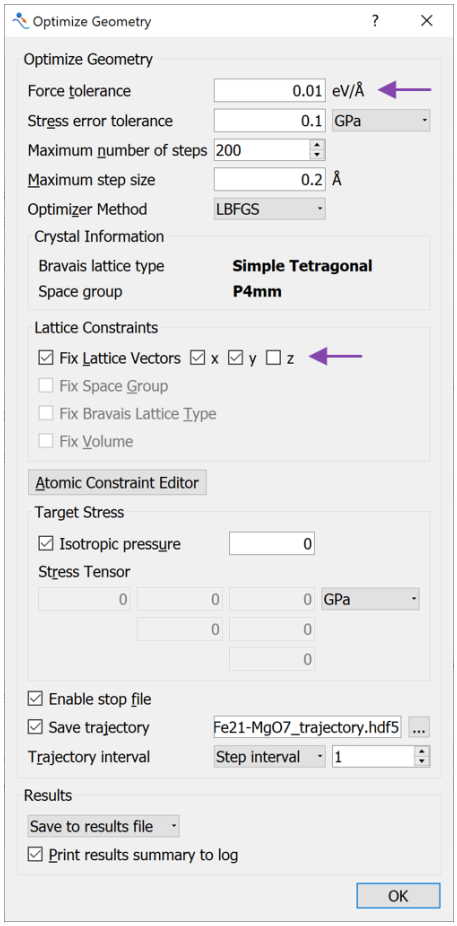
- **Add an** **LCAOCalculator block and open it (see image below):**

  - Change the **Spin** to *Polarized*. This is necessary since iron is magnetic and cannot be correctly modeled with an unpolarized calculation.
  - Increase the **Density mesh cut-off** to *140 Hartree*. For this configuration, the geometry optimization converges faster with this increase.
  - Increase the **k-point density** to *7 Å* (select from the *Preset Densities* combo box).
  - Leave the remaining settings as defaults and close the widget again.



- **Add an** **OptimizeGeometry block to the script and open it to apply the following changes (see image below):**

  - Change the **Force tolerance** to *0.01 eV/Å*
  - Uncheck the **Fix Lattice Vectors** for the z direction. This allows the C-lattice vector in the unit cell to be optimized. The A- and B- lattice vectors are kept fixed, although the atoms are allowed to move also in the x- and y-directions.



You are now ready to submit the calculations. Send the calculation to the **Job Manager** using the **Send-to** button and run the calculation. The calculation can take several hours to complete even when run with multiple MPI processes. For this reason we provide here the relaxed structure: `Fe21-MgO7-relaxed.py`. Either wait for the Geometry Optimization job to finish or download the relaxed configuration to obtain the relaxed configuration. Transfer the relaxed configuration to the **Script Generator**.

MagneticAnisotropyEnergy calculation

In the **Script Generator** do the following:

- **Add an LCAOCalculator and open it (see image below):**

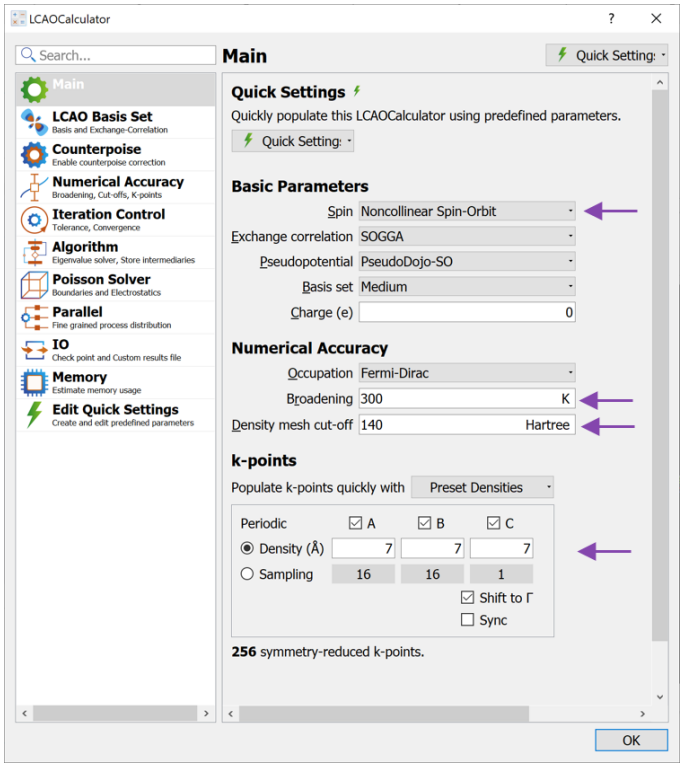
  – Change the **Spin** to *Noncollinear Spin-Orbit*.

  – Set the **Broadening** to *300 K*

  – Increase the **Density mesh cut-off** to *140 Hartree*.

  – Increase the **k-point density** to *7 Å* (select from the **Preset Densities** combo box).

  – Leave the remaining settings as defaults and close the widget again.

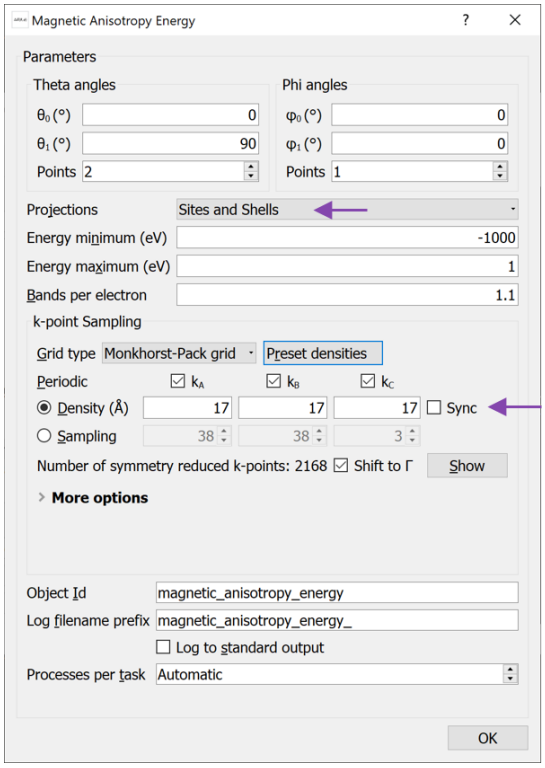


•Add a MagneticAnisotropyEnergy study object and open it (see image below):

–Change **Projections** to *Sites and Shells*. This will calculate the contribution to the MAE from the s, p, d and f shells on each atom.

–Increase the **k-point density** to *17 Å* (choose this value from the **Preset densities**).

–Leave the remaining settings as defaults and close the widget again.



Note: The total MAE will always be calculated irrespective of which **Projections** have been selected. The choice of **Projections** only determines which kind of analysis can be performed. The default choice of `Sites` allows a decomposition of the MAE onto atomic sites, but no information about which orbitals are involved. Choosing `Sites and Shells` gives additional information about which shells (s, p, d, f) contribute, while choosing `Sites and Orbitals` give detailed information about individual orbitals, e.g. p_x, p_y, p_z etc.

If more detailed projections are chosen, more memory will be required and the calculation time will also increase.

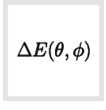
If you are only interested in the total MAE value, it can be beneficial to choose `No Projection` as this will lower the required memory and reduce the computation time.

Send the calculation to the **Job Manager** using the **Send-to** button and run the calculation. The calculation can take several hours. On a single node with 24 cores, the calculation takes about two hours.

Analyzing the results

Once the calculation has finished we are ready to analyze the results:

- Check the `hdf5` file on the **LabFloor**.
- Mark the **MagneticAnisotropyEnergy** object and open the analyzer **Magnetic Anisotropy Energy**



The **Magnetic Anisotropy Energy** analyzer opens with a window showing the site-resolved contributions to the MAE (if `No Projection` was chosen when setting up the MAE object, this plot will be empty). The type of projections can be selected to the left of the plot.

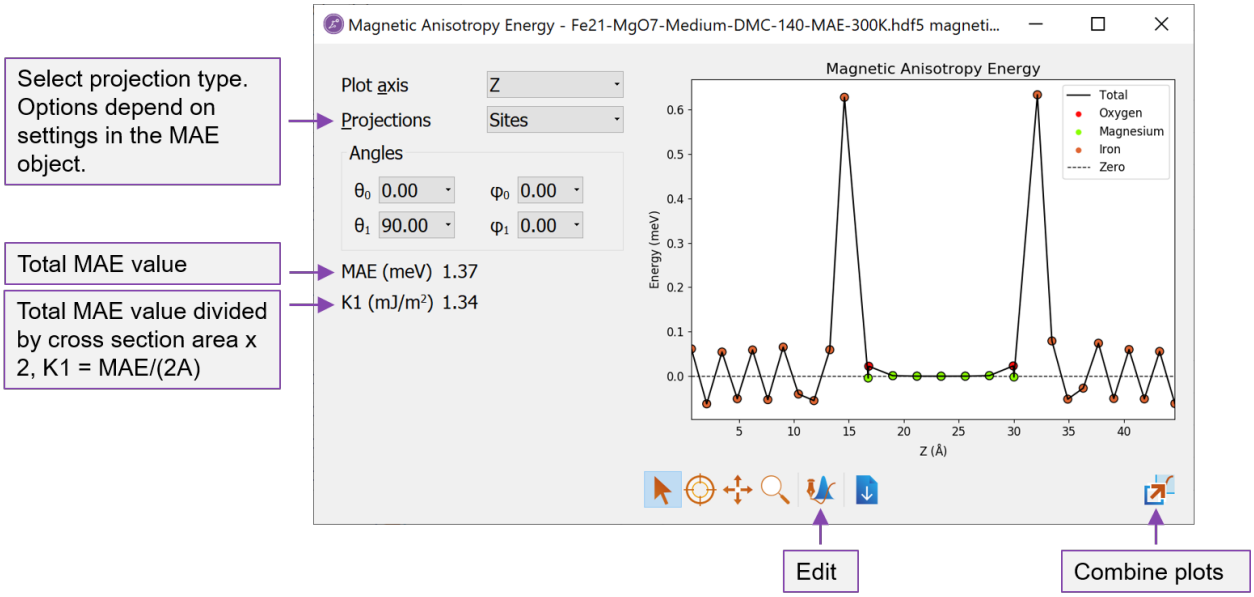


Fig. 3.4: The **Magnetic Anisotropy Energy** analyzer shows both the total MAE and the projected values.

In the lower left, the **total MAE** is shown in units of meV. Just below is shown the **K1** value, which here is defined as $K1 = MAE/(2 \cdot A)$ where A is the cross section area. The factor $1/2$ accounts for the fact that most systems will have two equivalent interfaces. If this is not the case, the **K1** value needs to be determined manually.

From the analyzer, we see that:

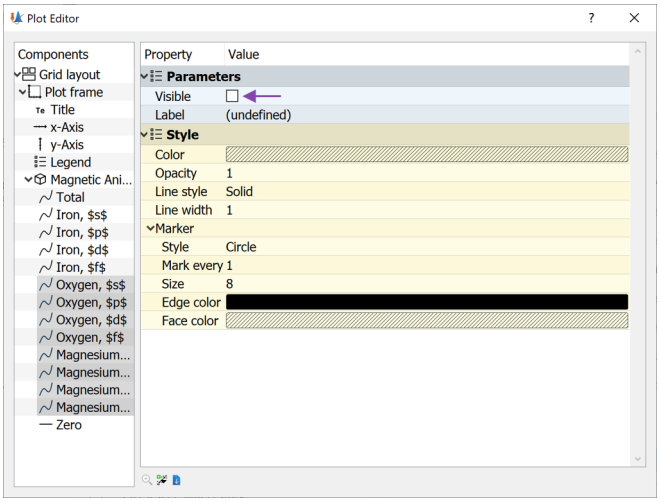
- The MAE value is positive showing that the perpendicular (out-of-plane) magnetization is the energetically most favorable and the Fe-MgO-Fe structure is thus suitable for a PP cell design (note however, that the shape anisotropy, which favors in-plane magnetization, is not taken into account).
- The contribution to the positive MAE mainly comes from the interface Fe layers.
- The bulk Fe layers furthest away from the Fe-MgO interface have a smaller contribution to the MAE and shows an oscillating behaviour, summing up to a very small contribution. This means that K1 equals the surface anisotropy energy density, σ.
- The Mg and O atoms essentially do not contribute to the MAE.

Since the MagneticAnisotropyEnergy object was calculated with **Projections** set to `Sites and Shells` we also have the possibility to analyze which orbital shells are responsible for the MAE:

- Change **Projections** to *Shells* in the MAE analyzer window.

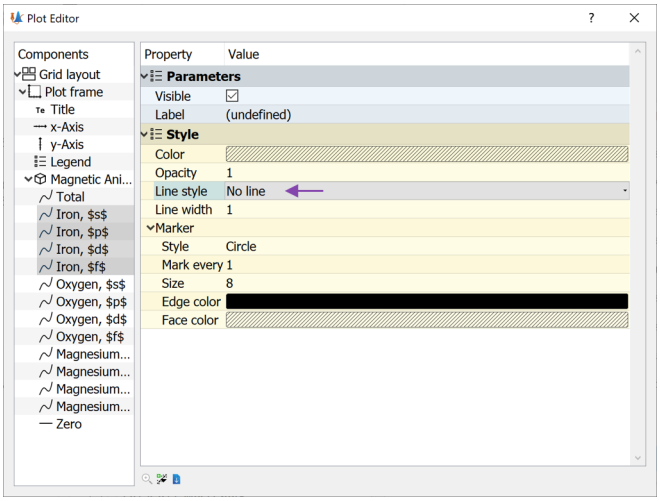
Several new lines are now added to the plot and at first sight it appears difficult to analyze. However, in **QuantumATK** it is very easy to customize plots. Since the Mg and O atoms are unimportant for the total MAE, we do not want to show results for those. In order to edit the plot do the following:

- Press the **Edit** button (see image above) or simply press **e**.
- Mark all the *Oxygen* and *Magnesium* lines
- Un-check the **Visible** box (see image below)

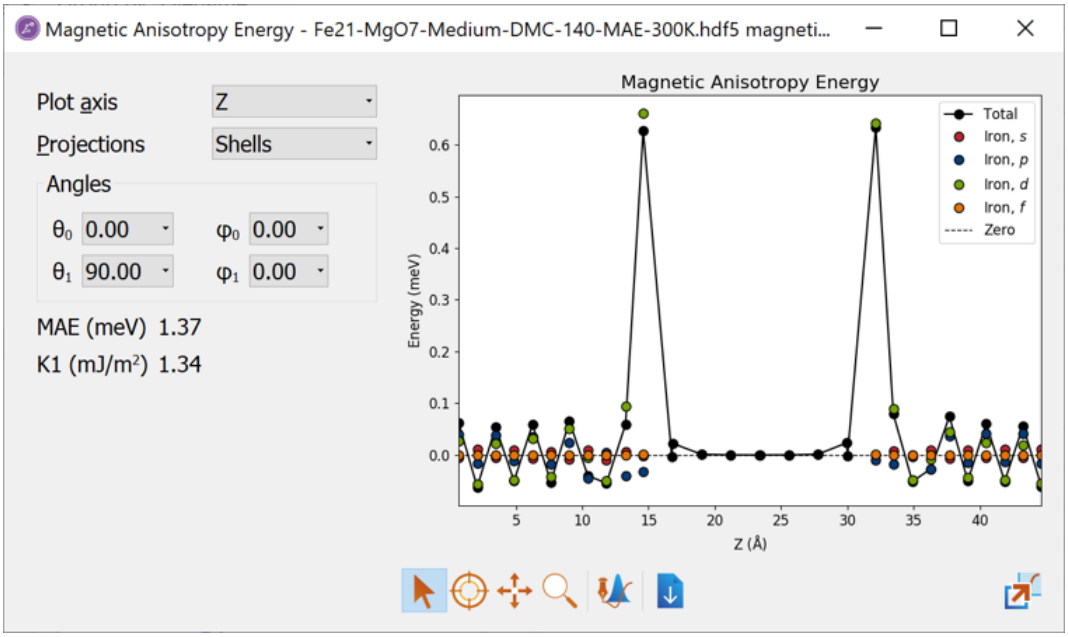


•Now mark all the *Iron* lines

•Change the **Line style** to `No line` (see image below)



We have now removed all the oxygen and magnesium data from the plot, as well as the lines between the points for the iron atoms. Now the analyzer should look like the image below.



It is now evident that the finite MAE value essentially only comes from the Fe d-orbitals. Such information can indeed be very useful since it provides insight into how the MAE can be optimized by modifying the Fe d-orbitals.

Tip: Such analysis and experiments have been the focus of the Horizon 2020 *COSMICS project*.

Orbital moment analysis

We learned from the analysis above that the MAE in the Fe-MgO-Fe MTJ structure essentially comes from the Fe d-orbitals. Due to this simple contribution and since the spin-orbit coupling in iron is rather weak, it is possible to estimate the MAE with a more perturbative approach using the Bruno formula[2]:

$$MAE = -\frac{\xi_{Fe-d}}{4}(L_x - L_z)$$

Here L_x is the x-component of the orbital moment, when the spin orientation is along the x-axis ($\theta = 90°$) and L_z is the z-component of the orbital moment, when the spin orientation is along the z-axis ($\theta = 0°$). ξ_{Fe-d} is the spin-orbit coupling strength from the Fe d-orbitals.

The orbital moment can be calculated in QuantumATK, for systems with **Spin** set to *Noncollinear Spin-Orbit*. Usually a non-selfconsistent spin-orbit calculation restarting from the polarized one is sufficient.

Since we already have non-selfconsistently updated spin-orbit calculations from the MagneticAnisotropyEnergy we can use these for an **OrbitalMoment** analysis. In the script, where the MagneticAnisotropyEnergy was calculated, we can insert the following lines at the end of the script:

```
# Get the non-selfconsistently updated spin-orbit configurations for the specified
# (theta, phi) angles.
configuration_so_0 = magnetic_anisotropy_energy.updatedSpinOrbitConfiguration(0*Degrees,␣
↪0*Degrees)
```

(continues on next page)

[2] Patrick Bruno. Tight-binding approach to the orbital magnetic moment and magnetocrystalline anisotropy of transition-metal monolayers. *Phys. Rev. B*, 39:865–868, Jan 1989. URL: https://link.aps.org/doi/10.1103/PhysRevB.39.865, doi:10.1103/PhysRevB.39.865.

(continued from previous page)

```
configuration_so_90 = magnetic_anisotropy_energy.
↪updatedSpinOrbitConfiguration(90*Degrees, 0*Degrees)

# ------------------------------------------------------------
# Orbital Moment
# ------------------------------------------------------------
kpoints = KpointDensity(
    density_a=7.0*Angstrom,
    force_timereversal=False,
    )

orbital_moment = OrbitalMoment(
    configuration=configuration_so_0,
    kpoints=kpoints,
    temperature=300.0*Kelvin,
)
nlsave('Fe21-MgO7.hdf5', orbital_moment, object_id='Orbital moment 0')

orbital_moment = OrbitalMoment(
    configuration=configuration_so_90,
    kpoints=kpoints,
    temperature=300.0*Kelvin,
)
nlsave('Fe21-MgO7.hdf5', orbital_moment, object_id='Orbital moment 90')
```

Note: The MagneticAnisotropyEnergy is a study object, which has a number of task to complete, when called with `magnetic_anisotropy_energy.update()`. The study upject keeps track on which tasks have already been finished and will not do them again. Therefore, when the lines above to your script with the MagneticAnisotropyEnergy calculation, the MAE calculation will not do any work (except for detecting that it has already finished all the tasks), and the script will quickly proceed to the last part.

The orbital moment can also be setup using the **Script Generator**. In this case, it is important to remember that the analysis of orbital moment using the Bruno formula requires two calculations for different spin orientations. Such a script is provided here, where a self-consistent polarized calculation is followed by two non-selfconsistent spin orbit calculation for two different initial spin orientations: `orbital-moment-script.py`.

Once the orbital moments have been calculated, the results can be analyzed with the following script.

```
import pylab

# File name.
filename = 'Fe21-MgO7.hdf5'

orbital_moment_z = nlread(filename, object_id='Orbital moment 0')[0]
orbital_moment_x = nlread(filename, object_id='Orbital moment 90')[0]

# Spin-orbit coupling strength
e_so = 60 * meV

# Get the total moment
L_z = orbital_moment_z.orbitalMoment()[2] / bohr_magneton
```

(continues on next page)

(continued from previous page)

```
L_x = orbital_moment_x.orbitalMoment()[0] / bohr_magneton

# Calculate the MAE using Bruno's formula
mae = -e_so / 4 * (L_x - L_z)

nlprint('Total MAE (Bruno formula) = {: .2f} meV'.format(mae.inUnitsOf(meV)))

# Get the atom resolved moments
L_z_atom = orbital_moment_z.atomResolvedOrbitalMoment()[:, 2] / bohr_magneton
L_x_atom = orbital_moment_x.atomResolvedOrbitalMoment()[:, 0] / bohr_magneton

mae_atom = -e_so / 4 * (L_x_atom - L_z_atom)

# Get the z-coordinates
z = orbital_moment_z._configuration().cartesianCoordinates()[:, 2].inUnitsOf(Ang)

pylab.figure()
pylab.plot(z, mae_atom, 'ko-')
pylab.xlabel('z ($\\AA$)')
pylab.ylabel('MAE (meV)')
pylab.show()
```

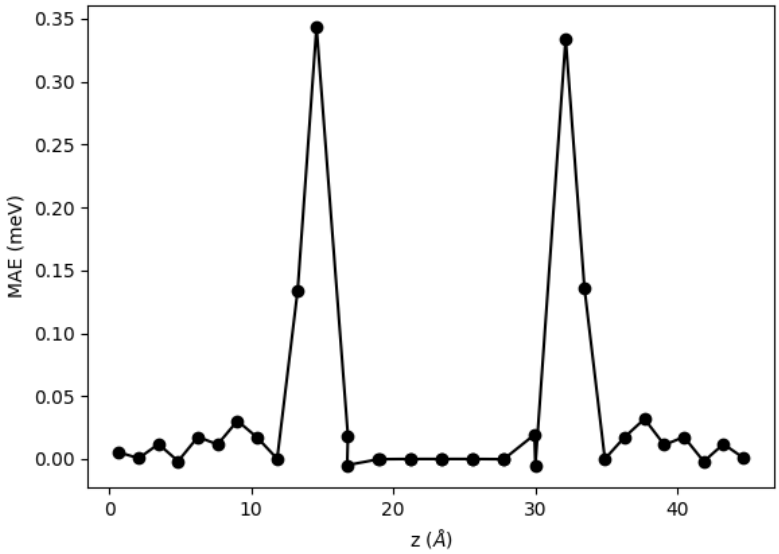
Note: In the analysis we use that the spin-orbit coupling energy of the Fe d-orbitals is 60 meV[3].

The outcome of the script is that the total PMA obtained from the Bruno formula is

```
Total MAE (Bruno formula) = 1.16 meV
```

The total MAE (PMA) is thus in fairly good agreement with the Force theorem (FT) result obtained from the *MagneticAnisotropyEnergy* object of 1.37 meV. It is also possible to get an atom-resolved plot as shown below, which is also produced by the same script:

[3] G.ăAutes, C.ăBarreteau, D.ăSpanjaard, and M.ăDesjonqueres. Magnetism of iron: from the bulk to the monatomic wire. *Journal of Physics: Condensed Matter*, 18(29):6785–6813, jul 2006. doi:10.1088/0953-8984/18/29/018.



The atom-resolved MAE obtained from the Bruno formula clearly shows a similar behavior as the site-resolved MAE plot shown above: The main contribution comes from the interface Fe layers, while the bulk Fe has a vanishing contribution. However, there are some quantitative differences. The results obtained from the orbital moment and the Bruno formula show a rather large contribution from the second interface layer, which is not evident in the FT results. The oscillations in the bulk part of the Fe also comes out slightly smaller from the Bruno formula than from the FT.

The fairly good agreement between the Bruno formula and the FT method serves to validate both approaches. It should, however, be noticed that such a good agreement is not always the case. In calculations including heavier elements with stronger spin orbit coupling, it has been shown that the Bruno formula does not agree with the FT method[4] or self-consistent total energy calculations. The Bruno formula should therefore be used with care, while the FT method used in the MagneticAnosotropyEnergy object is in good agreement with total energy calculations, also for heavy elements[Page 394, 4]. For more details about comparing the FT method with total energies see the tutorial *Bulk Magnetic Anisotropy Energy*.

What causes the PMA?

In the above sections we have seen that the contribution to the interfacial PMA comes mainly from the interface Fe layers, while bulk Fe has much smaller contribution. But what causes the positive interfacial PMA? There can be (at least) three sources:

1. Fe-O hybridization. The Fe d-orbitals hybridizes with the O orbitals. In previous studies it has e.g. been shown theoretically and experimentally that hybridization with graphene or C60 increases the PMA of Co surfaces.
2. Strain and relaxation effects. The atomic positions are slightly distorted close to the surface compared to the bulk coordinates.
3. Interface asymmetry. This asymmetry exist at any interface, also at a Fe surface, i.e. a Fe - vacuum interface.

In this section we will try to analyze and quantify the contribution from each of the three sources. Since the calculations are performed in the same way as above, we will focus on the results and analysis. We will do that by comparing the total and projected MAE for different configurations as detailed below.

We will start by analyzing the relative importance of the Fe-O hybridization vs. the interface asymmetry. For doing this, we remove the MgO layers from the relaxed Fe-MgO-Fe configuration, and calculate the MagneticAnisotropyEnergy

[4] M.ăBlanco-Rey, J.I. Cerda, and A.ăArnau. Validity of perturbative methods to treat the spin–orbit interaction: application to magnetocrystalline anisotropy. *New J. Phys.*, 21:073054, 2019. URL: https://iopscience.iop.org/article/10.1088/1367-2630/ab3060.

for this 21 layer Fe slab. Since we do not want to mix in contributions from strain effects, we keep the Fe atoms in the same positions and do not perform any further relaxations. The calculation can be run with this script `Fe21-vacuum.py`.

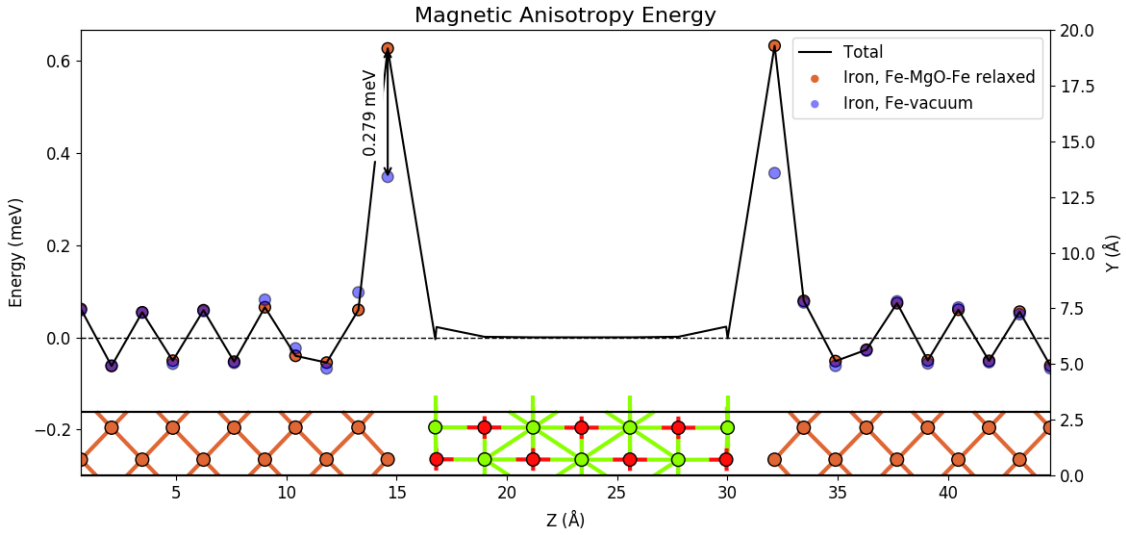
In order to address the effect of strain effects, we also repeat the MagneticAnisotropyEnergy calculation for the unrelaxed configuration produced directly by the MTJ builder plugin. The calculation can be run with this script `Fe21-MgO7-unrelaxed.py`.

The total PMA calculated for the three systems is shown in the table below. The total PMA is largest for the relaxed Fe-MgO-Fe structure.

Structure Fe-MgO-Fe Relaxed	Fe-MgO-Fe Unrelaxed	Fe-vacuum
1.37 meV	0.68 meV	0.79 meV

The figure below compare the relaxed Fe-MgO-Fe structure with the Fe-vacuum structure, where the Fe atoms are in the same positions. We observe that the interface Fe layes have a higher PMA value when hybridizing with the oxygen atoms in the Fe-MgO-Fe structure than when interfacing vacuum in the Fe-vacuum system. For each interface Fe atom the PMA is increased by 0.28 meV. The Fe-O hybridization thus have a significant influence increasing the total PMA from 0.79 meV for the Fe-vacuum structure to 1.37 meV for the Fe-MgO-Fe structure. It is interesting to see that the Fe-O hybridization is a very local effect essentially only affecting the PMA value of the interface Fe layers, while all the other Fe atoms essentially have the same PMA value in the Fe-MgO-Fe and Fe-vacuum structures.

The interface asymmetry, which is present in both the Fe-MgO-Fe structure and the Fe-vacuum structure (although a different asymmetry) is also an important effect since the Fe-vacuum structure also has a reasonably high PMA value of 0.79 meV, whereas bulk Fe has close to zero PMA.



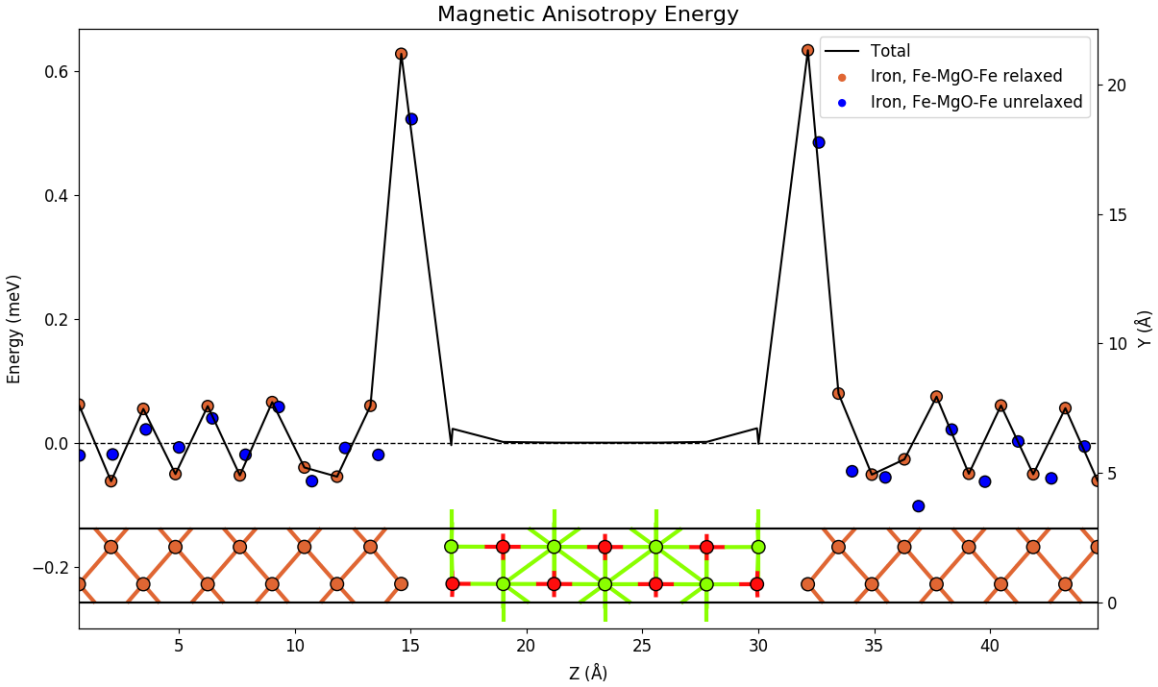
Tip: The figure above shows the structure of the configuration together with the MAE plot. This figure has been made with the following procedure:

- Open the Magnetic Anisotropy Energy analyzer for both the Fe-MgO-Fe and the Fe-vacuum structures and edit the plots individually.
- Combine the two plots by dragging one onto the other using the **Combine plots** button (see Fig. 3.4 above).
- Mark the Fe-MgO-Fe structure on the **LabFloor** and select the **Configuration Plot** from the right column of analyzers.

•Combine the Configuration plot with the MAE plots.

•Adjust y-axis limits to make the plot look as you want (use the edit button or press e - see Fig. 3.4 above)..

Next we address the effect of strain and relaxation effects. From the table above we see that the unrelaxed Fe-MgO-Fe structure has a total PMA value of 0.68 meV, i.e. only about half the value of the relaxed structure. This difference illustrates the importance of including the strain and relaxation effects and it also shows that PMA values are very sensitive to small details in the atomic structure.



The above figure compares the atomic contributions to the PMA for relaxed and unrelaxed Fe-MgO-structure. The unrelaxed structure has smaller PMA values at the interface layers and shows smaller oscillations in the bulk part of the Fe. However, the qualitative picture of the PMA being determined by the interface layers, remain the same for the two configurations.

COSMICS project

The **MagneticAnisotropyEnergy** study object has been developed within the project COSMICS founded by the European Unions Horizon 2020 research and innovation program under Grant Agreement No. 766726. Details about the object can be found on the manual page here *`MagneticAnisotropyEnergy`*. Application of the *MagneticAnisotropyEnergy* object to metallic slabs and comparison with QuantumEspresso and tight-binding calculations are presented in ref[5].

More information about the COSMICS project can be found here: http://cosmics-h2020.eu/

3.1.13 Heisenberg exchange coupling of iron and cobalt

Version: S-2021.06

In this tutorial you will learn how to use the *HeisenbergExchange* analysis object to calculate the Heisenberg exchange coupling parameters of bulk Fe and Co. You will also learn how to calculate the Curie temperature and exchange stiffness from the coupling parameters.

Introduction

When studying magnetic properties of materials, density functional theory (DFT) often provides a good description. From the spin-density it is possible to calculate the zero-temperature magnetization and magnetic ordering and one can calculate the exchange splitting from the bandstructure or density of states. It is, however not a standard analysis to calculate excited state properties such as the exchange stiffness, Curie temperature, spin wave dispersions, or magnetization dynamics.

When studying such quantities the starting point is often the Heisenberg model. The Heisenberg exchange Hamiltonian is given by[1],[2]

$$H = -\sum_{i \neq j} J_{ij} \hat{e}_i \hat{e}_j \tag{3.2}$$

where $\hat{e}_i$ is the normalized local spin vector on atom i, and J_{ij} is the Heisenberg exchange coupling constant. In the following short *Theory* section we will detail how the exchange coupling matrix elements are calculated from DFT calculations and we will also show how to obtain the Curie temperature and exchange stiffness.

Theory

We calculate the exchange coupling matrix elements $J_{i\mathbf{0},j\mathbf{R}}$ between an atom i in the central unit cell labeled $\mathbf{0}$ and atom j in a different unit cell displaced from the central one with a lattice vector $\mathbf{R}$. We use a real-space Greens function implementation[3],[4] of the original Liechtenstein-Katsnelson-Antropov-Gubanov (LKAG) formula[Page 397, 1]:

$$J_{0i,\mathbf{R}j} = -\frac{1}{4\pi} \int_{-\infty}^{E_F} d\epsilon \mathrm{Im}\mathrm{Tr}\left[\Delta_i G_{i,j}(\epsilon, \mathbf{R}) \Delta_j G_{i,j}(\epsilon, -\mathbf{R})\right] \tag{3.3}$$

where i and j label atomic indices within a unit cell, $\mathbf{R}$ is a lattice vector, and where $\Delta_i = H_i^{\uparrow} - H_i^{\downarrow}$ is the on-site difference between the up and down part of the Hamiltonian matrix. More details about the implementation can be found in the reference manual *Notes*.

Curie temperature

The Curie temperature, T_C, of a ferromagnet is the temperature at which the average magnetic moment becomes zero due to random fluctuations of the local magnetic moment directions. T_C can be estimated from the Heisenberg model in different ways. Within the mean field approximation (MFA) one have[2]

$$T_C^{MFA} = \frac{2}{3k_B} \sum_{j\mathbf{R}\neq i\mathbf{0}} J_{i\mathbf{0}j\mathbf{R}} \tag{3.4}$$

The MFA formula typically overestimates the Curie temperature when compared to experiments as will also be evident below. A different approach is based on the random phase approximation (RPA)[Page 397, 2]:

$$\frac{1}{k_B T_C^{RPA}} = \frac{6\mu_B}{M} \frac{1}{N_q} \sum_{\mathbf{q}} \frac{1}{E(\mathbf{q})} \tag{3.5}$$

where $E(\mathbf{q})$ is the spin wave energy at q-point $\mathbf{q}$ and M is the magnetic moment per atom and μ_B is the Bohr magneton. Since an average over the Brillouin zone is performed, the RPA calculation needs to be converged with respect to the number of q-points. This will be illustrated below.

Exchange stiffness

The exchange stiffness describes the energy of a long wavelength spin wave excitation. In particular, if the energy as function of wave number q is written as

$$E(q) = E_0 + A_{ex} q^2 + \ldots$$

the exchange stiffness constant, A_{ex} is seen to be given by the curvature of the $E(q)$ vs. q curve. A_{ex} can be calculated from the Heisenberg exchange parameters as[Page 397, 2]:

$$A_{ex} = \frac{2\mu_B}{3M} \sum_{\mathbf{R}} \sum_{ij} J_{i\mathbf{0},j\mathbf{R}} r_{i\mathbf{0},j\mathbf{R}}^2 \tag{3.6}$$

where $r_{i\mathbf{0},j\mathbf{R}}$ is the distance between atom i in cell $\mathbf{0}$ and atom j in cell $\mathbf{R}$. In practice, (3.6) can be difficult to converge with respect to the sum over lattice vectors $\mathbf{R}$. This is particularly pronounced in the case of iron where the exchange parameters are very long ranged. In this case it is possible to dampen the oscillations and extrapolate the result to zero damping as:

$$\begin{aligned} A_{ex} &= \lim_{\eta\to 0} A_{ex}(\eta) \\ A_{ex}(\eta) &= \frac{2\mu_B}{3M} \sum_{\mathbf{R}} \sum_{ij} J_{i\mathbf{0},j\mathbf{R}} r_{i\mathbf{0},j\mathbf{R}}^2 e^{-\eta r_{i\mathbf{0},j\mathbf{R}}} \end{aligned} \tag{3.7}$$

Below we will see how to perform the extrapolation to $\eta \to 0$ in practice.

Setting up calculations

We are now ready to start calculating the Heisenberg exchange parameters for Fe and Co. In order to enable a direct comparison to ref.[Page 397, 2] we will be studying Co in the FCC phase. We will start by performing calculations and analysis for Co(FCC). The calculations for Fe (BCC) are performed in the same way, but the analysis, and in particular the calculation of the exchange stiffness, will require a special treatment in the case of Fe.

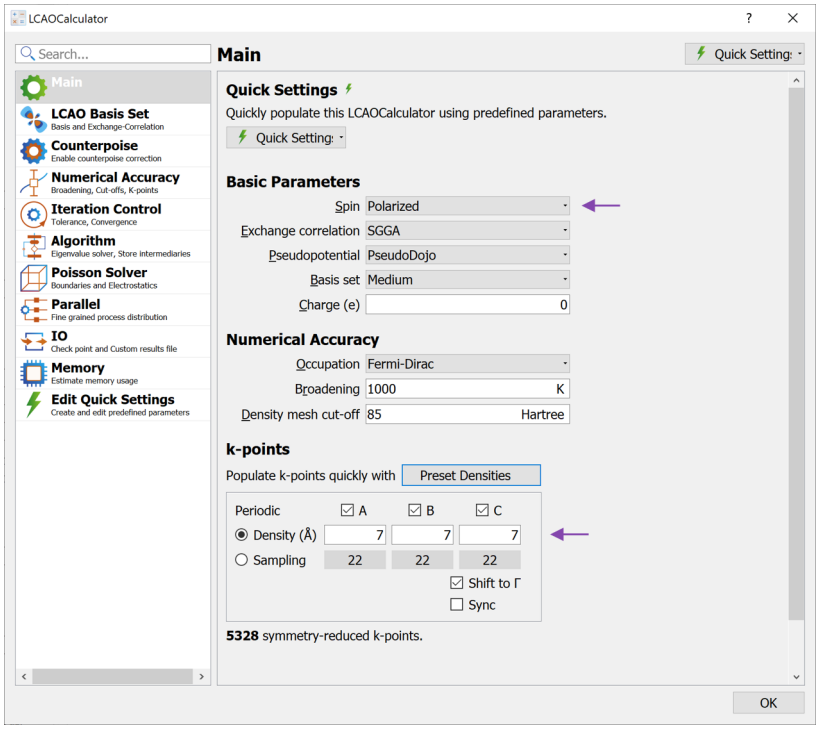
Open the **Builder** and add **Cobalt (alpha)** from the crystals database. Send the configuration to the **Script Generator**.

Now do the following:

- Add an **LCAOCalculator** to the script, open the **LCAOCalculator** widget and apply the changes on the main page (see image below)

– Change **Spin** to *Polarized*

– Increase the **k-point density** to *7* (select from the *Preset Densities*).



– Close the **LCAOCalculator** widget.

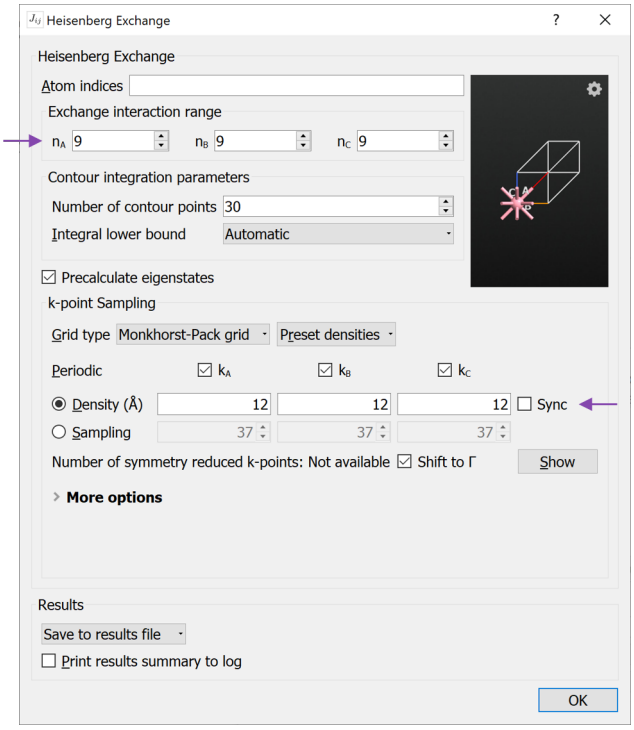
- Add a **HeisenbergExchange** analysis object to the script and open the **HeisenbergExchange** widget. Apply the changes (see image below)

– Change exchange interaction range to $n_A = 9$, $n_B = 9$, $n_C = 9$.

Note: The exchange interaction range determines how many times the input configuration is repeated when performing summations over $\mathbf{R}$ in the formula above. An exchange interaction range of $n_A = 9$ means that translations corresponding to $-5R_A, -4R_A, \ldots 4R_A, 5R_A$ are included, where R_A is the lattice vector in the A-direction. Therefore, the exchange interaction range needs to be an odd integer.

– Increase the **k-point density** to *12* (select from the *Preset Densities*). The **k-point density** determines how many k-points are used when calculating the real-space Greens function (See (4.3) in the reference manual *Notes*).

– You may also check the box **Precalculate eigenstates**. By checking this box, the calculation will run faster. This should however only be used for configurations with relatively few atoms as the memory requirements will be increased.



–Close the **HeisenbergExchange** widget.

•Finally change the name of the **Results file** to `Co-FCC.hdf5` and run the calculation.

Note: The calculations are here performed using the experimental lattice constants. For more complicated structures like interfaces, a structural relaxation should be performed before the **HeisenbergExchange** calculation.

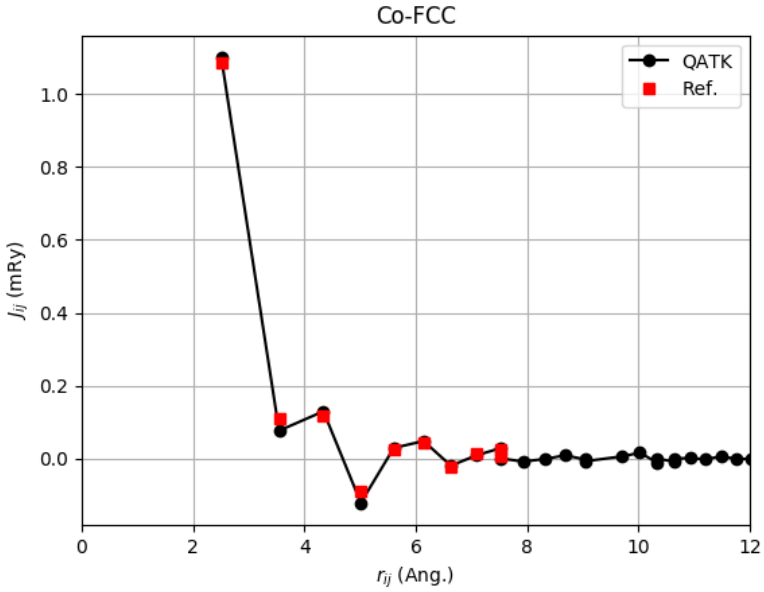
Analyzing the results

When the calculation has finished we are ready to analyze the results. Since no dedicated HeisenbergExchange analyzer has been developed yet, the analysis will be based on python scripts.

Exchange coupling element vs. distance

First, we will look at the exchange interactions elements themselves and make a plot of $J_{i\mathbf{0},j\mathbf{R}}$ vs. $r_{i\mathbf{0},j\mathbf{R}}$. The script `plot_Jij_vs_r.py` loads the just calculated **HeisenbergExchange** object and extracts the relevant data and plots the result. Together with the QuantumATK data we plot the data from ref.[Page 397, 2] for Co-FCC. Download and run the script `plot_Jij_vs_r.py`.

Now run the script. The script will produce a figure like the image shown below. Note that in order to make a direct comparison to the numbers from ref.[Page 397, 2] (Table I) we plot the exchange coupling values in units of mRy.



The positive sign of the nearest neighbor coupling elements shows that Co is a ferro-magnet. Due to the minus-sign in (3.2) the energy is lowered for aligned spins, when the coupling elements are positive leading to ferromagnetic coupling.

Note: There is no clear consensus in the literature about the sign-convention in (3.2) and sometimes the minus-sign is omitted.

Curie temperature

We now turn to the calculation of the Curie temperature. As mentioned above, there are two approximations included in QuantumATK. The mean-field approximation (MFA) formula is the most simple and the result is simply obtained:

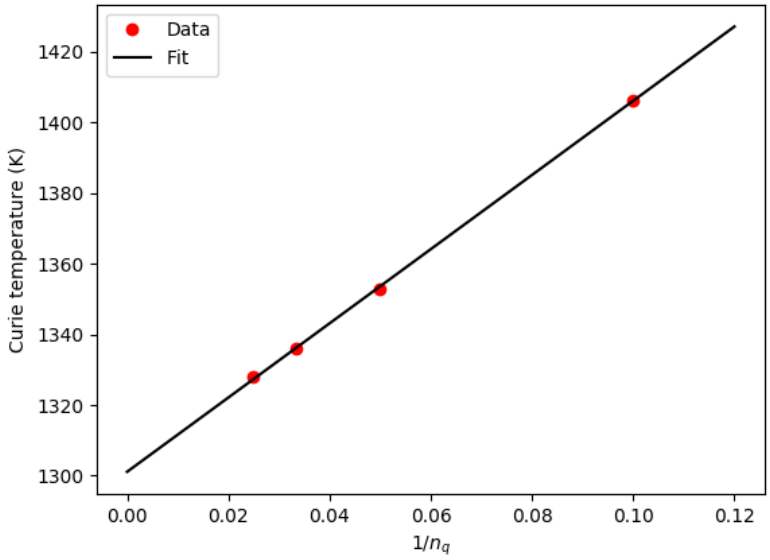
```
T_C_mfa-tutorial = heisenberg_exchange.curieTemperature()
```

The random phase approximation includes a sum over q-points, and convergence with respect to the number of q-points should be checked. The default value might not be high enough for all cases. In the case of Co, it turns out the RPA calculated Curie temperature scales linearly with the inverse number of q-points in each direction. By performing a linear fit, it is therefor possible to extrapolate the result to the limit of infinitely many q-points by evaluating the fit $1/n_q = 0$. This is done in the script `curie_temperature.py`, which both calculates the MFA result and the RPA result extrapolated to infinite q-point sampling. Download and run `curie_temperature.py`. The output of the script is

```
-------------------------------------------------
Curie temperature:
-------------------------------------------------
MFA                                  :  1648.9 K
RPA (default q-grid)                 :  1435.0 K
RPA (extrapolate to infinite q-grid) :  1301.1 K
-------------------------------------------------
```

The figure below is made by the script and illustrates the linear scaling of the RPA Curie temperature as a function of

the inverse number of q-points.



The experimentally determined Curie temperature for Co is 1388-1398 K[Page 397, 2]. It is evident that the RPA result is in reasonable agreement with the experimental value, while the MFA clearly overestimates the Curie temperature.

Exchange stiffness

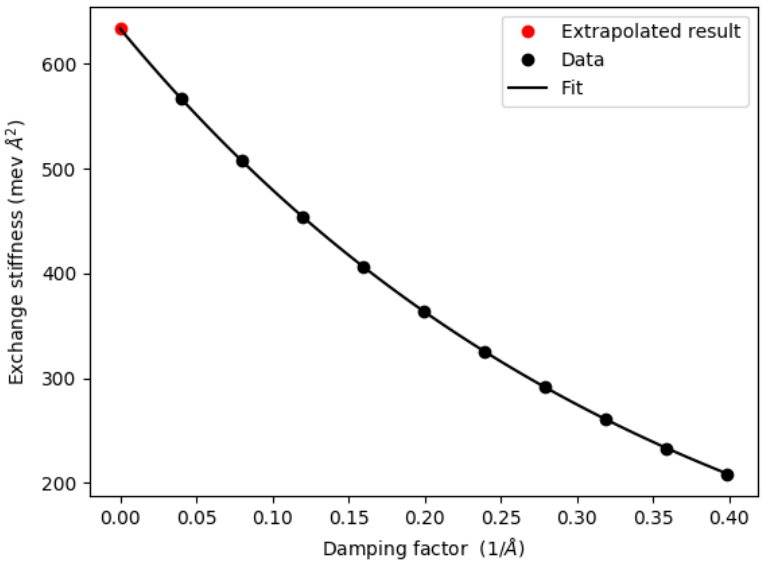
We will now see how to calculate the exchange stiffness for Co. The exchange stiffness given by (3.6) is obtained as

```
exchange_stiffness = heisenberg_exchange.exchangeStiffness()
```

As discussed above and in Ref.[Page 397, 2] it is sometimes necessary to dampen the long-range interaction and subsequently extrapolate to zero dampening following (3.7). The procedure for doing so is

```
extrapolated_exchange_stiffness, exchange_stiffness_vec, damping_factor_range, p_fit \
    = heisenberg_exchange.extrapolatedExchangeStiffness()
```

where the final extrapolated result is given by *extrapolated_exchange_stiffness*. The other returned quantities are a vector of calculated exchange stiffness values obtained for the damping factors given by *damping_factor_range*. The *damping_factor_range* is by default determined automatically as ranging from $0.1/d_0$ to $1/d_0$, where d_0 is the nearest neighbour distance. Finally the polynomial fit is also returned. Together, these allow for a visual inspection of the fitting and extrapolation as done in the script `exchange_stiffness.py` and shown in the figure below.



Download and run the `exchange_stiffness.py`. The output of the script is

```
-------------------------------------------------
Exchange stiffness:
-------------------------------------------------
A_ex                          :  633.8 meV*Ang**2
A_ex (extrapolated)           :  633.7 meV*Ang**2
-------------------------------------------------
```

It is evident that both the direct evaluation using (3.6) and the extrapolated results are in close agreement. While this is often the case, the situation for Fe is a bit more complicated.

Exchange stiffness for Fe

We will now study the Heisenberg exchange of Fe in the BCC phase. Find **Iron (alpha)** in the crystal database in the **Builder** and repeat the steps above for calculating the J_{ij} **HeisenbergExchange**. When modifying the **HeisenbergExchange** object we need to include a longer interaction range:

- Open the **HeisenbergExchange** widget and change exchange the interaction range to $n_A = 13$, $n_B = 13$, $n_C = 13$.
- The other settings used for Co can be applied for Fe as well.
- Finally change the name of the **Results file** to `Fe-BCC.hdf5` and run the calculation.

When the calculation is done the exchange stiffness can be analyzed with the script `exchange_stiffness_Fe.py`. Download and run the script to get the output

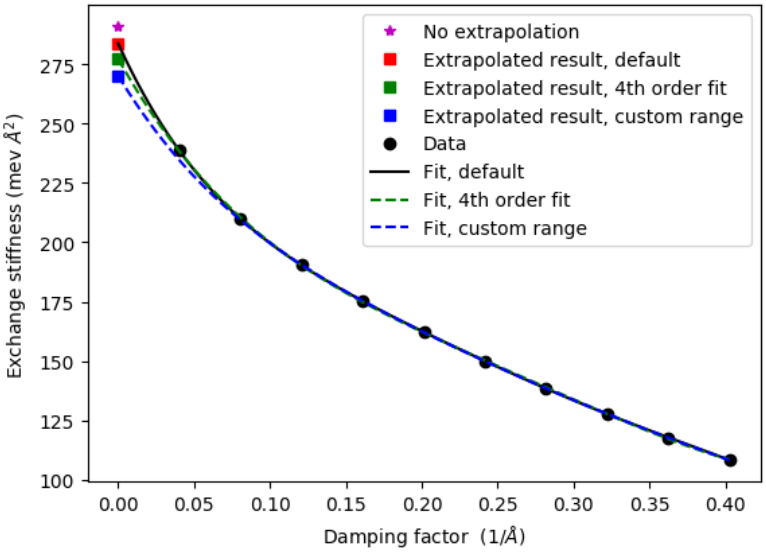
```
-------------------------------------------------------
Exchange stiffness:
-------------------------------------------------------
A_ex                                :  290.7 meV*Ang**2
A_ex (extrapolated, default)        :  283.7 meV*Ang**2
A_ex (extrapolated, 4th order fit   :  277.2 meV*Ang**2
```

(continues on next page)

(continued from previous page)

```
A_ex (extrapolated, custom range)  :  270.2 meV*Ang**2
-------------------------------------------------------
```

and the figure



The script shows how to customize the extrapolation of the exchange stiffness by either (i) changing the polynomial order from the default value of 5 to 4, or (ii) by customizing the damping factor range. All fits look perfectly reasonable, but the extrapolated exchange stiffness constants differ somewhat. This illustrates that in the case of Fe it is difficult to define an exactly calculated exchange stiffness. More discussion on this topic can be found in Ref.[Page 397, 2].

Summary of results

The tables below summarizes the Curie temperature and exchange stiffness results and compares with calculated and experimental values from Ref. [1] =[Page 397, 2]. The values of extrapolated exchange stiffness are obtained using the default settings.

Curie temperatures (K)	QATK	Calc. [1]	Exp. [1]
Co, MFA	1648	1645	1388-1398
Co, RPA	1301	1311	1388-1398
Fe, MFA	1353	1414	1044
Fe, RPA	894	950	1044

Exchange stiffness (meV Å^2)	QATK	Calc. [1]	Exp. [1]
Co	634	663	580
Fe	284	250	280

It is evident that the Curie temperature results from QuantumATK matches well with the calculated results

from[Page 397, 2]. It is also evident that the MFA overestimates the Curie temperature quite significantly compared to experiments whereas the RPA results (extrapolated to infinite q-point sampling) are significantly closer to the experimental values.

The exchange stiffness values are also in good agree with both reference calculations and experimental values.

In summary, this tutorial shows how to calculate the Heisenberg exchange coupling parameters of iron and cobalt. It is demonstrated how to calculate the Curie temperature and exchange stiffness and the obtained values are compare favorably with theoretical- and experimental results from the literature.

COSMICS project

The **HeisenbergExchange** analysis object has been developed within the project COSMICS founded by the European Unions Horizon 2020 research and innovation program under Grant Agreement No. 766726. Details about the object can be found here *HeisenbergExchange*.

More information about the COSMICS project can be found here: http://cosmics-h2020.eu/

3.1.14 Building an model of an epoxy thermoset material

Version: S-2021.06

In this tutorial you will learn how to build a model of a thermoset material created by cross-linking different molecules using the example of an epoxy-amine system. You will then learn how to analyze the cross-linking reaction to estimate the gel point of the material. Understanding the structure and properties of different thermoset materials is critical in choosing the correct material for a wide range of applications. It can also help in designing new materials with certain desired properties. This tutorial demonstrates how you can use the QuantumATK tools to simulate cross-linking reactions between different molecules. This methodology can be applied to a wide range of materials and chemical reactions.

To generate a model of the thermoset material, a combination of classical molecular dynamics and a cross-linking algorithm is used to create a trajectory of how the material may be formed through reaction. This results in giving a series of final structures at high degrees of cross-linking. The properties of these structures, such as glass transition temperature or Youngs modulus can then be further investigated using molecular dynamics. This tutorial focuses on building the initial model of the material. A further tutorial, *Analyzing the thermo-mechanical properties of a polymer material* demonstrates how to estimate the thermo-mechanical properties of the thermoset material using the model built in this tutorial.

Theory

Epoxy-Amine Materials

Polymer materials can be generally categorized as either thermoset or thermoplast materials. Thermoplast materials typically melt on heating, and are usually constructed of individual polymer chains that are bound together through non-bonding forces. Plastic materials such as PVC (polyvinyl chloride), PET (polyethylene terepthalate) and polyethylene are all types of thermoplast polymers. In constrast, thermoset materials typically do not melt on heating, and are constructed of a 3D covalently bonded network. This network can be formed through post-synthetic cross-linking of polymer chains or by using reactant monomers that are able to link more than two other monomers. Common thermoset materials include Bakelite, vulcanized rubbers and polyester resins.

Epoxy resins are one industrially important class of thermoset materials. These materials are commonly made of two components. The first is the resin containing epoxy functional groups. The second is a molecule containing functional groups that react with the epoxy to form a covalent network. This second molecule is often termed a hardener, and commonly contains amine functional groups. Primary amines and epoxy functional groups can react in a two-stage process requiring one amine and two epoxy groups. In the first step the amine nitrogen attaches to an epoxy carbon, opening the epoxy ring and transferring a hydrogen to the epoxy oxygen. This forms a secondary amine and alcohol functional groups. This secondary amine is able to react again with another epoxy group using the same mechanism, this time producing a tertiary amine. This reaction scheme is illustrated in the figure below.

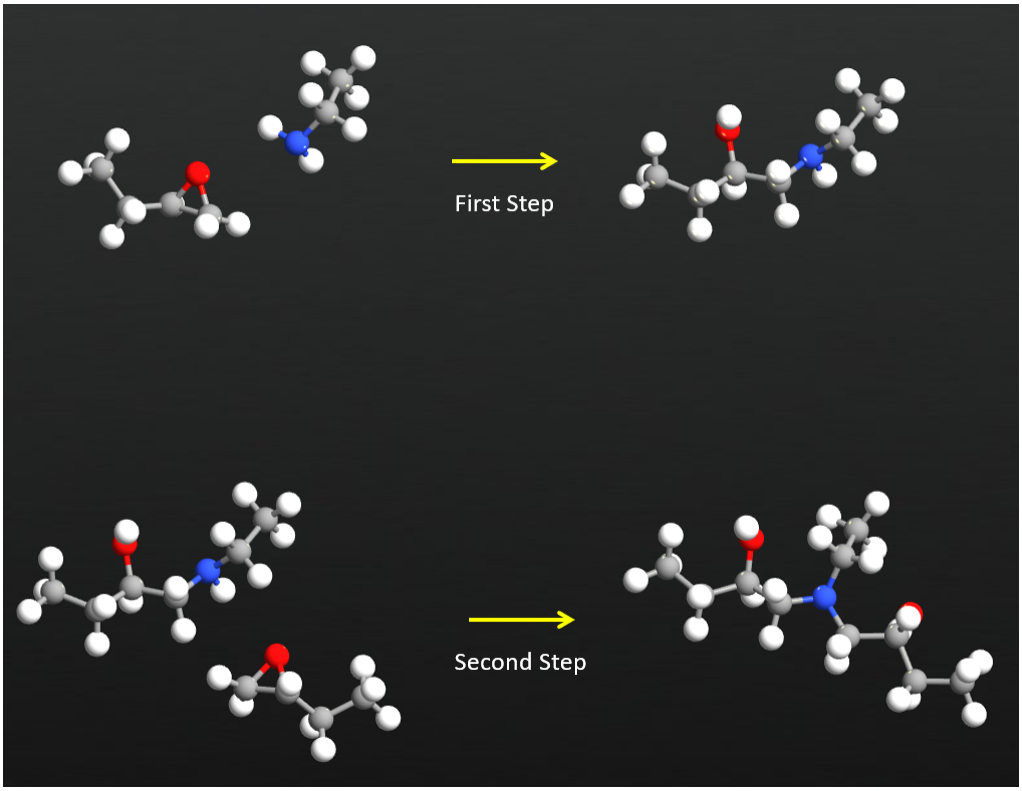

Fig. 3.5: The reaction mechanism of epoxy-amine cross-linking.

Thermoset Building Algorithm

In order to build a representative model of a thermoset material, it is necessary to arrange the molecules in such a way so that the internal bonding energy is minimized and the resulting structure is in a relaxed configuration. Given the various constraints on each molecule this is very difficult to construct directly. A more productive approach is to start with a system of necessary reactants, and then progressively react and relax the structure so as to mimic the actual chemical process used to form the final structure. Variations of this type of building approach have been published and have shown to produce realistic models[1][2][3].

An overview of the building algorithm implemented in QuantumATK is shown in the figure below. The building process starts with an initial configuration of the system before cross-linking. The iterative building process starts with saving a snapshot of the current configuration. Available cross-linking reactions are then performed according to a reaction scheme specified as input to the calculation. As this chemically transforms the structure, new atom types and potential terms are automatically calculated for the new configuration. The system is then relaxed using NVT molecular dynamics. In this step reaction coordinates from the previous cross-linking reaction are gradually relaxed over the whole duration of the dynamics step. This ensures that additional strain is not added to the configuration by the rapid minimization of internal coordinates. Finally, an NPT molecular dynamics step is carried out to further relax the configuration and also correct the density of the overall system. This loop continues until the reaction is completed, producing a trajectory of structures along the path between initial and final cross-linked structures.

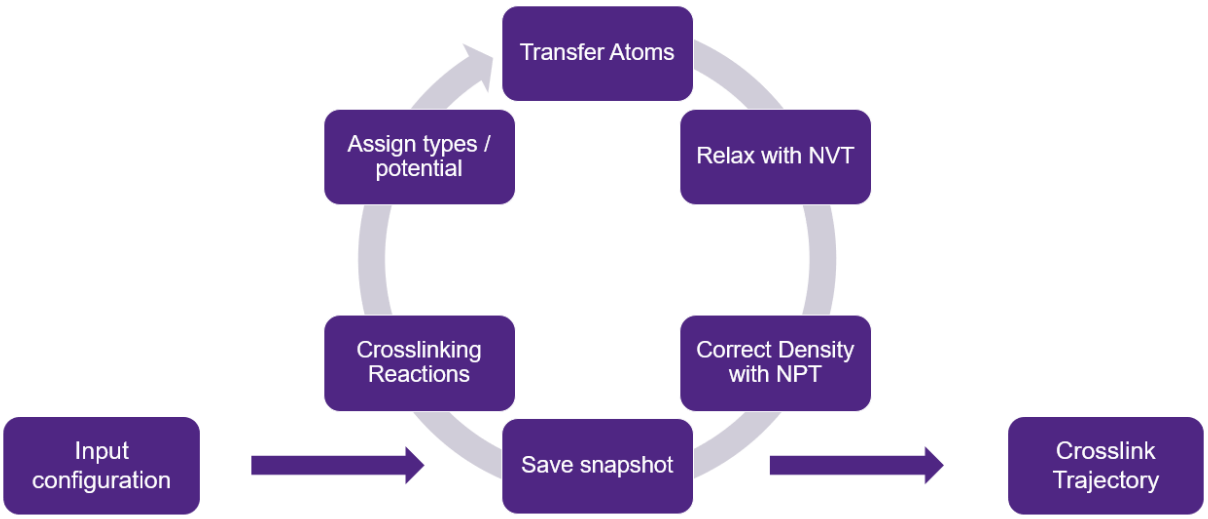

Fig. 3.6: The general algorithm used to build cross-linked structures.

In this simulation the reaction scheme used to transform the configuration can be specified in one of two ways. The simplest way is to use a *ReactionTemplate* class. Here molecular configurations are given that represent the reacting functional groups at different stages of the reaction. These templates are then used to identify reacting groups in the input configuration by scanning the bond graph. Some templates for common cross-linking reactions are also defined in the **CrosslinkBuilder** script block. The second way reacting atoms can be specified is using a *CrosslinkReaction* class. Here the reaction scheme, including bonds formed and broken, are specified using tags which correspond to tags in the configuration. Using this method it is possible to have complete control over which atoms react in each step. In this tutorial we will use one of the pre-defined templates.

With the reactions defined, further rules are used to determine which atoms react at each step. Bond and angle limits are employed that specify that no reaction can take place if it creates bonds lengths longer than or bond angles more narrow that particular cutoffs. This ensures that distortions to the overall chemical structure are limited when reacting the configuration. It is also possible to limit the total number of reactions performed at each step. During the NVT relaxation step two different approaches to relaxing bonds are taken. For atoms that are only connected to the structure through a single extended bond, the position of these atoms is directly optimized before the NVT step begins. This is most commonly applied to hydrogens migrating from one atom to another. For newly formed bonds that connect two different substructures, these are relaxed gradually over NVT simulation. This is done by shifting the minimum in the bond potential for those atoms from the initial extended bond length to the final equilibrium bond length.

The final completion point of the reaction is determined by three criteria which, if any one is satisfied the reaction is determined to be complete and the building process is complete. The first criterion is that a specified extent of reaction is achieved. This allows cross-linking calculations to be stopped at any point along the building process. A second criteria is that no reactions are found during a set number of steps. As the building process is carried out it is possible to not find any possible reactions that conform to the bond and angle limits. If this happens after a set number of consecutive cycles, it can be assumed that there are no more viable reactions to be found and the building process is complete. The final criteria is when a specific bond cutoff is reached. During the reaction cycles it is possible to increase the reaction bond cutoff if no reactions are found during the cycle. This allows the building process to prioritize bonding molecules that are relatively close and only later include longer bond formation when necessary.

Building the thermoset model

Building the epoxy-amine configuration

To start building the epoxy-amine system, we first have to build epoxy and amine molecules. In this tutorial the molecules diglycidyl ether of bisphenol F (EPON-862) and diethylenetoluenediamine (DETDA) are used. The structures of each of these molecules are shown in the figure below. Open the **Builder** and select *Add* → *New Configuration*. Start by building a molecule of DETDA. This can be done by switching to the molecular builder. Here atoms in the existing configuration can be replaced by selecting atoms or chemical groups and clicking on hydrogen atoms. New atoms can also be added by clicking and dragging from an existing atom. This will add an atom bonded to the selected atom. Bonds can also be added to the configuration by clicking and dragging between two atoms. For bonds to be created the option *Static bonds* needs to selected. When *Static bonds* is enabled the displayed bonds are saved with the configuration. Once a molecule of DETDA is created, add another configuration to the builder and create a molecule of EPON-862. At this stage it is also convenient to set the appropriate forcefield tags for the molecules. In this simulation the OPLS-AA forcefield is used. To calculate the forcefield types go to the **Forcefield Types** plugin in the **Selection Tools** section. Select the `OPLS-AA` forcefield and then click the *Calculate Types* button. This automatically assigns types based on the elements and the bond graph of the configuration.

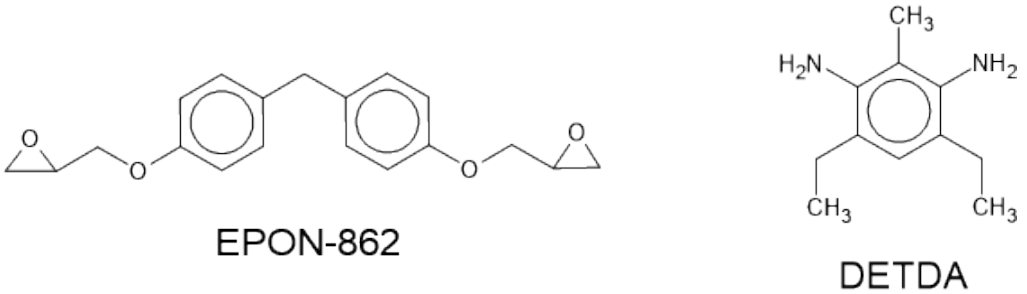

Fig. 3.7: The chemical structures of the initial reactants EPON-862 and DETDA.

Note: The molecular builder is a powerful tool that enables you to easily build a wide range of molecules. For a more

detailed introduction to the many features, see the molecular builder tutorial video here.

To build the initial starting structure for the cross-linking reaction, these molecules need to be packed into a simulation cell. This can be done using the **Packmol** builder plugin. Open the plugin and add both molecules from the **Stash** into the molecules box. As both molecules have two functional groups, and two epoxies are able to react with each amine group, a stoichiometric mixture contains two epoxy molecules for every amine. In the **Packmol** plugin, set the amine count to `128` and the epoxy count to `256`. Also set the *Cell density* to `0.6`gram cm^{-3}. The **Packmol** input dialog is shown below. Clicking *Create* will now add the starting configuration to the **Stash**.

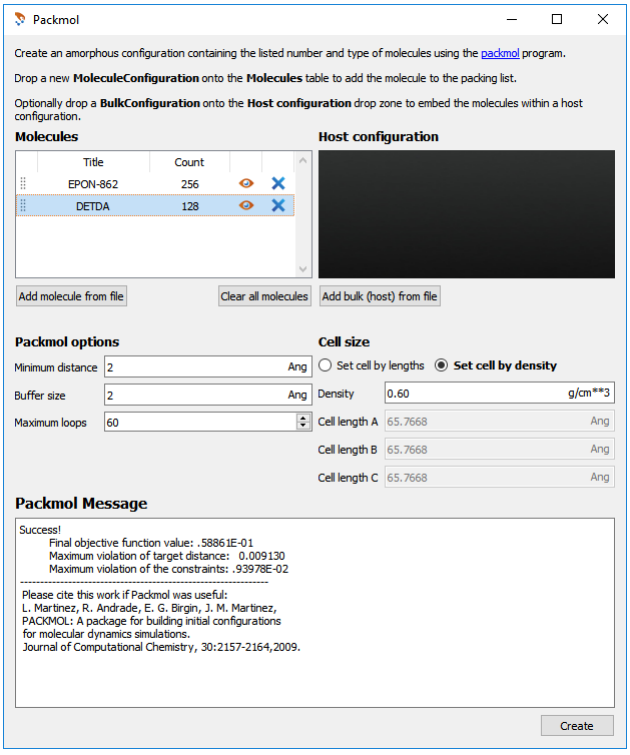

Fig. 3.8: The input options used in the Packmol plugin.

As **Packmol** provides only an approximate molecular packing, it is recommended to improve the initial packing of the molecules by running an additional molecular dynamics calculation. To set up this simulation, send the structure generated by **Packmol** to the **Scripter** using the **Send To** icon. First add a **Forcefield** calculator block to the script. To select the forcefield, open the calculator block and in the buttons on the right select *New –> OPLS-AA*. This adds an OPLS-AA potential builder to the script that will construct an OPLS-AA forcefield for the starting configuration. All of the default options for the potential are suitable, so just click *OK* on the resulting dialogs and return to the script generator.

Next, the molecular dynamics simulation can be defined. Since both the velocities and density of the structure need to be equilibrated, the *Stable NPT* template can be used. This defines three different molecular dynamics methods that equilibrate first the velocities and then the densities in a way that allows for high-energy or approximate starting structures. To add the template, in the *Template* drop-down menu select *Molecular Dynamics –> Forcefield –> Stable NPT Equilibration*. The default for this template equilibrates the structure to a temperature of 300K. As the cross-linking is being done at 480K, the configuration should be equilibrated to this higher temperature. Open the last molecular dynamics block and set the *Reservoir Temperature* and *Final Temperature* to `480`K.

The final MolecularDynamics dialog is shown above. With the OPLS-AA forcefield and the molecular dynamics defined the script is now ready to run. Send the script to the **Job Manager** and run by using the icon. This will

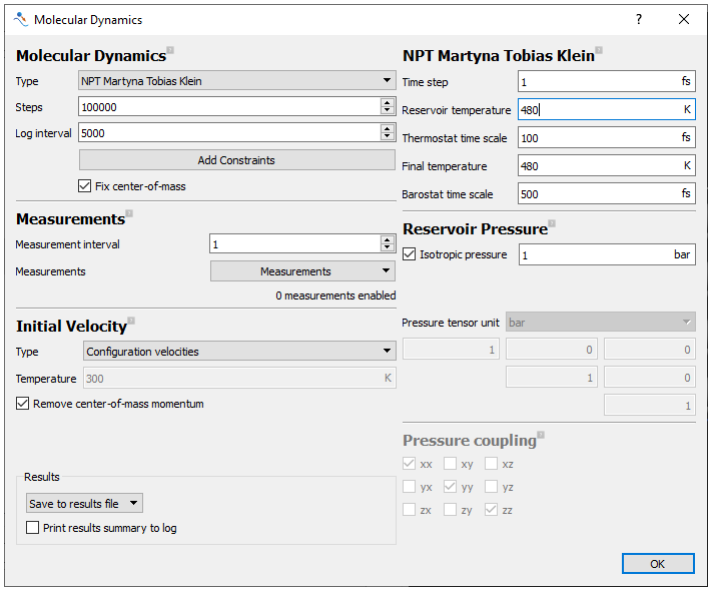

Fig. 3.9: The input options used in the initial molecular dynamics equilibration.

produce three molecular dynamics trajectories equilibrating the initial structure. The final image in the last trajectory will next be used as a starting configuration for the cross-linking simulation.

Building the Cross-linked Thermoset Material

Start by dragging the final image of the previous trajectory onto the **Scripter** . This opens the configuration in the **Scripter** where the script for the cross-linking simulation can be created. Set the output file to `Epoxy_Amine_Thermoset.hdf5`. Next, add a **CrosslinkBuilder** block from the **Optimization** group. This is the block that carries out the cross-linking simulation. The forcefield to be used is defined as part of this block, so a calculator does not need to be added first.

Open the **CrosslinkBuilder** block to set the parameters for the reaction. Start by choosing a reaction scheme. This is done by pushing the *Select start group* button. This brings up a database of the available reaction templates. The reaction templates define both the atoms in the configuration that are able to react and the way in which the bonding changes during each reaction step. An animation of each reaction scheme is shown in the window below the list of reactions. In this system an epoxy is reacting with an aromatic amine, so select the *Epoxy Aromatic Amine* reaction and select *Add*. This adds this reaction template to the script.

Next the parameters for the reaction need to be set. In this dialog:

- Select the *Maximum number of reactions* and set the value to `20`. This limits the number of reactions per step to 20. This can prevent high-energy configurations freezing in during the initial steps of the reaction.
- Set *Temperature* to `480`K. This is the temperature used in the MD relaxation steps.
- Set *Bond search radii increment* to `0.25`Å.
- Set *Maximum bond search radii* to `10`Å. These two options set how reactions are searched for. After each cycle, if no possible reactions are found, the bond search radii is increased by the set increment. When the bond search radii reaches the maximum value, the simulation is completed. In this way the bond search radii is used as a termination criteria. The options *Finish after cycles without reaction* and *Reaction percentage* can also be used as termination criteria for the simulation.

The final dialog box is shown in the figure below. The calculation is now ready to be run. Send the script to the **Job Manager** and run by using the **Send To** icon . The script produces a Trajectory containing a snapshot of the configuration after each NPT equilibration following the reaction. This calculation may take several hours, as it typically goes through around 100 reaction cycles before completion.

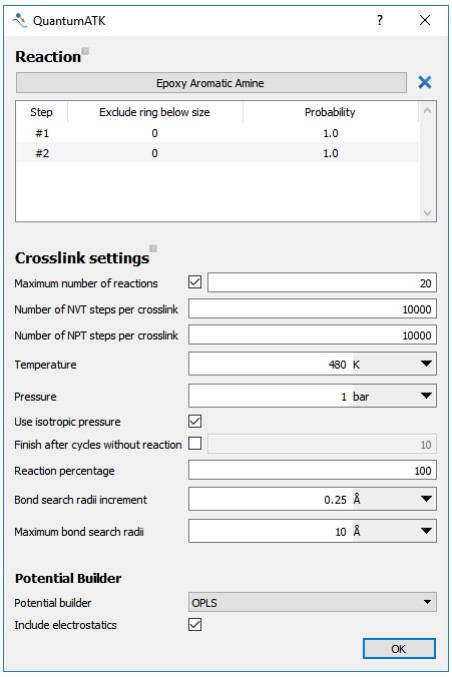

Fig. 3.10: The input options used in the CrosslinkBuilder.

Analyzing the Thermoset Reaction

Once the calculation has completed the cross-linking reaction can be examined. In this section the precise configuration produced by the simulation depends on the initial starting configuration and assigned molecular dynamics velocities, which are randomized. Each calculation will therefore produce similar, but non-identical final configurations. During the calculation information about the number of reactions performed, the density of the material and the stage of the simulation is written to the calculation log. An example of the expected output is shown below.:

```

```

Information about the progress of the reaction is also written to the Trajectory. Select the trajectory on the Lab Floor and open it using the **Movie Tool**. Right-click on the configuration to bring up the context menu to display bonds and to show the structure unwrapped. By playing the movie you can see the progress of the reaction. In the graphs on the left you can also see the density, relative energy, bond search radius and percentage of reaction completed for each frame. In particular, the change in density enables the estimation of shrinkage during the cross-linking process. The example calculation is shown in the movie tool below.

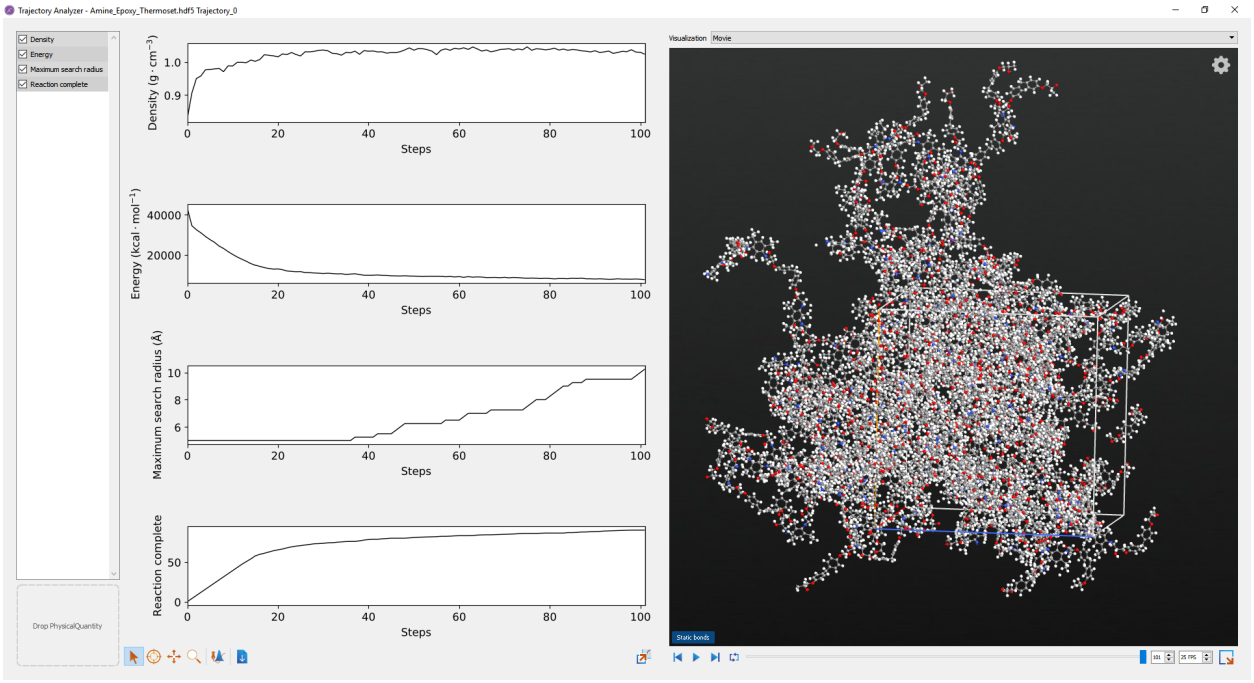

Fig. 3.11: An example epoxy-amine cross-linking calculation.

It is also possible to see the formation of larger molecular structures when cross-linking by viewing the trajectory in the **Viewer** . Select the trajectory in the Lab Floor and drag it over to the **Viewer**. Here you can color atoms in the structure based on the molecule that they belong to. Molecules are determined by the bond graph of the configuration. In the viewer plugins open the **Color Atoms** plugin and set *Color by* to `Molecules`. Also select *Maximize color difference*. This calculates the color difference independently for each image so that it is easier to see each molecule in the image. Select apply and then run the trajectory. As the trajectory is animated the atoms change color depending on the molecule that they are part of.

Note: In the trajectory there may be some unreacted molecules remaining at the end of the simulation. This occurs due to the relatively short time used between cross-linking steps. To increase the amount of cross-linking, a larger relaxation time between cross-linking steps can be used. This increases the diffusion of reactive groups between cross-linking steps brings more groups within bonding range. In this system a relaxation time of 50000 steps in both the NVT and NPT cycles leads to the formation of one network structure with no remaining independent molecules.

Using the cross-linking trajectory it is also possible to estimate the gel point of the material. One method of characterizing this is by estimating the point at which the central sub-structure grows through the periodic simulation boundaries in each direction. The change in periodicity in the sub-structure typically leads to a change in its rheology. To calculate the periodicity of the substructure in each frame of the reaction trajectory, download the provided script `Find_Gel_Point.py`. This takes the file name of the trajectory as an input argument, and plots the resulting periodicity and number of molecules in each frame. A typical plot from the example system is shown in the figure below. This shows that the system starts to become periodic at around 64% conversion. This is close to the theoretical gel point at 58%[4].

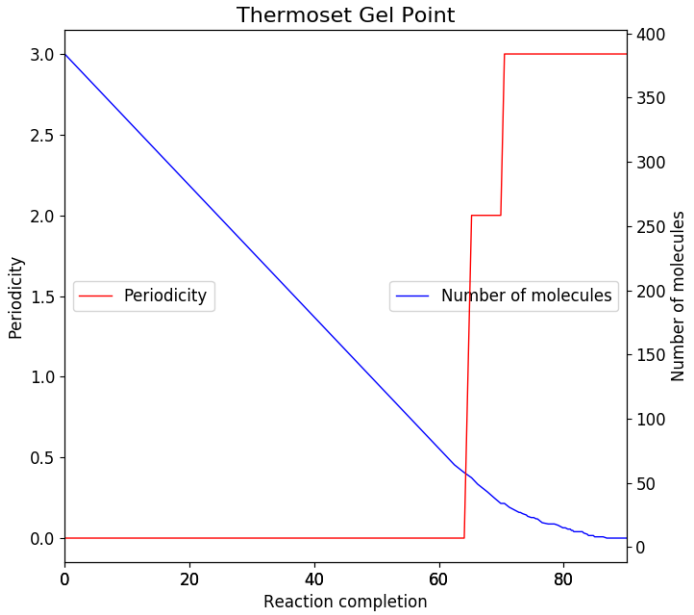

Fig. 3.12: Estimating the gel point by calculating the periodicity of the molecular sub-structure.

Another means of estimating the gel point is to examine the changing molecular mass of the system during the reaction. As the reaction starts, individual molecules react together forming larger molecules. As the gel point is reached these larger structures join together to form one dominant sub-structures. This can be observed by calculating the average reduced molecular mass of the system. The reduced molecular mass is simply the molecular mass ignoring the largest molecule. During the reaction the average reduced molecular mass typically reaches a maximum near the gel point, as the large individual molecules join the dominant sub-structure[Page 407, 1]. To calculate the reduced molecular mass, download the attached script `Find_Molecular_Mass.py`. As before, this script takes the file name of the trajectory as an argument, and plots the average total and reduced molecular mass during the reaction. A typical plot for the example calculation is shown in the figure below. From this plot it can be seen that the maximum in the reduced mass occurs at 61%, close to the previous estimates of the gel point.

[4] E. Hädicke, H. Stutz: Comparison of the structure of step-growth networks obtained by Monte Carlo simulation and branching theory J. Appl. Polym. Sci. 85, 929 (2002)

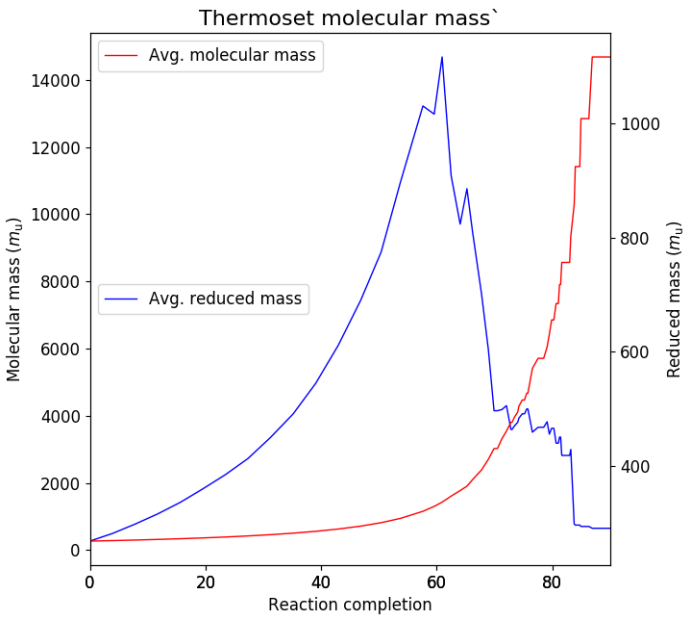

Fig. 3.13: Estimating the gel point by calculating the average reduced molecular mass.

Conclusions

In this tutorial the process for building a typical epoxy-amine thermoset material was outlined. Using the **CrosslinkBuilder** tool, a high degree of cross-linking was able to be achieved, although this can be increased by using a longer time step between cross-linking events. Analyzing the reaction process showed that the building process also exhibits a realistic gel point, even at shorter cross-linking intervals. Overall this tutorial shows how reliable models of complex thermoset materials can be easily created in QuantumATK.

3.1.15 Analyzing the thermo-mechanical properties of a polymer material

Version: S-2021.06

In this tutorial you will learn how to estimate the thermo-mechanical properties of a polymer system, most notably the glass transition temperature, Youngs modulus and Poisson ratio. These properties are critical performance parameters in many applications. They can determine, for instance, the operating temperature or the maximum load of a given material. As these properties are determined by the atomic structure of the polymer system they can be estimated using molecular simulation.

The material used as an example will be a epoxy-amine thermoset material consisting of diglycidyl ether of bisphenol F (EPON-862) and diethylenetoluenediamine (DETDA). The tutorial *Building an model of an epoxy thermoset material* demonstrates the steps required to build a model of this material. This tutorial continues from that tutorial by demonstrating how the properties of the model can be simulated. The procedure outlined here is quite general, and can be applied to different types of polymeric and non-polymeric materials. Most notably, the same simulation procedure can be used on models of linear thermoplast polymers, such as poly(methyl metacrylate) and polyvinyl chloride, built using the **Polymer Builder** tools. It is not necessary that a polymer system be cross-linked for these methodology to give good results.

Contents

•*Analyzing the thermo-mechanical properties of a polymer material*

–*Glass Transition Temperature*

–*Youngs Modulus and Poisson Ratio*

–*Conclusions*

Glass Transition Temperature

One important property of many polymer materials is the glass transition temperature. This is the temperature at which the material changes from a rigid, glassy state to a more flexible rubbery state. This transition from glassy to rubbery states in linear polymers usually corresponds to more torsional movement of the polymer chains as well as an increase in free volume. The glass transition temperature is typically estimated using a simulated annealing process, where the material is cooled during an NPT molecular dynamics simulation. Crossing the glass transition temperature also involves a change in the rate of thermal expansion, which can be identified by a change in the gradient of the density vs. temperature plot.

To calculate the glass transition temperature, an annealing simulation must first be performed. To set up this simulation, start by downloading the thermoset polymer model. Send this model to the **Scripter** by first opening it in the **Builder** and then using the icon to send the configuration to the **Scripter**. Alternatively you can save the HDF5 file in your project directory, open the file on the Lab Floor, and then drag the *Bulk Configuration* directly onto the **Scripter**. Start by adding a **ForceField** calculator. Open the calculator block and using the buttons on the right select *New* –> *OPLS-AA* to add an OPLS-AA forcefield. The next step is to equilibrate the system at an appropriate starting temperature[1]. This can be achieved by adding a **PolymerEquilibration** block from **Study Objects**. The most important parameter to set here is the final temperature for equilibration. This temperature should be high enough above the glass transition temperature that it enables getting an estimate of the thermal expansion rate above the glass transition temperature. Open the **PolymerEquilibration** block and set the *Final Temperature* to `600`K. The remaining default parameters are all appropriate. Once the system is properly equilibrated the annealing calculation can be performed. To do this, add a **MolecularDynamics** block from the **Optimization** group. Open this block and make the following changes:

•Select the `NPT Martya Tobias Klein` ensemble.

•Set the *Steps* to `1750000` and *Log interval* to `1000`.

•In the *Measurements* section, add measurements for temperature, volume and density.

•Set the initial velocity to `Configuration velocities`.

•Set *Reservoir temperature* to `600`K and *Final temperature* to `250`K. Note that this sets a temperature sweep of 350K over 1.75ns at a rate of 0.2K/ps.

The remaining default parameters are suitable. The final molecular dynamics dialog is shown in the figure below.

The script is now ready to be run. Send it to the **Job Manager** and run the script by using the **Send To** icon . This will produce the annealing trajectory that can be used to estimate the glass transition temperature. Note that as the script is performing over 3 million molecular dynamics steps, running it will take several hours.

Once the calculation is completed, open the trajectory from the Lab Floor using the **Glass Transition Temperature Analyzer**. This tool provides a plot of the density of the system with respect to temperature. It also estimates the glass

transition temperature through fitting lines to the low and high temperature data, and then calculating the temperature at which the lines intersect. Click the *Estimate fit limits* button to automatically estimate the glass transition temperature. This adds limits indicating the high and low temperature fitting regions, as well as an estimate of the glass transition temperature. The limits can be manually adjusted to improve the quality of the fit. The glass transition temperature analyzer using the example calculation is shown in the figure below. This shows a glass transition temperature of 417K. This is in agreement with the range of experimental estimates of the glass transition temperature of this material[23].

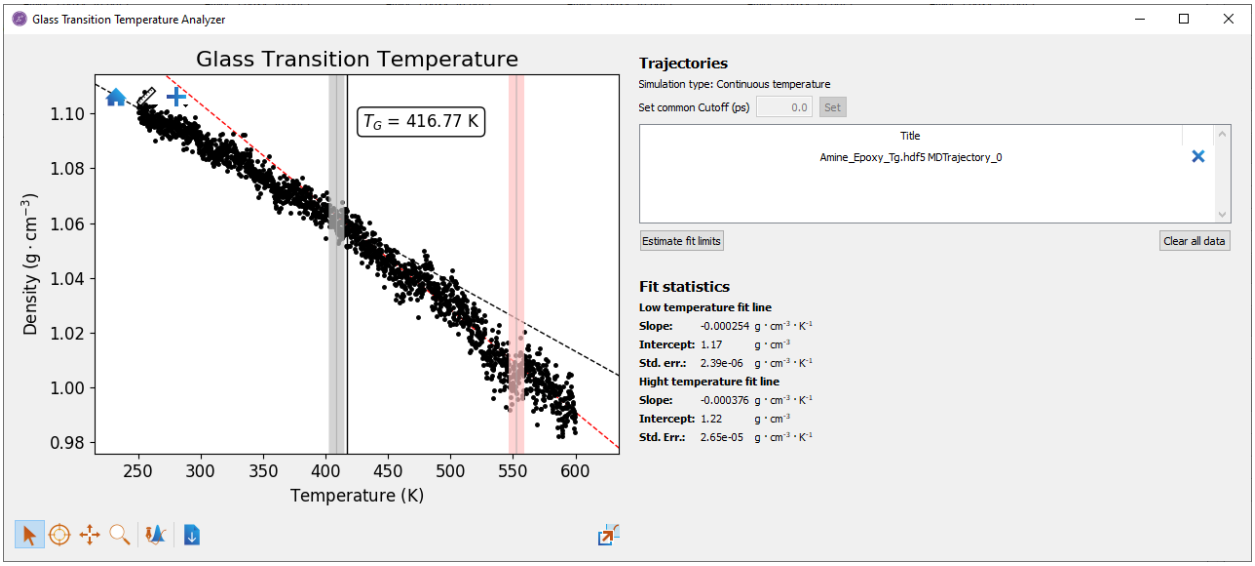

Fig. 3.15: Glass transition temperature analyzer showing predicted Tg.

Youngs Modulus and Poisson Ratio

Another important property of many epoxy systems is the Youngs Modulus. This is a measure of the amount of stress required to produce a given strain in the elastic deformation region. The Youngs modulus can be directly simulated using molecular dynamics. Here the strain is added by by progressively extending one of the simulation cell lengths. The resulting stress in this direction is then recorded. The gradient of the stress vs. strain curve then gives the Youngs modulus.

To carry out a simulation of the elastic properties of the material, a starting structure first must be selected. In the previous step a simulated annealing calculation was carried out, resulting in structures close to equilibrium at a range of temperatures. One option for selecting a starting structure is to take configurations from this annealing trajectory at the temperatures of interest. As these configurations are close to equilibrium, they may only need a relatively short equilibration calculation of around 100ps at the temperature of interest before starting the stress-strain simulation. This is possible because in the annealing calculation the starting configuration was first well-equilibrated at the starting temperature. As the Youngs modulus can change significantly, especially when crossing the glass transition temperature, this can be an efficient way to calculate the Youngs modulus at a range of temperatures. If the glass transition temperature has not been previously calculated, it is then still advisable to ensure that the starting configuration is well equilibrated at the temperature of interest using a reliable equilibration protocol. This is the approach that will be used in the following calculations, where the Youngs modulus of the example material will be estimated at room temperature.

To start setting up the calculation of Youngs modulus, open the final structure from the Crosslink Builder in the **Scripter** . As with the glass transition temperature, start by adding a **Forcefield** Calculator and then a **PolymerEquilibration** block from **Study Objects**. Open the **PolymerEquilibration** block and check the default parameters. As the system is being equilibrated to room temperature, all of the default parameters are appropriate. The required molecular dynamics calculations for simulating the stress-strain relationship can now be added. As the epoxy-main material is isotropic, the Youngs modulus should be the same in each dimension. The Youngs modulus can therefore be calculated in each direction and the average taken to provide a final value. Add 3 **MolecularDynamics** blocks from **Optimization** to the script. Each block will be used to simulate the Youngs modulus in a specific direction. Open the first **MolecularDynamics** block and set the following parameters.

•Set the *Type* to `Stress Strain`.

•Set *Steps* to 100000 and *Log Interval* to 1000.

•In the *Measurements* section, add all of the diagonal (xx, yy and zz) strains.

•In the Initial Velocity section, set *Type* to `Configuration velocities`.

•In the Stress Strain MD section, select the `xx` as the *Strain Direction*. Also set the the final strain to 20%.

Note: In this simulation the cell is being strained by 20%. This is much larger than strictly required for a Youngs modulus calculation. Typically a total strain of around 2% is required is required for an estimate of the Youngs modulus. Here a larger strain is being used to illustrate the yield point on the stress-strain plot. As the calculated Youngs modulus can depend on the strain rate, it is generally better to use a lower strain rate.

Repeat the same steps for the remaining two molecular dynamics blocks, except in these set the *Strain direction* to `yy` and `zz` respectively. For setting the strain in the X direction, the molecular dynamics dialog should look like the one below.

Before running the script, a few simple manual edits need to be performed. Open the script by sending it to the **Editor** using the **Send To** icon . By default calculations are chained together so that the resulting configuration from one calculation is used as the input for the next. In this case however, that would result in the material strained in one direction would be used as the input for straining in the next direction. The script needs to be changed so each

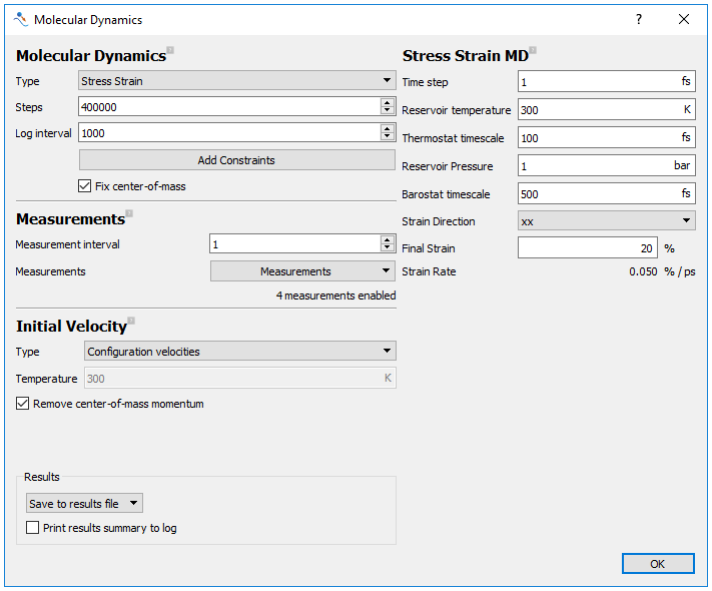

Fig. 3.16: Settings for the annealing calculation to estimate Tg.

stress-strain simulation starts from the same equilibrated structure. The links connecting each molecular dynamics calculation should be removed. These links occur in the line:

```
bulk_configuration = md_trajectory.lastImage()
```

Here the starting bulk configuration is being over-written with the final bulk configuration from the molecular dynamics simulation. Delete this after each stress-strain molecular dynamics calculation. This will mean that the bulk configuration is not updated, resulting in the same bulk configuration being used as input for each dynamics simulation.

With these changes the script is now ready to run. Send it to the **Job Manager** and run the script by using the **Send To** icon . The final output of the calculation will be three molecular dynamics trajectories with the longitudinal stress and the three diagonal strains recorded in it. As before, since this script performs 2.8ns of molecular dynamics it can take several hours to run.

Once the calculation is finished, open the resulting HDF5 file on the Lab Floor. Open one of the MDTrajectories in the **Movie Tool** and observe the trajectory. You should see the material being extended along the longitudinal direction, while the material shrinks in the transverse directions. In the stress-strain simulation an NPT ensemble is used, allowing the transverse directions to respond according to the applied strain. To calculate the Youngs modulus a plot of the stress with respect to the strain should be created. In the Lab Floor, open the **Data Plot** tool. From the first trajectory drag the strain in the xx direction onto the X axis, and the xx stress only the Y axis. Click *Create line* to generate the plot.

In general, stress can fluctuate widely during an NPT molecular dynamics calculation compared to the stress resulting from the applied strain. This can obscure some of the important details of the stress-strain plot. To make it clearer, open the **Plot Editor** by clicking on the *Edit* icon at the bottom-left of the plot. This window shows the different elements in the plot and enables editing their properties. Select the curve and set the *Opacity* in the **Plot Editor** to `0.1`. Right-click on the curve and select *Add analysis* → *Rolling average*. This will help to average out some of the fluctuation in the stress. Select the rolling average, move the ranges to the edges of the plot and in the **Plot Editor** set *Window* to `1000`. The rolling average should be linear at low strain, and then deviate from linearity at higher strain. To find the gradient at low strain right-click on the original plot and select *Add analysis→Polynomial fit*. This adds a line of best fit onto the plot. Use the fitting ranges to move the line over the initial linear region of the stress-strain plot. The gradient and intercept of the line is shown in the **Plot Editor** with the *Fit line* selected. It is also shown by simply hovering the mouse over the line. Below is an example plot from the model system strained in the X direction.

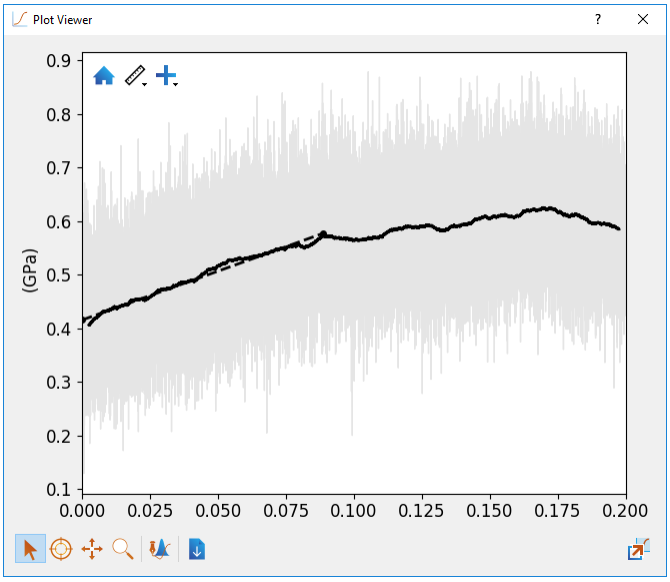

Fig. 3.17: Plot of stress with respect to strain in the X direction in the epoxy-amine thermoset material.

A similar procedure can be used to estimate the Poisson ratio. This is the ratio of the strain in transverse direction to the applied strain. In each simulation the strain in each direction was saved in the MDTrajectoy. These can be plotted in the same way as the stress and strain to produce plots that can be fitted with lines of best fit. The gradient of these lines is then the Poisson ratio.

In the example calculation, averaging over the 3 strain directions and 6 Poisson ratios gives an average Youngs modulus of 2.0GPa and Poisson ratio of 0.35. The Youngs modulus in this case is lower than measured experimental values[Page 416, 2Page 416, 3]. This is likely due to the incomplete cross-linking reaction in the initial building of the epoxy-amine material. The starting configuration used in this tutorial was obtained from the *Building an model of an epoxy thermoset material* tutorial, which used a relatively low number of steps between cross-linking reactions. Increasing the number of NVT and NPT steps per cross-linking step increases the time between cross-linking events and also the distance that reactive atoms can move towards each other. In other simulations where the number of steps was set to 50000 for both NVT and NPT it was possible to link all reactant molecules into one large periodic structure. Increasing the degree of cross-linking results in a corresponding increase in the Youngs modulus. In calculations using a model built with more steps between cross-linking reactions, the same protocol for calculating the Youngs modulus resulted in values between 2.45GPa and 3.11GPa in the range of 90-95% completed cross-linking. This is in line with the experimentally measured Youngs modulus. The Poisson ratio however appears less sensitive to the degree of cross-linking. Here the calculated value of 0.35 is in agreement with the experimental value[4].

Conclusions

In this tutorial the glass transition temperature, Youngs modulus and Poisson ratio of a thermoset polymer material were estimated using molecular dynamics simulation. Here these showed good agreement with the experimental glass transition temperature and Poisson ratio, while the Youngs modulus was somewhat less than the experimental value. This was due to the incomplete cross-linking in the original configuration due to the short time between cross-linking steps. Overall this tutorial shows how reliable models of complex thermoset materials can be easily created and their properties accurately simulated in QuantumATK. These methods can be successfully applied across a range of materials, including thermoset and thermoplast polymers.

3.1.16 Generating A Moment Tensor Potential for HfO_2 Using Active Learning

Version: T-2022.03

Background

Machine learned interatomic potentials (MLIPs) have become popular in recent years since they can provide ab initio level of accuracy in energies, forces and stresses needed for MD simulations, geometry optimizations and single point calculations at modest computational effort. Moment tensor potentials (MTPs) are a class of MLIPs that have been identified to provide high performance for a given accuracy when compared to other MLIP models in the literature[1]. On training an MTP for a system of interest, our goal is to establish a structure-property relationship - here, structure is the atomistic description of the system (3N Cartesian coordinates) and property is the systems potential energy surface (PES - 3N dimensional function).

Within MTP framework, the total energy of a configuration is computed as the sum of energy contributions from atomic neighborhoods. Atomic neighborhoods are defined as the representation of the immediate chemical environment of each atom in the system within a cutoff radius. Since Cartesian coordinates are not invariant to translations, rotations and permutations of atoms in the configuration, they can not be used as such as inputs in MTP training. Moment tensors include the radial, angular, and many-body distribution of atoms within a cutoff sphere. Their contractions into scalar basis functions provide an invariant representation of atomic environments (structure) needed as input for MTP training[2]. An electronic structure method, such as density functional theory (DFT), that describes the system of interest accurately is chosen as the reference method to compute the properties of interest. A reference data set includes the reference configurations representing the system of interest along with their energies (E), atomic forces (F) and stress tensors (S) computed using the chosen reference method.

A MTP can be trained by fitting a linear regression model to the reference data set. MTP training on a reference data set can be performed in two ways: batch learning and active learning. In batch learning, an MTP is trained on a precomputed reference data set. In active learning, a preliminary reference data set is improved on-the-fly by actively adding missing configurations to it. This is done by first training a preliminary MTP on the initial reference data and starting an MD simulation using this MTP potential. When geometries that are very different from the initial reference geometries are encountered in the MD, they are added to the reference data set after computing their E, F and S using the reference method as described in[3] and[4].

It is important to understand that MTPs or any other MLIPs are trained to describe a system accurately (very close to the reference method) within the configurational space of the system sampled in the training data set. Unlike many empirical potentials with physical functional forms, MLIPs are not highly transferable. Therefore, an MLIP trained for a bulk material might not describe free surfaces or nanoparticles of that material accurately unless such geometries are explicitly included in the training data set. Moreover, an MLIP trained for room temperature behavior of a system might not work reliably to describe the system at high temperatures unless disordered structures relevant at high temperatures are included in the training dataset. To improve transferability, active learning of the system at its desired state (high temperatures or surface geometries) should be carried out in order to include the missing reference data.

In this tutorial we will generate an MTP for bulk HfO_2 that can predict DFT quality E, F and S of both crystalline and amorphous configurations using **NanoLab** GUI. Since DFT is used as reference method, this will take 4 to 6 days depending on the computational resources available.

Tip: If you are only interested in training an MTP to simulate crystal structures, you can skip the active learning part and go from the initial reference geometries directly to the final training in Step 3.

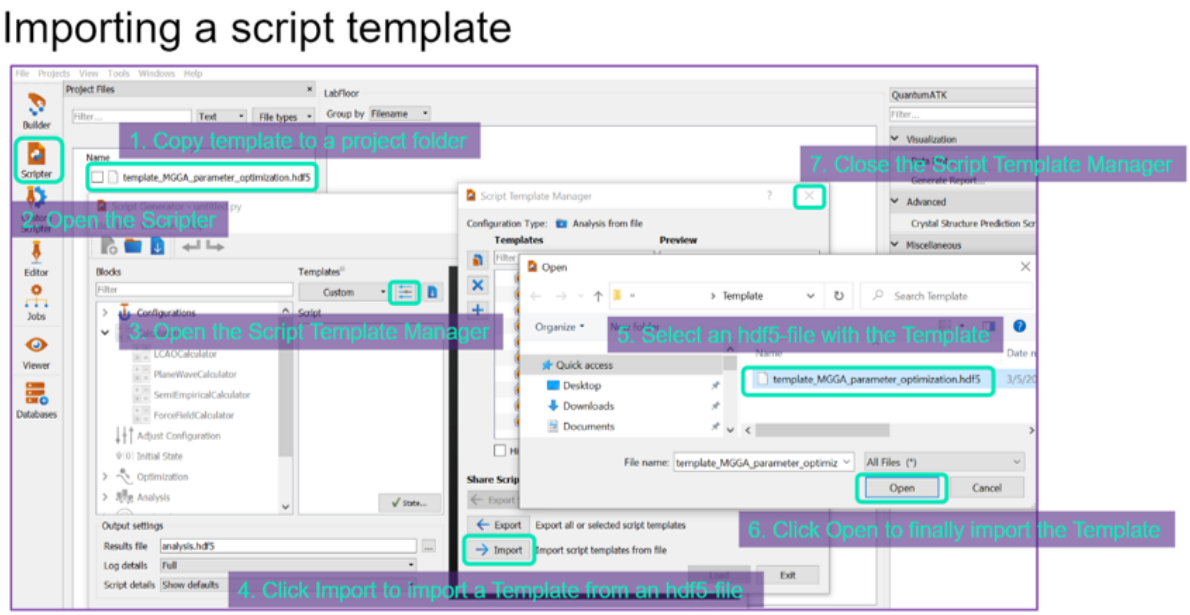
Getting Started

Create a new project folder in **NanoLab** and copy the following files containing different bulk phase configurations of crystalline HfO_2 (`cubic.hdf5`, `monoclinic.hdf5`, `orthorhombic.hdf5`).

Tip: Crystal reference geometries can be conveniently obtained using the open databases such as Materials Project that is accessible via NanoLab

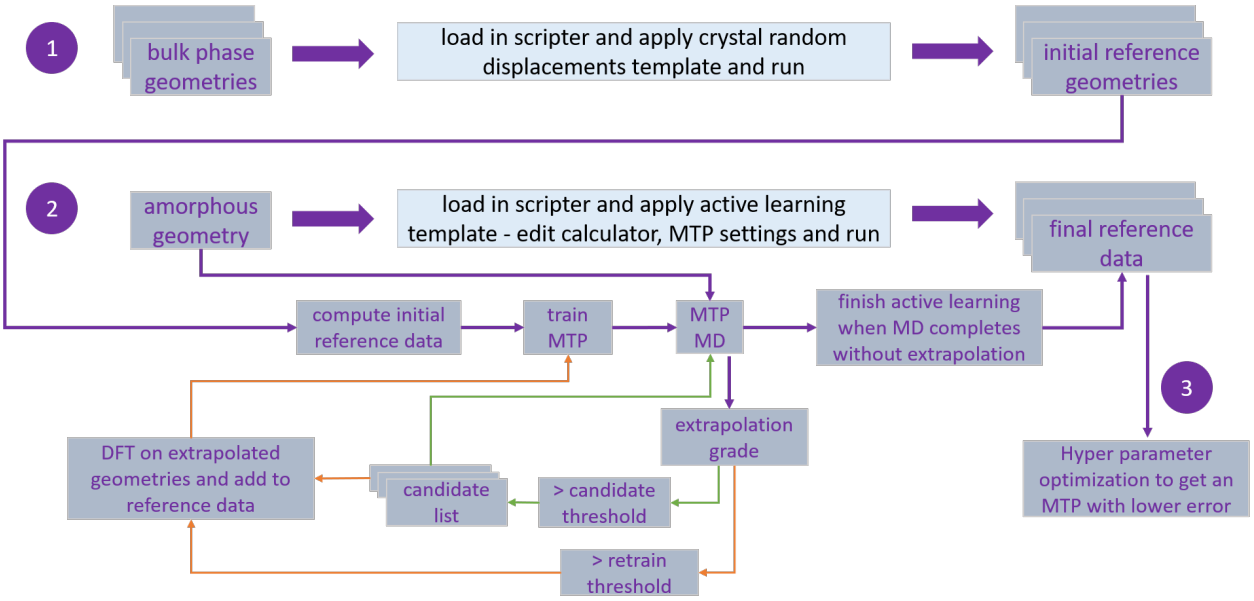
---

As the next step, import the following two templates `random_displacement_template.hdf5` and `active_learning_template.hdf5` to the script generator following the procedure given in the below graphic.

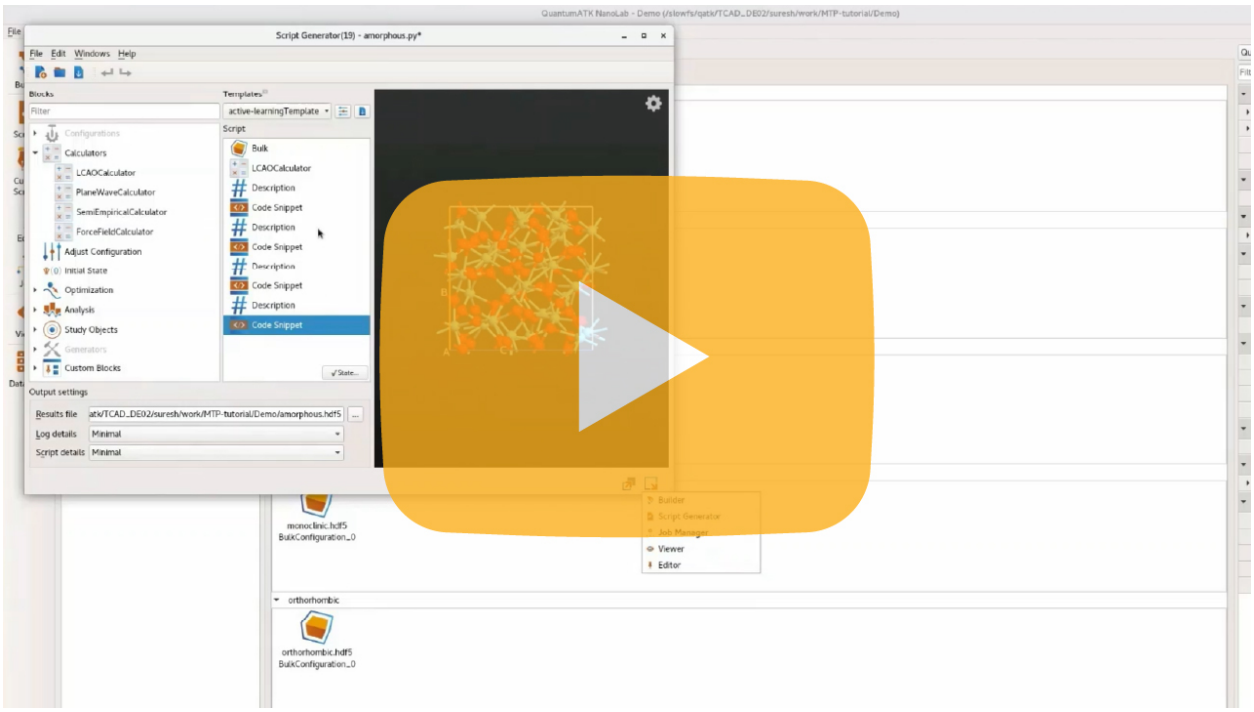


Workflow

An schematic illustration of the workflow is shown below. There are three steps involved which are detailed in the text further below.



A video demonstrating the workflow can be viewed below.



Step 1: Prepare Initial Reference Configurations

Load one of the bulk phase configurations of HfO_2 on to the script generator and apply the *random_displacement_template*. This will add a code snippet for *crystalTrainingRandomDisplacements* in which the user can edit the supercell repetition list, ionic and cell rattle amplitudes to create random configurations based on the geometry. These randomly generated geometries will be stored as a list in the file named *initial_training_sets.hdf5*. Choose large repetitions for small unitcells and *vice-versa*. Save the script and run it locally as it takes only a few seconds.

Repeat the above procedure for the other two bulk phase configurations of HfO_2 . The corresponding python scripts used for this tutorial can be downloaded here (`cubic.py`, `orthorhombic.py` and `monoclinic.py`). Notice that, in the above scripts, the supercell repetition list is different for the different crystal phases depending on the size of the unitcell. The template uses (1x1x1) and (2x2x1) supercells by default. However, for the cubic phase, include (2x2x2) and (3x3x3) instead of the default as in the scripts above. The resulting *initial_training_sets.hdf5* file will contain three lists one for each bulk phase.

Note: The above scripts must be run in sequence and can be run locally (via atkpython in terminal or via JobManager) as it takes only a few seconds.

Warning: If you alter the scripts from above, different repetition list or rattling amplitudes, then the training geometries will be different and ultimately result in a different MTP fitting parameter set. Thus, the users might find that the exact training and testing errors differ a bit from what is given further below.

Step 2: Compute Reference Data and Setup Active Learning

Now that we have a set of initial reference geometries from step 1, we can proceed to compute reference data using DFT and improve the initial training data using active learning molecular dynamics on bulk amorphous configuration of HfO_2 . For this, use the amorphous configuration from this file `amorphous.hdf5`. This initial amorphous configuration was generated using the Packmol Builder plugin and preoptimized with Trinastic_HfOSiTaTi_2013 forcefield. Send this configuration to the script generator and apply active learning template. This loads a calculator and 4 code snippet blocks to the script generator that can be edited.

Calculator: The reference calculator to use for MTP training

For this example, the DFT settings we have chosen include LCAO PseudoDojo medium basis set and PBE exchange-correlation functional. Detailed calculator settings can be found in the script `active-learning.py`.

Note: For accurate MTP training, higher accuracy settings than the ones used in this tutorial may be needed.

Snippet 1: Import reference geometries

In the first snippet, there is code to extract the training data parameters for the reference configurations automatically from *initial_training_sets.hdf5*. The snippet also includes optional code to extract geometries from a *Trajectory* or *MDTrajectory* objects, which can be uncommented if one wants to use configurations from MD trajectories as initial training data.

Snippet 2: Compute reference data

In the second snippet, we use *MomentTensorPotentialTraining* object to compute reference energies, forces and stress using the DFT reference calculator loaded earlier. The user can modify the values for *number_of_processes_per_task*, to set the number of MPI processes used for each reference calculation and for the *log_filename_prefix*. The other settings can be left as such. This snippet will create a file named *reference-data.hdf5* which includes the initial reference data set corresponding to the geometries from step 1 to be used in active learning.

Note: We suggest running this script on a node with several cores as this could take 1 to 2 days using 16 cores.

Snippet 3: Customize MTP training

In the third snippet, the user can set values of key parameters needed for the MTP training. This includes the following:

NonLinearCoefficientsParameters : User can specify if they like to perform optimization of the non linear coefficients that determine the shape of the basis functions for each element pair. If set to *True*, then there are options to perform optimization using energy only, maximum optimization iterations and a random seed to initialize the coefficients. Please note that this is a local optimization in the MTP parameter space, and different initial values may result in different solutions. How to find initial values for a good fit will be discussed below.

constant_terms: No need to edit this part of the snippet as it automatically computes the isolated atomic energies of the elements in the reference data set using the reference calculator, which is not yet automatically computed for active learning.

MomentTensorPotentialFittingParameters: In this part of the snippet, the size of the basis set to be used, cutoff radii for atomic neighborhood description and force cap on configurations can be provided. Note that geometries with a maximum atomic force above the *forces_cap* value will be ignored during training.

Snippet 4: Set up active learning

In this final snippet all settings relevant for active learning will be provided.

ActiveLearningSimulation: In this part, user can provide the threshold values for the extrapolation grades and an interval at which they will be computed in MD[Page 420, 4]. The configuration will be added to a candidate list when the extrapolation grade goes above *candidate_threshold* value and the MD will stop if the extrapolation grade goes over *retrain_threshold*. The *max_forces_check* value sets the force value, which, when encountered during the simulation, will trigger computation of extrapolation grade for the corresponding MD configuration.

MaxwellBoltzmannDistribution: is included to initialize the velocities at a target temperature for MD. In this tutorial example, we chose to run active learning at 3000 K.

NPTMartynaTobiasKlein: is used as the default MD ensemble method which relaxes both ions and volume. This can be changed to other ensemble methods if needed.

The method *runMolecularDynamics* starts an active learning MD simulation of the amorphous HfO_2 geometry. Every time the *retrain_threshold* is reached, this method will be restarted until the MD simulation completes the set number

of time steps. Before each restart, unique geometries from the candidate list will be selected and reference calculations on those geometries will be performed using the reference calculator. The additional reference data is then added to the initial dataset and a new MTP will be generated using the settings in snippet 3. This updated MTP will be used for the restarted MD simulation.

The script that is used for this tutorial is available here `active-learning.py`.

At the end of active learning simulation, a file named *active_learning_candidates.hdf5* is created, that contains the additional reference data.

Note: A common source of problems in MTP active learning is the following error message:

No new candidates found in active learning MD.

This is often accompanied by large values for the extrapolation grade. The reason for this problem is in most cases that the condition number of the training matrix is too large, which causes numerical inaccuracies when inverting this matrix to calculate the extrapolation grade and selecting the candidates via the maxvol algorithm. In this case it usually helps to reduce the number of MTP basis functions to improve the condition number and the numerical stability of the maxvol calculation. Alternatively, one can also try to include more different training configurations in the initial training set.

To repeat active learning simulation with a different MD setting, the training data computed so far should be put-together as the initial training data. In this case, *reference-data.hdf5* consists of the crystalline random displacement data as a *MomentTensorPotentialTraining* object and *active_learning_candidates.hdf5* contains data for unique amorphous geometries found in active learning as a *Trajectory* object. The *initial_training_data* parameter in the *ActiveLearningSimulation* block in the script should be a list of either *Trajectory* objects or *MomentTensorPotentialTraining* objects. We can convert a *MomentTensorPotentialTraining* object in file *reference-data.hdf5* into a *Trajectory* object and prepare the updated initial training data for consecutive active learning simulations as

```
moment_tensor_potential_training=nlread('reference-data.hdf5',
↪MomentTensorPotentialTraining)[-1]
traj_1=TrainingSet(moment_tensor_potential_training, recalculate_training_data=False)
traj_1=traj_1.configurations()

traj_2=nlread('active_learning_candidates.hdf5',Trajectory)[-1]

initial_training_data = [traj_1, traj_2]
```

In a similar way, the *initial_training_data* can be augmented from several active learning simulations.

Step 3: Find an MTP with Lowest Error

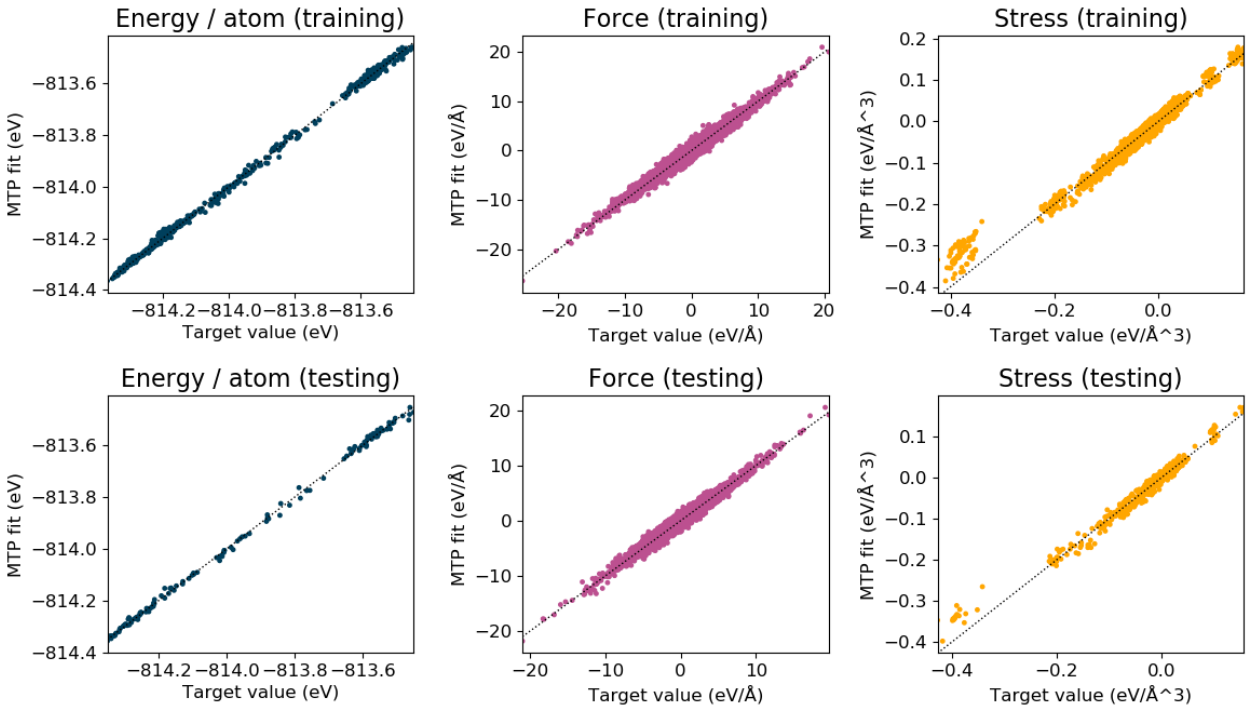
In active learning, the non linear coefficients are randomly initialized. So, in order to find an MTP with the lowest error, we have to train several MTPs with different initial non linear coefficients. This is synonymous with randomly sampling several points in the MTP hyper parameter space and performing a local optimization of the non linear coefficients.

This can be done using a script like this `MTP_training.py` which uses a for loop over different *random_seed* value used to initialize the coefficients. Training data from the files *reference-data.hdf5* and *active_learning_candidates.hdf5* are used as input in this batch training. This script also uses 80% of the reference data for training and 20% for testing.

Note: This step involves training about 200 MTPs in sequence and might take several hours. For better performance choose MPI over openMP, as the MTP training implementation primarily supports MPI parallelization. Users could reduce the number of MTPs trained in line 32 of the script. By default, the script runs a non-linear coefficients

optimization for each fit. To accelerate the training, users can turn the optimization off by specifying *perform_optimization=False* and *initial_coefficients=Random*. Then the fits run without local optimization of the non-linear coefficients and the user can choose to separately optimize the coefficients for the best fit from the 200.

The log output lists training errors for all of the MTPs generated from running the script and the MTP with lowest error for the training/test set (Energy RMSE: 10.7/10.7 meV/atom; Force RMSE: 0.39/0.40 eV/Å; stress RMSE:10.5/9.5 meV/Å^3) is chosen for the validation MD test. Scatter plots comparing the energy, force and stress computed from MTP and reference method are shown below.



Note: Please note that training errors and the above plot will look different when any change to the scripts in steps 1, 2 and 3 are made. As long as the errors are comparable to the above given values, the MTP can be used in validation MD.

The MTP stated above can be generated using this script `MTP_training_best.py`, provided the same reference data obtained from executing `active-learning.py` is used.

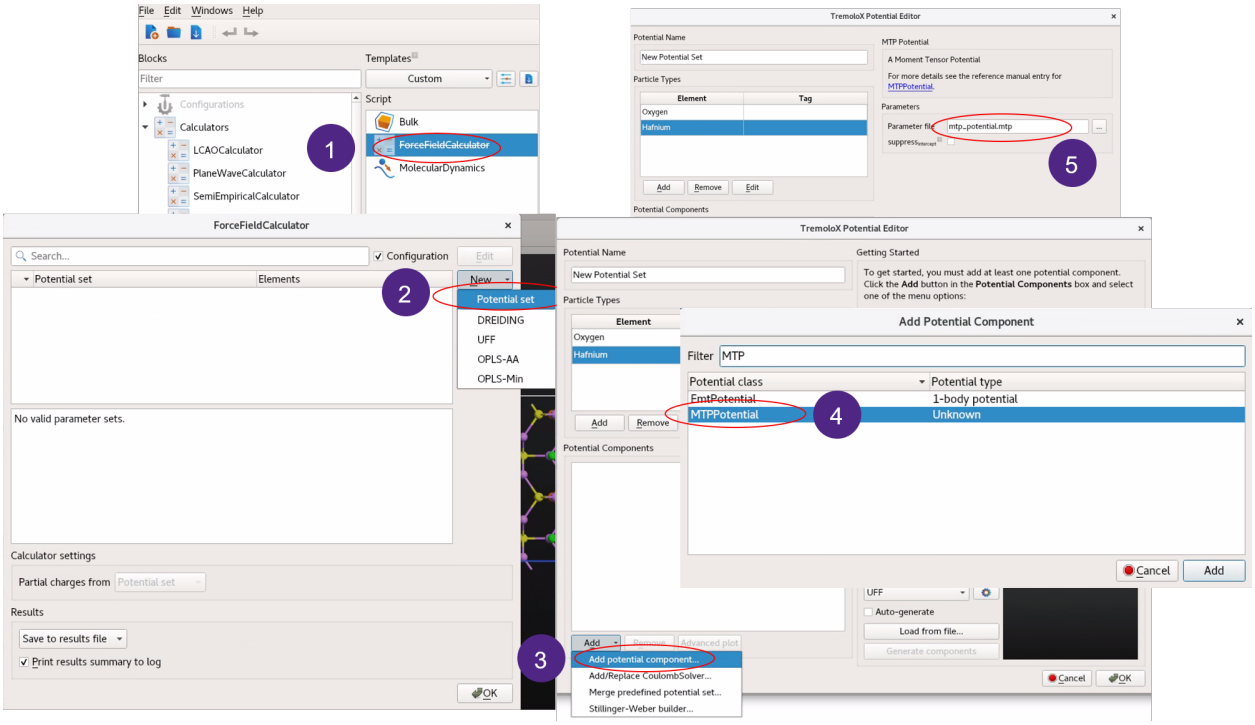
Note: In the above script, the random seed for initializing the non linear coefficients is choosen as that which gave the lowest force RMSE when running MTP_training.py script. It is an optional step since the final mtp file is available from the output of MTP_training.py anyways.

The scatter plot shown above can be created by running atkpython in a terminal and calling the below lines of code while inside the folder with the results for MTP_training_best.py.

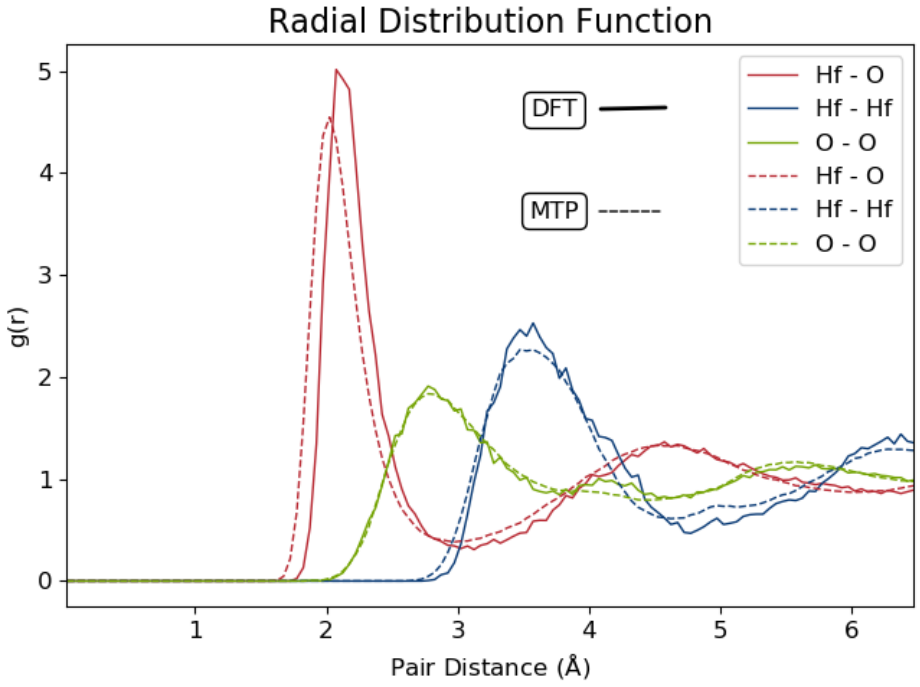
```
moment_tensor_potential_training=nlread('MTP_training.hdf5',
↪MomentTensorPotentialTraining)[-1]
moment_tensor_potential_training._nlplotScatter(fit_index=0)
```

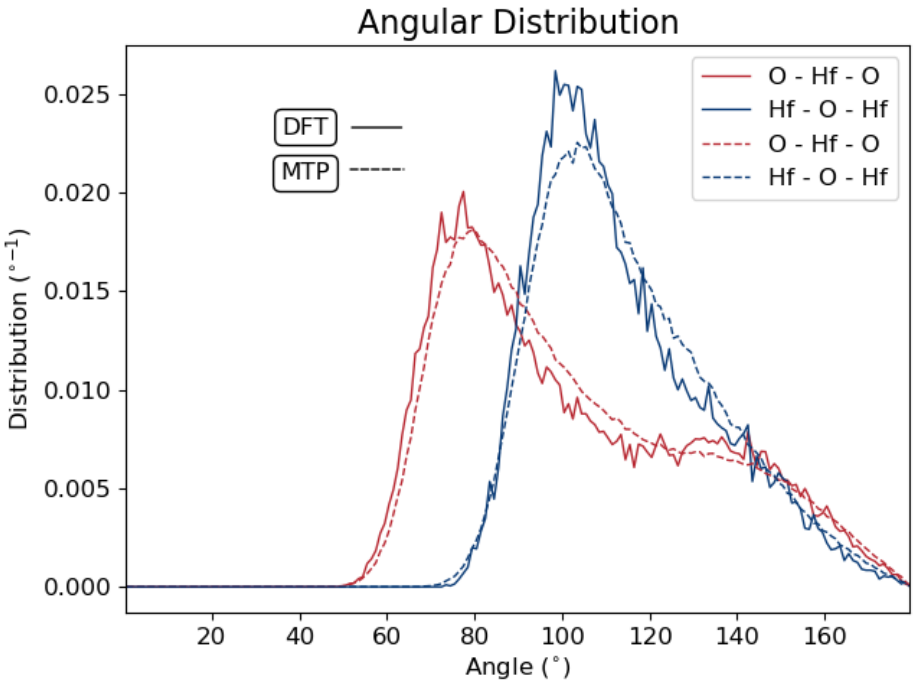
Validation MD Simulation

Now, the MTP obtained in Step 3 will be employed in an MD simulation of amorphous HfO_2 for 0.1 ns using this script `MD.py`. The mtp file used in this script can be found here `mtp_potential.mtp`. This mtp parameter file can be loaded to the script generator via GUI as shown below (click the graphic to see enlarged).



The radial and angular distribution functions from the resulting trajectory is compared with those from a DFT-MD simulation using the same XC functional but reduced basis set as shown below.





As can be seen from the images above, there is a good agreement between the MTP generated trajectory and the DFT trajectory.

The above procedure can be directly applied to train accurate MTPs describing any bulk system of interest with minimal effort using **QuantumATK**.

References

FAQ Section

Q1. In step 1, one prepares the initial configurations for their system. How important is it to define all of the different phases of the material since in the next step (during active learning), the missing configurations are added anyways?

A1. Active learning is used to find and add missing configurations in the initial dataset with the objective to map out the configurational space of interest. But for active learning to work well, the initial training data should have at least coarsely sampled all relevant regions of the configurational space of interest to some extent. So, for example, if your interest is to get the properties of one particular crystalline phase of HfO_2 only – then it is enough to include the randomly displaced crystalline geometries of that crystalline phase only in step 1. Then the active learning, using the chosen crystalline phase as the initial geometry for molecular dynamics, ensures finding missing geometries to represent that crystalline phase accurately. Now, if describing amorphous HfO_2 is your goal, then it helps to include crystal displacement data for all available phases in step 1 and do the active learning as described in the tutorial.

Q2. Is step 1 always necessary or can one start from active learning directly?

A2. If one looks at the workflow figure in the tutorial, it mentions training a preliminary MTP from the initial training data and use it to run the active learning MD (not DFT MD). DFT is employed only when missing geometries are found and needed to be added to the training data. So, we want to make sure that this preliminary MTP is already good enough to sample the equilibrium around the crystal geometries. This is where step 1 helps us immensely and becomes necessary.

Q3. This question is bout the fitting parameter options in step 2, snippet3. Is there some way to guess these options for particular system - for example cutoff radii (check if they have any sense) without actually finishing step 2.

A3. In snippet 3, there are three blocks. The constant term block is parameter free. Keywords in non-linear optimization block are also mostly universal. System specific keywords are in the MTP training block. Outer radii can be chosen based on the radial distribution function of the system and how many coordination shells you would like to include in the atomic description. Basis set size should be chosen based on the complexity of the atomic environment. Our suggestion is to start active learning with a smaller basis set (around 300 functions) and repeat it with increased basis. Step 2 includes computing the initial training geometry and active learning in which the former is the computationally expensive part. Once the initial training data is computed, re-running the script in the same folder will use the already computed initial reference data and only perform active learning part again. The costly step in active learning is the DFT calculation of the missing geometries. So every time you repeat active learning, the active learning candidates from previous run can be added to the initial training data set.

Q4. Under non-linear parameters optimization, what else could be optimized if energy_only option is False and when this is recommended?

A4. When this keyword is set to False, then the non-linear parameters are optimized with respect to E, F and stresses. We suggest using energy only optimization in active learning. If needed, you can optimize on forces and stresses in batch learning. Note that this is only a local optimization in the hyper parameter space.

Q5. In the user example for ActiveLearningSimulations in the manual, Hf and O isolated energies are given in the example script but here, in the tutorial, we dont have them defined. Why is that?

A5. In snippet 3, there is a code block to compute the constant terms, which are the atomic energies of the elements in the system. They are computed automatically before training the preliminary MTP for active learning.

Q6. In step 3, it is said that this may take several hours to get done. Where could one define the parallel options? Would it be possible to do in parallel the steps from the loop?

A6. Yes, one can run the script in step 3 multiple times with different random state while keeping the index in the loop smaller. Then consolidate the results from all the individual log files to find the one with the lowest error.

Q7. Regarding the MTP_training.py and MTP_training_best.py, the former contains a loop over random seeds values, while in the second one the value is given. Is the best (lowest RMSE) seed chosen automatically (given somewhere in main output of MTP_training.py) or user need to actually screen all these mtp_fit_mtp_i.log files?

A7. In this example, the best random seed is not found automatically. The output of MTP_training.py (MTP_training.log) contains a list of RMSEs and the corresponding MTP file names at the end of the file. One can choose the .mtp file with the lowest force error and use it for validation MD. So, it is optional to run MTP_training_best.py. However, one can write a print statement (print(i,rand)) in line 34 of the script MTP_training.py to get the values of rand printed to the log file.

Q8. This question is about validation MD simulation step. MD.py script contains MTP obtained in the step 3. But on the last two pictures there displayed also results of DFT-MD calculations. So what basis sets were used for the DFT-MD run?

A8. For validation, a short DFT-MD with PBE XC functional and FHI Single Zeta Polarized basis set is performed to get the DFT results.

3.1.17 Simulating Si Deposition using Silane

Version: R-2020.09-SP1

In this tutorial, we will look at a QuantumATK workflow to simulate the reaction mechanisms involved in the deposition of Si using silane. We will perform surface-science style slab calculations using plane-wave DFT to study the adsorption and dissociation of silane along with the formation and desorption of H_2 from the surface.

Background

Using thermal chemical vapor deposition (TCVD) technique, Si is deposited by gas phase pyrolysis of SiH_4 . SiH_4 molecules impinge on the Si substrate and donates H atoms to the Si surface followed by the deposition of SiH_x . The H atoms on the surface form H_2 molecules and desorb at elevated temperatures. This is the process we will simulate in this tutorial following the reference article[1]. This can be done in 3 steps. Step 1 involves computing the reference bare Si(100) surface in a supercell and an SiH_4 molecule in the gas phase. In step 2, we study the adsorption and dissociation of SiH_4 on the relaxed Si(100) surface. Step 3 concerns the formation and desorption of an H_2 molecule from the Si surface.

[1] ThongăN.-M. Le, P.ăRaghunath, LamăK. Huynh, and M.ăC. Lin. A computational study on the adsorption configurations and reactions of SiHx (x=1-4) on clean and H-covered Si(100) surfaces. *Appl. Surf. Sci.*, 387:546–556, 2016. URL: http://www.sciencedirect.com/science/article/pii/S0169433216313289, doi:https://doi.org/10.1016/j.apsusc.2016.06.099.

Getting started

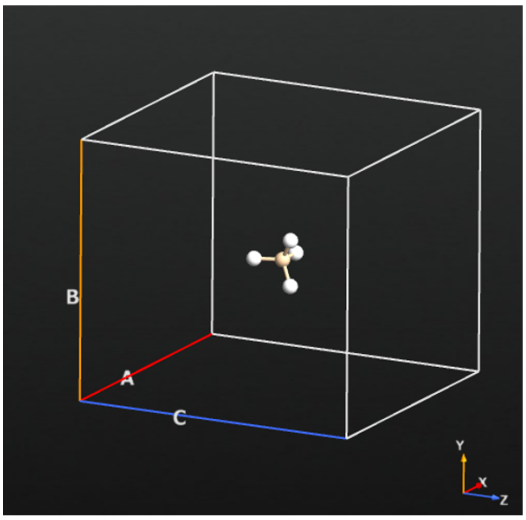
Open the QuantumATK GUI, NanoLab, and select Create New in the Project Dialog. Create a new project in an empty folder with an appropriate name.

Step 1: Reference Calculations

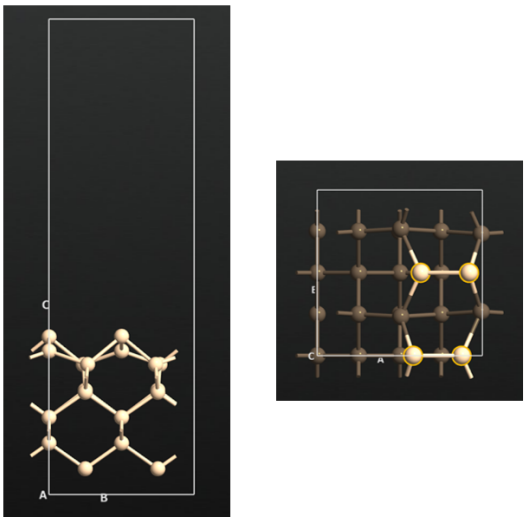
We will perform calculations for the reference SiH_4 molecule and the bare Si(100) surface using a similar setup as the reference article[Page 430, 1]. The relevant python scripts are found here `SiH4.py`, `Si-alpha-100.py`. Panel a in the figure below shows the SiH_4 molecule in a simulation box. Panel b in the figure shows the side and top views of the reconstructed Si(100) surface. From the top view one can see the Si-dimer formation on the surface and these are the reactive sites for SiH_4 adsorption and dissociation. Total electronic energies of these two calculations are summed up to give the reference energy value of the noninteracting system for adsorption energy calculations. The adsorption energy is the difference between the total energy after the process step (interacting) and before the process step (noninteracting) energies:

$$E_{\text{adsorption/binding}} = E_{\text{interacting}} - E_{\text{noninteracting}}$$

a) SiH_4 molecule in a box

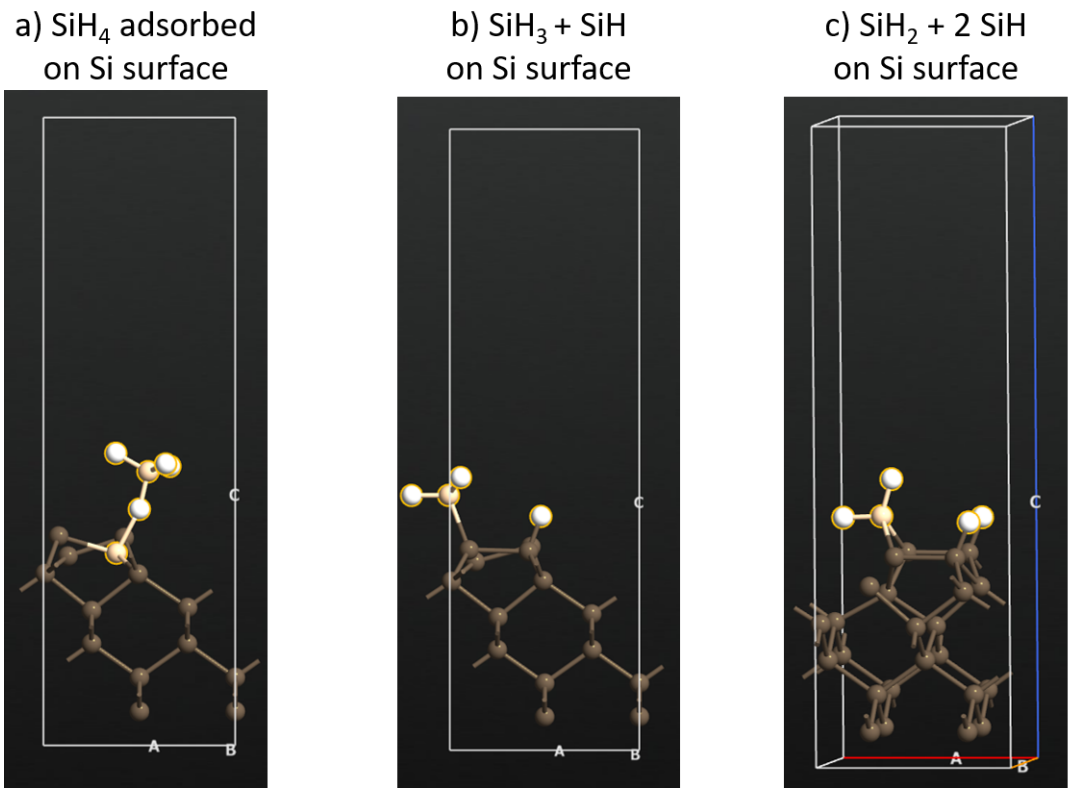


b) Reconstructed α-Si(100) surface in a box

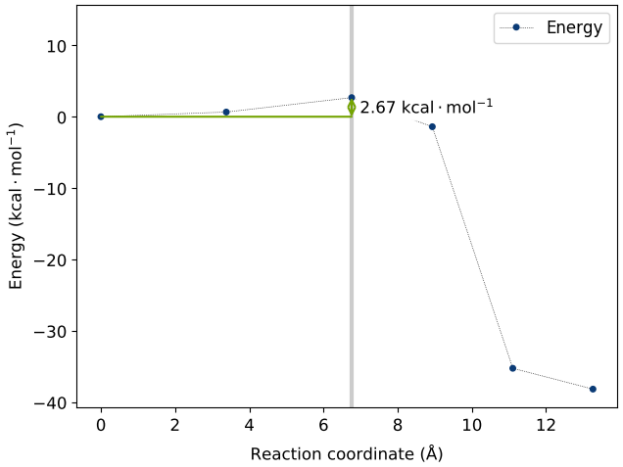


Step 2: Adsorption and Dissociation of SiH_4

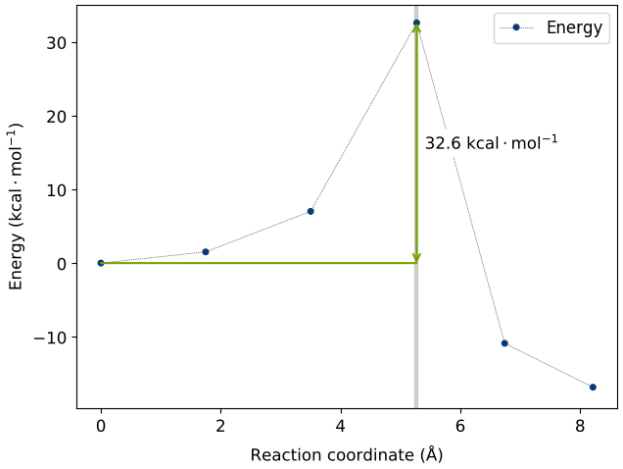
Next step is to adsorb an SiH_4 molecule on the reconstructed Si surface and study the interaction between the two. Panel a in the figure below shows the adsorbed state of SiH_4 on the Si surface in which the molecule is intact and only a weak binding energy of -2.99 kcal/mol (reference article: -2.6 kcal/mol). Panel b in the figure shows a dissociated state of SiH_4 in which a Si-H bond from the molecule dissociates and forms a surface bound Si-H and SiH_3 species. The dissociated state has a binding energy of -41.27 kcal/mol (reference article: -41.3 kcal/mol) which is exoergic and thus favorable. Panel c shows another dissociated Si-H bond from the SiH_3 fragment and formation of 2 Si-H species on the surface in total with a binding energy of -58.11 kcal/mol (reference article: -58.2 kcal/mol). On the reconstructed surface, there are two Si dimers. The SiH_2 fragment takes the bridge site along one of the two surface Si dimers and the H atoms bind to the Si atoms of the other dimer. The scripts to run these geometry optimizations can be downloaded here: `SiH4-Si.py`, `SiH3-SiH.py`, `SiH2-2SiH.py`. A python script to compute the binding energies of these geometries can be downloaded here `adsorption_energies.py`.



Now we can compute the dissociation pathways from the intact adsorbed state (a) towards the two dissociated states (b and c) shown in the picture above. For this we will use the climbing image nudged elastic band approach implemented in QuantumATK. We have used 4 interpolated images between (a and b) and between (b and c). The relevant scripts to run these calculations can be downloaded here: `NEB-a-b.py`, `NEB-b-c.py`. The converged pathways with a maximum force on atoms within 0.1 eV/Å are shown in the animated gifs below. The activation barrier for the first H dissociation connecting geometries a and b is a very low value of 2.67 kcal/mol (reference aricle: 5.2 kcal/mol). This process should not require high temperatures to proceed spontaneously.



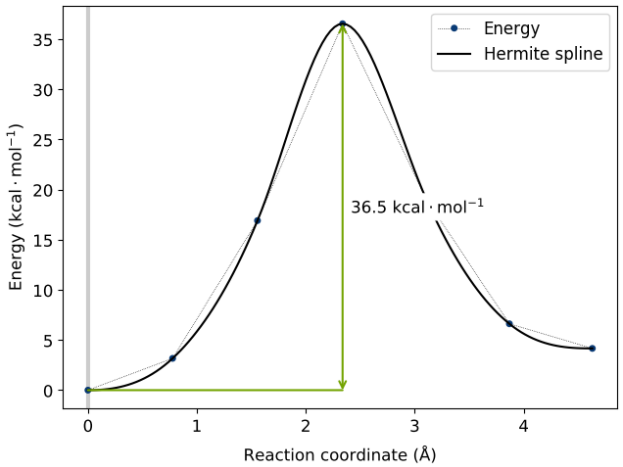
The second H dissociation pathways connecting b and c has an activation barrier of 32.6 kcal/mol (reference article: 31.1 kcal/mol). This pathway requires elevated temperatures to breach the energy barrier.



Step 3: Formation and Desorption of H_2

The H atoms on the surface can diffuse on the Si surface and form H_2 molecule and desorb from the surface. This would then result in the deposition of Si and the removal of H ensures further adsorption of silane molecules on the surface. To study this process, we modified geometry c to have a H_2 molecule adsorbed on the Si surface instead of two separated H atoms. A python script for this calculation can be downloaded here `SiH2-H2.py`. This calculation resulted in the newly created H_2 molecule desorbing into the vacuum spontaneously upon optimization as shown in the below animation.

This means that there is no activation barrier for the desorption of an H_2 molecule once it is formed on the surface. However, there will be an activation barrier for the diffusion of H on the surface which we will compute next. For this, we choose geometry b from before and compute the activation barrier for the diffusion of H from the atop Si site of one dimer to the other as shown in the animation below. The calculated energy barrier is computed to be 36.5 kcal/mol (reference article - Fig.4 TS2: 34.8 kcal/mol). This is a large barrier, however, it is known to be breached at a temperature of 570 K[2].



[2] J.ăH.ăG. Owen, D.ăR. Bowler, C.ăM. Goringe, K.ăMiki, and G.ăA.ăD. Briggs. Hydrogen diffusion on Si(001). *Phys. Rev. B*, 54:14153–14157, Nov 1996. URL: https://link.aps.org/doi/10.1103/PhysRevB.54.14153, doi:10.1103/PhysRevB.54.14153.

Conclusions

In this tutorial, we computed the energetics related to the mechanisms involved in the Si deposition process and compared the results to a previously published article that used a different PAW based plane-wave DFT code. We showed an excellent agreement with the published research article. This tutorial demonstrates the capabilities of QuantumATk in modeling the complex mechanisms involved in thin film processing.

3.2.1 Phonon-limited mobility in graphene using the Boltzmann transport equation

Version: Q-2019.12-SP1

Downloads & Links

DynamicalMatrix *HamiltonianDerivatives* *ElectronPhononCoupling* *Mobility*

In this tutorial you will learn how to calculate the phonon-limited mobility in graphene. The mobility will be calculated using the Boltzmann transport equation (BTE) with the electronic structure, phonons and electron-phonon coupling calculated using density functional theory (DFT).

The mobility μ will be calculated using two different methods to calculate the relaxation times τ entering the BTE:

1. **Full angular (k,q)-dependence**: in this method, the full dependency of τ on the electron and phonon wave vectors $\mathbf{k}$ and $\mathbf{q}$ is taken into account, so that $\tau = \tau(\mathbf{k}, \mathbf{q})$. In the following, we will refer to this as the **(k,q)-dependent method**.
2. **Isotropic scattering rate**: in this method, only the energy dependence of τ is considered, so that $\tau = \tau(E)$, and $\tau(E)$ is assumed to vary isotropically in momentum-space. In the following, we will refer to this as the **E-dependent method**.

As it will be shown, the two methods give essentially the same results, but the second method is considerably faster than the first one.

In the *theory section*, you can read about the theoretical background. A more comprehensive description can also be found in the paper[1].

[1] T.ăGunst, T.ăMarkussen, K.ăStokbro, and M.ăBrandbyge. First-principles method for electron-phonon coupling and electron mobility: Applications to two-dimensional materials. *Phys. Rev. B*, 93:035414, Jan 2016. doi:10.1103/PhysRevB.93.035414.

Geometry and electronic structure of graphene

In the **Builder**, add a graphene configuration by clicking *Add* → *From Database* and searching for *Graphene* in the structure database.

Next, you have to increase the vacuum gap above and below the graphene. Click on *Bulk Tools* → *Lattice parameters* and set the lattice parameter along the C-direction to C = 20 Å.

Center the configuration by clicking on *Coordinate Tools* → *Center*, and press *Apply*. Now click on the button to send the structure to the **Script Generator**. In the main panel of the **Script Generator**, set the **Results file** to `Graphene_relax.hdf5`,

To perform an accurate calculation of the relaxation times τ and the mobility μ, the first important step is to optimize the lattice parameters A and B and calculate the electronic band structure. In order to do this, add an **LCAOCalculator** block and in the *Main* section set the following parameters:

- *Calculators* → *LCAOCalculator*

–Set the **Exchange correlation** to *LDA*

–Set the **Pseudopotential** to *FHI*

–Set the **Occupation method** to *Methfessel-Paxton*

–Set the **Density mesh cutoff** to *90 Ha*

–Set the **k-point sampling** to:

∗k_A = 33

∗k_B = 33

∗k_C = 1

–On the **Iteration Control** tab, Set the **Tolerance** to *0.000001*, i.e. 10^{-6}

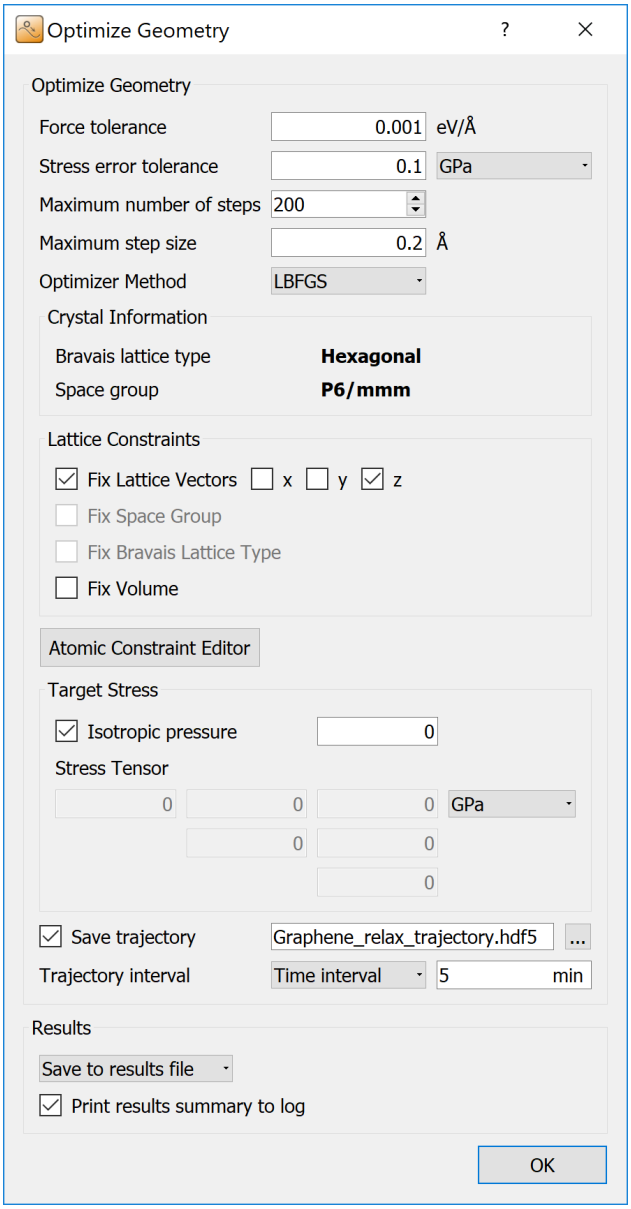
- *Optimization* → *OptimizeGeometry*

–Set the **Force tolerance** to *0.001 eV/Å*

–Untick **Fix lattice vectors** in the x and y directions.



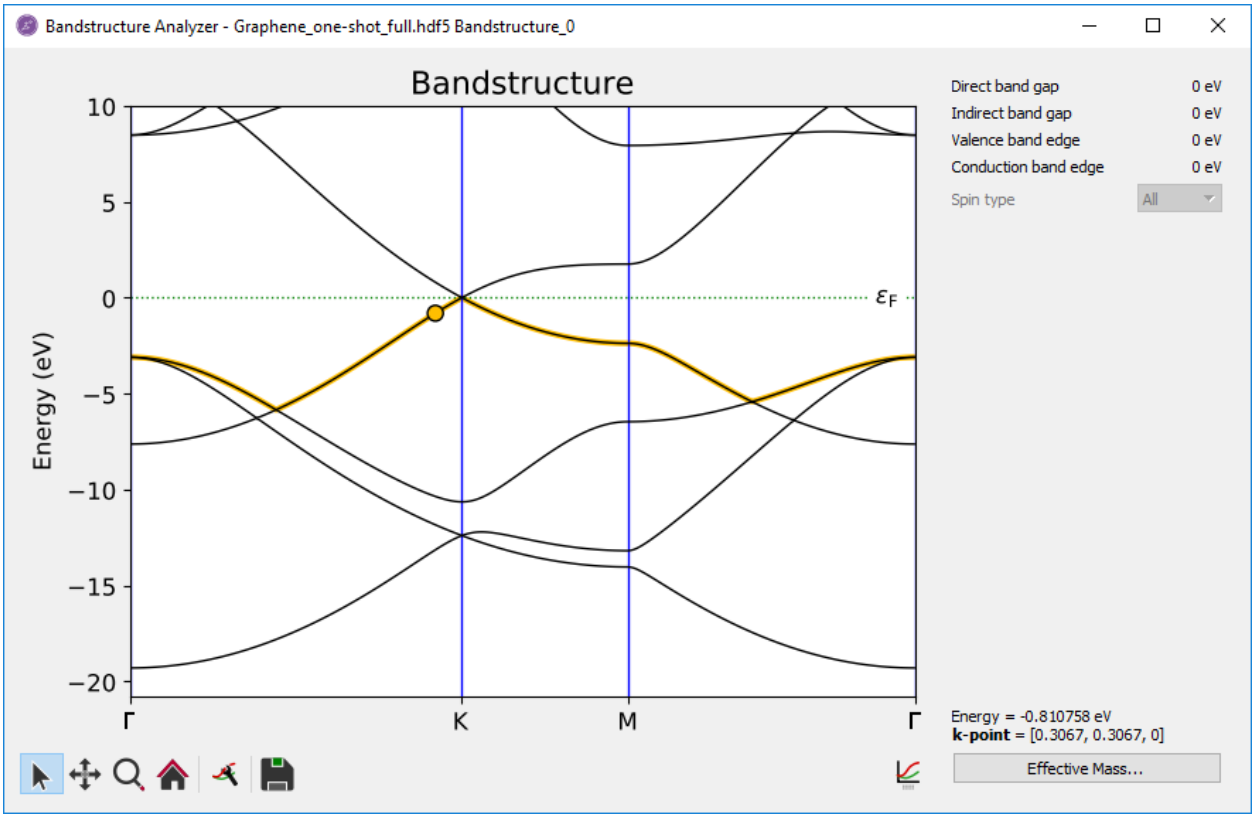
- *Analysis* → *Bandstructure*

–Set the number of **Points per segment** to *100*

–Set the **Brillouin zone route** to *G, K, M, G*

Now, send the script to the **Job manager**, save it as `Graphene_relax.py`, and click on the button to run the calculation.

When the calculation is done, click on the **Bandstructure** object contained in the file `Graphene_relax.hdf5` on the **LabFloor** and use the **Bandstructure Analyzer** to visualize the band structure.



By placing the mouse cursor on top of a band, information about the band is shown. You see that the valence band (highlighted in yellow in the figure above) is number 3 and the conduction band is number 4. These are the two electronic bands relevant for the calculation of the mobility, and in the following we will concentrate on these two bands.

Phonons in Graphene

The next step is to calculate the dynamical matrix of graphene. In order to test the quality of the result you will also calculate the phonon band structure, which is based on the calculated dynamical matrix.

Open the **Script generator** , and create a new script:

- Add an *Analysis from File* block and select *BulkConfiguration_1* in `Graphene_relax.hdf5`.
- Add a *Study Objects → DynamicalMatrix* block and modify the following settings:

  – Set **Repetitions** to *Custom*

  – Set the **Number of repetitions** to:

  $*n_A = 11$

  $*n_B = 11$

  $*n_C = 1$

Note: In previous versions of **QuantumATK** it was necessary to manually scale down the number of k-points when doing a **DynamicalMatrix** or **HamiltonianDerivatives** calculation to take into account the repeated cell. From **QuantumATK-2019.03** and later versions the k-points are automatically scaled to maintain the same accuracy as the unit cell, and we can simply re-use the calculator settings.

Tip: Due to the large dimensions of the 11×11 graphene super cell (242 atoms), the calculation of the *DynamicalMatrix* object is rather time consuming. However, the calculation can be parallelized over the atomic displacements. Since there are two atoms in the graphene unit cell, and each is displaced in the x, y and z directions, there are in total 6 calculations to be performed. Maximum efficiency is obtained when the number of calculations times the value of the parameter *Processes per displacement* matches the total number of cores used for the calculations. In the present case, the calculation takes about 30 minutes if *Processes per displacement* = *4* and the calculation is run on 24 cores.

- Add an *Analysis* → *PhononBandstructure* block and set the following parameters:
  - Set the number of **Points per segment** to *100*
  - Set the **Brillouin zone route** to *G, M, K, G*

Finally, in the main panel of the **Script Generator** set the **Default output file** to `Graphene_dynmat.hdf5`, send the script to the **Job manager**, save it as `Graphene_dynmat.py` and click on the button to run the calculation.

Warning: Remember to make the file `Graphene_relax.hdf5` available for the script if you are running on a cluster. In the **Job Manager** you can use the **I/O** tab to transfer additional files together with a script. In this case, you may also need to modify the path in the script before submitting to the cluster, to make sure it points at the correct location of the file.

When the calculation is done, go back to the in the **LabFloor**, and inspect the $\{\omega_i(\mathbf{q})\}$ **PhononBandstructure** object contained in the file `Graphene_dynmat.hdf5` using **Compare data** or **PhononBandstructure Analyzer**. The calculated phonon band structure should match with that shown in the figure below.

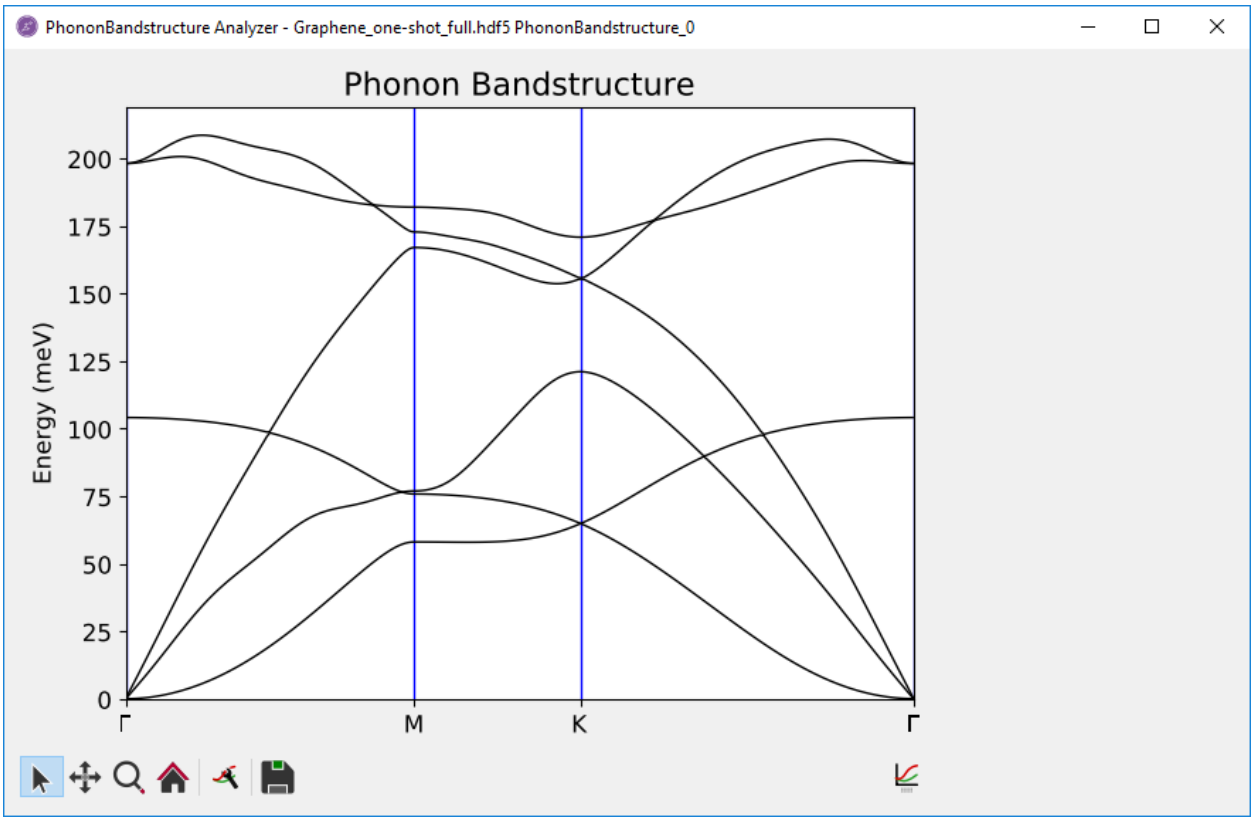

Fig. 3.18: Phonon bandstructure. There are three acoustic modes: The lowest, out-of-plane mode (ZA) has a $\propto \mathbf{q}^2$ for small $\mathbf{q}$, while the two next have linear $\mathbf{q}$-dependence with a constant velocity for small $\mathbf{q}$. The transverse acoustic (TA) mode is lower in energy than the longitudinal acoustic (LA) mode.

Mobility of graphene

In the following, the procedure to calculate the electron mobility in graphene will be described. Provided that one has already calculated the electronic structure and dynamical matrix of the system, the following three steps are necessary to evaluate the mobility:

1)Calculation of the **Hamiltonian derivatives**

2)Calculation of the **Electron-phonon couplings**

3)Calculation of the **Mobility**

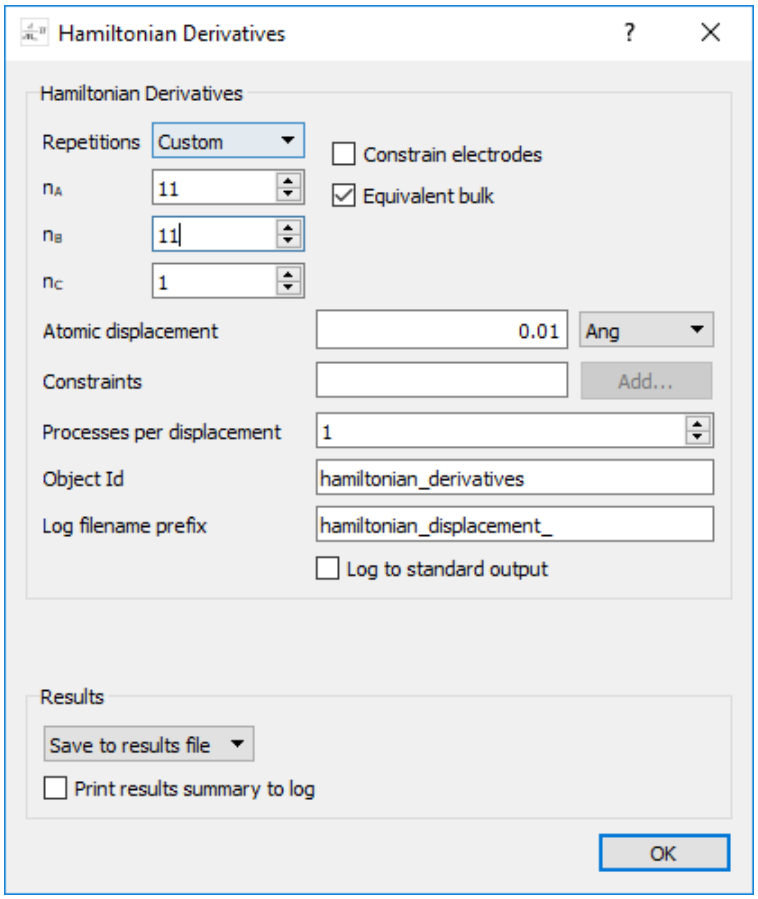
The two methods to calculate μ described above differ in the way in which steps 2 and 3 are carried out. These two steps will therefore be described separately for each method. The procedure for the **(k, q)-dependent method** is outlined in sections *1*, *2A* and *3A*, whereas the procedure for the **energy-dependent method** is outlined in in sections *1*, *2B* and *3B*

1. Hamiltonian derivatives

In order to calculate the electron-phonon coupling matrix, it is necessary to calculate the derivative of the Hamiltonian $\partial\hat{H}/\partial R_{i,\alpha}$ with respect to the coordinate of the i-th atom along the Cartesian direction α.

Open the **Script generator**, and modify the script as follows:

- Add an *Analysis from File* block and select *BulkConfiguration_1* in `Graphene_relax.hdf5`.
- Add a *Study Objects* → *HamiltonianDerivatives* block and set the **Number of repetitions** to:
  - n_A = 11
  - n_B = 11
  - n_C = 1



Warning: It is important that the number of repetitions matches the calculation of the dynamical matrix.

In the main panel of the **Script Generator**, set the **Results file** to `Graphene_dHdR.hdf5`, send the script to the **Job manager**, save it as `Graphene_dHdR.py` and click on the button to run the calculation.

Note: As for the **DynamicalMatrix**, the calculation of the **HamiltonianDerivatives** is rather time consuming, but can be parallelized over the atomic displacements. In the present case, the calculation takes around 1 hour if it is run on 24 cores with *Processes per displacement = 4* .

2A. Electron-Phonon couplings: (k,q)-dependent method

In order to calculate the lifetimes $\tau(\mathbf{k}, \mathbf{q})$ and the mobility μ, we need to calculate the electron-phonon coupling matrix on a fine grid of $\mathbf{k}$- and $\mathbf{q}$-points.

Open the **Script generator** , and modify the script as follows:

- Add an *Analysis from File* block and select *BulkConfiguration_1* in `Graphene_relax.hdf5`.
- Add an *Analysis → ElectronPhononCoupling* block.

You will notice that two additional blocks have been also added:

- *Study Objects → DynamicalMatrix* D_{ij}
- *Study Objects → HamiltonianDerivatives* $\frac{d}{d\mathbf{R}_\alpha}\hat{H}$

In the present case, both the dynamical matrix and the Hamiltonian derivatives have been calculated already and can be re-used. As they are study objects, this is automatically detected by QuantumATK if the provided filename and other input parameters are the same. Open each of them and change the repetitions to 11x11x1 and the filenames to `Graphene_dynmat.hdf5` and `Graphene_dHdR.hdf5`, respectively.

Now set the parameters in the *Analysis → ElectronPhononCoupling* block as shown below. We will sample k-points in a small area around the K-point at [1/3, 1/3, 0], and q-points in a small area around the Γ-point at [0,0,0].

Tip: If you are unsure of the coordinates of a particular symmetry point you may use the built-in functionality of the `BravaisLattice` class, f.ex. like this: `k0=bulk_configuration.bravaisLattice().symmetryPoints()['K']`)

Warning: For production calculations, it is strongly recommended to always converge the sampling resolution in q- and k-space. The above settings are a result of such a study, with more information shown in the appendix: *Convergence of q- and k-point sampling*

In the main panel of the **Script Generator**, set the **Results file** to `Graphene_eph.hdf5`. Send the script to the **Job manager**, save it as `Graphene_eph.py` and click on the button to run the calculation.

Warning: For graphene, we need quite dense samplings in $\mathbf{k}$- and $\mathbf{q}$-space, and therefore we have chosen to sample very finely a small area around the relevant high-symmetry points. This still includes the full angular dependence,

but neglects inter-valley scattering. We therefore recommend to sample the entire Brillouin zone if this could be an important effect.

Note: Sampling the **k**- and **q**-space using dense meshes means that the calculation might become very time consuming. Contemporary versions of QuantumATK automatically detect the relevant regions of **k**- and **q**-space, and do not compute matrix elements which will not contribute, considerably decreasing the computational time and memory requirements. The two parameters *energy_tolerance* and *initial_state_energy_range* govern the filters which reduce the number of calculated coupling elements. More information about these two parameters can be found on the manual page: `ElectronPhononCoupling`.

As QuantumATK parallelizes over **k**- and **q**-points, a high number of MPI processes can be used if sufficient memory is available. In the present case, the calculation took approximately 10 hours on a 16-core node on a cluster.

3A. Mobility: (k,q)-dependent method

Now open a new Script Generator window and add an *Analysis from File* block and then a *Analysis → Mobility* block. In the *Analysis from File* block, select the file `Graphene_relax.hdf5` and load *BulkConfiguration_1* included in the file. Remove the *ElectronPhononCoupling*, *DynamicalMatrix* and *HamiltonianDerivatives* blocks, and replace them with a *Custom blocks → Code snippet* block. This allows us to easily add arbitrary code to any script without editing the full script manually. Open the block, and write the following:

```
electron_phonon_coupling = nlread('Graphene_eph.hdf5', ElectronPhononCoupling)[0]
```

Set the parameters for the *Analysis → Mobility* block as shown below:

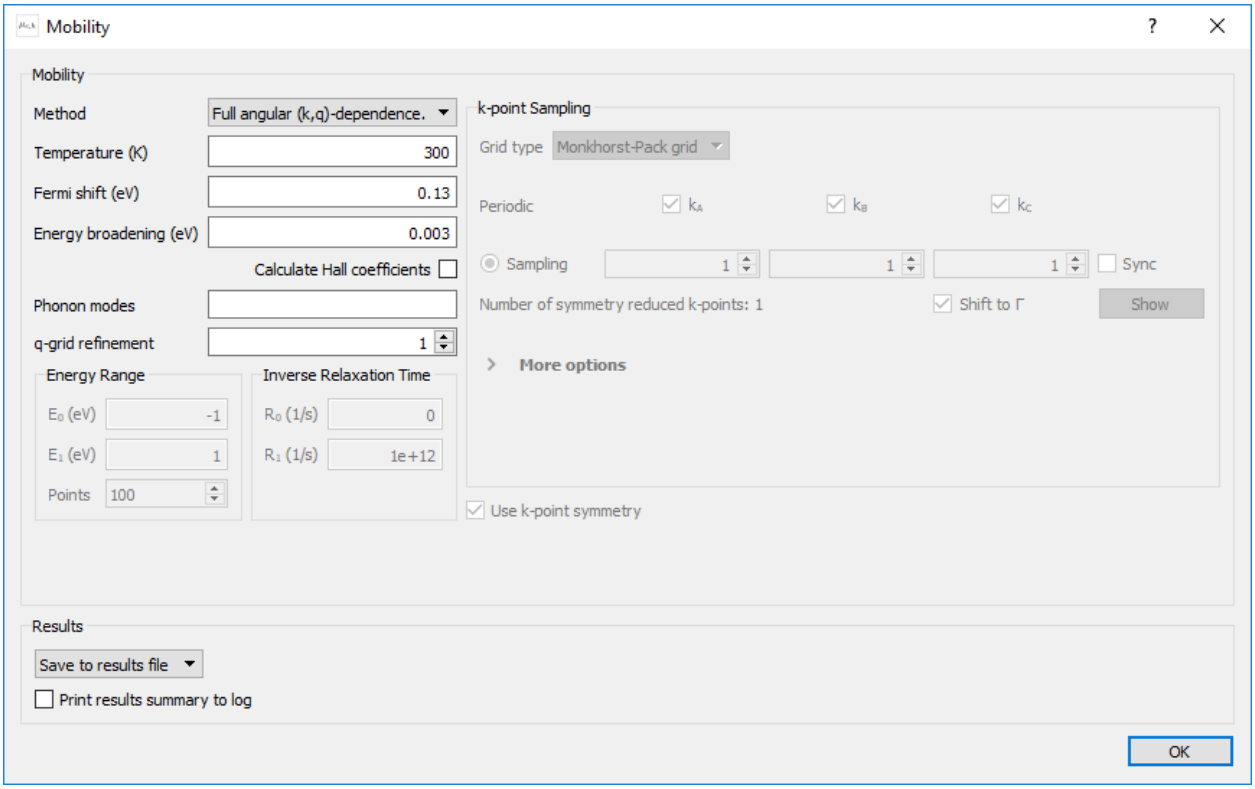
- Leave the **Method** at *Full angular (k,q)-dependence*
- Set the **Fermi shift** to *0.13 eV*
- Untick *Calculate Hall coefficients*

Note: The Fermi shift of 0.13 eV corresponds to a carrier concentration of $n = 10^{12}\mathrm{cm}^{-2}$

In the main panel of the **Script Generator**, set the **Results file** to `Graphene_mu-full.hdf5`, send the script to the **Job manager**, save it as `Graphene_mu-full.py` and click on the button to run the calculation. It should take no more than a few minutes on a laptop.

Note: You will get a notification that the Mobility block is invalid. You can ignore this warning, as NanoLab does not parse the *Code snippet* block and is thus unaware of the `ElectronPhononCoupling` object that will be loaded there.

Once the calculation is done, select the file `Graphene_mu-full.hdf5`, and on the **LabFloor**, select the $\mu_{e,h}$



Mobility object, and click on **Text Representation**. You should now see the following:

```

+--------------------------------------------------------------------------------+
```

The calculated electron mobility, highlighted in yellow, is $2.34 \cdot 10^5$ $\mathrm{cm}^2\mathrm{V}^{-1}\mathrm{s}^{-1}$, and agrees well with previously reported data at room temperature and $n = 10^{12}\mathrm{cm}^{-2}$[2].

Note: Note that the carrier density listed here is significantly lower than $n = 10^{12}\mathrm{cm}^{-2}$. The carrier density is calculated independently from the mobility, and converges much more slowly than the mobility itself. In this tutorial, the focus is on achieving a converged value for the mobility - converging also the carrier density would require inclusion of more **k**-points and/or a larger region in **k**-space in the **ElectronPhononCoupling** calculation. Alternatively, you can calculate the carrier density with a finer sampling directly from the DensityOfStates object: `carrier_density_test.py`.

Tip: Starting from version Q-2019.12, QuantumATK NanoLab includes a Mobility Analyzer. This will be presented in a future update of this tutorial.

2B. Electron-Phonon couplings: energy-dependent method

We will now calculate the electron-phonon couplings to be used for the calculation of the energy-dependent relaxation times $\tau(E)$. We will assume that the relaxation times vary isotropically in **k**-space. This means that it will be sufficient to evaluate the electron-phonon coupling matrix for a number of **k**-points along a line through one of the Dirac (K) points, thereby reducing significantly the computational workload of the calculation.

Open the **Script generator** , and modify the script as follows:

- Add an *Analysis from File* block and select *BulkConfiguration_1* in `Graphene_relax.hdf5`.
- Add an *Analysis → ElectronPhononCoupling* block.

You will notice that two additional blocks have been also added:

- *Study Objects → DynamicalMatrix*
- *Study Objects → HamiltonianDerivatives*

In the present case, both the dynamical matrix and the Hamiltonian derivatives have been already calculated and can be re-used. As they are study objects, this is automatically detected by QuantumATK if the provided filename and other input parameters are the same. Open each of them and change the repetitions to 11x11x1 and the filenames to `Graphene_dynmat.hdf5` and `Graphene_dHdR.hdf5`, respectively.

In the *Analysis → ElectronPhononCoupling* block, modify the parameters as follows:

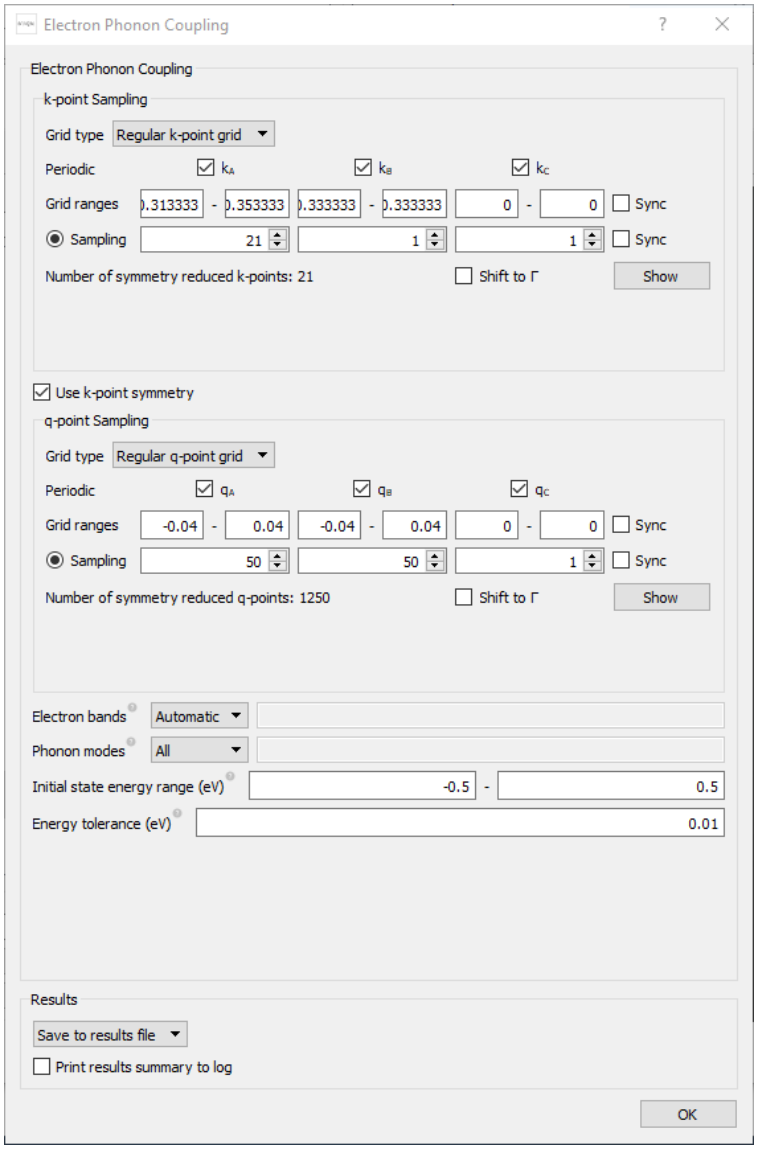
[2] Kristen Kaasbjerg, KristianăS Thygesen, and KarstenăW Jacobsen. Unraveling the acoustic electron-phonon interaction in graphene. *Physical Review B*, 85(16):165440, 2012.

•In the **k-point sampling**, set the **Grid type** to *Regular k-point grid*, and the sampling parameters as shown in the figure below.

Note: As you can see from the figure, the **k**-space is sampled only along a line!

•In the **q-point sampling**, set the **Grid type** to *Regular q-point grid*, and the sampling parameters as shown in the figure below.

•Set the **Energy tolerance** to *0.01* (eV) and the **Initial state energy range** to go from *-0.5* to *0.5*.



In the main panel of the **Script Generator**, set the **Results file** to `Graphene_eph-line.hdf5`, send the script to the **Job manager**, save it as `Graphene_eph-line.py` and click on the button to run the calculation.

Note: Since here we sample the **k**-space only along a line, the calculation will in general be faster than the one described in section 2A. In the present case, the calculation took approximately 50 minutes on a 16-core node on a

cluster, or about 1/10th of the full calculation in section 2A.

3B. Electron mobility: energy-dependent method

We will now use a two-step procedure to evaluate the room-temperature mobility μ based on the energy-dependent relaxation times $\tau(E)$:

- In the first step, the $\mathbf{k}$- and $\mathbf{q}$-dependent relaxation times $\tau(\mathbf{k}, \mathbf{q})$ are evaluated along the line outward from the K-point.
- In the second step, the values of $\tau(\mathbf{k}, \mathbf{q})$ are averaged in $\mathbf{k}$-space to obtain the values of $\tau(E)$, which are then used to calculate the mobility μ.

Now open a new Script Generator window and add an *Analysis from File* block and then a *Analysis → Mobility* block. In the *Analysis from File* block, select the file `Graphene_relax.hdf5` and load *BulkConfiguration_1* included in the file. Remove the *DynamicalMatrix* and *HamiltonianDerivatives* objects and replace the *Analysis → ElectronPhononCoupling* with a *Custom blocks → Code snippet* block. Open the block, and write the following:

```
electron_phonon_coupling = nlread('Graphene_eph-line.hdf5', ElectronPhononCoupling)[0]
```

Finally, set the parameters in the *Analysis → Mobility* block as shown below:

- *Analysis → Mobility*
  - Set the **Method** to *Full angular (k,q)-dependence*
  - Set the **Fermi shift** to *0.13 eV*
  - Untick *Calculate Hall coefficients*

Note: Note that we choose a $\mathbf{k}$-line direction somewhat arbitrarily here. The point is that a low number of $\mathbf{k}$-points can be used to generate an energy dependent rate. An alternative to a line could be to coarsely sample the entire BZ to capture the anisotropy in $\mathbf{k}$-space, but with fewer points than needed in the full ($\mathbf{k}$, $\mathbf{q}$)-dependent method.

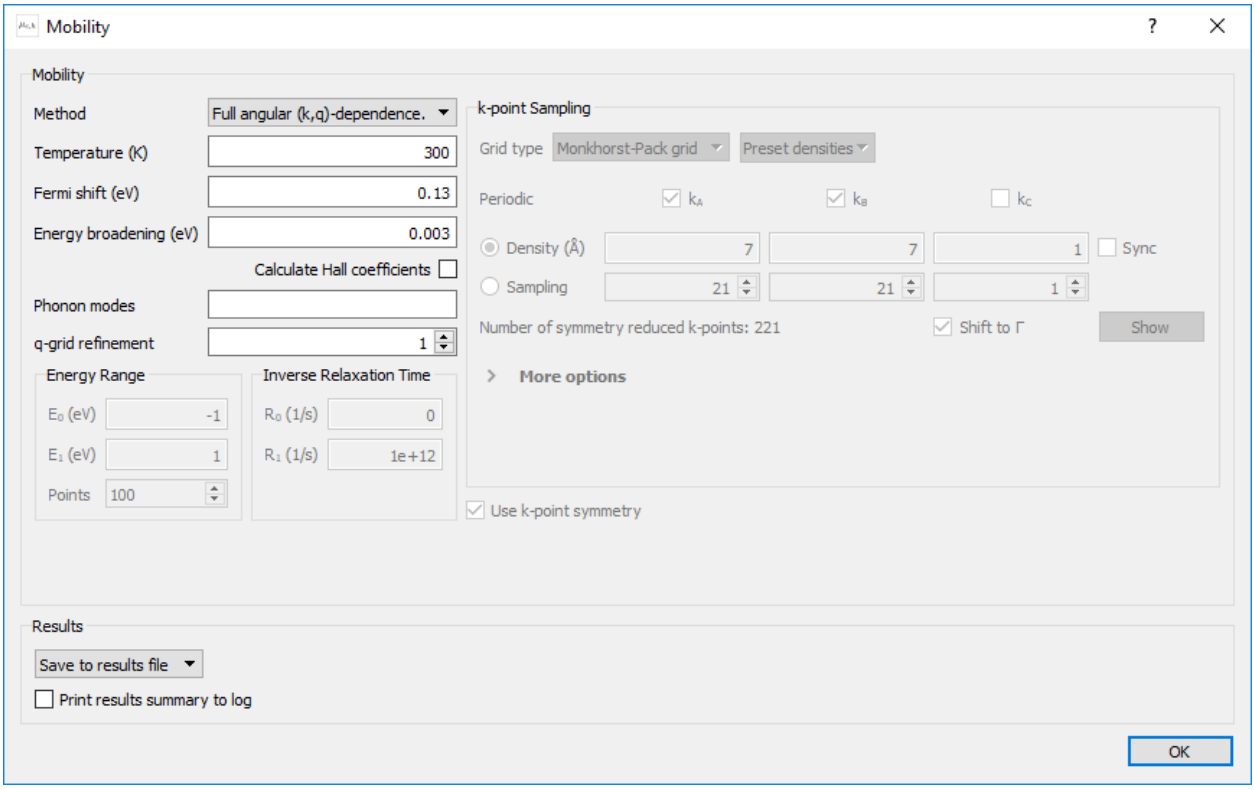
In the main panel of the **Script Generator**, set the **Results file** to `Graphene_mu-line-full.hdf5`, send the script to the **Job manager**,save it as `Graphene_mu-line-full.py` and click on the button to run the calculation. You will again see a warning that the script might be invalid, and you should ignore it this time as well.

Once the calculation is done, you are ready to calculate the mobility using the isotropic scattering rate method. In this case, you will re-use the bulk configuration and the full angular ($\mathbf{k}$, $\mathbf{q}$) -dependent mobility from the `Graphene_relax.hdf5` and `Graphene_mu-line-full.hdf5` files.

Go back to the **Script generator**, and open the *Custom → Code Snippet* block before the Mobility icon. Change the contents to:

```
mobility_full = nlread('Graphene_mu-line-full.hdf5', Mobility)[0]
```

Then modify the *Analysis → Mobility* block as follows:



- *Analysis* → *Mobility* $\mu_{e,h}$

–Set the **Method** to *Isotropic scattering rate*

–Set the **Fermi shift** to *0.13 eV*

–Untick *Calculate Hall coefficients*

–Set the following values of the **Energy Range**:

∗E_0 = -0.24 eV

∗E_0 = 0.24 eV

∗Points = 100

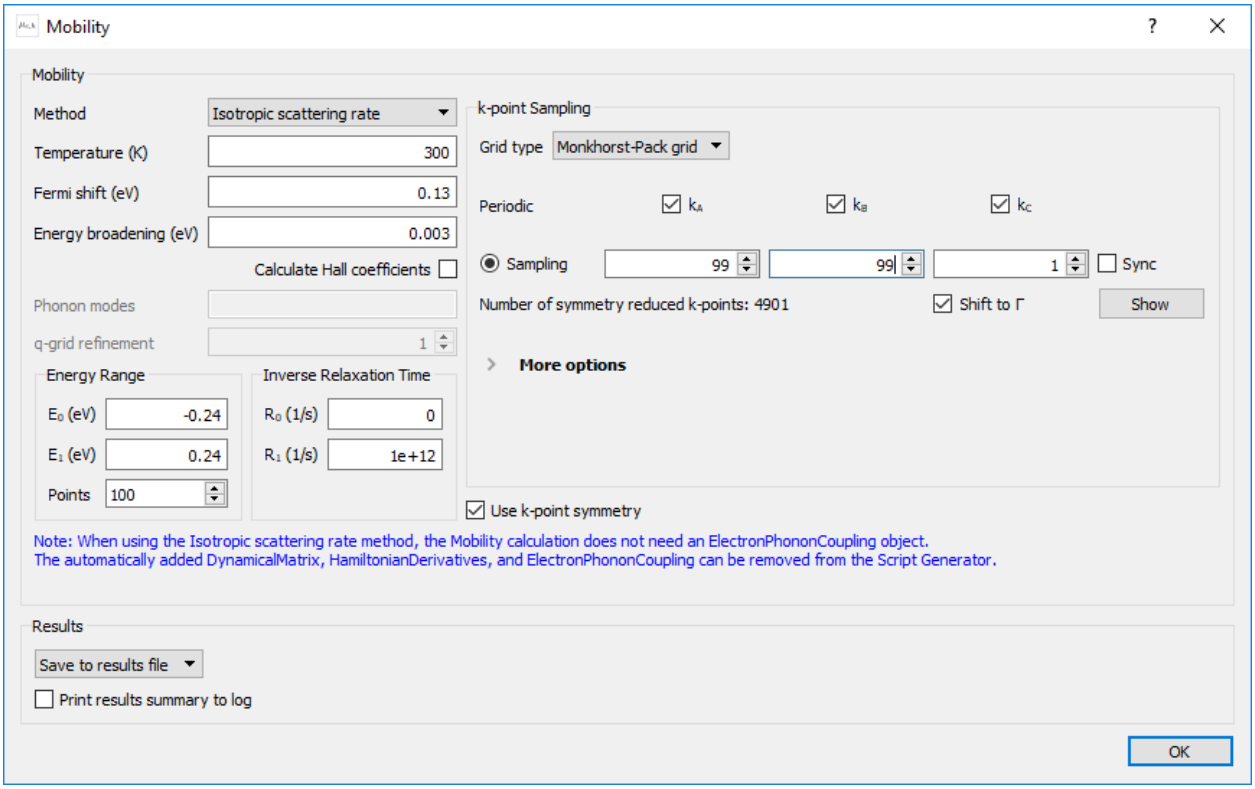
–Set the **k-point Sampling** to $99 \times 99 \times 1$

In the main panel of the **Script Generator**, set the **Results file** to `Graphene_mu-line-iso.hdf5`. Send the script to the **Editor**, change `mobility_object=None,` to `mobility_object=mobility_full,` and remove this line:

```
inverse_relaxation_time=numpy.linspace(0, 1e+12, 100)*Second**-1,
```

Send it to the **Job manager**, save it as `Graphene_mu-line-iso.py` and click on the button to run the calculation. This should take no more than a minute on a modern laptop.

Once the calculation is done, open the file `Graphene_mu-line-iso.hdf5`, select the $\mu_{e,h}$ **Mobility** object in the LabFloor and click on **Text Representation**.



```

```

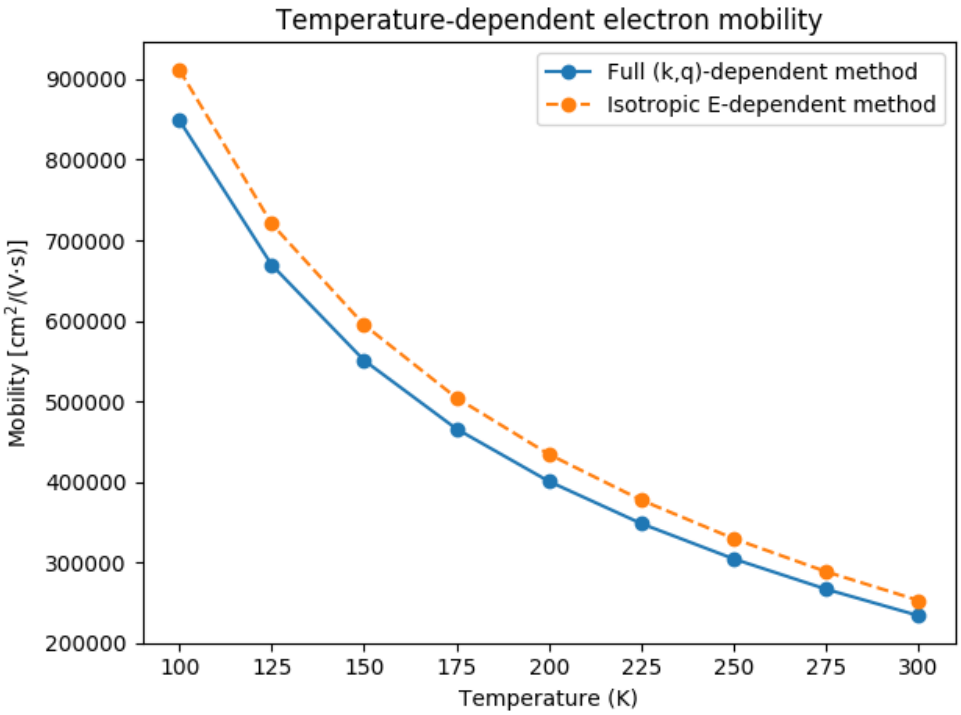
The calculated value for the electron mobility, highlighted in yellow above, is $2.53 \cdot 10^5$ $\mathrm{cm^2 V^{-1} s^{-1}}$, in good agreement with the value obtained by using the full $(\mathbf{k}, \mathbf{q})$ -dependent method.

Temperature dependence of the mobility: (k,q)-dependent method vs. energy-dependent method

A more stringent test for the reliability of the energy-dependent method is to calculate the temperature dependence of the mobility in an energy range up to room temperature.

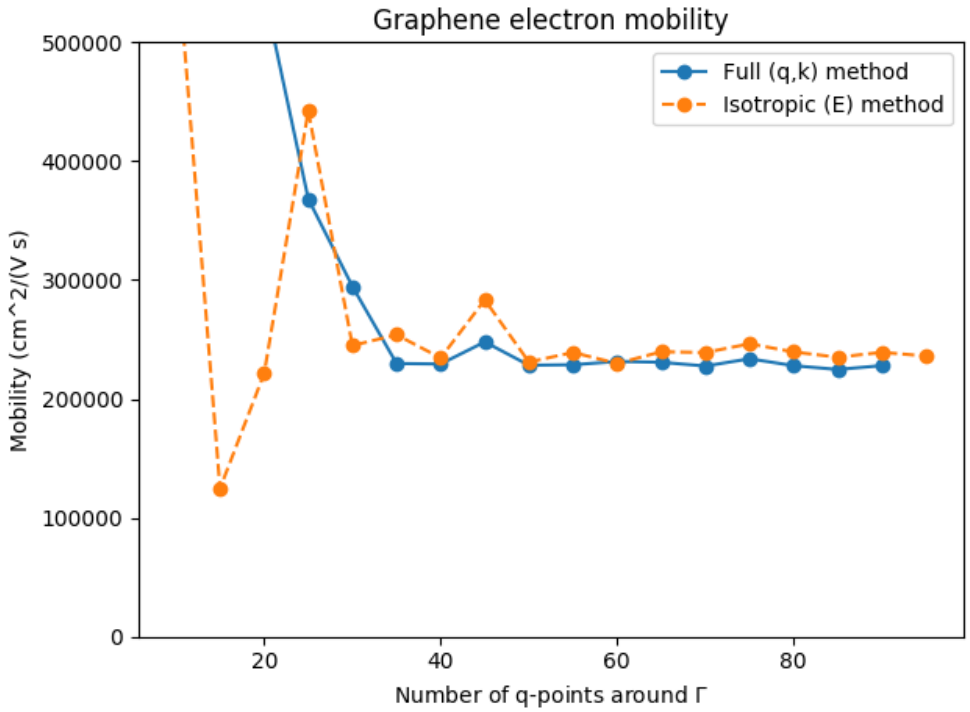
- In the **(k,q)-dependent method**, this can be done by simply modifying the value of the target temperature in the Mobility analysis object. `temperature_dependence_full_mobility.py`
- In the **energy-dependent method**, the two-step procedure must be repeated for each temperature, and the target temperature has to be set both when calculating the values of the $\mathbf{k}$- and $\mathbf{q}$-dependent relaxation times $\tau(\mathbf{k}, \mathbf{q})$ along the line, and when calculating the energy-dependent relaxation times $\tau(E)$. `temperature_dependence_isotropic_mobility.py`

As it can be seen from the figure below, where the T-dependency of μ is calculated in the temperature range $100\mathrm{K} \leq T \leq 300\mathrm{K}$, both methods reproduce well the expected $1/T$ behavior of μ. Script to create the plot: `plot_temperature_dependence_mobility.py`



Convergence of q- and k-point sampling

In order to select the appropriate samplings in $\mathbf{k}$- and $\mathbf{q}$-space, we first studied the mobility as a function of the number of $\mathbf{q}$-points, for a fixed sampling of $\mathbf{k}$-points:



We see that the mobility is reasonably converged for 50 $\mathbf{q}$-points and above. This corresponds to a density of at least 200 . We then study the mobility as a function of $\mathbf{k}$-points, and see that it converges very quickly in this case. We chose to use 20 k-points, corresponding to a density of about 160 .

Warning: This convergence study is only valid for this combination of system and computational settings. You should always study convergence for your system of interest and chosen computational model.

Theory section

The mobility μ is related to the conductivity σ via

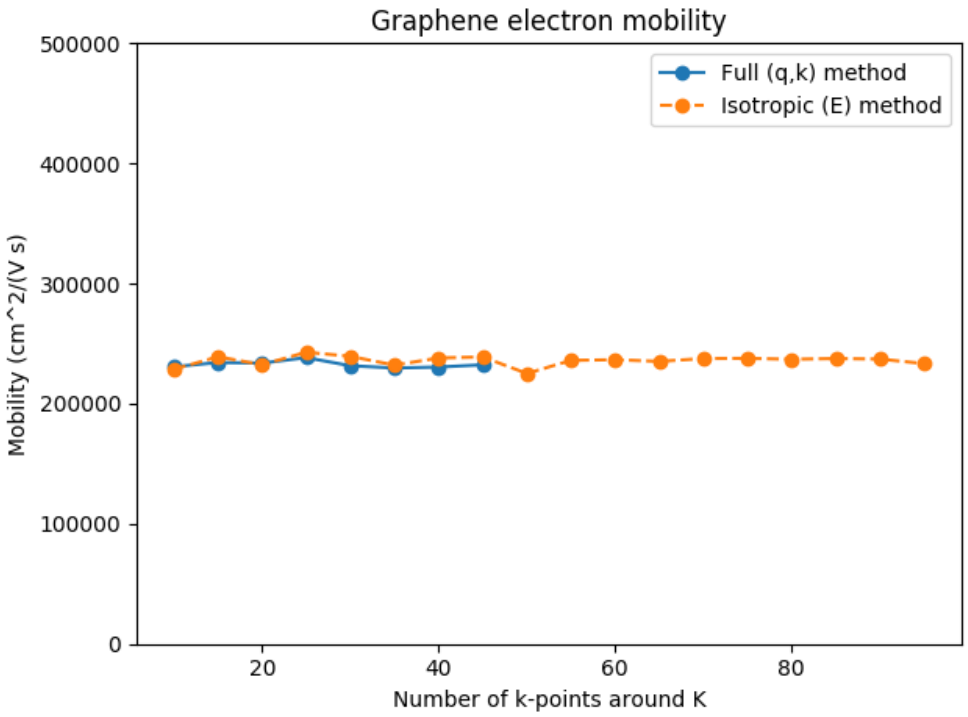
$$\mu = \frac{\sigma}{ne}, \tag{3.8}$$

where n is the carrier density, e is the electronic charge.

In this tutorial, you will calculate the conductivity using the semi-classical Boltzmann transport equation (BTE). In the case of zero magnetic field and a time-independent electric fields in the steady state limit the BTE simplifies to:

$$\frac{q\mathbf{E}}{\hbar} \cdot \nabla_{\mathbf{k}} f_{\mathbf{k}n} \approx \frac{q\mathbf{E}}{\hbar} \cdot \nabla_{\mathbf{k}} f^0_{\mathbf{k}n} = \left.\frac{\partial f_{\mathbf{k}n}}{\partial t}\right|_{coll} \tag{3.9}$$

The right hand side (RHS), often called the collision integral, describes different sources of scattering and dissipation that drives the system towards steady state. The left hand-side is approximated to linear order in the electric field by changing to the equilibrium distribution.



The electron-phonon scattering is described by the collision integral. Most commonly this is approximated by a relaxation time:

$$\left.\frac{\partial f_{\mathbf{k}n}}{\partial t}\right|_{coll} = \frac{\delta f_{\mathbf{k}n}}{\tau_{\mathbf{k}n}}$$

describing quasielastic scattering on acoustic phonons (relaxation time approximation). We let λ label the phonon modes, n the electronic bands, $\mathbf{k}$ the electron momentum. The transition rate from a state $|\mathbf{k}n\rangle$ to $|\mathbf{k}'n'\rangle$ is obtained from Fermis golden rule (FGR):

$$P^{\lambda nn'}_{\mathbf{k}\mathbf{k}'} = \frac{2\pi}{\hbar}|g^{\lambda nn'}_{\mathbf{k}\mathbf{k}'}|^2[n^{\lambda}_{\mathbf{q}}\delta\left(\epsilon_{\mathbf{k}'n'} - \epsilon_{\mathbf{k}n} - \hbar\omega_{q\lambda}\right)\delta_{\mathbf{k}',\mathbf{k}+\mathbf{q}}$$

$$+ (n^{\lambda}_{-\mathbf{q}} + 1)\delta\left(\epsilon_{\mathbf{k}'n'} - \epsilon_{\mathbf{k}n} + \hbar\omega_{-q\lambda}\right)\delta_{\mathbf{k}',\mathbf{k}-\mathbf{q}}],$$

where the first and last terms in the square brackets describes phonon absorption and emission, respectively. The electron-phonon coupling matrix elements $|g^{\lambda nn'}_{\mathbf{k}\mathbf{k}'}|$ are in **ATK** calculated using the **ElectronPhononCoupling** analysis module.

The general electron-phonon collision integral is given by

$$\left.\frac{\partial f_{\mathbf{k}n}}{\partial t}\right|_{coll} = -\sum_{\mathbf{k}'n'}\left[f_{\mathbf{k}n}\left(1 - f_{\mathbf{k}'n'}\right)P^{nn'}_{\mathbf{k}\mathbf{k}'} - f_{\mathbf{k}'n'}\left(1 - f_{\mathbf{k}n}\right)P^{n'n}_{\mathbf{k}'\mathbf{k}}\right] \tag{3.10}$$

Relaxation time approximation

In the relaxation-time approximation (RTA) one assumes a special simplified form of the RHS/collision integral:

$$\left.\frac{\partial f_{\mathbf{k}n}}{\partial t}\right|_{coll} = -\frac{\delta f_{\mathbf{k}n}}{\tau_{\mathbf{k}n}} \tag{3.11}$$

where $\delta f_{\mathbf{k}n} = f_{\mathbf{k}n} - f^0_{\mathbf{k}n}$. The linearized BTE becomes:

$$q\mathbf{E}\cdot\mathbf{v}_{\mathbf{k}n}\frac{\partial f^0_{\mathbf{k}n}}{\partial \epsilon_{\mathbf{k}n}} = -\frac{\delta f_{\mathbf{k}n}}{\tau_{\mathbf{k}n}}.$$

Hereby we find the solution:

$$\delta f_{\mathbf{k}n} = -q\mathbf{E}\cdot\mathbf{v}_{\mathbf{k}n}\frac{\partial f^0_{\mathbf{k}n}}{\partial \epsilon_{\mathbf{k}n}}\tau_{\mathbf{k}n}.$$

The relaxation-time can be evaluated from the general collision integral, (3.10). However, the specific form in eqn. (3.11) only applies in the limit of quasielastic scattering ($\omega_{q\lambda} \to 0$), in which case the collision integral, in eqn. (3.10), simplifies significantly:

$$\left.\frac{\partial f_{\mathbf{k}n}}{\partial t}\right|^{RTA}_{coll} = \sum_{\mathbf{k}'n'}\left(f_{\mathbf{k}'n'} - f_{\mathbf{k}n}\right)P^{nn'}_{\mathbf{k}\mathbf{k}'} \equiv -\frac{\delta f_{\mathbf{k}n}}{\tau_{\mathbf{k}n}},$$

since $P^{nn'}_{\mathbf{k}\mathbf{k}'} = P^{n'n}_{\mathbf{k}'\mathbf{k}}$ in this limit.

We then obtain the expression for the scattering rate or inverse relaxation-time:

$$\frac{1}{\tau_{\mathbf{k}n}} = \sum_{\mathbf{k}'n'}\left(1 - \frac{\delta f_{\mathbf{k}'n'}}{\delta f_{\mathbf{k}n}}\right)P^{nn'}_{\mathbf{k}\mathbf{k}'} \tag{3.12}$$

where we applied the detailed balance equation in this limit, $P^{nn'}_{\mathbf{k}\mathbf{k}'}(f^0_{\mathbf{k}'n'} - f^0_{\mathbf{k}n}) = 0$, and assumed isotropic scattering.

To evaluate the relaxation time we introduce the scattering angle

$$cos(\theta_{\mathbf{k}\mathbf{k}'}) = \frac{\mathbf{v}_{\mathbf{k}'n'}\cdot\mathbf{v}_{\mathbf{k}n}}{|\mathbf{v}_{\mathbf{k}'n'}||\mathbf{v}_{\mathbf{k}n}|}$$

where $\mathbf{v}_{\mathbf{k}n}$ is the electron velocity. Following[Page 434, 1] we obtain

$$\frac{1}{\tau_{\mathbf{k}n}} = \sum_{\mathbf{k}'n'}\frac{(1 - f^0_{\mathbf{k}'n'})}{(1 - f^0_{\mathbf{k}n})}\left(1 - cos(\theta_{\mathbf{k}\mathbf{k}'})\right)P^{nn'}_{\mathbf{k}\mathbf{k}'}$$

Mobility

Once knowing the relaxation times one obtain the mobility as:

$$\mu = -2q\frac{\sum_{\mathbf{k}n} v^2_{\mathbf{k}n}\frac{\partial f^0_{\mathbf{k}n}}{\partial \epsilon_{\mathbf{k}n}}\tau_{\mathbf{k}n}}{\sum_{\mathbf{k}n} f^0_{\mathbf{k}n}} \tag{3.13}$$

where the factor 2 accounts for spin degeneracy.

3.2.2 Effective mass of electrons in silicon

In this tutorial, you will learn how to compute the electron effective mass for silicon.

Introduction

It is well known that DFT methods, or to be more specific the LDA and GGA exchange-correlation functionals, are not very adept at predicing the band gap of semiconductors. They do, however, in many cases give rather accurate curvatures of the bands. We can use this to compute the effective mass of holes and electrons by fitting a parabola to the minimum/maximum of the conduction/valence bands.

The effective mass is a parameter that depends on several assumptions and definitions, so it will be important to properly understand the underlying concept, instead of just using it as a black box. For other materials, these assumptions may be different!

Background

The lowest conduction band of Si has 6 equivalent minima, located along (101) (called Δ) and its permuted equivalent directions in reciprocal space. The minimum is located at (x,0,x) where x is about 0.425, or 85% of the distance to the first Brillouin zone boundary at X=(1/2,0,1/2). At this point, the energy isosurfaces are ellipsoids, thus you get different values for the effective mass depending on if you look in the longitudinal (along) or transverse (perpendicular to Δ) directions. See Refs.[1] and[2] for more details.

By (1/2,0,1/2) we mean a k-vector $K = (\mathbf{G}_A + \mathbf{G}_C)/2$, where $\mathbf{G}_A$, $\mathbf{G}_B$, $\mathbf{G}_C$ are the three unit vectors that span the reciprocal unit cell. If we express this point in Cartesian coordinates (still in reciprocal space) we find that the Δ direction is parallel to $\mathbf{K}_Y$. Obviously then, $\mathbf{K}_X$ and $\mathbf{K}_Z$, which are parallel to $\mathbf{G}_B + \mathbf{G}_C$ and $\mathbf{G}_A + \mathbf{G}_B$, respectively, are perpendicular to $\mathbf{K}_Y$. Thus the transverse directions are (011) and (110), and the longitudinal one is (101) - see the figure below illustrating the Brillouin zone of silicon.

What we now need to do is:

1. generate a sequence of points k around a specified point k_0, in a given direction;
2. compute the energy eigenvalues $E(k)$ for the lowest conduction band for these k-points;
3. perform a numerical (finite difference) second order derivative of the band, $d = \partial^2 E(k)/\partial k|_{k=k_0}$;
4. compute the effective mass as $m^* = \hbar^2/(2d)\, m_e$ where m_e is the free electron mass.

If we do this for the longtitudinal (L) and transverse (T) directions, we will obtain three values, m^*_L, m^*_{T1}, and m^*_{T2} (actually, for Si $m^*_{T1} = m^*_{T2} = m^*_T$), which we can insert in the well-known expressions for the conductivity and density of states effective masses:

$$m^*_C = 3/(1/m^*_L + 2/m^*_T)$$
$$m^*_{DOS} = 6^{2/3}(m^*_L (m^*_T)^2)^{1/3}$$

where the factor 6 which enters the expression for the conductivity mass is the number of equivalent Δ valleys.

[2] http://www.iue.tuwien.ac.at/phd/dhar/node18.html

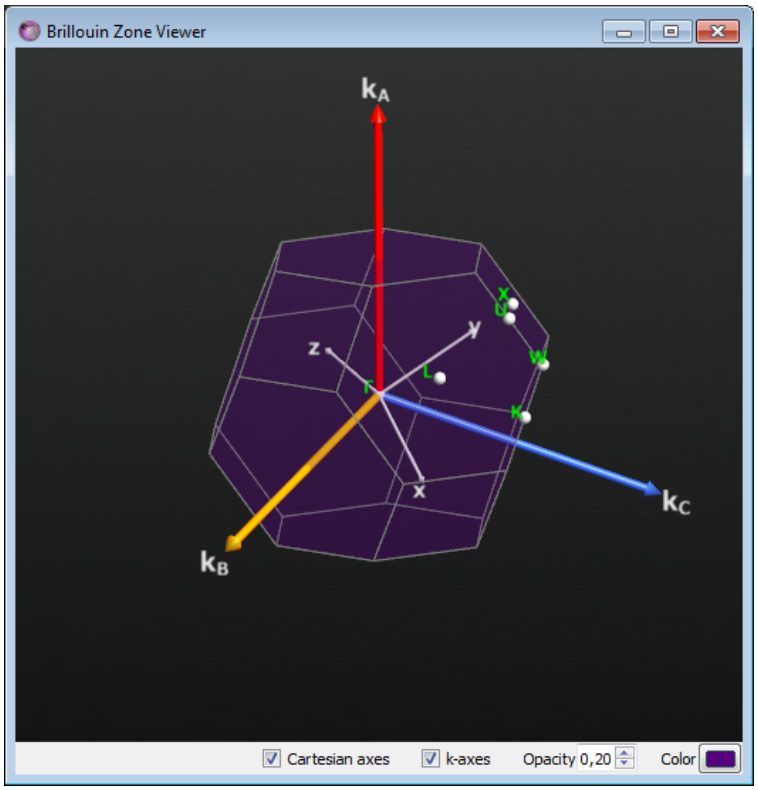

Fig. 3.19: Brillouin zone of silicon. In the **Builder** use *Bulk Tools* → *Brillouin Zone Viewer* to visualize the Brillouin zone, fractional- and Cartesian directions and the high-symmetry points.

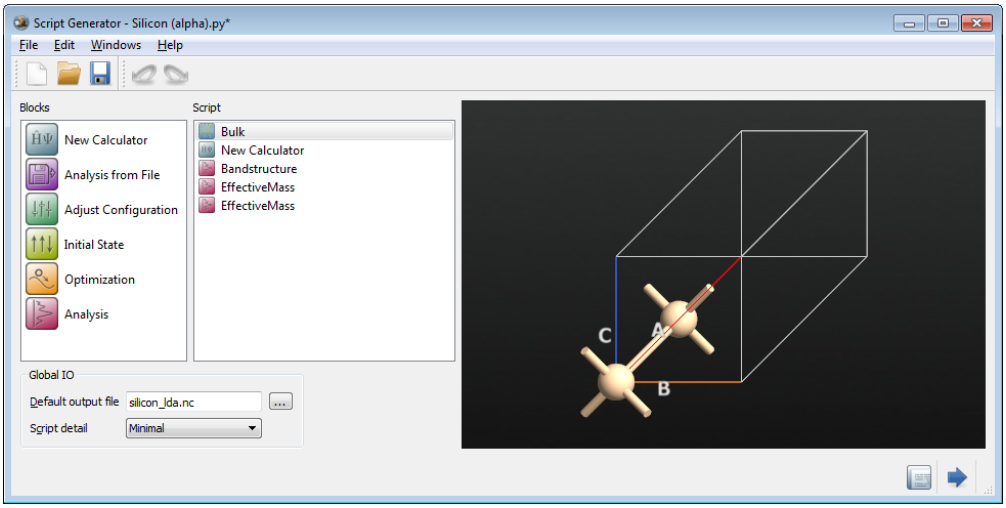
Set up the calculation

The first step is to do a self-consistent DFT calculation for Si.

The details involved in such a task are described in the *Calculate the band structure of a crystal*. There, the extended Hückel method was used, so you should modify the calculator to use **ATK-DFT** instead. Note that by default the LDA exchange correlation functional is used and you just need to specify a proper k-point mesh, i.e. 15x15x15.

Before saving and running your DFT calculation, you can set up the effective mass analysis directly from the Scripter. Add *Analysis* → *EffectiveMass* analysis after the calculator:

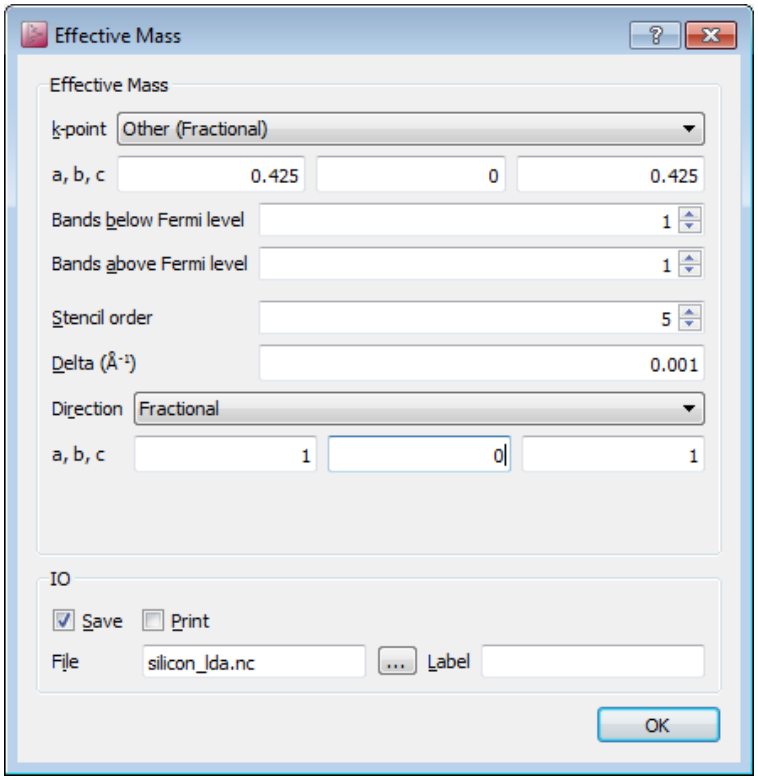


Double-click on EffectiveMass to set up the effective mass calculation. Here, you have several options and you can find all the details for each of these options in the `EffectiveMass`.

In order to calculate the effective mass at the conduction mass minimum enter the following parameters:

- Change the k-point to Other (Fractional) and use the [0.425, 0, 0.425] coordinates.
- Select one band above the Fermi level (conduction band only) and one band below the Fermi level. However, feel free to select as many bands as you wish!
- As you will see later they will be conveniently listed in the LabFloor. Only remember that the effective masses calculated for all these bands correspond to the specified [0.425, 0, 0.425] point.
- Set the Direction to **Fractional** and set a=1, b=0, c=1, corresponding to the longitudinal direction, c.f. *Background*.
- Leave all the other default parameters.
- Add a second EffectiveMass analysis object with the same settings, except the direction which should be a=1, b=1, c=0, corresponding to one of the transverse directions.

Finally, set the output filename, `silicon_lda.hdf5` for example, save and run the script. The job will take just a few seconds.



Analyze the results

Bandstructure

You will now find the Bandstructure and EffectiveMass objects in the LabFloor. Lets first check the bandstructure: double-click on it and use the Bandstructure Analyzer tool to plot it.

Inspecting the bandstructure its clear that the band gap is severly underestimated, but the shape is essentially correct; the gap is indirect and we do have a conduction band minimum at about 85% of the distance to X.

Effective mass 1

Select one of the **EffectiveMass** object from the LabFoor and use the **Effective mass analyzer** to inspect it:

The **Effective mass analyzer** window will then open:

Here, the effective mass corresponding to the specified band and direction is reported. From the two **EffectiveMass** objects you will obtain:

- Longitudinal effective mass, [1,0,1] direction, $m^* = 0.90\, m_e$.
- Transverse effective mass, [1,1,0] direction, $m^* = 0.187\, m_e$.

With these values we can now compute the density of states mass $m^*_{DOS} = 1.05$ and $m^*_C = 0.26$, very close indeed to the reference values 1.08 and 0.26 (see e.g. http://ecee.colorado.edu/~bart/book/effmass.htm). Thus DFT actually does reproduce the effective mass of the electrons in the Δ valley very well.

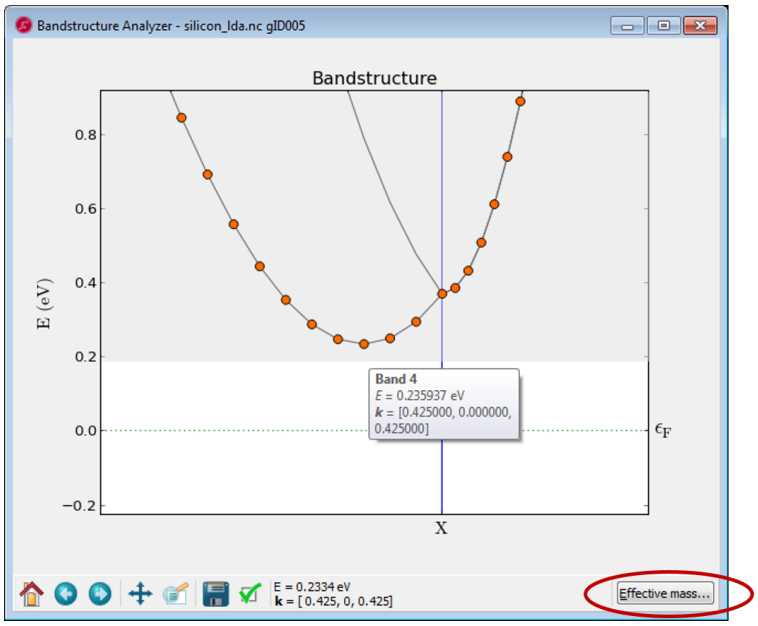
Effective mass 2

You may have noticed at the bottom right corner of the **Bandstructure analyzer** window the **Effective mass** button. You do have indeed a second interactive tool at your disposal to calculate the effective masses.

This is a very convenient tool since you can select the k-point for which the effective mass will be calculated directly from the plot:

•zoom in in the desired region of the plot and left-click to the desired point



•Click on Effective mass to open the effective mass tool:

Here, all the relevant parameters such as bandindex and k-point coordinates corresponding to the clicked point will be automatically set. Note that you can change and refine these parameters.

•Press Calculate to calculate the effective mass.

•Check on the LabFloor where the Effective Mass object is stored and follow the steps above to get the effective mass.

The effective mass tools contain a couple of additional parameters which we have not mentioned.

•Stencil order: it is possible to select the number of k-points that will be used to generate the band structure for which we perform the numerical derivative.

•Delta: this parameter controls how far away from the chosen k-point we go. The default is typically fine; if the band structure is strongly non-parabolic, the value can be decreased a bit perhaps.

Calculate

Going further

You can now also try the same calculation with the extended Hückel method.

If you followed the *Calculate the band structure of a crystal* you already have the necessary HDF5 file. The band minimum is not at x=0.452 this time, but closer to x=0.445. The results are very similar, however ($m_L^* = 1.00$ and $m_T^* = 0.17$).

Hole masses in Si

For Si, we compute a light hole mass (at the point [0,0,0]) $m_{LH}^* = -0.16$ (band index=1), and for the two degenerate heavy hole bands the result is $m_{HH}^* = -0.25$ (band indices 2 and 3, respectively). These values are obtained in the directions of the Cartesian axes (i.e. if we use the same directions as for the electron, along Δ from Γ to X). If, however, we look in the Λ direction from Γ to L (by setting the direction in the Analyzer to [1,1,1]), we find $m_{HH}^* = -0.64$ and $m_{LH}^* = -0.09$, a result of fact that the constant-energy surfaces for holes are strongly warped in Si, especially for the heavy hole bands[Page 457, 1Page 457, 2].

To get proper hole masses that can be compared to experiments one should however also include spin-orbit interaction.

References

3.2.3 Spin-orbit splitting of semiconductor band structures

The spin-orbit coupling (SOC) is a relativistic effect that causes splitting of the electronic bands in many materials, including semiconductors. This effect is not included in standard calculations.

In this tutorial, you will learn how to take spin-orbit coupling into account in density functional theory calculations (ATK-DFT) and also in semi-empirical Slater-Koster calculations (ATK-SE) for semiconductors.

Outline

- We start off with a short introduction to relativistic effetcs in electronic structure theory, including spin-orbit coupling.
- You will then use ATK-DFT to study how the SOC splits the electronic bands of Silicon around the Γ-point, leading to the so-called split-off valence band and bands with heavy and light holes.
- You will then employ a SO+MGGA method to get not only the correct band splits but also a reliable estimate of the indirect band gap.
- Lastly, you will consider the gallium-arsenide crystal, and use the Slater–Koster method with SOC parameters to compute the GaAs band structure.

Relavistic effects in Kohn-Sham DFT

The standard time-independent Kohn-Sham Hamiltonian describes *non-relativistic* electrons moving in an external field set up by atomic nuclei (and possibly any other external time-independent fields). Relavistic effects are therefore completely disregarded. This is usually a very good approximation for valence electrons outside the atomic cores, but for heavy elements, like gold and lead, relativistic contributions to the electronic structure can be crucial. Moreover, **spin-orbit coupling**, which cannot be captured in a strictly non-relativistic description, will often break degeneracy in solid band dispersions, and thereby lead to experimentally observed band splittings.

Electronic-structure software employing pseudopotentials, like the ATK-DFT engine does, will usually incorporate relativistic effects on core electrons in an approximate manner by using scalar-relativistic pseudopotentials. This is a computationally efficient and quite reliable approach.

However, calculations including spin-orbit coupling require fully relativistic pseudopotentials and a **noncollinear** representation of the electronic spin degrees of freedom. This can be computationally intense, but is mandatory if relativistic effects on the electronic ground state are to be taken fully into account.

Silicon band splitting with ATK-DFT

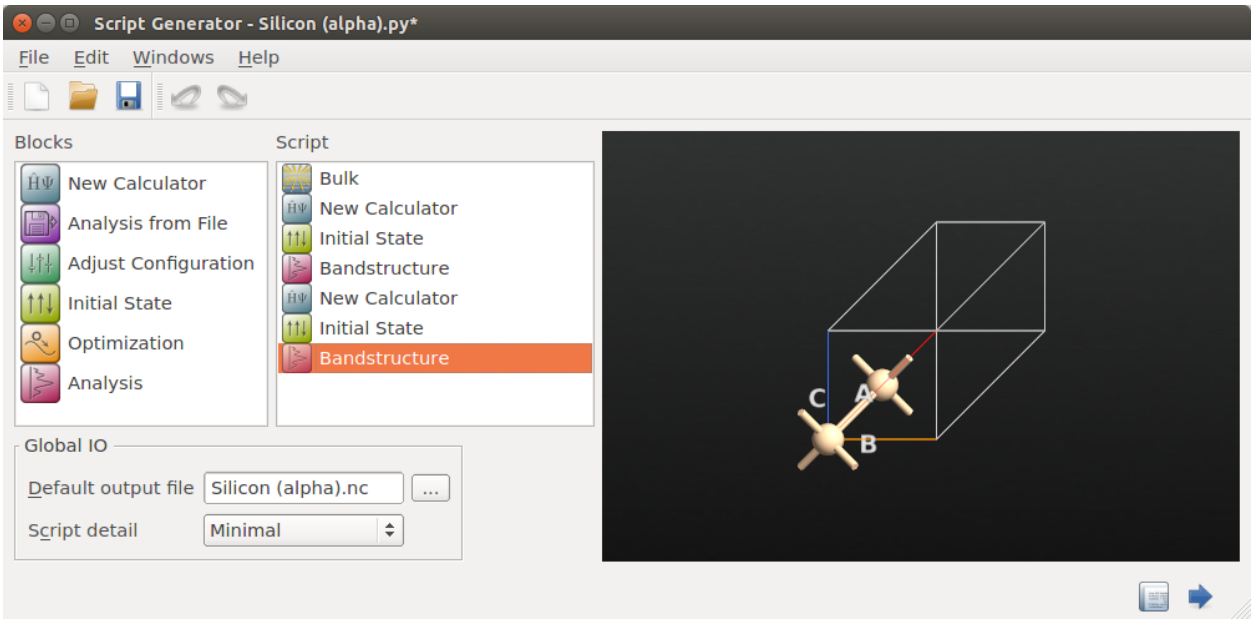
You will now use ATK-DFT to calculate the LDA bandstructure of silicon with and without spin-orbit coupling.

Note: Spin-orbit DFT calculations are more expensive than standard LDA or GGA methods and will often require more SCF iterations to converge. Usually, it is therefore more efficient to first do a spin-polarized ground state calculation, and then use this state as an initial guess for the spin-orbit DFT calculation. This procedure reduces the number of spin-orbit SCF steps and significantly reduces the overall computational time.

Warning: Not all pseudopotentials can be used for spin-orbit DFT calculations. The OMX potentials supplied with QuantumATK contain the required SO terms, while the FHI potentials do not.

Hint: Please remember that OMX pseudopotentials have in general more valence electrons in the cores than the FHI potentials do. Therefore, the OMX potentials usually require good basis sets and higher density-mesh cutoff energies (e.g. 200 Hartree).

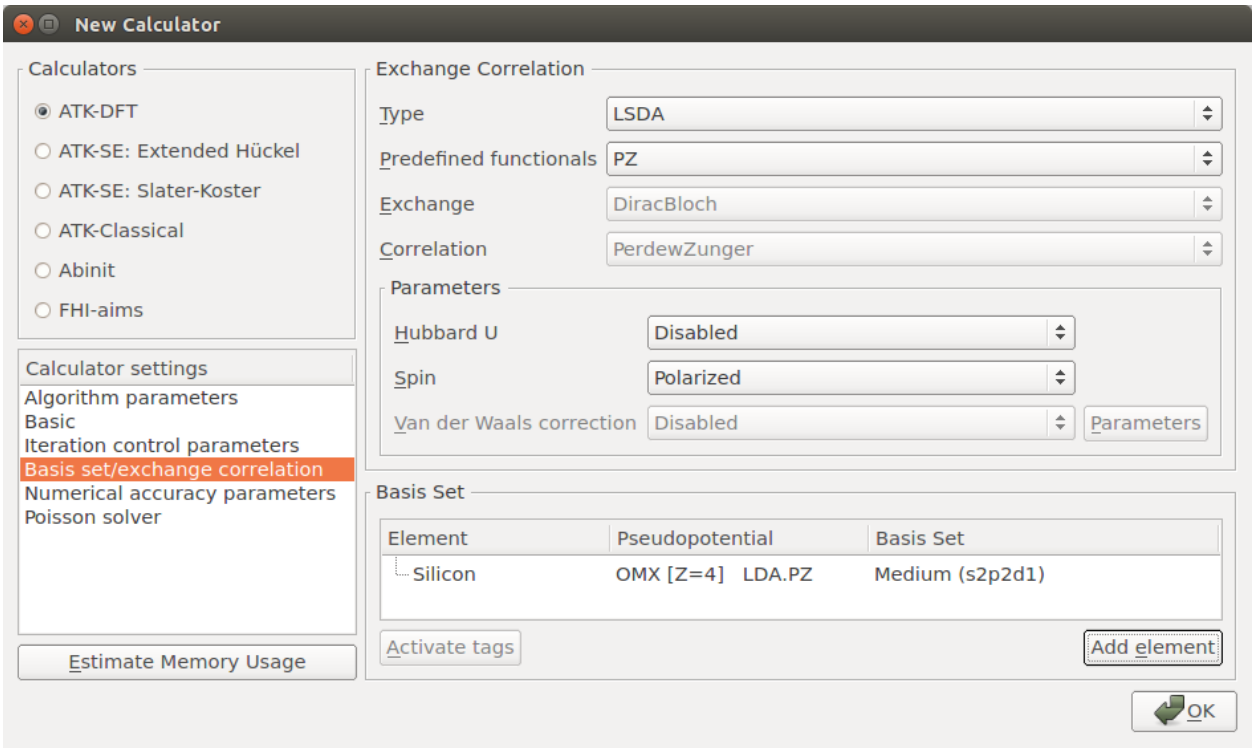
- Use the **Builder** to set up the silicon crystal with the default (experimental) lattice constant.
- Send the bulk configuration to the **Script Generator** and add two sets of the following three blocks: New Calculator, Initial State, and Bandstructure.



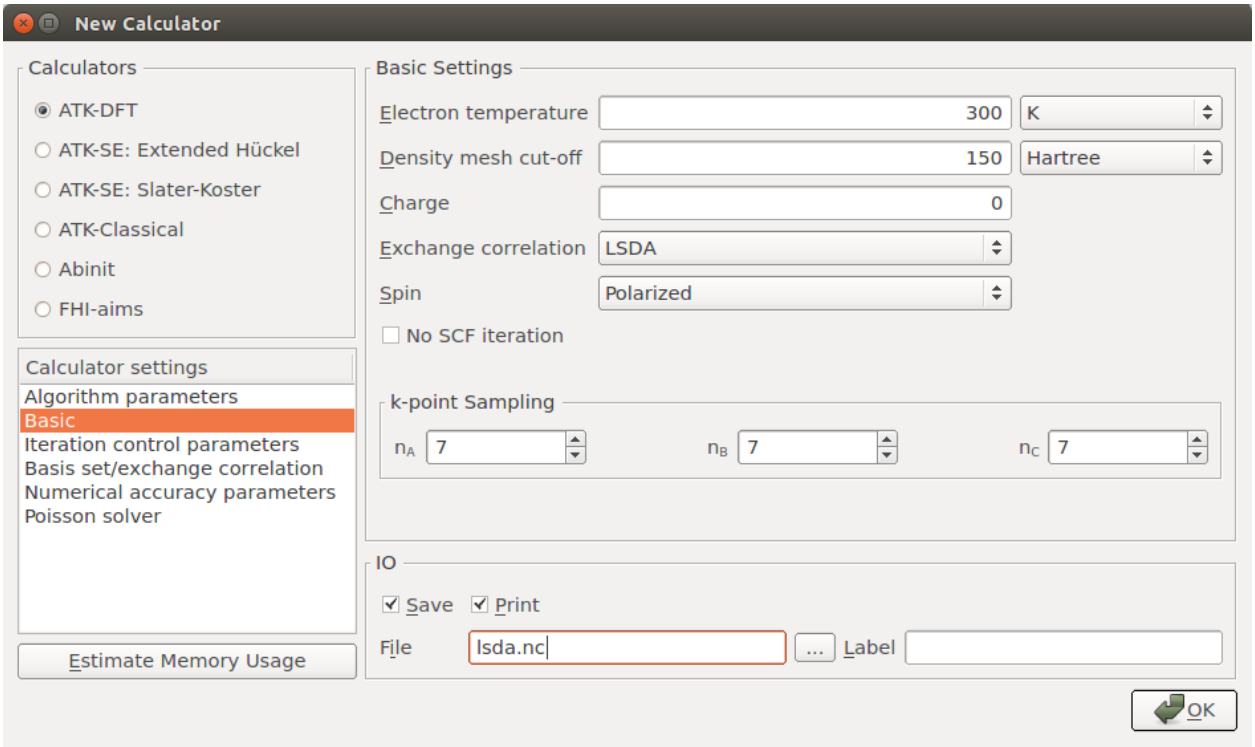
LSDA initial guess for the ground state

•Double-click the first New Calculator block, and make the following changes to it:

–Select the OMX pseudopotential with 4 valence electrons, and use the Medium accuracy basis set:



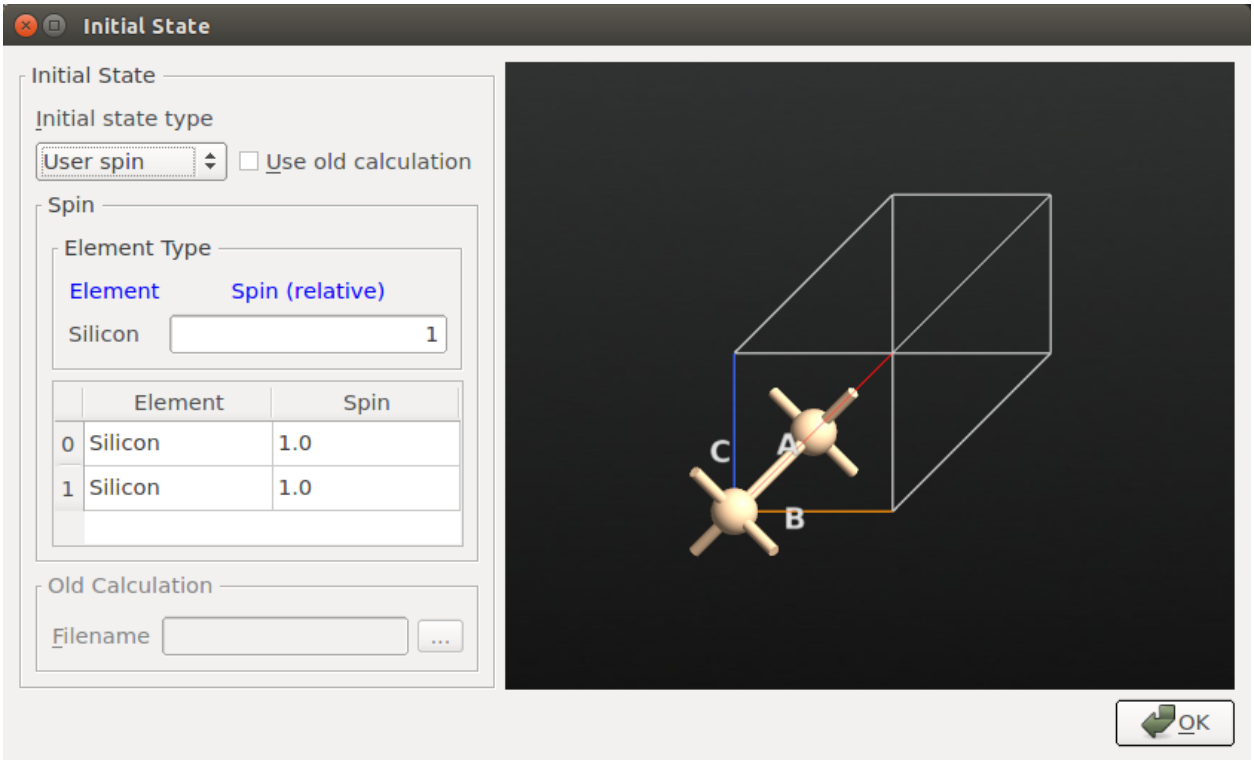
–In the Basic calculator settings, increase the density-mesh cutoff to 150 Hartree, select Polarized spin, set up a 7x7x7 k-point grid, and use `lsda.nc` as output file:



–Click OK to close the widget.

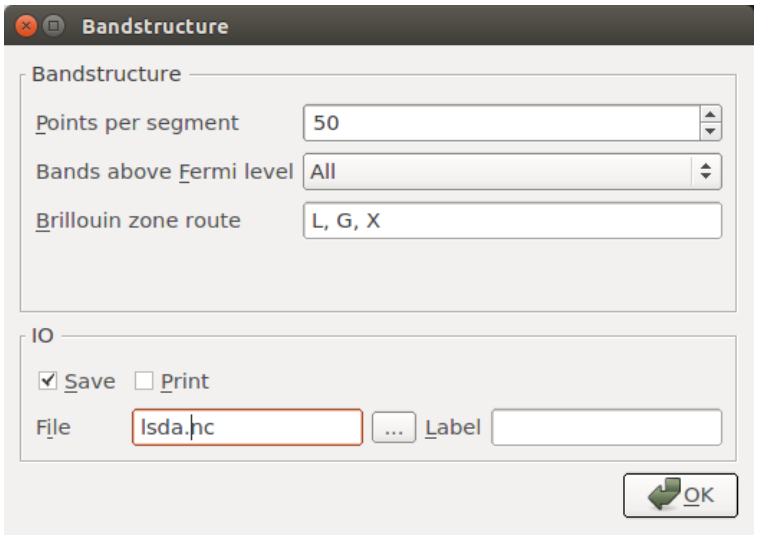
•Double-click the first Initial State block, and set up an initial guess for spin polarization of the silicon crystal:

–Change Initial state type to User spin. Then click OK.



Note: This defines a non-zero initial guess for the silicon polarization, even though we know that silicon is not magnetic. Indeed, we will find that it is not, because the self-consistent polarization will be close to zero. However, a self-consist LSDA calculation is usually a good starting point for noncollinear calculation, with or withour spin-orbit.

•Edit the first Bandstructure block, such that it maps out the $L-\Gamma-X$ path with 50 points per segment, and saves the data in the `lsda.nc` file:



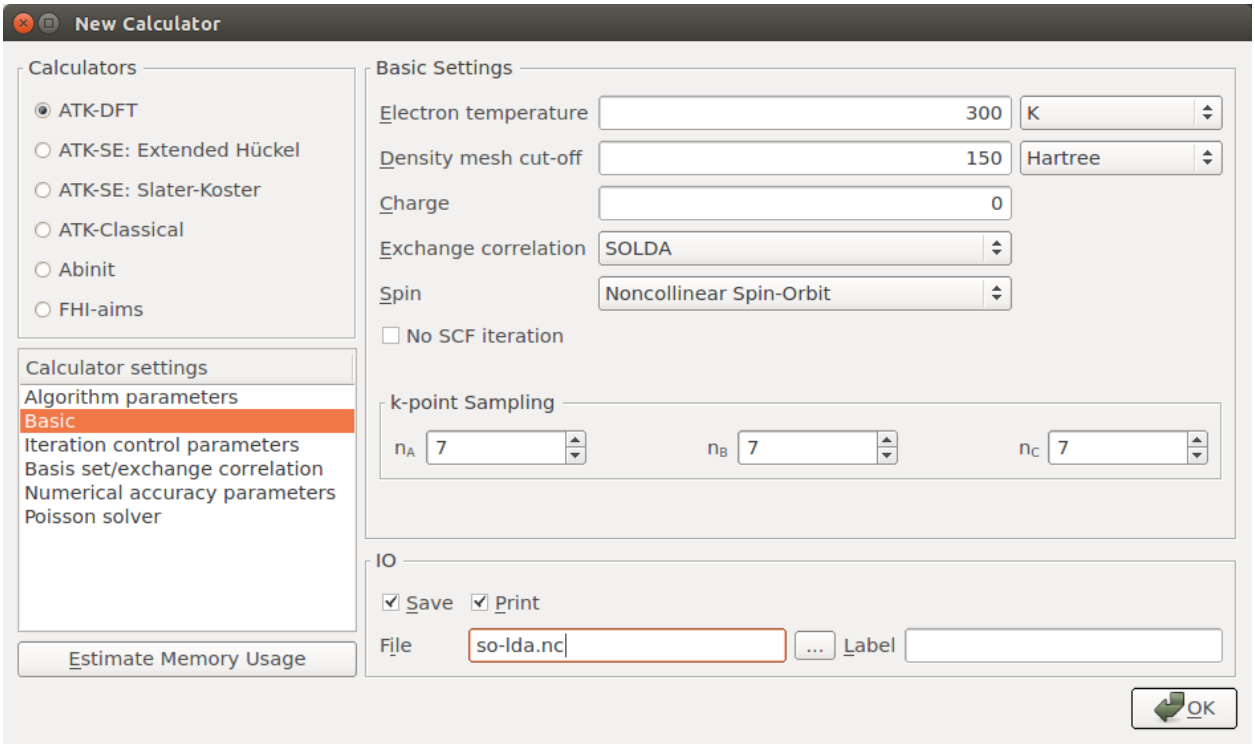
•That fully defines the LSDA ground state calculation followed by a band structure analysis.

SOLDA calculation

Next, you will set up a similar workflow for SOLDA calculations, but use the LSDA ground state as an initial guess for the SOLDA ground state.

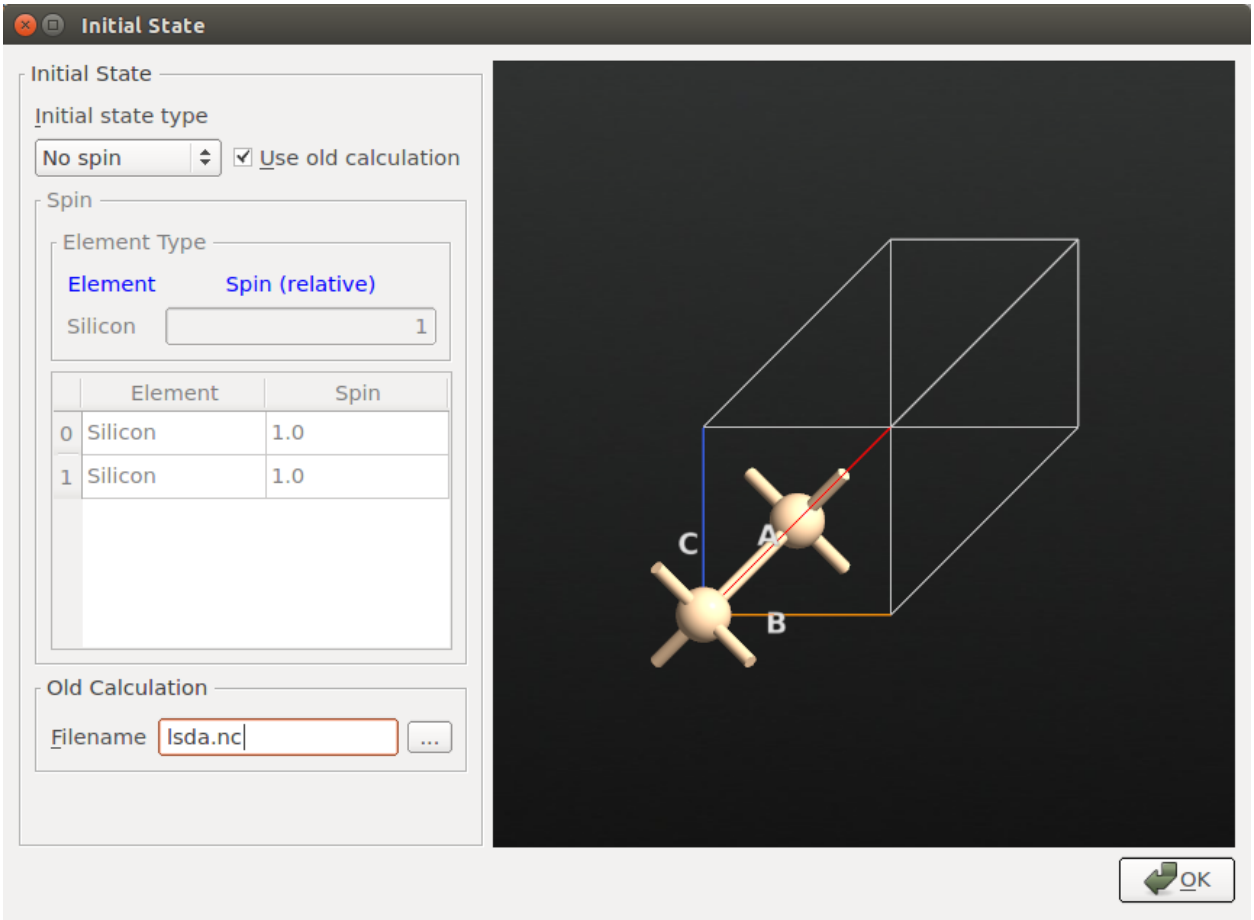
•Modify the second New Calculator block such that it is similar to the first one, but choose the Noncollinear Spin-Orbit spin option and save the results in `so-lda.nc`.

Hint: Remember to also choose the correct basis set and pseudopotential.

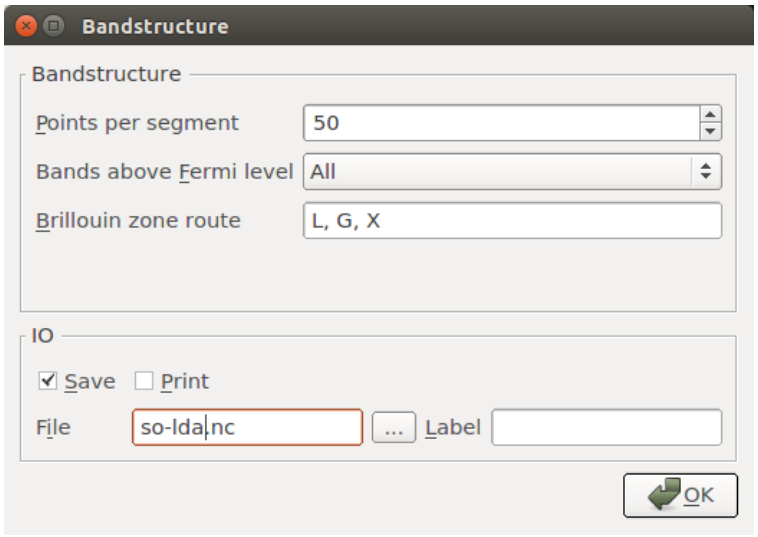


•In the second Initial State block, select Use old calculation and point to `lsda.nc` as the file from where to read the initial state:

Warning: If you use a non-polarized calculation as initial state for the spin-orbit calculation, you should set the initial spin to zero.

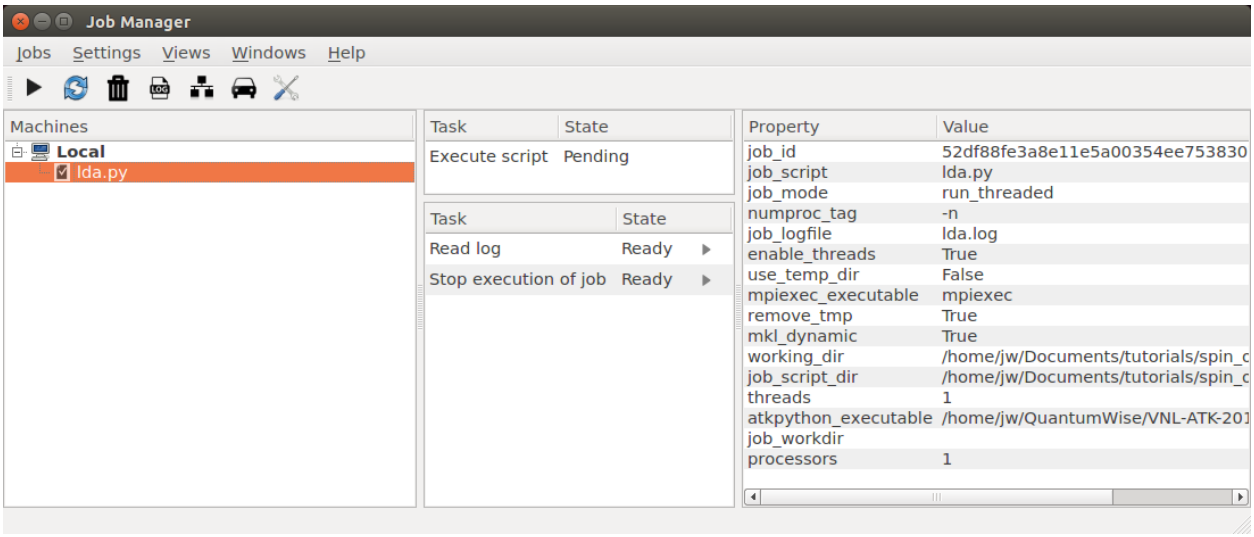


•Set up the last Bandstructure block similarly to the first one, and save the results in `so-lda.nc`:

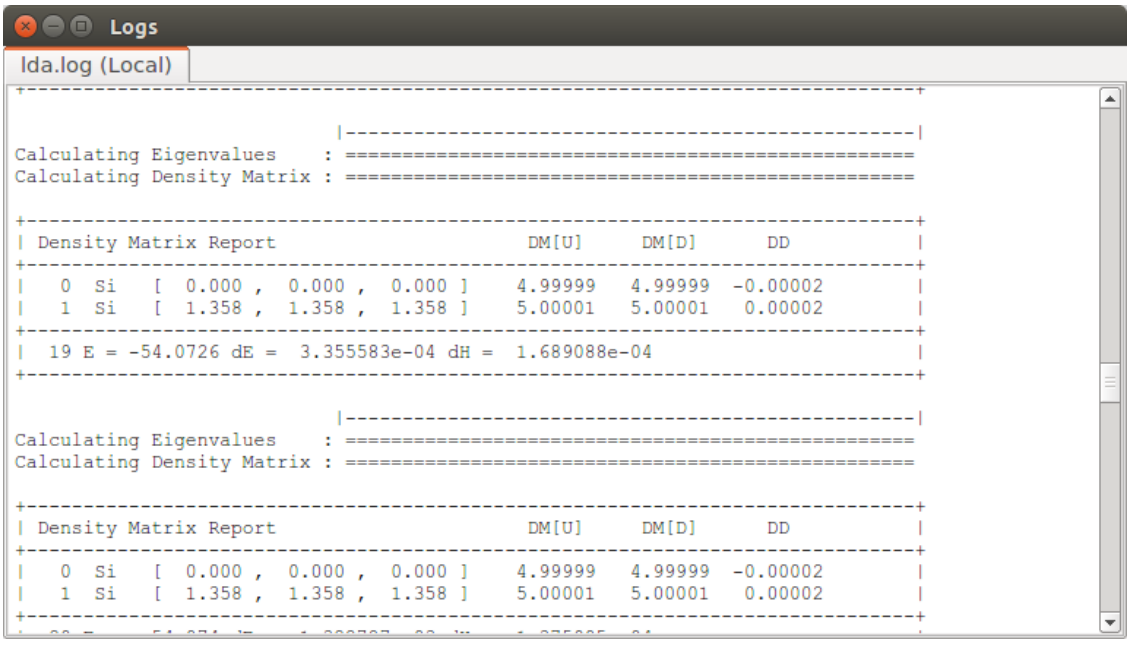


The ATK-DFT script is now done. It can also be downloaded from here: `lda.py`.

Send the script to the **Job Manager** , save it as `lda.py`, and run it in serial on your local machine. It should take only a few minutes to finish.

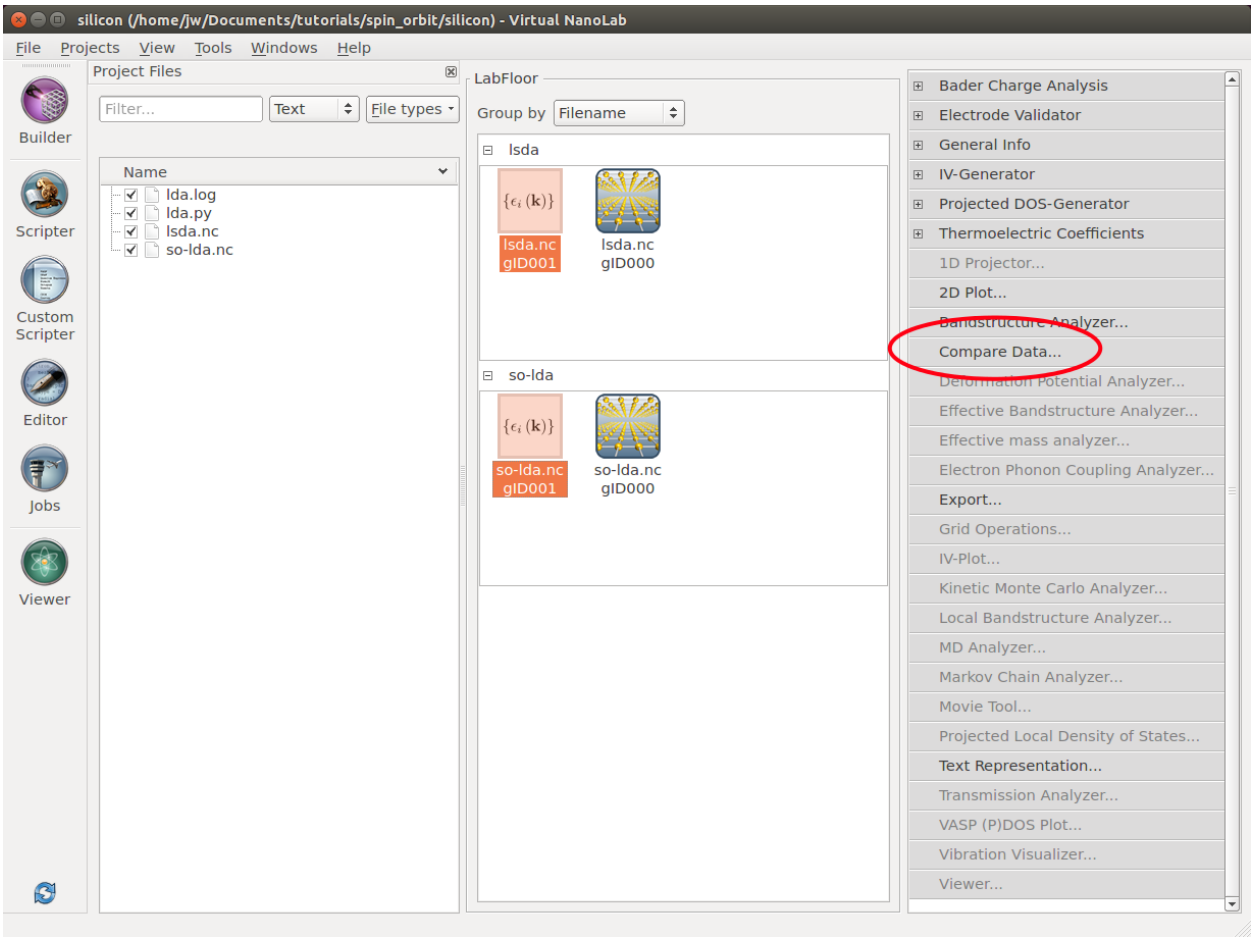


You should be able to monitor the progress of the job while it is running:



Results

Once the results have appeared on the **LabFloor**, highlight the two bandstructure objects and use the **Compare Data** plugin to directly visualize the LSDA and SO+LDA band structures in the same plot:



Several observations can be made:

- As expected, the LSDA spin-up and spin-down bands are identical (blue lines).
- At first sight, SO+LDA and LSDA bands appear indistinguishable. In particular, they both yield and indirect band gap of around 0.5 eV.
- However, if you zoom in around the highest valence bands at the Γ-point (see below), the SO coupling has partly lifted the degeneracy of those bands by splitting them:
  - The top band has split into two bands, corresponding to heavy and light holes.
  - The third band is now separated from the two others by the so-called split-off energy, experimentally measured to be 42.6 meV[1]. With SO+LDA we find 44 meV.

[1] Zhiyi Yu, YXăHuang, and SCăShen. Spin-orbit splitting of the valence bands in silicon determined by means of high-resolution photoconductive spectroscopy. *Physical Review B*, 39(9):6287, 1989.

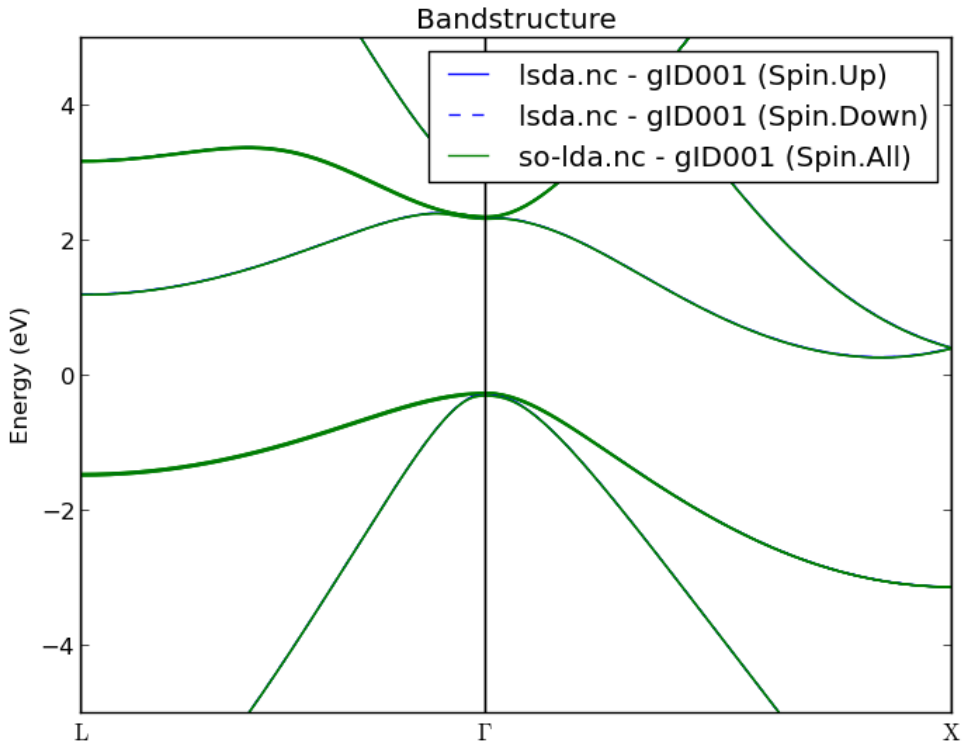


Fig. 3.20: Comparison of the LSDA (blue) and SOLDA (green) band structures of silicon.

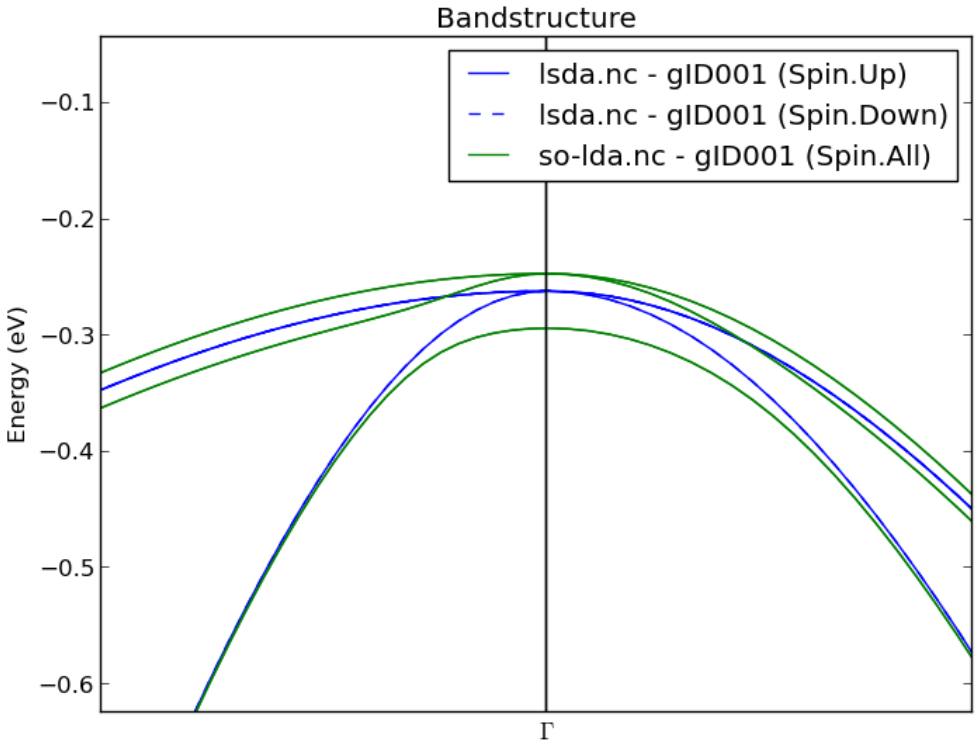

Fig. 3.21: Valence-band top at the silicon Γ-point calculated with LSDA (blue) and SOLDA (green). The latter leads to significant spin-orbit splitting of the bands, and predicts a split-off energy of 44 meV.

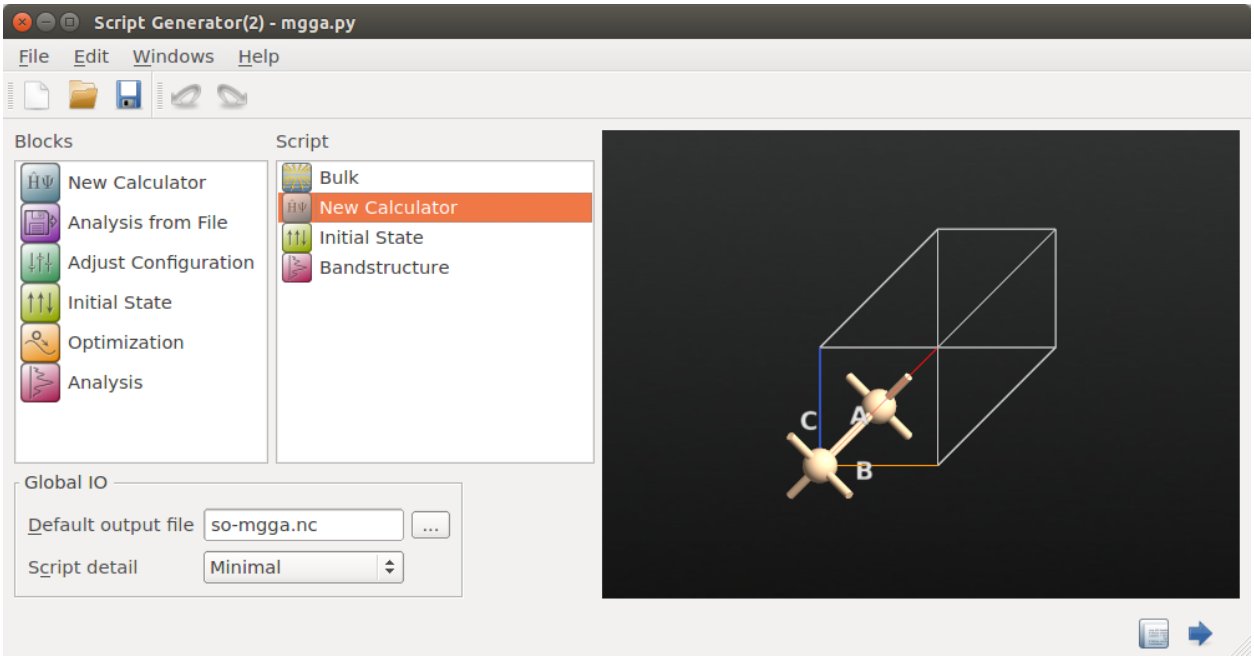
SO+MGGA band gap

The band splitting obtained above with the SO+LDA method is in very good agreement with the experimental splitting (42.6 meVPage 473, 1) However, the band gap is less than half of the experimental value (1.12 eV).

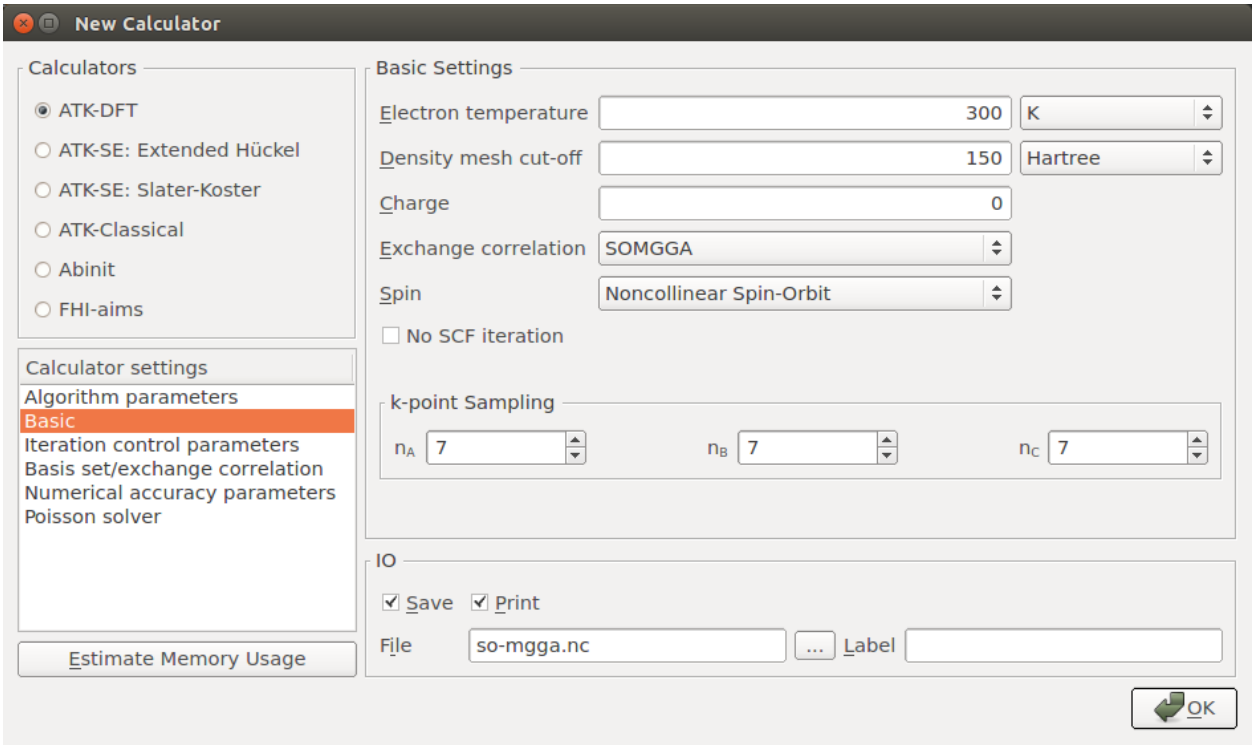
This is largely remedied by applying the TB09LDA method, which employs a meta-GGA exchange-correlation potential and gives remarkably accurate band gaps for semiconductors[2]. We should therefore expect the SO+MGGA method to accurately predict band splittings as well as band gaps.

- Go back to the **Script Generator** and delete the first set of three blocks from the script.
- Change the exchange correlation functional to SOMGGA and use `so-mgga.nc` as output.
- Make sure that the Initial State block reads in the ground state from `lsda.nc`, and that the Bandstructure analysis block saves its output in `so-mgga.nc`.
- Save the script as `mgga.py`. You can also download it if needed: `mgga.py`.
- Run the job – it may take 5-10 minutes to finish if run in serial. This can be reduced to 3 minutes if the job is run in parallel with 4 MPI processes.

Tip: The scf convergence can for small bulk systems be speed-up by increasing the damping factor to 0.5 in the iteration control parameters setup.



[2] F.ăTran and P.ăBlaha. Accurate band gaps of semiconductors and insulators with a semilocal exchange-correlation potential. *Phys. Rev. Lett.*, 102:226401, 2009. doi:10.1103/PhysRevLett.102.226401.



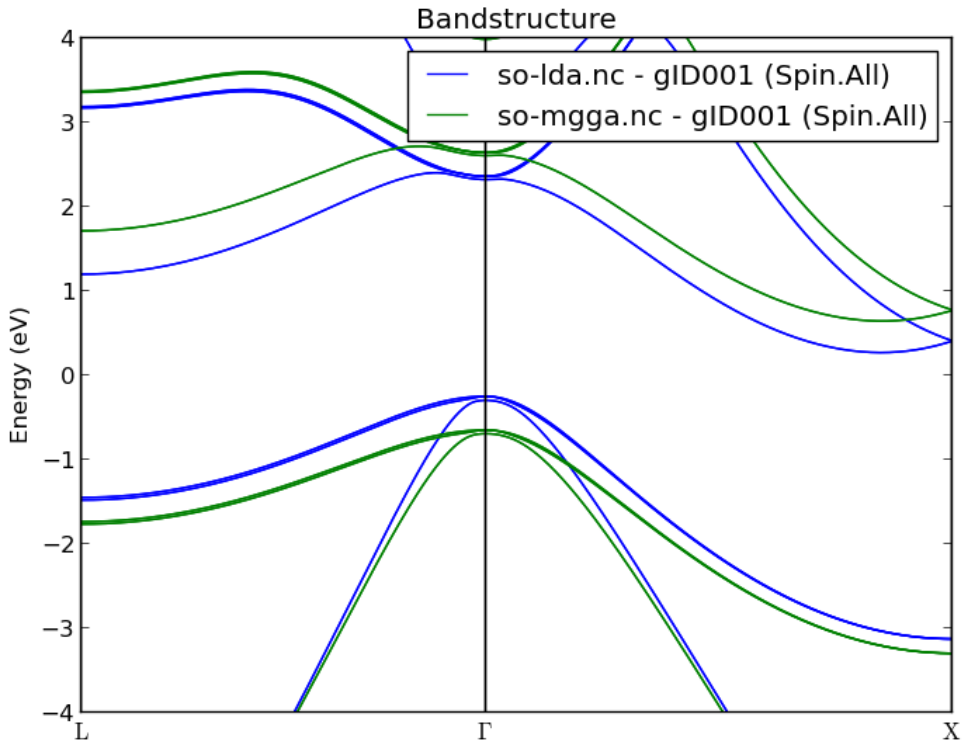


Fig. 3.22: Comparison of the SOLDA and SOMGGA bandstructures of silicon. The SOMGGA indirect band gap of 1.3 eV is close to experimental values.

Results

Using again the Compare Data plugin, you can now compare the SO+LDA band structure to the SO+MGGA one.

In the figure above it is clear that SO+MGGA has increased the distance from valence to conduction bands. Try to use the **Bandstructure Analyzer** plugin to measure the SO+MGGA indirect band gap. You should find ~1.3 eV.

The figure below zooms in on the split valence bands. They have not changed much from the SO+LDA results, apart from a vertical shift.

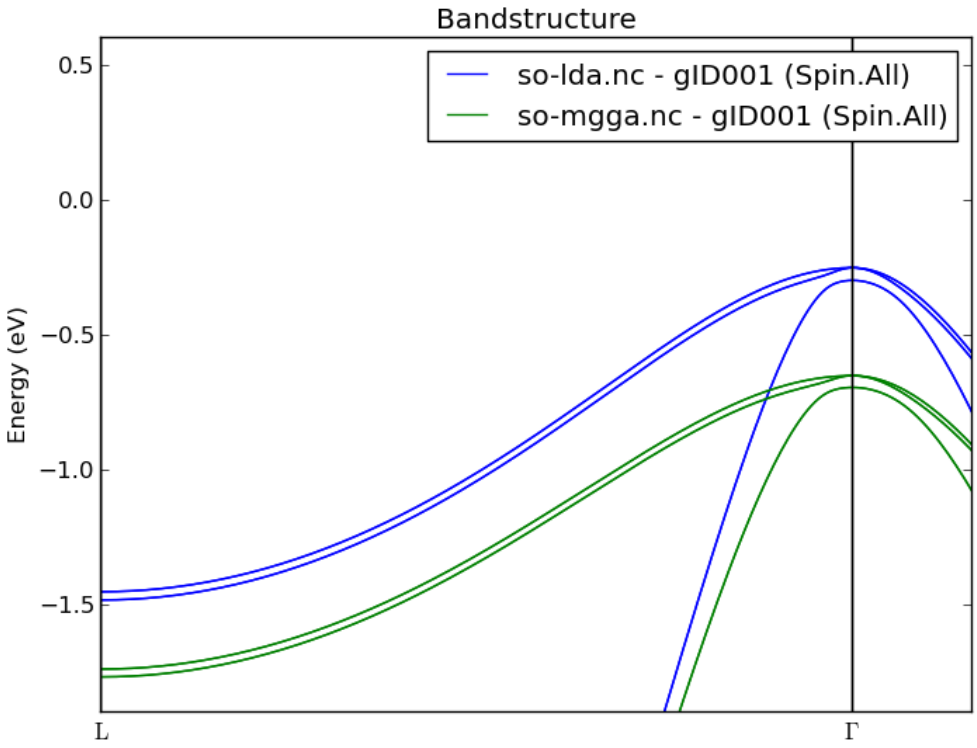

Fig. 3.23: Zoom-in on the split valence bands of silicon.

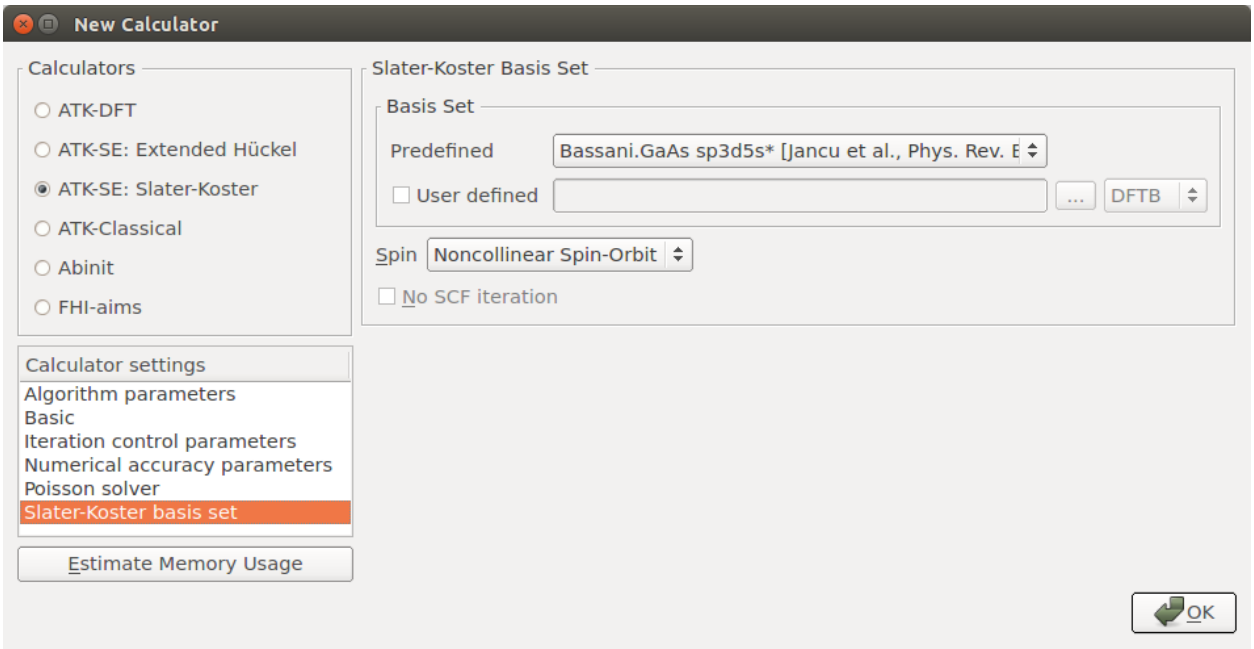
GaAs band structure with ATK-SE and SO coupling

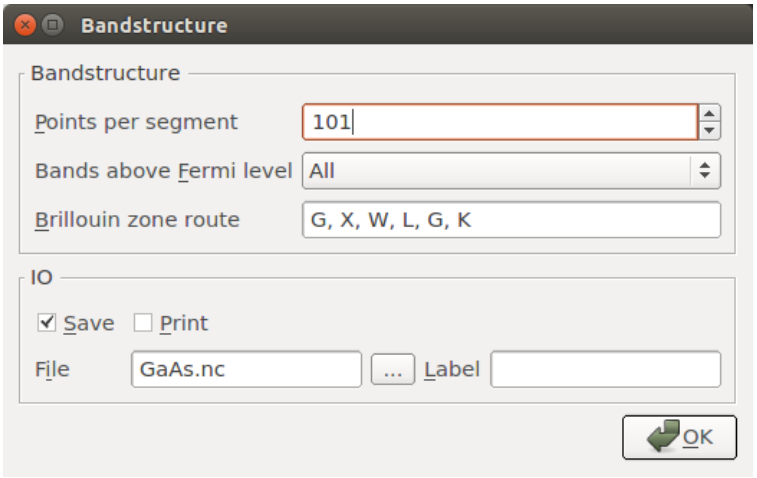
The ATK-SE engine offers tight-binding models for electronic structure calculations as a parametrized alternative to DFT. The Slater–Koster (SK) model is one such method, and includes spin-orbit coupling through a speciel SOC parameter, which is implemented in the ATK-SE engine.

Use the Builder to create the GaAs bulk configuration with experimental lattice constant, and use the Scripter to set up the Slater–Koster calculation:

- Add the New Calculator and Bandstructure blocks.
- Choose the **ATK-SE: Slater-Koster** calculator engine and the *Bassani.sp3d5s* basis set, and choose *Noncollinear Spin-Orbit* for the spin.



•In the Bandstructure block, increase the *Points per segment* to 101 in order to finely sample the band structure between each high-symmetry point, and trim the default *Brillouin zone route* such that it reads G, X, W, L, G, K.



Run the calculation – it will only take a few seconds – and then use the Bandstructure Analyzer to plot the results. The SO induced spin-splitting of the GaAs band structure is clearly visible. If you zoom in a bit you can measure a direct band gap of 1.51 eV at the Γ-point, which is virtually identical to the experimental gap at zero Kelvin.

References

3.2.4 Silicon p-n junction

In this tutorial you will:

•Learn how to build a p-n junction device.

•Learn how to study the current-voltage characteristic of such a device.

•Compare two different methods: **ATK-SE** and **ATK-DFT**.

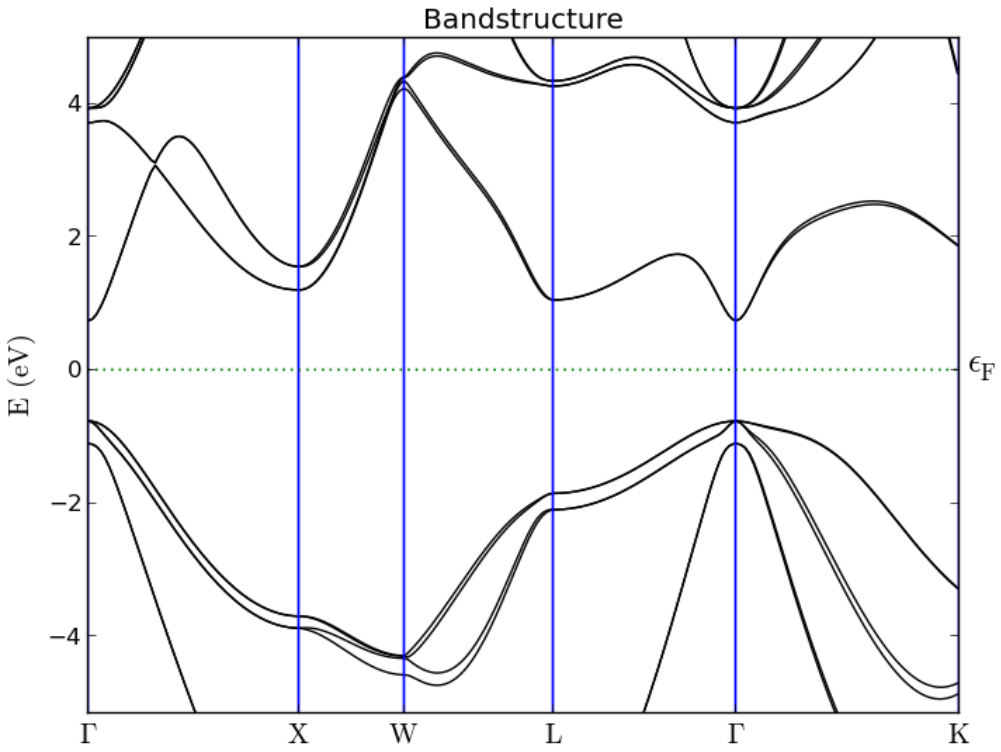


Fig. 3.24: Slater–Koster spin-orbit band structure of GaAs.

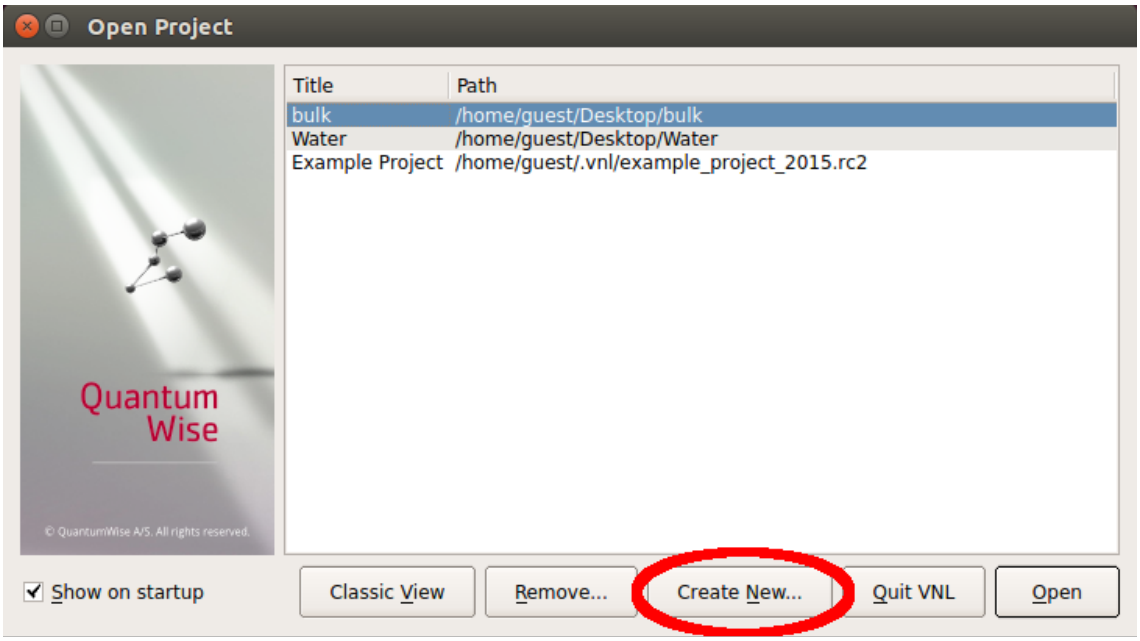
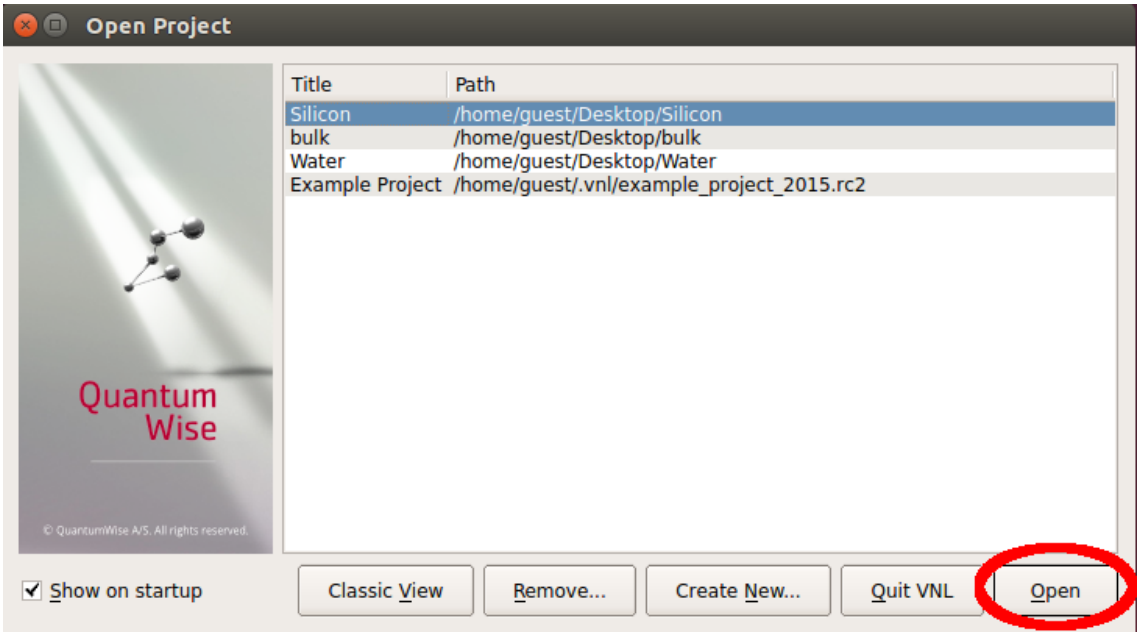
•Analyze the electronic structure of the p-n junction by studying and plotting the device density of states at zero bias and at reverse and forward bias.

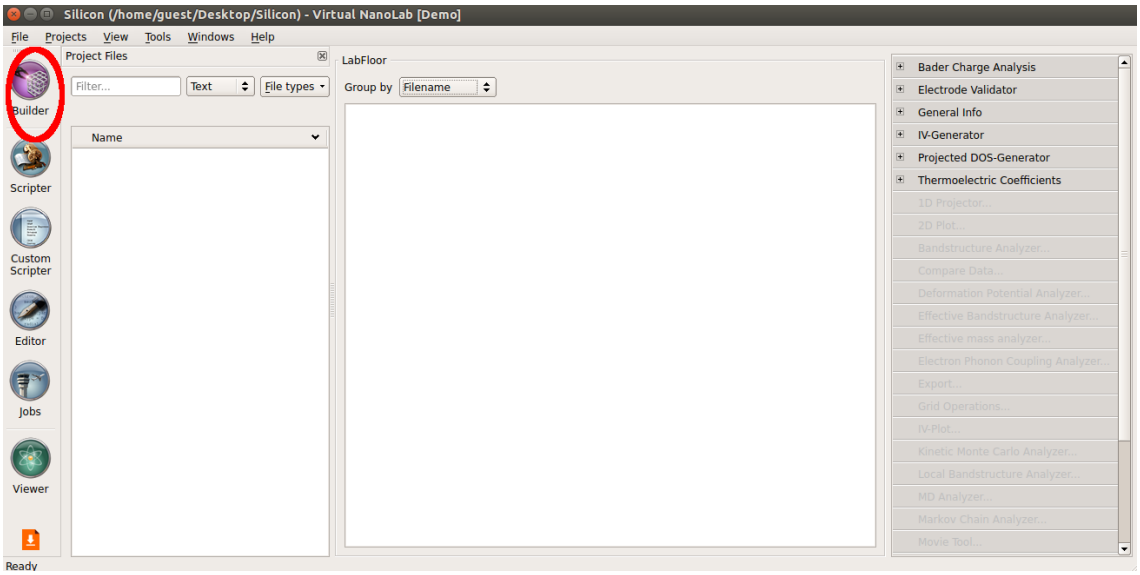
Silicon bulk: Slater-Koster vs DFT-MGGA

1.Open **QuantumATK** and create a new project by clicking on **Create New**. Give the project a *Title* (here: *Silicon*), select a folder for the project, click **OK** and then **Open** to start the project.

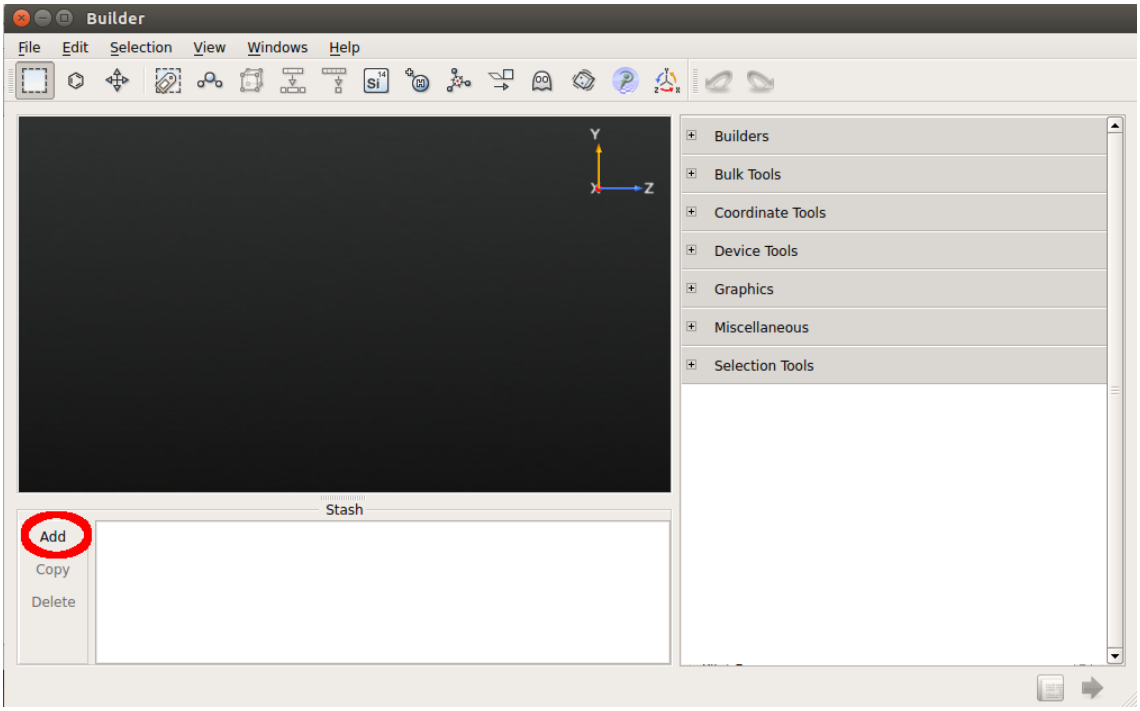


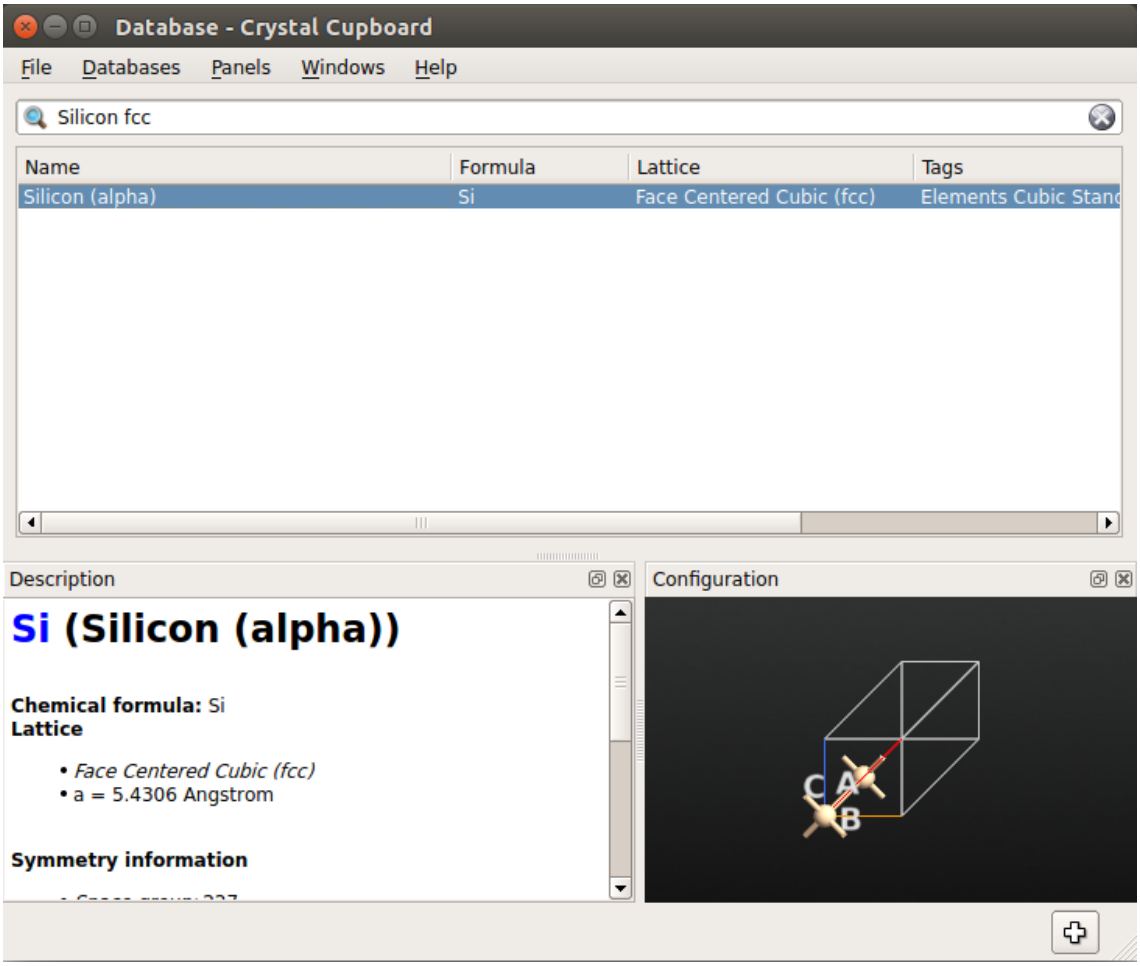


2.In the **QuantumATK** main window, click on the icon to open the **Builder**.



3. In the **Builder**, go to the **Stash**, click *Add* → *From Database* and from the menu navigate to *Databases* → *Crystals* and search for *silicon* in the search window. Then, select *Silicon (alpha)* and click the icon, or double-click its line in the list, to send it to the **Stash**.

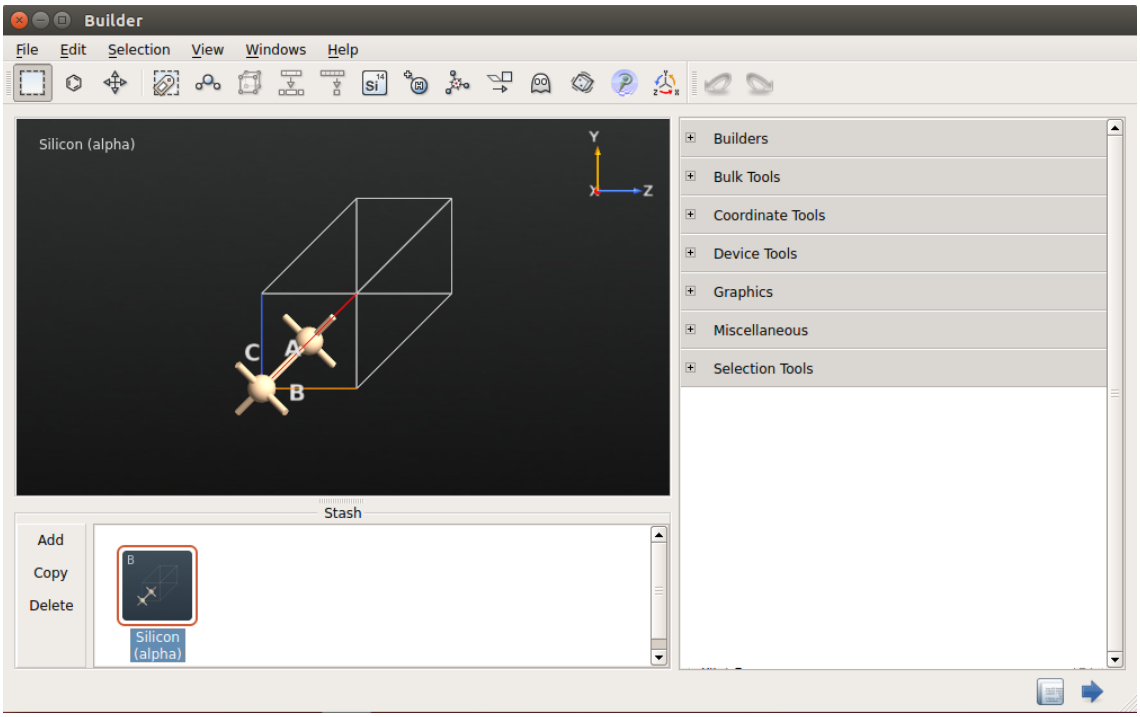




Slater-Koster calculation

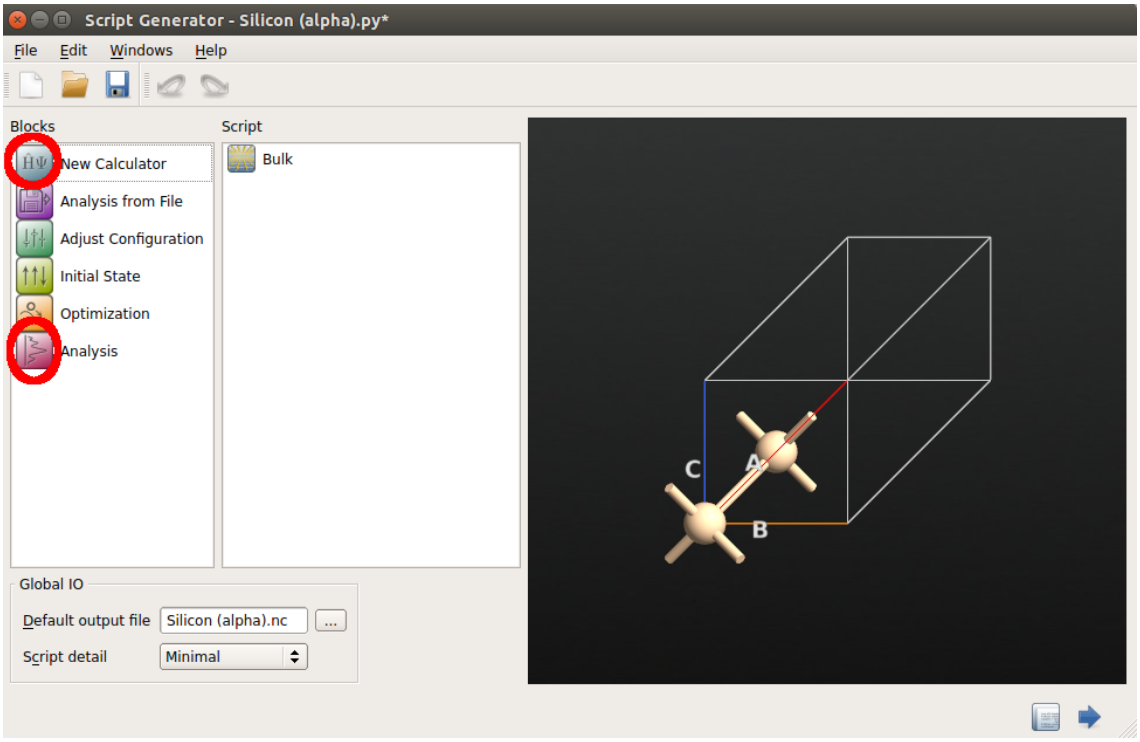
You will now set up an **ATK** semiempirical (**ATK-SE**) calculation using the Slater-Koster model Hamiltonian.

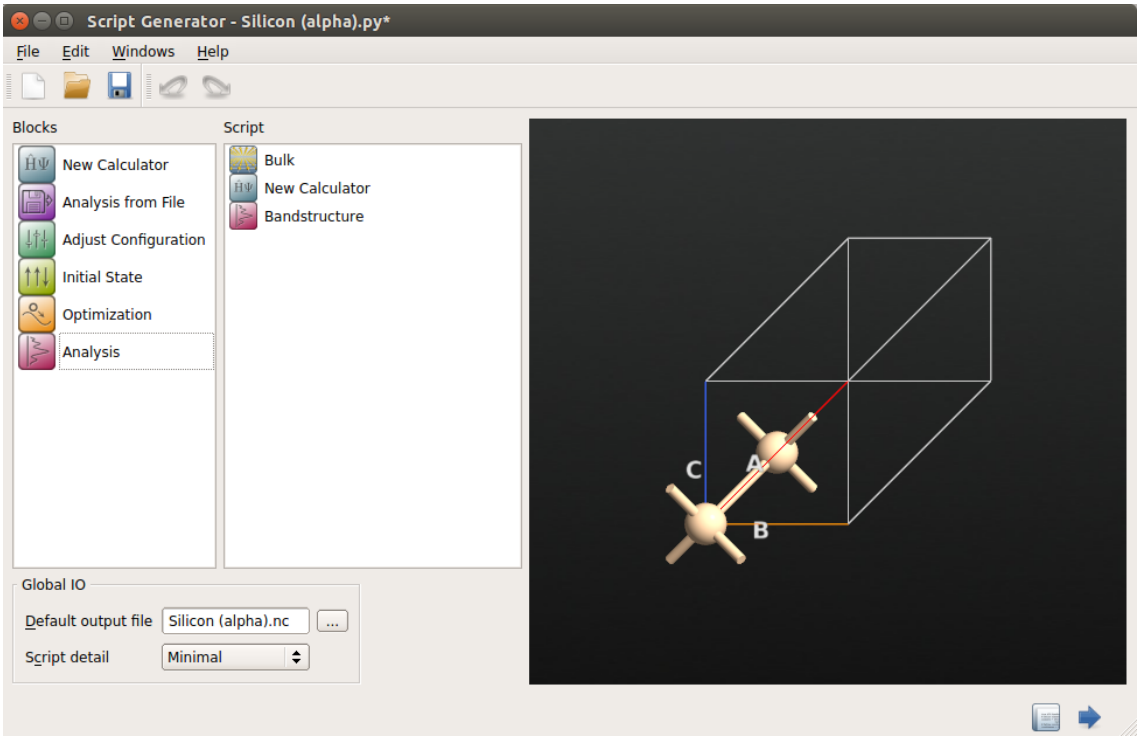
1. Send the bulk configuration from the **Builder** to the **Script Generator** using the button.



2.Add the following blocks to the *Script* by double-clicking the correspoding icons in the *Blocks* panel:

- New Calculator.
- *Analysis* → *Bandstructure*.





3.Open the **New Calculator** by double-clicking it.

- Select the *ATK-SE Slater-Koster* calculator.
- Use a 25x25x25 k-point sampling.
- Uncheck the *No SCF iteration* box.
- Select the *Bassani.Si* basis set.

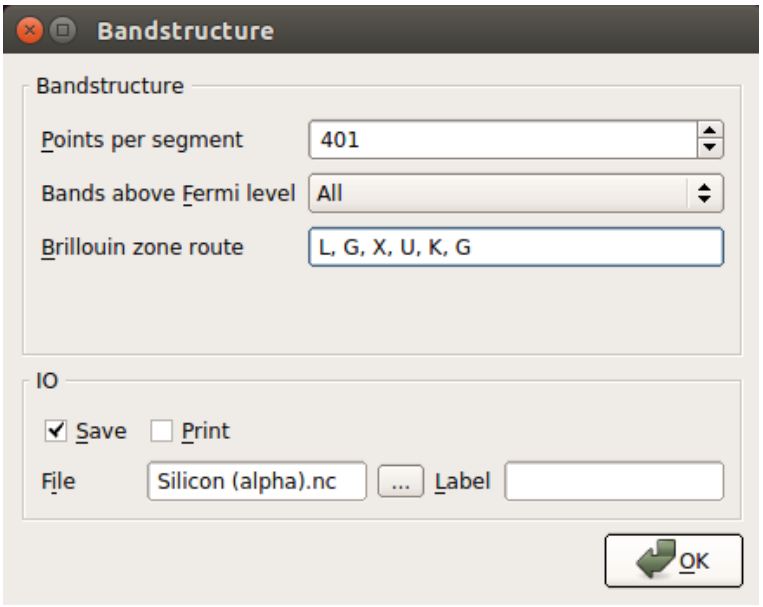
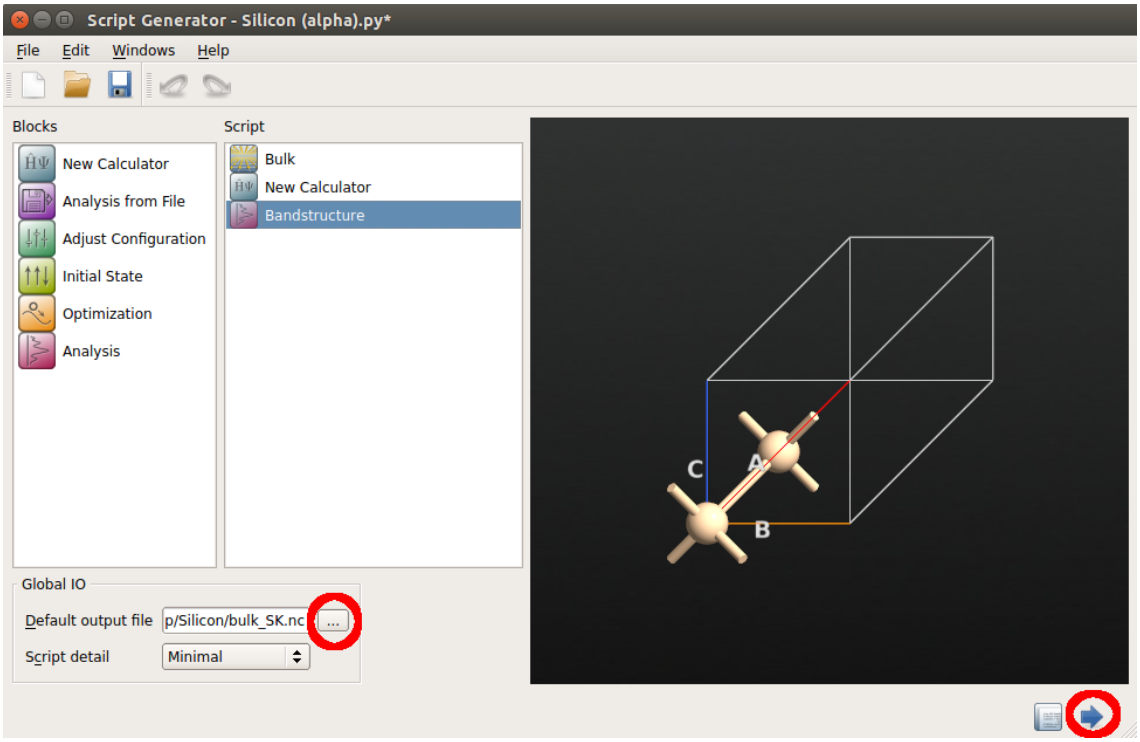
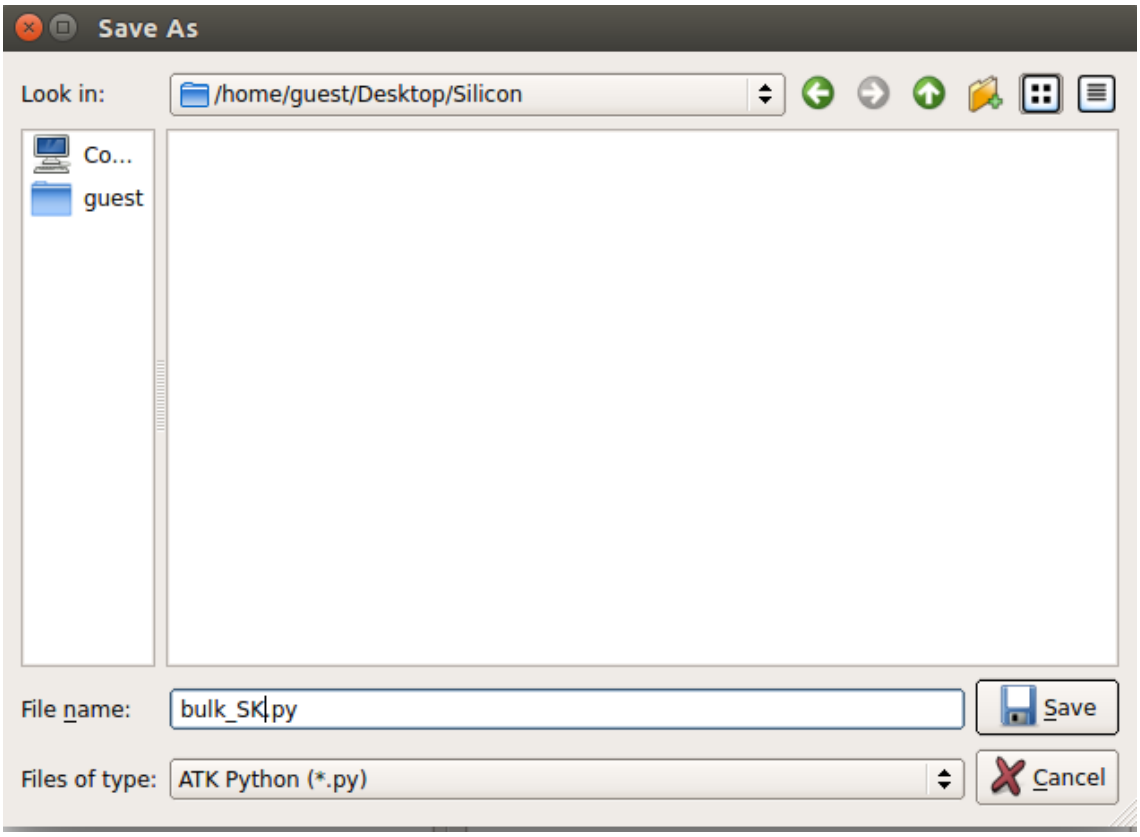
4.In **Bandstructure**, select the L, G, X, U, K, G Brillouin zone route and 401 points per segment.



5.Back in the **Script Generator**, set the output filename to `bulk_SK.hdf5`, and send the script to the **Job Manager** using the button.



6.Save the script in the window that shows up and use the ▶ botton to run the job.

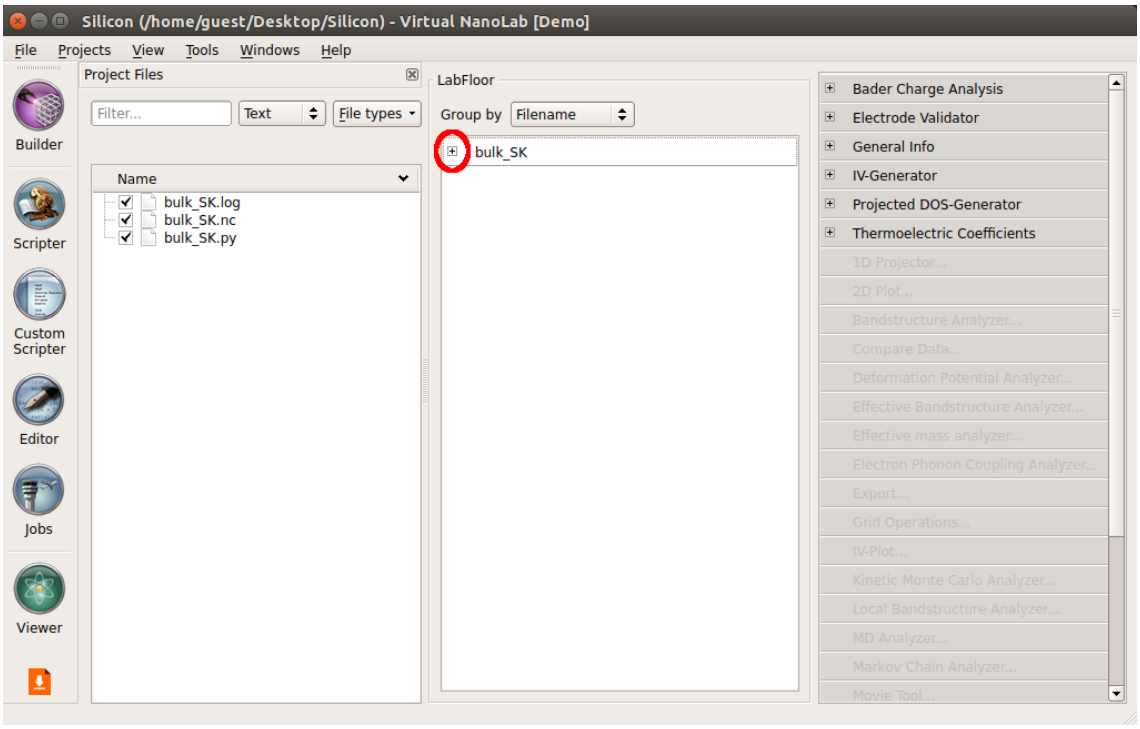


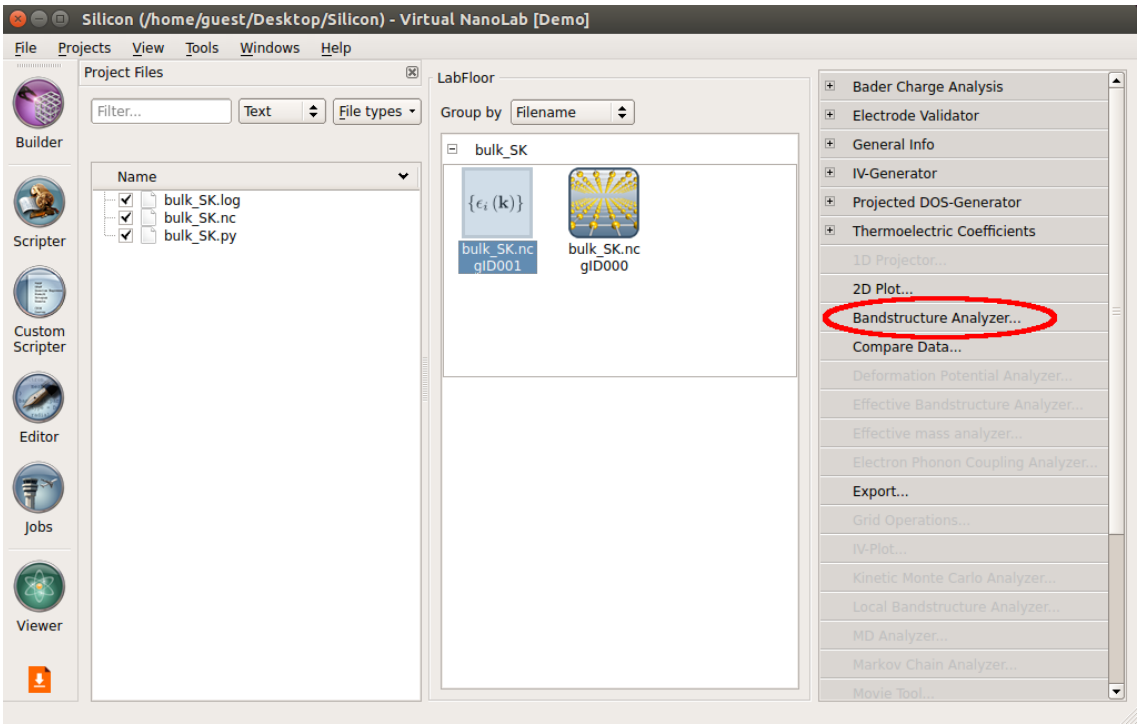
7.Once the calculation is done (it will only take a few seconds) you can find in the **LabFloor** your **Bandstructure** object,

which is saved in `bulk_SK.hdf5`:

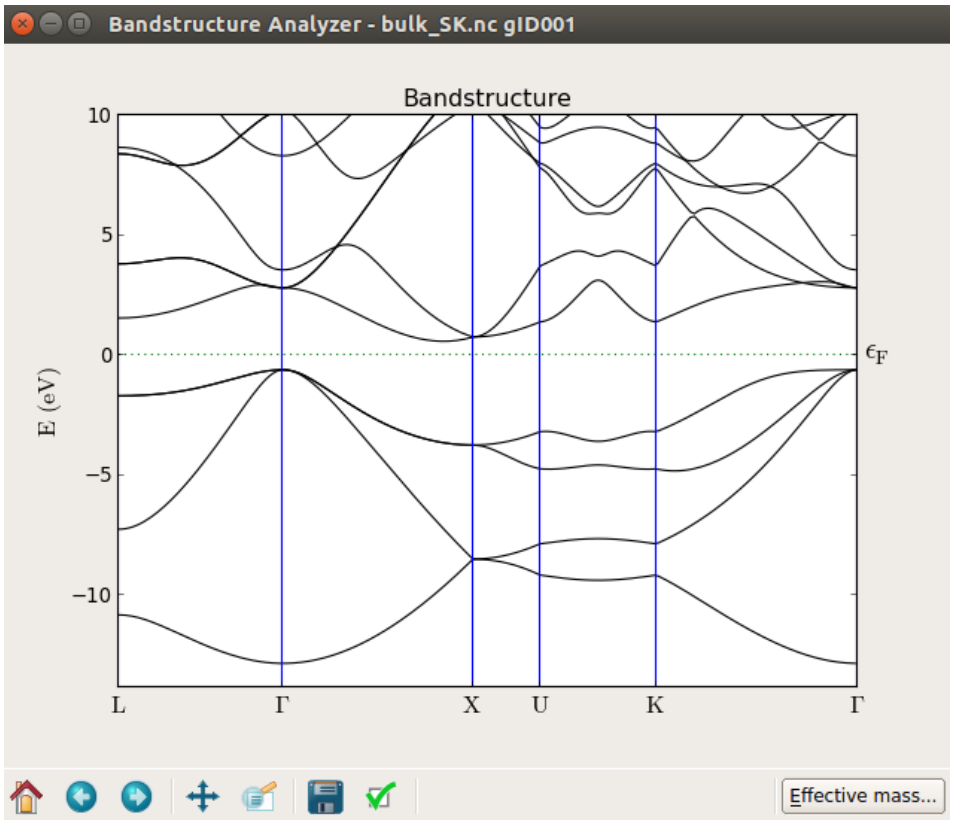
$$\{\epsilon_i(\mathbf{k})\}$$

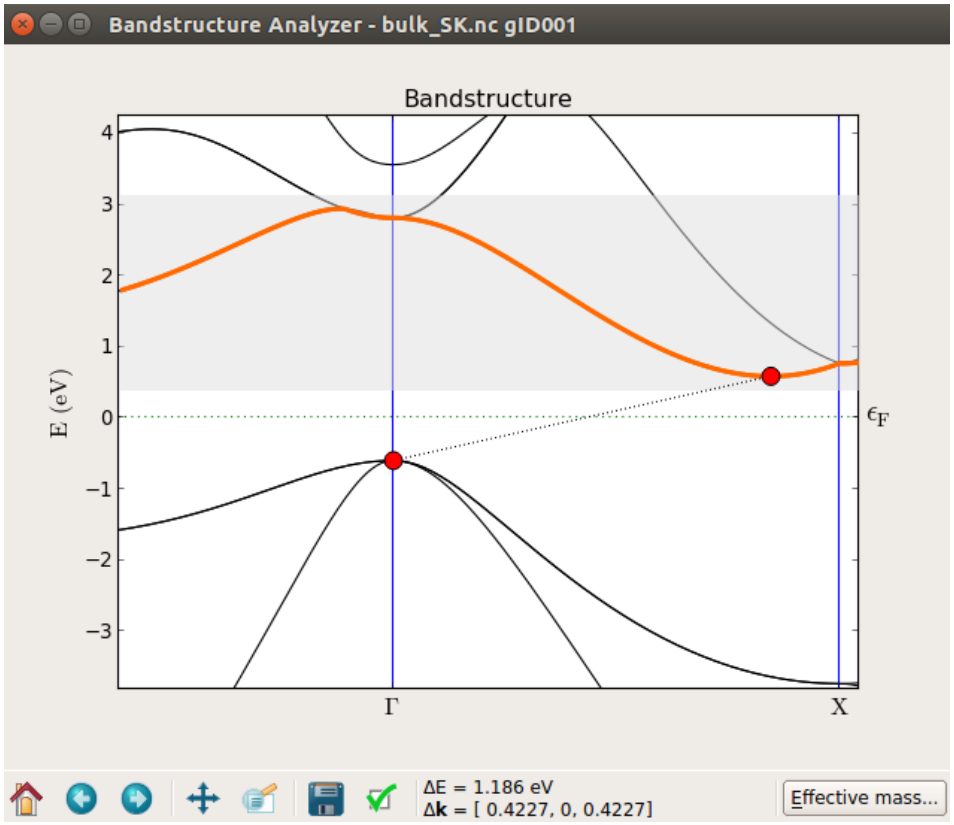
Highlight the object and use the **Bandstructure Analyzer** plugin to plot the bandstructure.





8. You can zoom into a region close to the band edges and precisely measure the calculated indirect band gap, 1.186 eV.





DFT-MGGA calculation

The TB09-MGGA approximation[1] available in **ATK-DFT** is fully explained in the tutorial *Meta-GGA and 2D confined InAs*. In order to compare the Slater-Koster results with results from the TB09-MGGA method, you will fit a parameter (c) such the TB09-MGGA band gap of silicon matches that calculated with Slater-Koster. Throughout this tutorial you will use this fitted c parameter for the TB09-MGGA calculations.

1. From the **Builder**, send the *Silicon bulk configuration* to the **Script Generator** and add a **New Calculator** to the script. Then edit the calculator parameters:

- Select *ATK-DFT* and the *MGGA* exchange-correlation functional.
- Use a 25x25x5 k-point sampling.
- Select the *SingleZetaPolarized* basis set in order to speed up calculations.

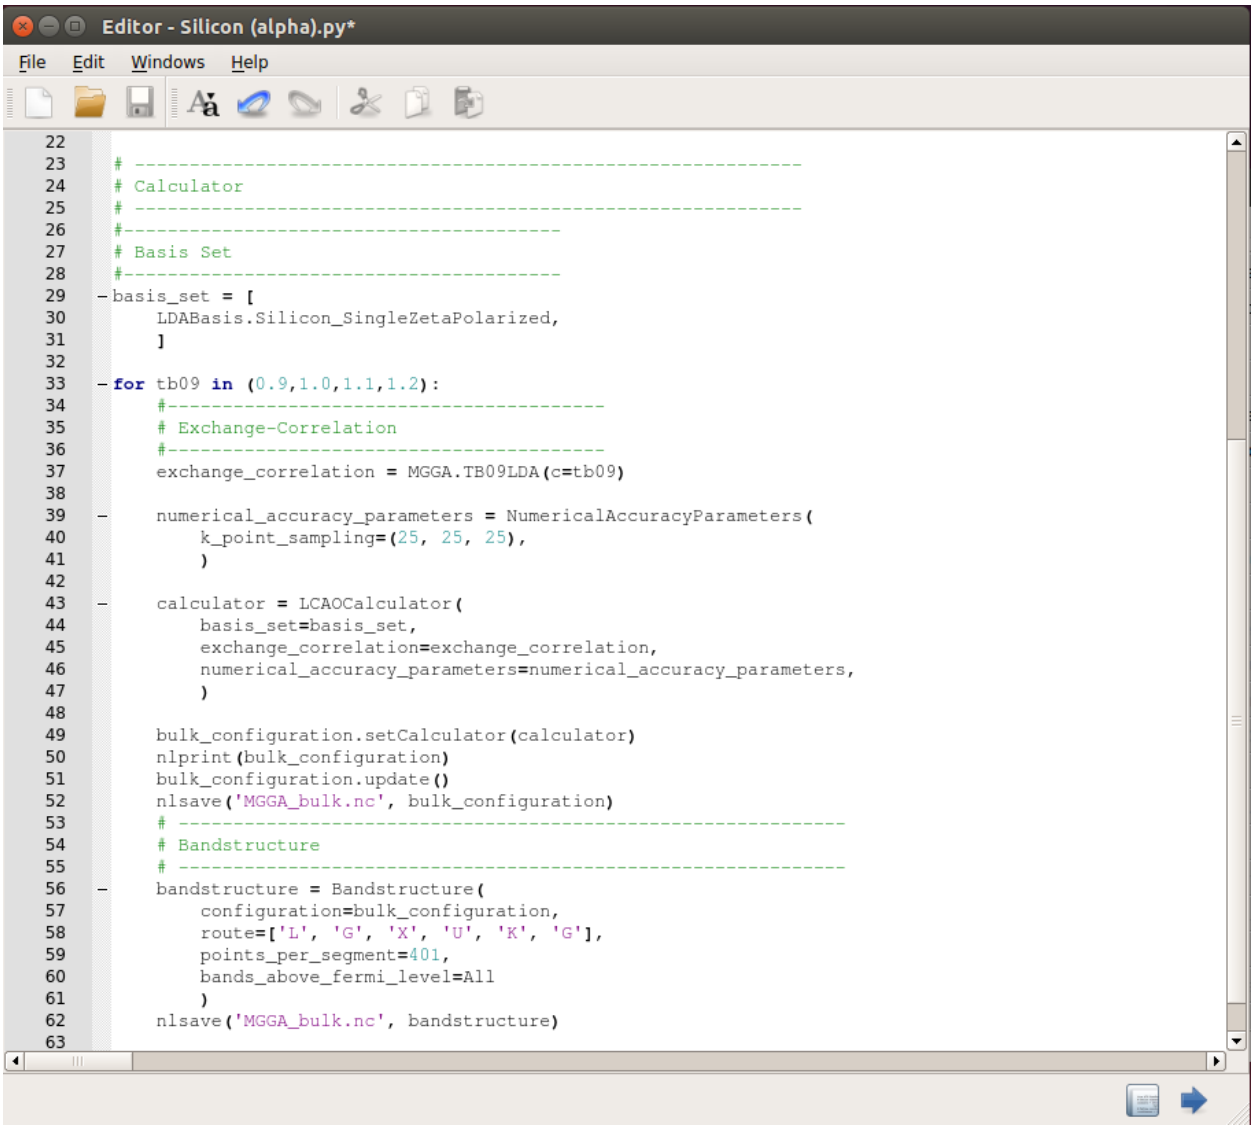
2.Add also a **Bandstructure** analysis object and set it up as you did for the Slater-Koster calculation.

3.Back in the **Script Generator**, set the output filename to `MGGA_bulk.hdf5`.

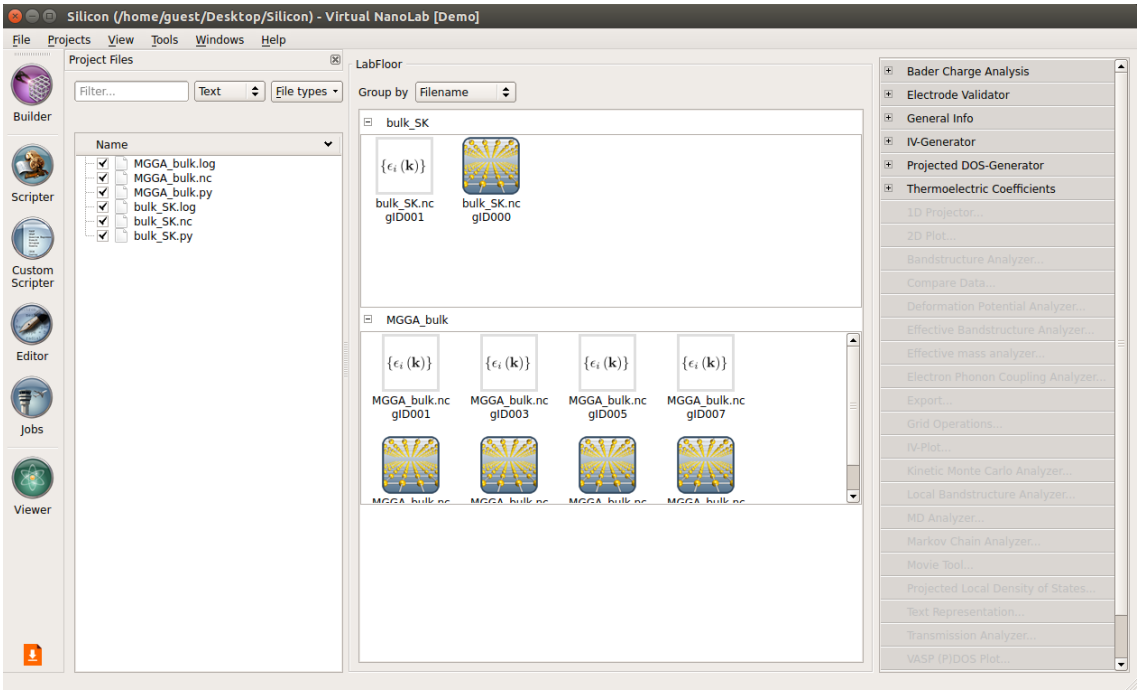
4.In order to fit the c parameter to the Slater-Koster band gap you will need to run a few calculations for different c parameters and make a linear interpolation. Here, you will run four TB09-MGGA calculations for c = 0.9, 1.0, 1.1 and 1.2. A little manual editing of the script is needed:

•Send the script to the **Editor** using the button, and modify the exchange-correlation section as shown in the image below. Also, add a loop over the c values to run the four calculations with a single Python script (you can download a copy of the script here: `MGGA_bulk.py`):



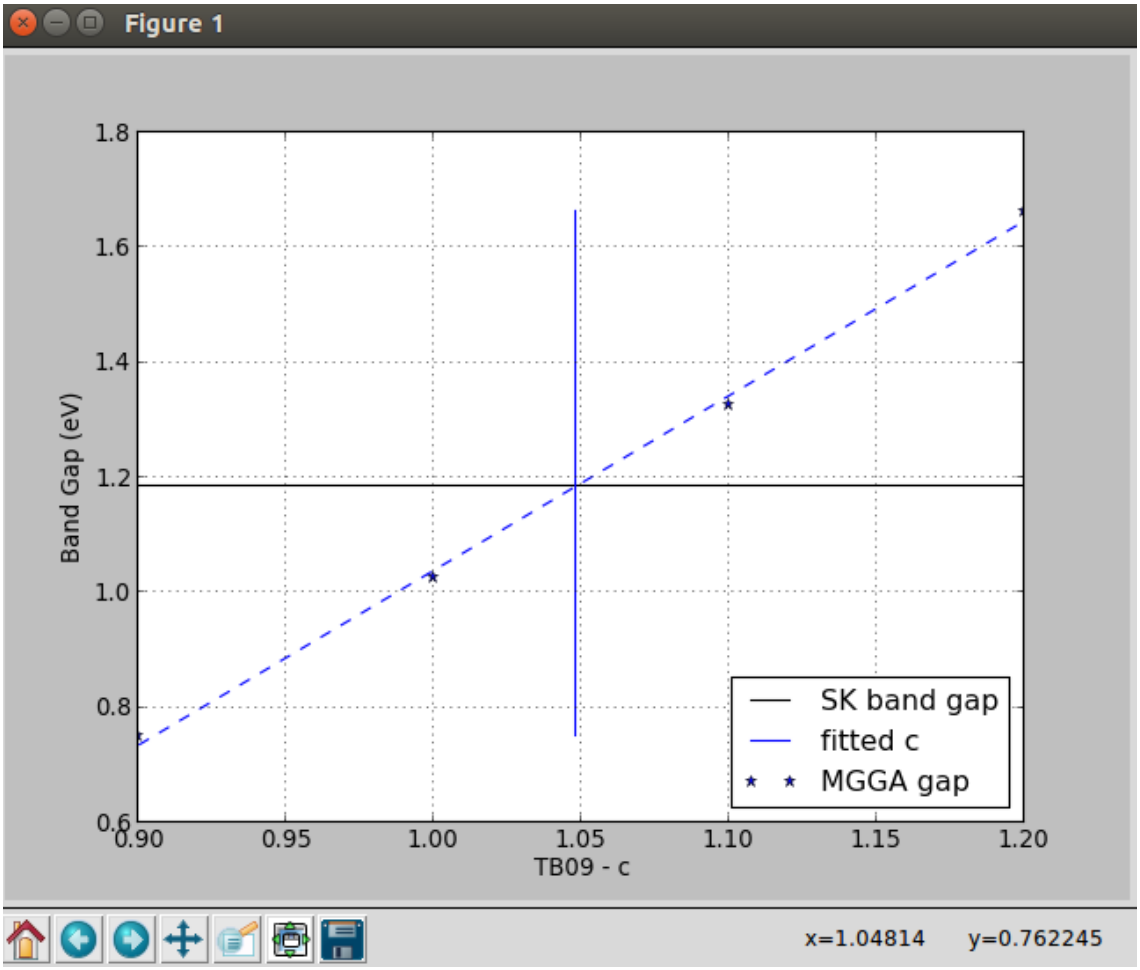
5.Send the script to the **Job Manager** and run the job.

6.On the **LabFloor** you will now have four different **Bandstructure** objects included in the *MGGA_bulk.hdf5*.



7.You will use the following script to fit the c-parameter: `bandstructure_fit.py`. Save it in the project directory.

8.Execute the fitting script using the **Job Manager**. The plot shown below should pop up.



It is clear that the TB09 c-parameter has a significant influence on the calculated band gap, and that the dependence is quite linear. The fitted value of c is 1.048.

Note: If you take a closer look at the script `bandstructure_fit.py`, You will see that band gaps are calculated from a **Bandstructure** object like this:

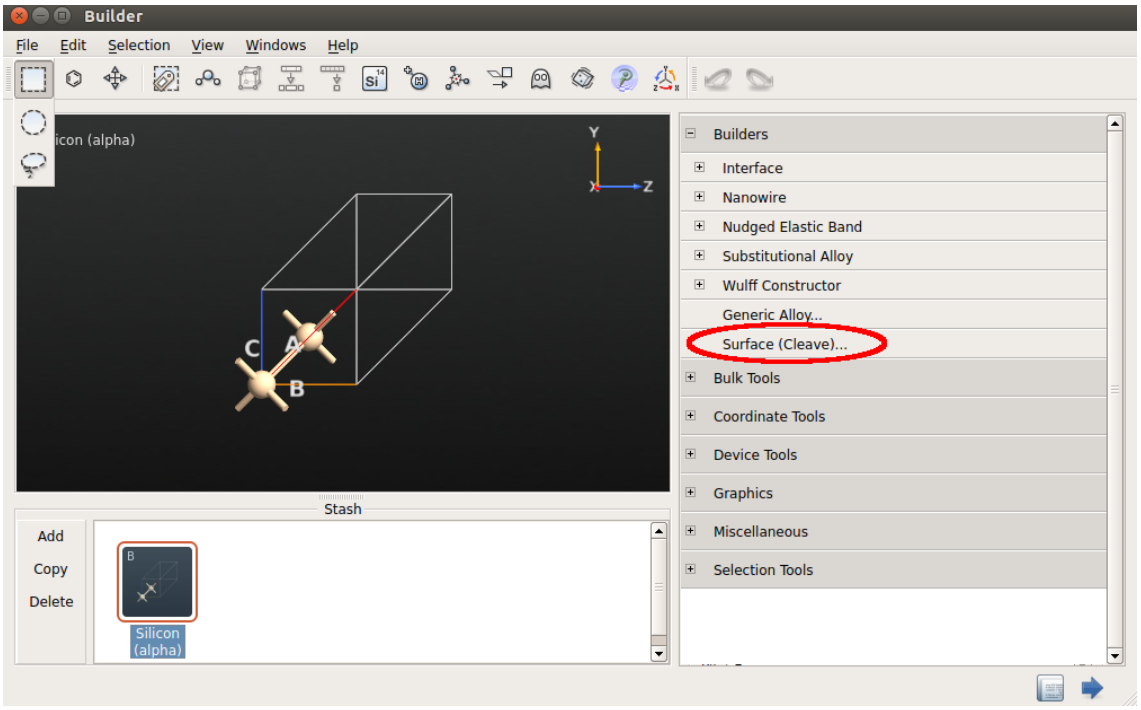
```
bandstructure = nlread("file.hdf5", Bandstructure)[0]
gap_direct   = bandstructure.directBandGap().inUnitsOf(eV)
gap_indirect = bandstructure.indirectBandGap().inUnitsOf(eV)
print "direct gap:   %.2f eV" % gap_direct
print "indirect gap: %.2f eV" % gap_indirect
```

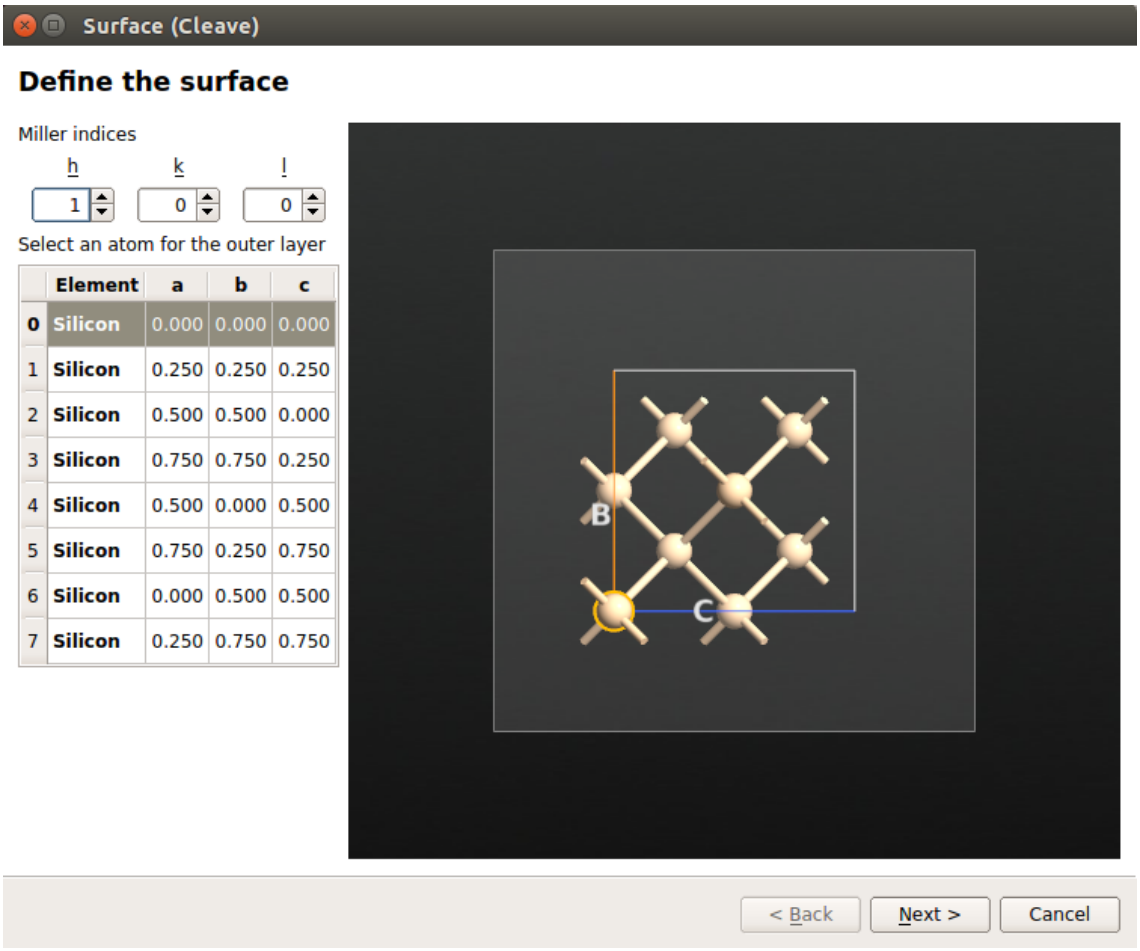
Silicon device

You will now set up the silicon device.

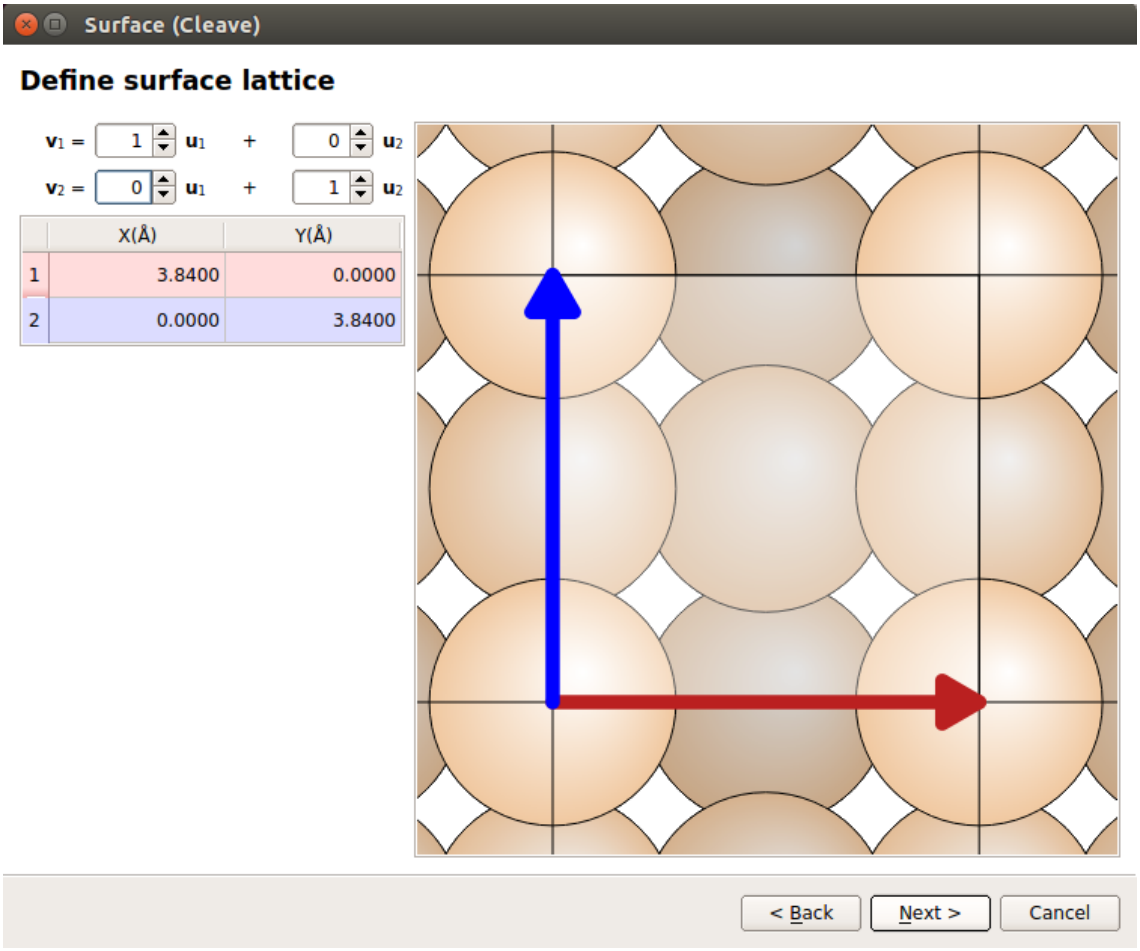
1. Open the **Builder**, highlight *Silicon (alpha)* in the **Stash**, and start creating a Si(100) surface:

- Navigate to *Builders* → *Surface (Cleave)*.
- In the **Surface (Cleave)** window, choose the [1,0,0] Miller indices and click *Next*.

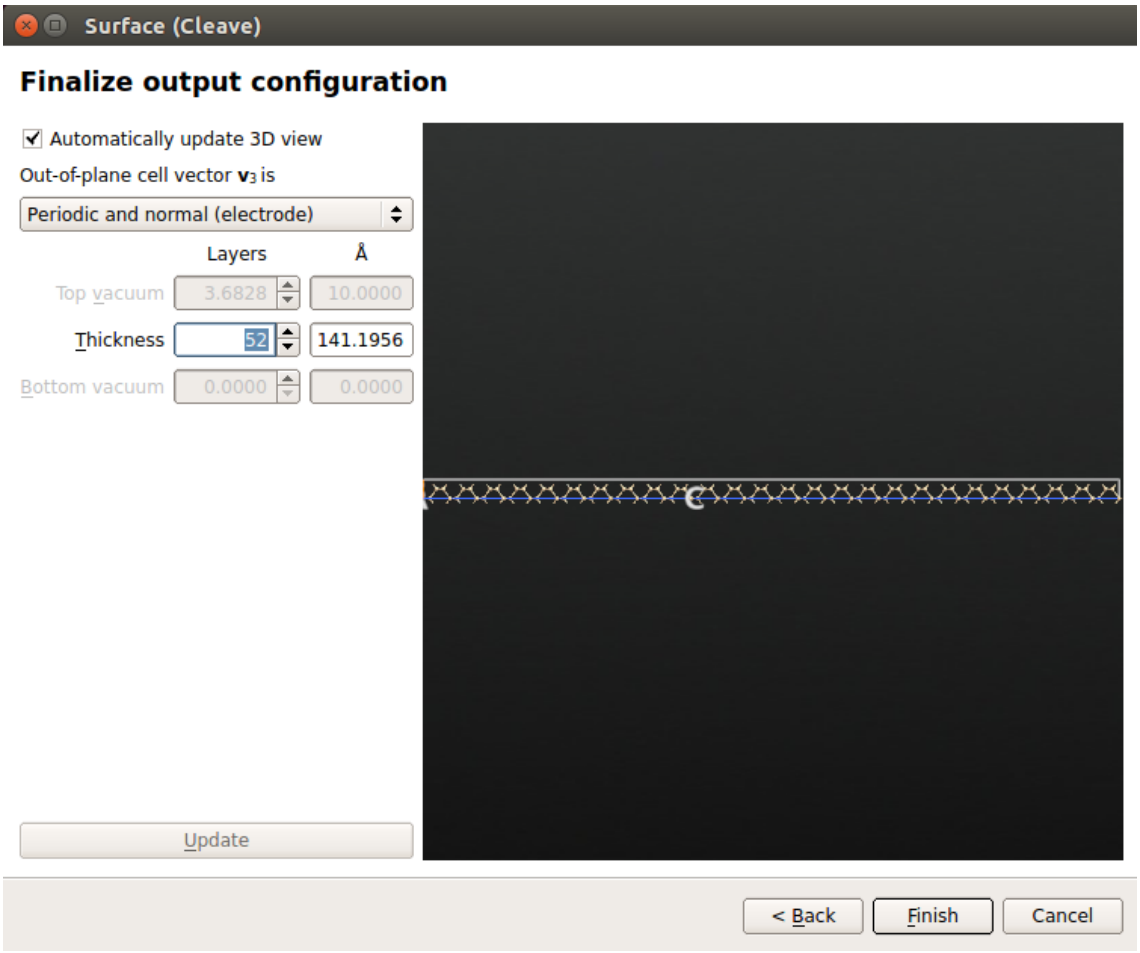




2.Keep the 1×1 surface unit cell and click *Next*.

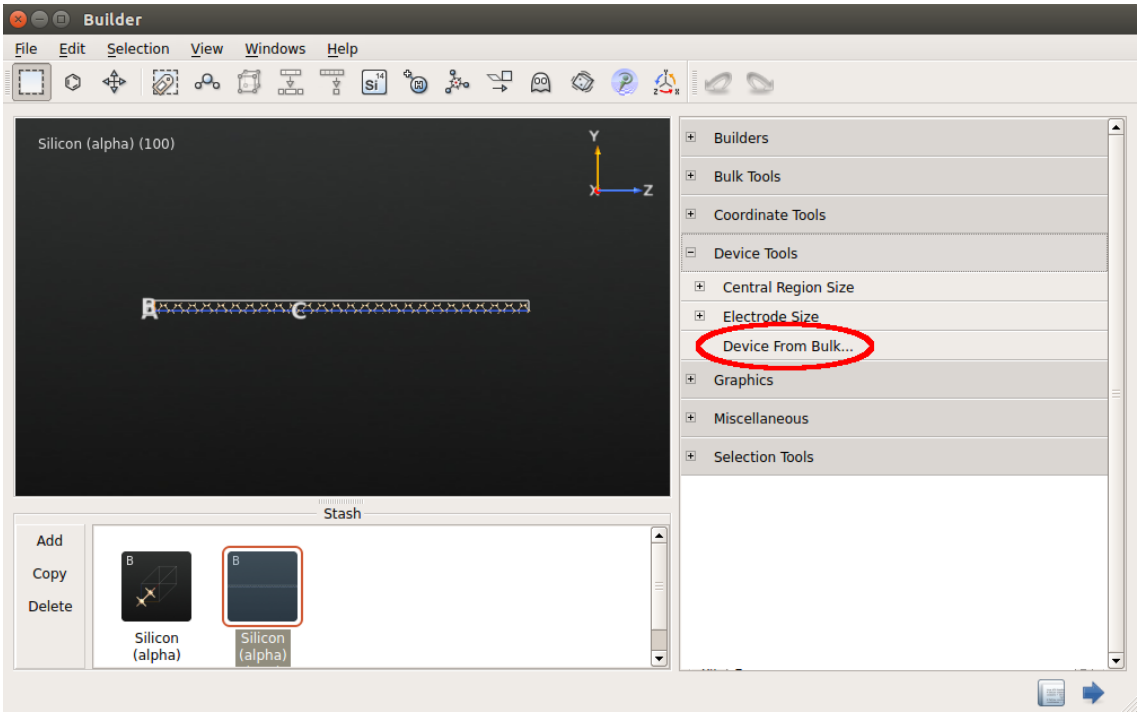


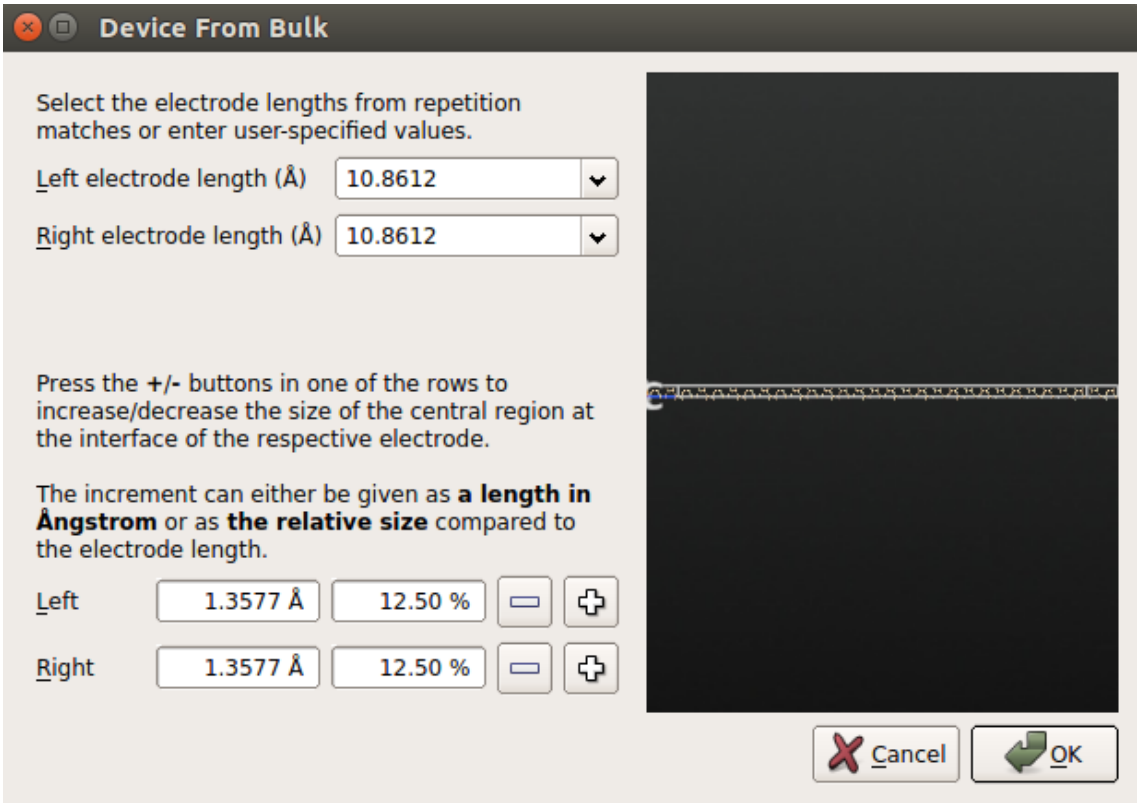
3.Select a thickness of 52 layers and click *Finish*.



Note: The 52 layers will constitute the central region of your device. You need such a relatively long device (~14 nm) because of the long screening length in the silicon semiconductor, as explained in the *NiSi2–Si interface* tutorial. Still, as you will see later, this device is not long enough to have perfectly converged results. However, you will use the 52 layers device throughout this tutorial to be able to perform the TB09-MGGA calculations faster.

4. Your Si(100) configuration is now constructed, and you will use it to construct a device with the transport direction along (100). Navigate to *Device Tools* → *Device From Bulk*, keep the default parameters, and simply click *OK*.





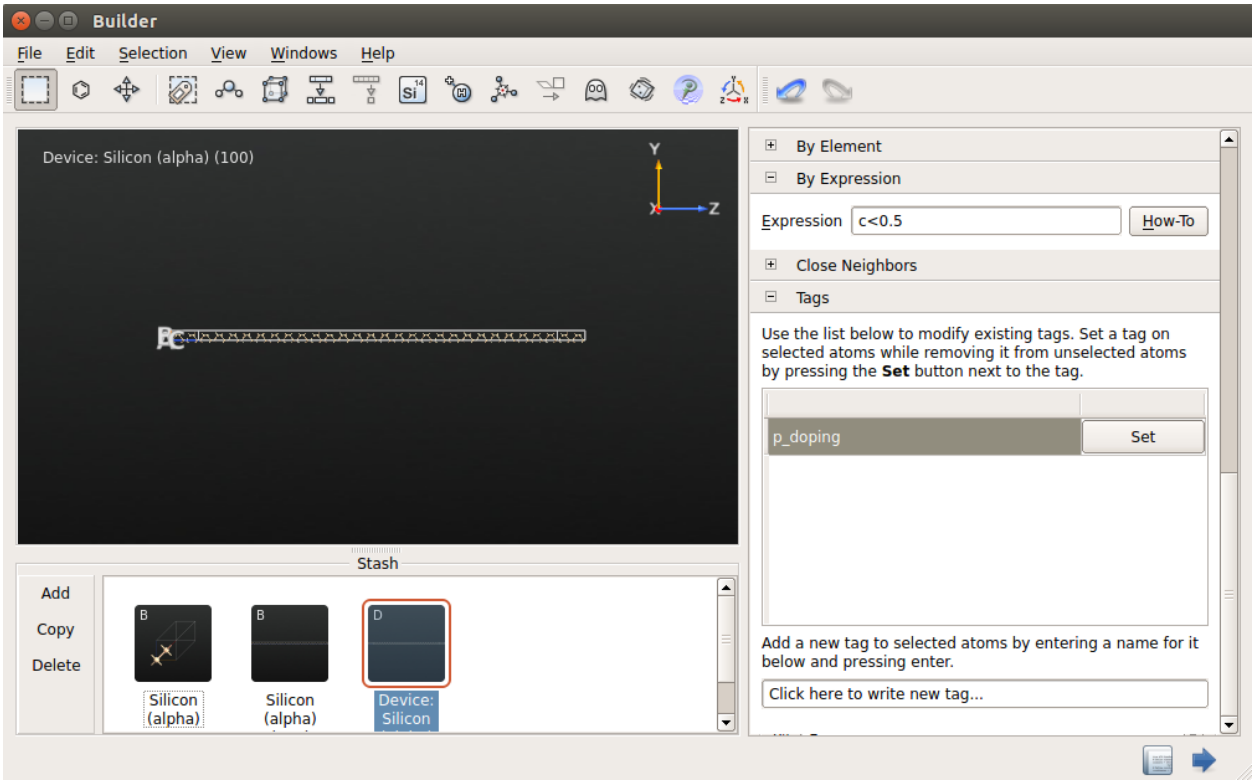
5.It will prove convenient to assign tags to atoms in the regions that should be doped p-type and n-type, respectively.

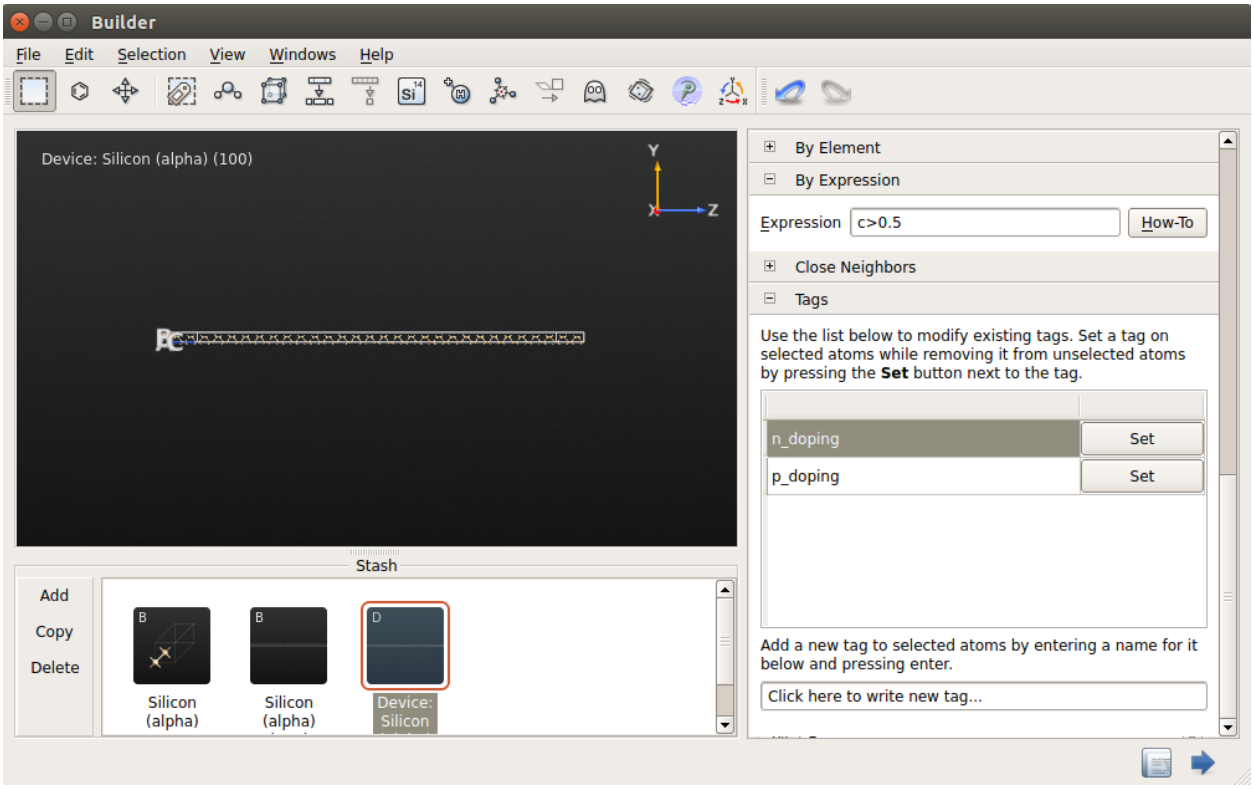
•Highlight the device configuration in the **Stash** and go to *Selection Tools* → *By Expression*.

•Type in $c < 0.5$ and press *Enter* to select all atoms in the left hand side of the device.

•Use *Selection Tools* → *Tags* to assign the tag *p_doping* to the selected atoms.

•Follow the same procedure to select atoms with $c > 0.5$ and assign the tag *n_doping* to those atoms.





Slater-Koster IV curve

You will use the Slater-Koster model to calculate the I-V characteristics for the p-n doped silicon junction.

1. Send the device configuration from the **Builder** to the **Script Generator**.

2. Add a **New Calculator** to the script and set the following parameters:

   - Select the *ATK-SE Slater-Koster* calculator.
   - Use a 7x7x100 k-point sampling.
   - Select the *Bassani.Si basis set* and uncheck the *No SCF iteration* box.

3. You can now add all the analysis objects needed. Add the following ones:

   - **ElectronDensity**
   - **DeviceDensityofStates**
   - **ElectrostaticDifferencePotentials**
   - **IVCurve**

4. Edit the **DeviceDensityofStates** parameters:

   - Increase considerably the k-point sampling. Use a 21x21 grid.

•Energy: from -2 to 2 eV with 401 points.

5.Edit the **IVCurve** parameters:

•*Voltage Bias*: sample from -1 V to 1 V with 21 points.

•*Energy*: from -1.1 eV to 1.1 eV with 401 points.

•*k-point sampling*: 21x21.

Note: A full explanation of all the parameters is given in the *Doping in QuantumATK: the Ni silicide - :ref:`nisi2-si* and in the ATK Reference Manual.

6.Change the output filename to something like `IV_2e19_SK.hdf5`.

Doping the silicon junction

You need to set up the proper doping to finally have a p-n junction. To this end, send the script to the **Editor** and locate the part of the script that defines the device configuration:

```
device_configuration = DeviceConfiguration(
central_region,
[left_electrode, right_electrode]
)
```

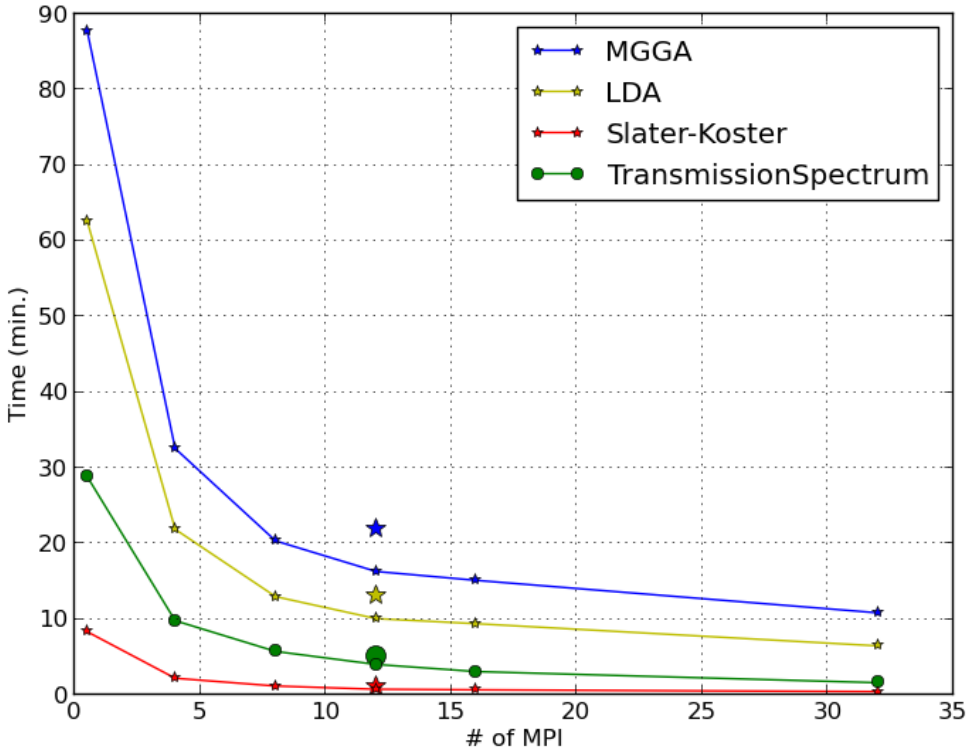
Just before those lines, add the following lines to define a p-n junction with a doping concentration of $2 \cdot 10^{19}$ cm^{-3}:

```
# ------------------------------------------------------------
# Add Doping
# ------------------------------------------------------------
doping_density = 2e+19
# Calculate the volume  and convert it to cm^-3
# Note: right and left electrodes have the same volume,
volume = right_electrode_lattice.unitCellVolume()
volume = float(volume/(0.01*Meter)**3)
# Calculate charge per atom
doping = doping_density * volume / len(right_electrode_elements)
# Add p- and n-type doping to the central region
external_potential = AtomicCompensationCharge([
     ('p_doping', -1*doping), ('n_doping',doping)
     ])
central_region.setExternalPotential(external_potential)
# Add doping to left and right electrodes
left_electrode.setExternalPotential(
   AtomicCompensationCharge([(Silicon, -1*doping)]))
right_electrode.setExternalPotential(
   AtomicCompensationCharge([(Silicon, doping)]))
```

Running the calculation

Send the script to the **Job Manager** and run the calculation.

Depending on the analysis objects included in the script, and on the number og parallel processes executed by the **Job Manager**, the calculation may take a few minutes for the zero bias part and up to few hours to calculate the whole IV curve. The performance of **ATK 2014** for different methods (**ATK-SE** and **ATK-DFT**) and for a transmission spectrum calculation are reported in the figure below.



Note: The calculations are run in parallel on different Intel Xeon e5472 3.0 GHz machines. The single points at 12 MPI are run with QuantumATK 13.8. Overall, QuantumATK 2014 is 25-30% faster compared to QuantumATK 13.8.

Calculation details: zero-bias, 7x7x100 k-point sampling for SCF part and 21x21 for the transmission spectra. All other parameters are set as in this tutorial.

Note that the Slater-Koster SCF calculation is much faster than the post-SCF calculation of the transmission spectrum.

DFT-MGGA IV curve

While the Slater-Koster job is running you can set up the DFT-MGGA calculation. Simply go back to the **Script Generator** and change the **Calculator** block:

- Choose *ATK-DFT*.
- Exchange correlation: *MGGA*.
- *SingleZetaPolarized* basis set.

Remove all analysis objects except the **IVCurve**. Then set up the device doping and run the calculation.

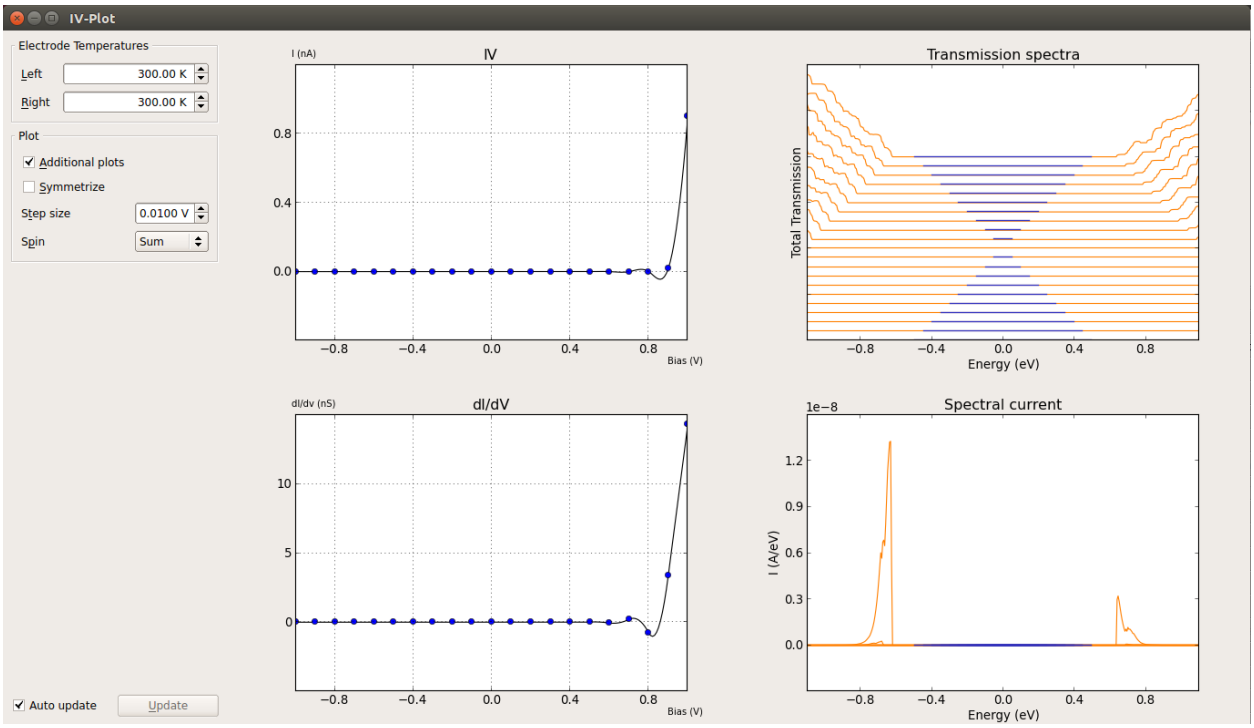
Analyzing the results

IV Curve

Once the two calculations are done and you have the output nc files in the project directory you will see the two **IVCurve** objects loaded in the **LabFloor**:

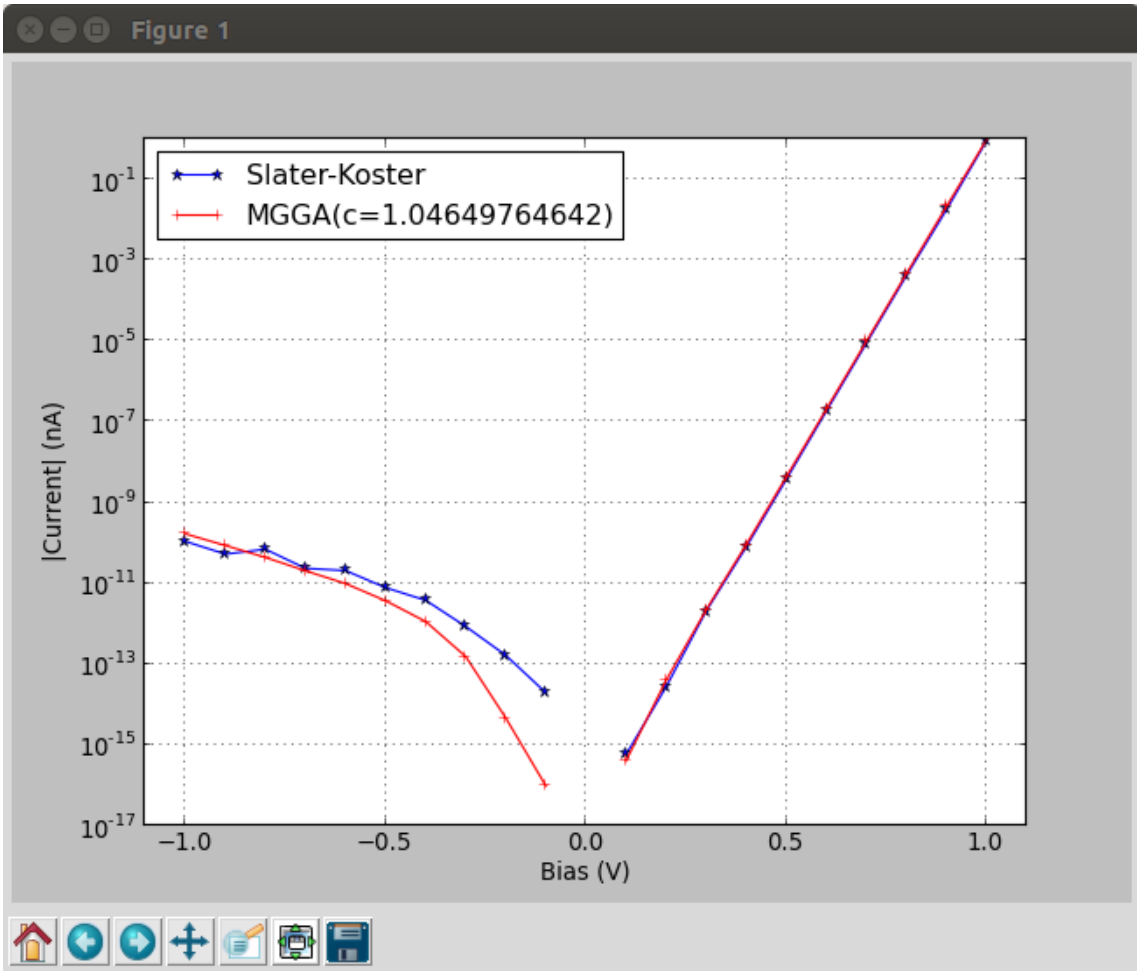
$$I\,(V)$$

1. Select one of the **IVCurve** objects and use the **IV-Plot** plugin to plot the IV curve. If you check the *Additional plots* option, you will also see plots of dI/dV, transmission spectra, and the spectral current.



2. In order to compare the **Slater-Koster** and **MGGA** IV curves, and send the script to the **Job Manager** to create

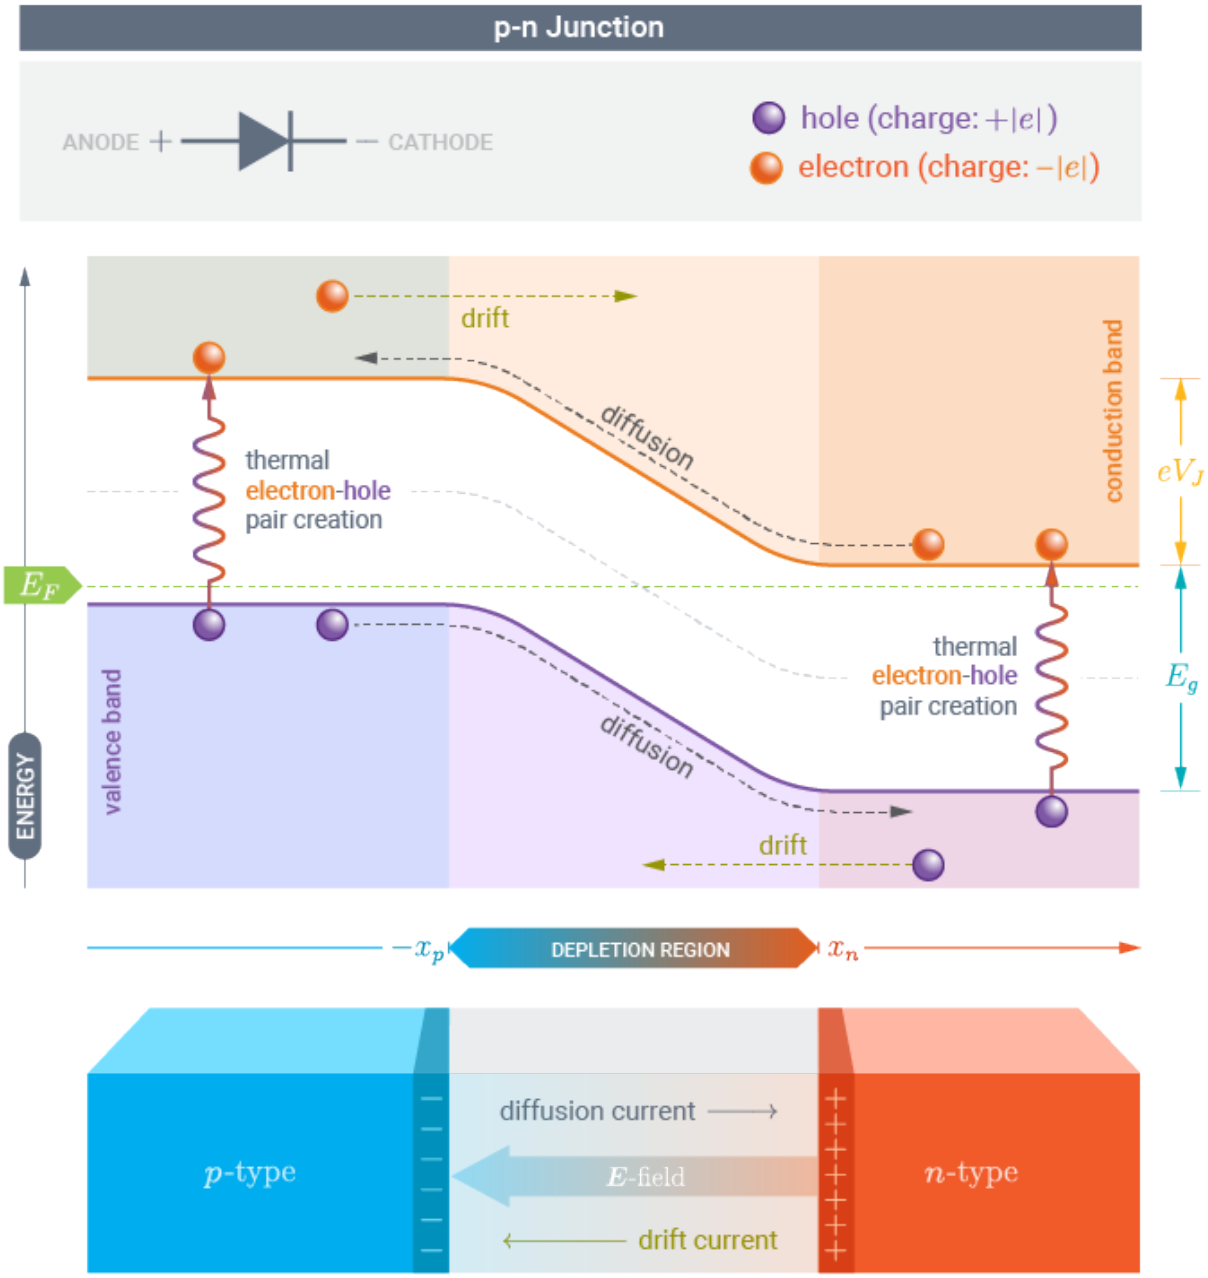
the figure below, where you can compare directly the two IV curves. You can also open the script with the **Editor** and modify it to tune the plot to your best convenience.



Attention: From the plot above you can see that the results from the semiempirical **Slater-Koster** model and the **DFT-MGGA** method are virtually the same.

Device Density of States

A classical picture of the electronic structure of a p-n junction is the one reported below, where the potential energy is plotted as a function of position along the transport direction of the device.



Using **QuantumATK** and **ATK** it is possible to perform this analysis through the **DeviceDensityOfStates** or the **LocalDensityOfStates** analysis objects.

Attention: Here, you will analyze the **DeviceDensityOfStates** and plot it along the device transport direction using a script.

In order to run the script and make the plots shown below you need an `.hdf5` file containing the analysis objects **DeviceConfiguration**, **DeviceDensityOfStates** and **ElectrostaticDifferencePotential**. You can open the script with the **Editor** and customize the plot according to your wish.

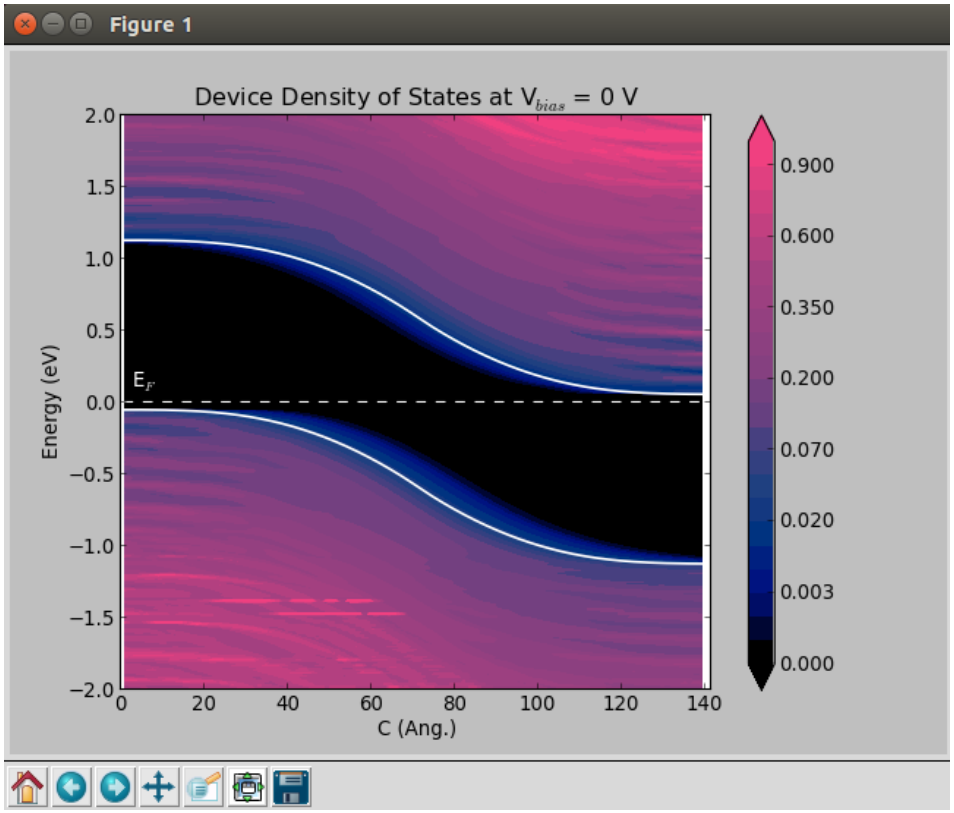
In particular, the `ddos_edp.py` script will read:

- **DeviceConfiguration**: to determine the spatial resolution along the device by defining a projection list used to plot the DDOS. Also, the electrode voltages are extracted from this object.
- **DeviceDensityOfStates**: besides reading and plotting the projected density of states, this object is also used to exctract the band edges at the left electrode. These informations are printed and used to align the electrostatic difference potential plots.
- **ElectrostaticDifferencePotential**: to plot the average electrostatic difference potential across the device.

In order to get the **DeviceDensityOfStates** plot without an applied bias, run the script from a terminal:

```
atkpython ddos_edp.py IV_2e19_SK.hdf5
```

where `IV_2e19_SK.hdf5` contains the analysis objects described above. You can also create plots for finite bias. See the section *Finite-bias calculations*. Results are illustrated below.



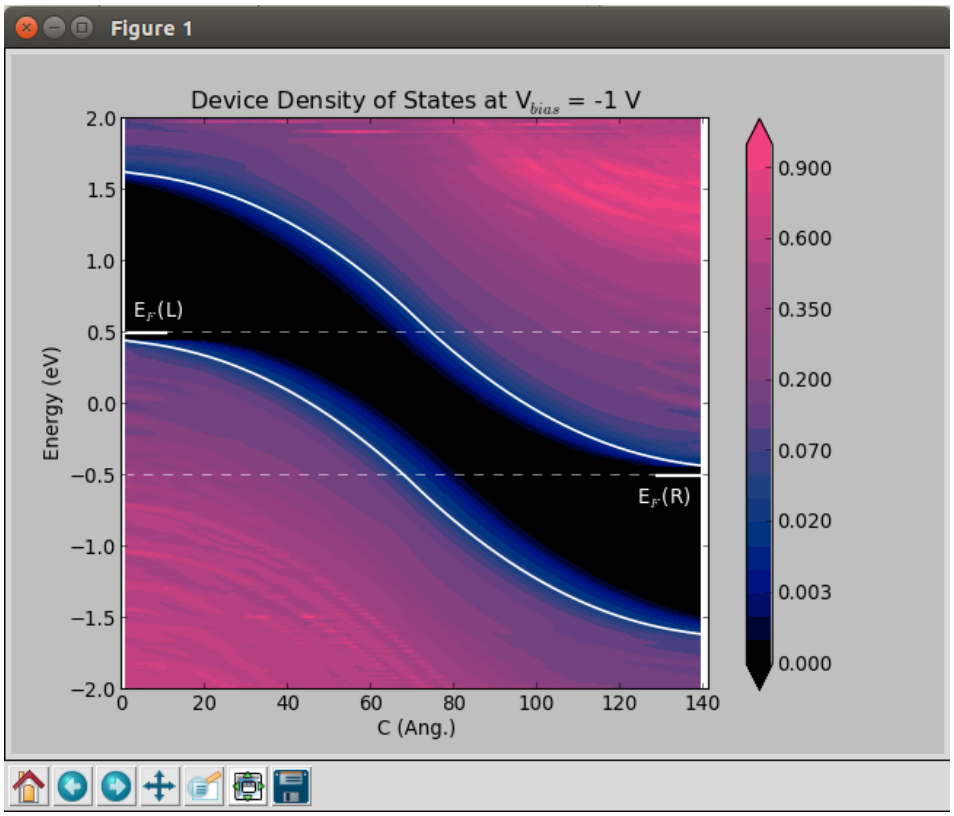


Figure 1
Device Density of States at V_{bias} = -1 V

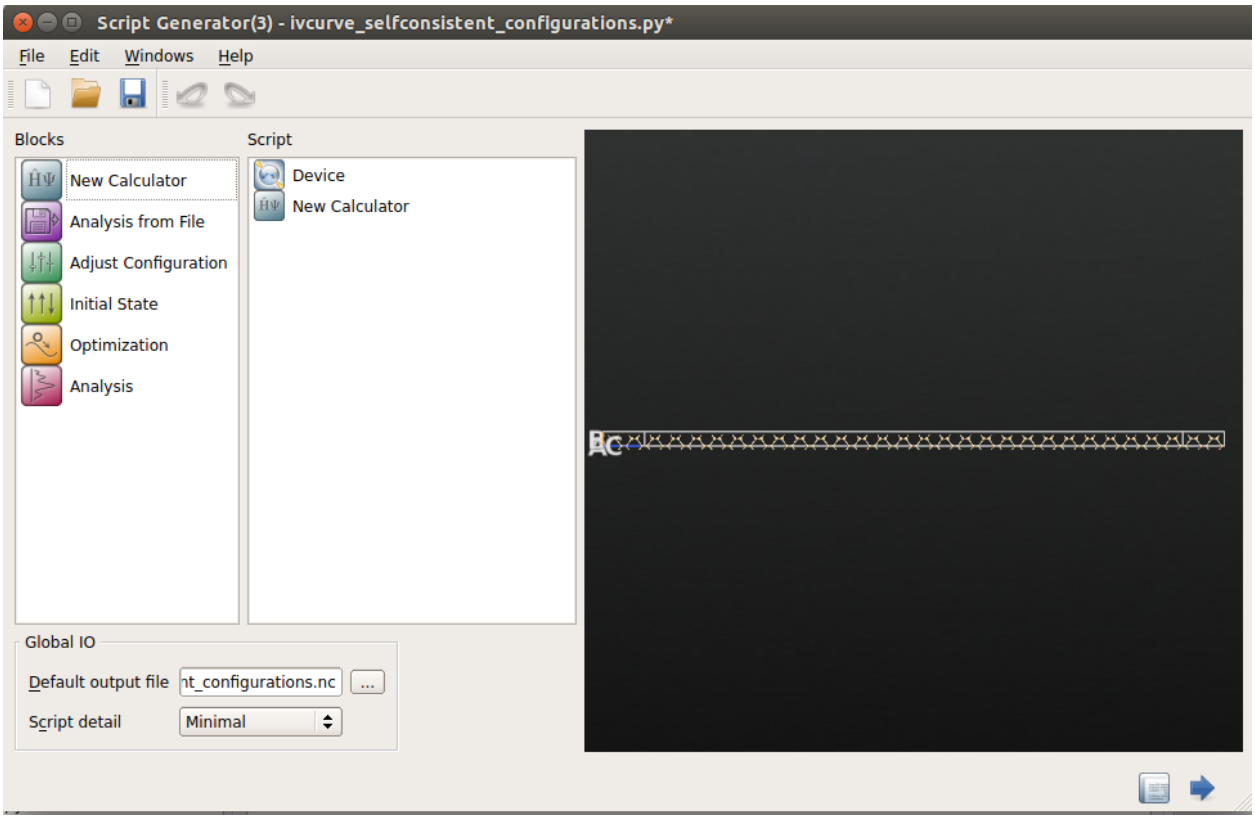
Finite-bias calculations

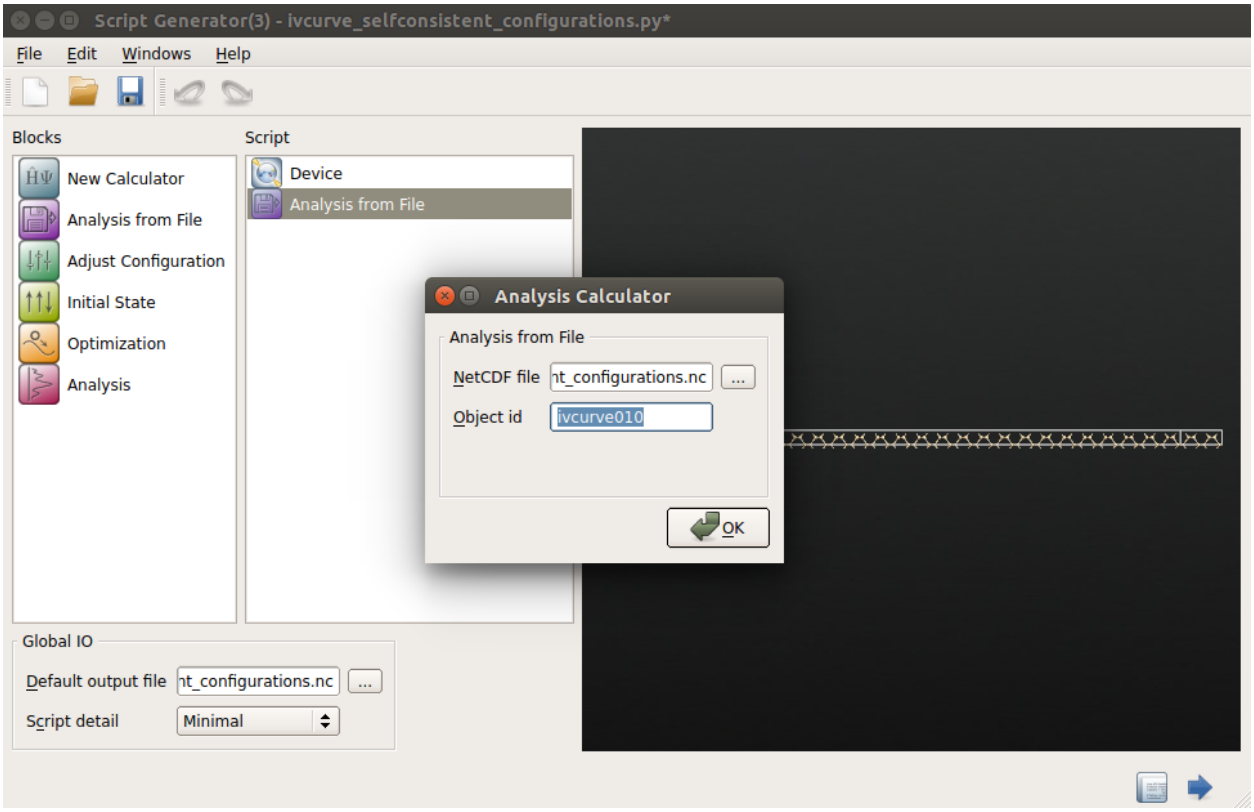
In order to create the finite-bias plots (V_{bias} = -1 and 1 V), do as follows:

1. Go to the **Labfloor** and from the `ivcurve_selftconsistent_configuration.hdf5` file select the device configuration obtained at V_{bias} = -1 V, and drag and drop it onto the **Scripter**. The following window will show up.



2. Remove the **New Calculator** object and add instead **Analysis from File**.

3. In **Analysis from File**, set the *HDF5* file and the *Object id* of the device configuration object.



4. Then, add the **Electrondensity**, **DeviceDensityOfStates** and **ElectrostaticDifferencePotential** analysis objects and set the parameters as described above.

5. Change the output file to `Analysis_ivcurve_10.hdf5`.

6. Before running the job, send the script to the **Editor**, and add the following line to get the *device_configuration* file within the `Analysis_ivcurve_10.hdf5` output file.

```
# ------------------------------------------------------------
# Analysis from File
# ------------------------------------------------------------
device_configuration = nlread('ivcurve_selfconsistent_configurations.hdf5', object_id=
↪'ivcurve010')[0]
```

7. After this part and just before **ElectronDensity**, add the following line:

```
nlsave('ivcurve_selfconsistent_configurations.hdf5', device_configuration)
```

8. Lastly, save the script and run the job. Once the job have finished, run the script `ddos_edp.py` in order to get the *Device Density of States* plot. Run the script as follows:

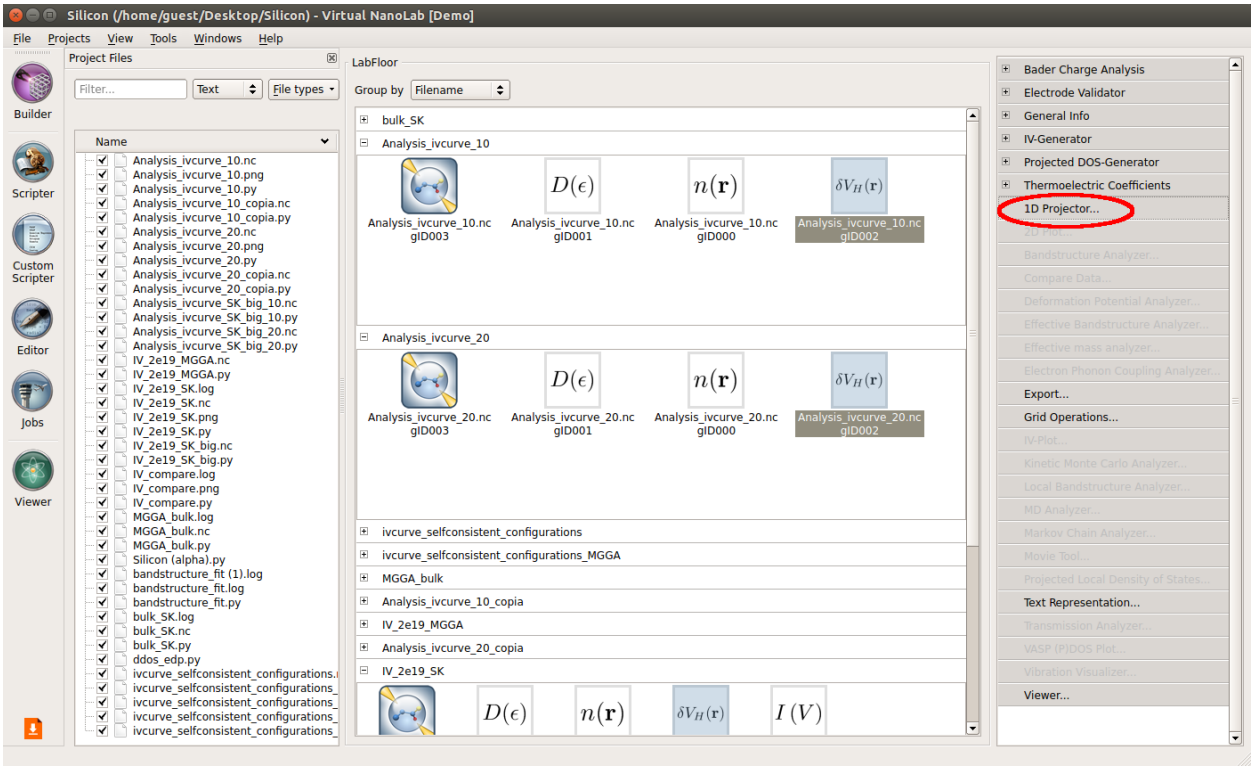
```
atkpython ddos_edp.py Analysis_ivcurve_10.hdf5
```

You can plot the *Device Density of States* plot following the same procedure for the `ivcurve_selftconsistent_configuration.hdf5ivcurve020` file.

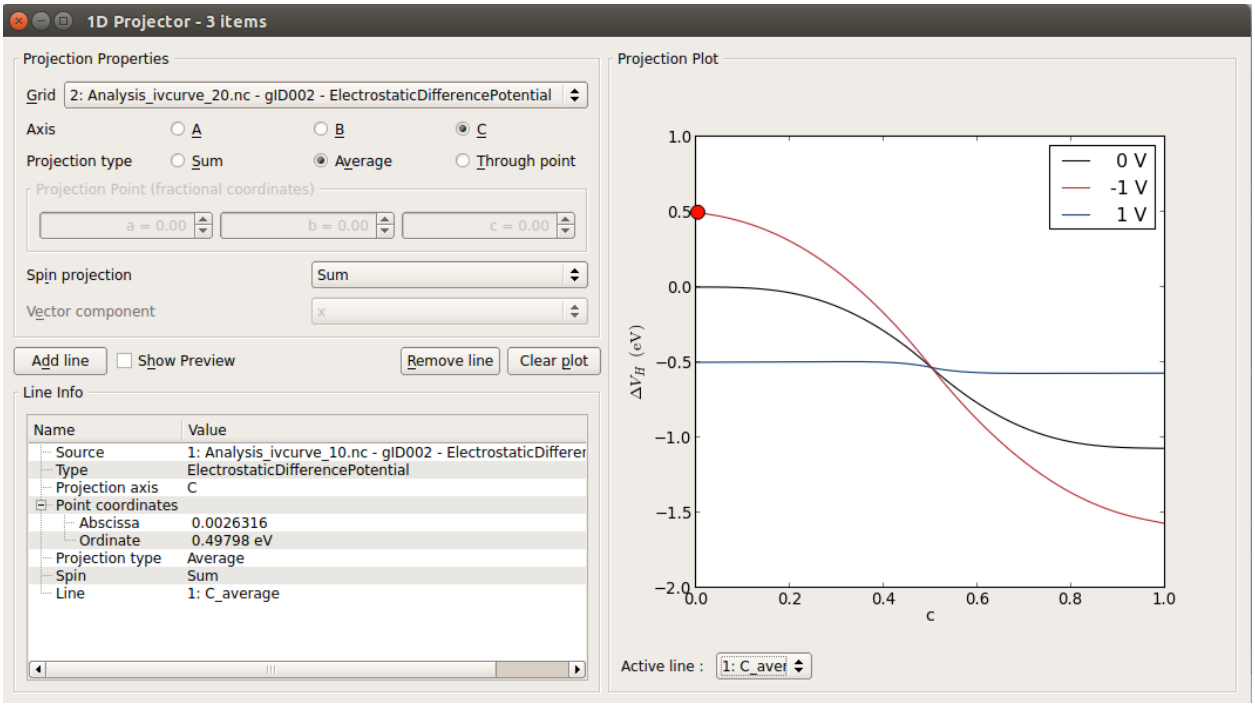
Electrostatic potential

$\delta V_{\mathbf{E}}(\mathbf{r})$

1.In the **Labfloor**, select the **ElectrostaticDifferencePotential** objects obtained for V_{bias} = 0, -1, 1,



2.Use the **1D Projector** plugin to plot the data.



You can see that the results are not perfectly converged wrt. the length of the device, because the gradient of the electrostatic potential is not zero at the ends of the device central region. The figure below compares the **ElectrostaticDifferencePotential** of the device used in this tutorial with results for a longer one.

3.2.5 Optical Properties of Silicon

Introduction

The purpose of this tutorial is to show how **ATK** can be used to compute accurate electronic structure, optical, and dielectric properties of semiconductors from DFT combined with the meta-GGA functional by Tran and Blaha[1] (TB09). TB09 is a semi-empirical functional that is fitted to give a good description of the band gaps in non-metals. The results obtained with the method are often comparable with very advanced many-body calculations, however with a computational expense comparable with LDA, i.e. several order of magnitudes faster. Thus, the TB09 meta-GGA functional is a very practical tool for obtaining a good description of the electronic structure of insulators and semiconductors.

It is important to note that the TB09 functional does not provide accurate total energies[Page 515, 1], and it can therefore only be used for calculating the electronic structure of the materials, while the GGA-PBE functional should be used for computing total energies and atomic geometries.

It is assumed that you are familiar with the general workflow of **QuantumATK**, as described in the Basic QuantumATK Tutorial.

This tutorial uses silicon as an example. As for most semiconductors, GGA/LDA both severely underestimate the Si band gap (between 0.5 and 0.6 eV), while the experimental band gap of 1.18 eV is reproduced almost exactly by TB09. The experimental dielectric constant is also reproduced by the optical properties module in **ATK** to within a few percent.

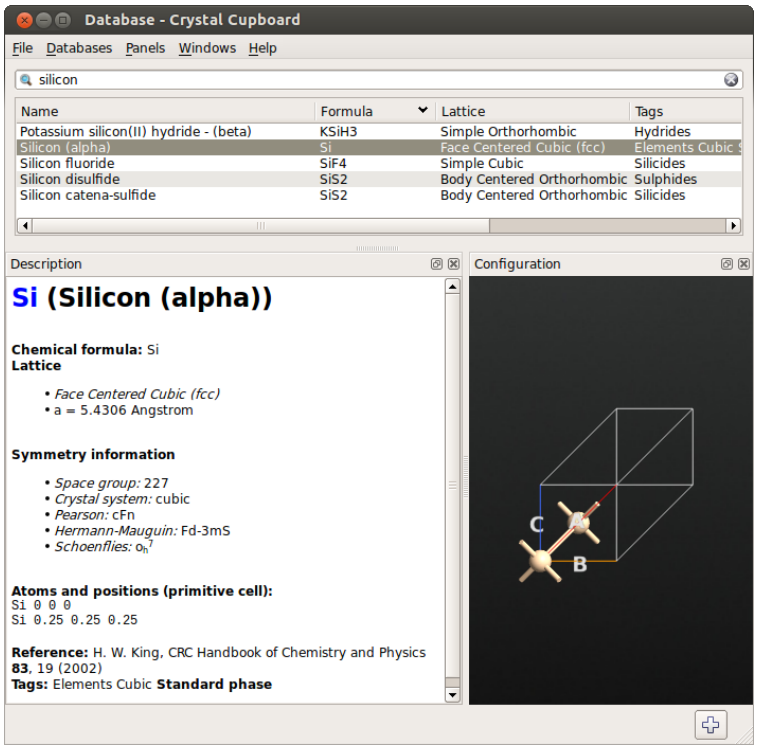
Electronic structure and optical properties of silicon

Setting up the calculation

Start **QuantumATK**, create a new project and give it a name, then select it and click Open. Launch the Builder by pressing the icon on the toolbar.

In the builder, click *Add* → *From Database*. Type silicon in the search field, and select the silicon standard phase in the list of matches. Information about the lattice, including its symmetries (e.g. that the selected crystal is face centered cubic), can be seen in the lower panel.

[1] F.Tran, P. Blaha, *Phys. Rev. Lett.*, **102**, 226401, 2009.

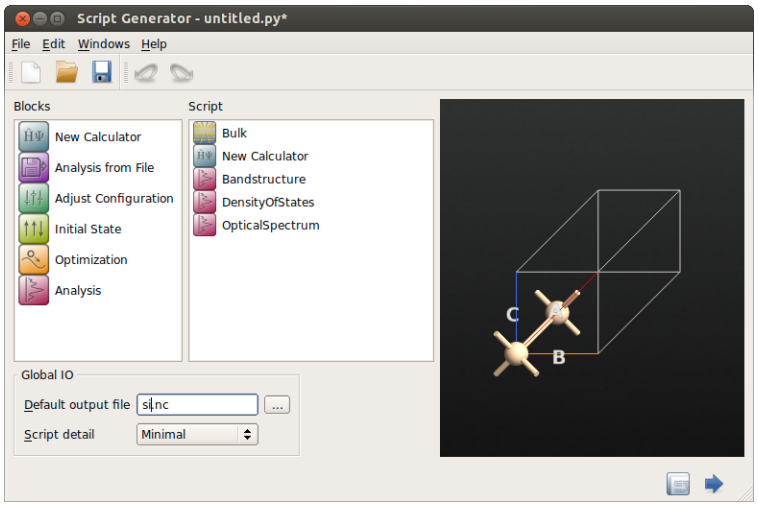


Double-click the line to add the structure to the Stash, or click the icon in the lower right-hand corner.

Now send the structure to the **Script Generator** by clicking the Send To icon in the lower right-hand corner of the window, and select **Script Generator** (the default choice, highlighted in **bold**) from the pop-up menu.

In the Script Generator,

- Add *New Calculator*.
- Add *Analysis* → *Bandstructure*.
- Add *Analysis* → *DensityOfStates*.
- Add *Analysis* → *OpticalSpectrum*.
- Change the output filename to `si.nc`.



The next step is to adjust the parameters of each block, by double-clicking them:

•Open the New Calculator block, and

–select the ATK-DFT calculator (selected by default),

–set the k-points to (4,4,4),

–select the exchange-correlation functional to MGGA,

–under Basis set/exchange correlation, set Pseudopotential to **HGH[Z=4] LDA.PZ**,

–and finally select the **Tier 3** basis set for Si.

–Close the dialogue by clicking OK in the lower right-hand corner

•Open the DensityOfStates block, and

–select 15 x 15 x 15 kpoints.

•Open the OpticalSpectrum block, and

–select 15 x 15 x 15 k-points,

–use 10 bands below and 20 above the Fermi level (this controls how many bands are included in the calculation of the optical matrix elements).

Note: For this calculation you will use the Hartwigsen, Goedecker, Hutter (HGH) pseudopotentials[2]. The calculation of optical properties requires a good description of virtual states far above the Fermi level. The Tier 3 basis set for Si consists of optimized 3s, 3p (2 orbitals), 3d, 4s orbitals. Going higher to Tier 4 would add another 3s orbital, and so on, but this appears to have no significant influence on the band gap (just taking longer time). With a smaller basis set, however, the band gap comes out incorrectly even with TB09-MGGA.

Save the script from the Editor for future reference.

2 C.Hartwigsen, S. Goedecker, J. Hutter, *Phys. Rev. B*, **58**, 3641, 1998.

Running and analyzing the calculation

Transfer the script to the **Job Manager** and start the calculation. The job will finish after a few minutes. The file `si.nc` should now be visible under Project Files in the main **QuantumATK** window. On the LabFloor select Group by Item Type.

DOS of silicon

Select the **DensityOfStates** (gID002), then click the **2D Plot** button on the plugin panel. From the density of states it is possible to determine the band gap of silicon.

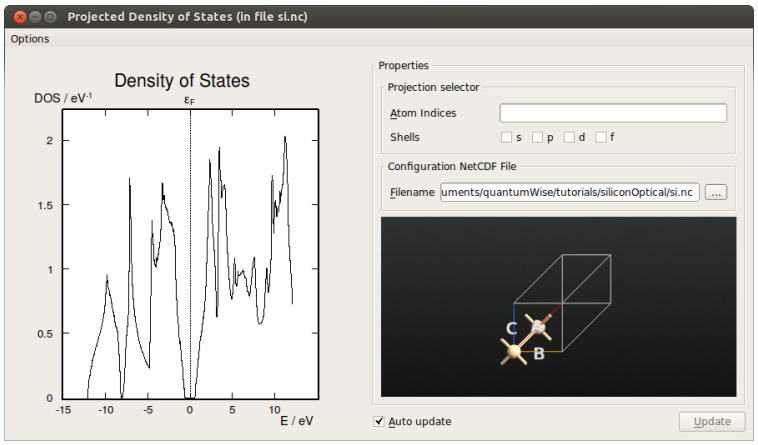


Fig. 3.25: Density of states (DOS) of Si, computed with meta-GGA.

To read off the band gap, you may zoom the plot or export the DOS data to a file (or simply select **Text Representation** instead of **2D Plot**). The band edges are located around -0.59 eV and 0.57 eV, resulting in a band gap of 1.16 eV. This is in excellent agreement with the experimental band gap of 1.17 eV (at 0 Kelvin), in contrast to the LDA band gap of 0.55 eV.

Optical spectrum

Next select the **OpticalSpectrum** (gID003), then click the **2D Plot** button on the plugin pane. The plot is shown below.

By zooming in (right-click on the plot), in the figure, you can determine the static dielectric constant, $\mathrm{Re}[\epsilon(\omega = 0)] = 10.9$, in qualitative agreement with the experimental value of 11.9 (with a bit larger basis set we can get values around 12.2, but also note that we did not optimize the k-point sampling).

The absorption coefficient and refractive index are related to the dielectric constant, see for instance the ATK Reference Manual.

The script below calculates the absorption coefficient and refractive index from the dielectric constant and plots it as a function of the wavelength.

```
# Load the optical spectrum
spectrum = nlread('si.nc', OpticalSpectrum)[-1]

# Get the energies range
energies = spectrum.energies()
```

(continues on next page)

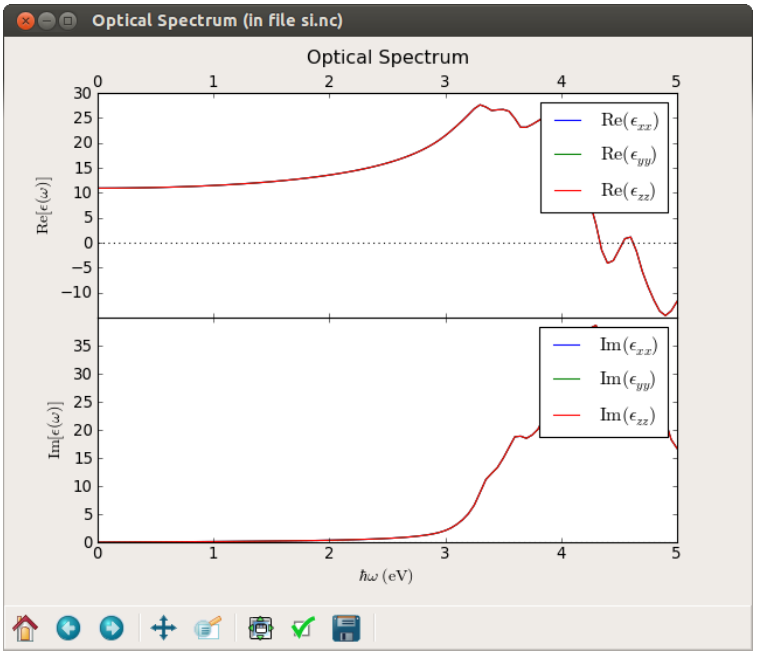

Fig. 3.26: Real and imaginary parts of the diagonal components of the dielectric constant. Since silicon has cubic symmetry the dielectric constant is isotropic, i.e. $\epsilon_{xx} = \epsilon_{yy} = \epsilon_{zz}$.

(continued from previous page)

```
# get the real and imaginary part of the e_xx component of the dielectric tensor
d_r = spectrum.evaluateDielectricConstant()[0, 0, :]
d_i = spectrum.evaluateImaginaryDielectricConstant()[0, 0, :]

# Calculate the wavelength
l = (speed_of_light*planck_constant/energies).inUnitsOf(nanoMeter)

# Calculate real and complex part of the refractive index
n = numpy.sqrt(0.5*(numpy.sqrt(d_r**2+d_i**2)+d_r))
k = numpy.sqrt(0.5*(numpy.sqrt(d_r**2+d_i**2)-d_r))

# Calculate the adsorption coefficient
alpha = (2*energies/hbar/speed_of_light*k).inUnitsOf(nanoMeter**-1)

# Plot the data
import pylab
pylab.figure()
pylab.subplots_adjust(hspace=0.0)
ax = pylab.subplot(211)
ax.plot(l, n, 'b', label='refractive index')
ax.axis([180, 1000, 2.2, 6.4])
ax.set_ylabel(r"$n$", size=16)
ax.tick_params(axis='x', labelbottom=False, labeltop=True)
ax = pylab.subplot(212)
ax.plot(l, alpha, 'r')
ax.axis([180, 1000, 0, 0.24])
ax.set_xlabel(r"$\lambda$ (nm)",  size=16)
```

(continues on next page)

(continued from previous page)

```
ax.set_ylabel(r"$\alpha$ (1/nm)", size=16)
pylab.show()
```

Save the script to the project folder and execute the script by dropping it on the **Job Manager** icon on the toolbar.

The script will generate the figure below.

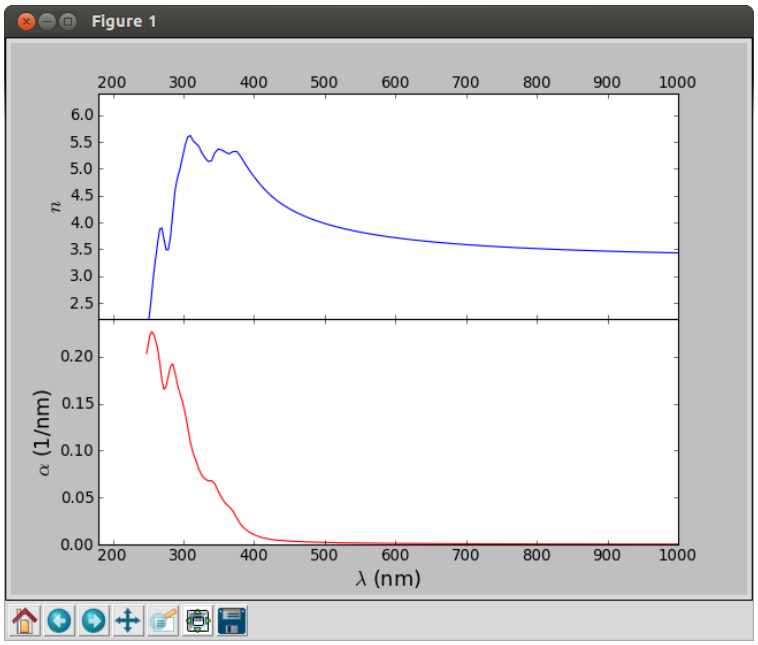

Fig. 3.27: Refractive index (blue) and adsorption coefficient (red) of silicon as function of the wavelength of the incoming light.

References

3.2.6 $NiSi_2$–Si interface

In this tutorial you will study a doped $NiSi_2$-Si interface and its electronic transport properties. In particular you will:

- create the device to calculate the transport properties of such interface;
- learn how to add the proper doping to simulate a real device;
- analyze the results in terms of electrostatic potentials, electron density and density of states, by using the tools included in **QuantumATK**.

Warning: If you are running this tutorial with QuantumATK v2017.2 or higher, be aware that you will have to set explicitly the electronic temperature to $T = 300$ K in all the electronic structure calculations performed for either a *BulkConfiguration* or for a *DeviceConfiguration*, in order to reproduce the results presented in the case study.

Create the $NiSi_2$/Si device

1. Create a new empty project and open the **Builder** (icon).

2. The first thing you have to do is to create a device configuration starting from the LDA-optimized $NiSi_2$-Si bulk configuration of the interface. The latter can be downloaded here: `Interface.py`.

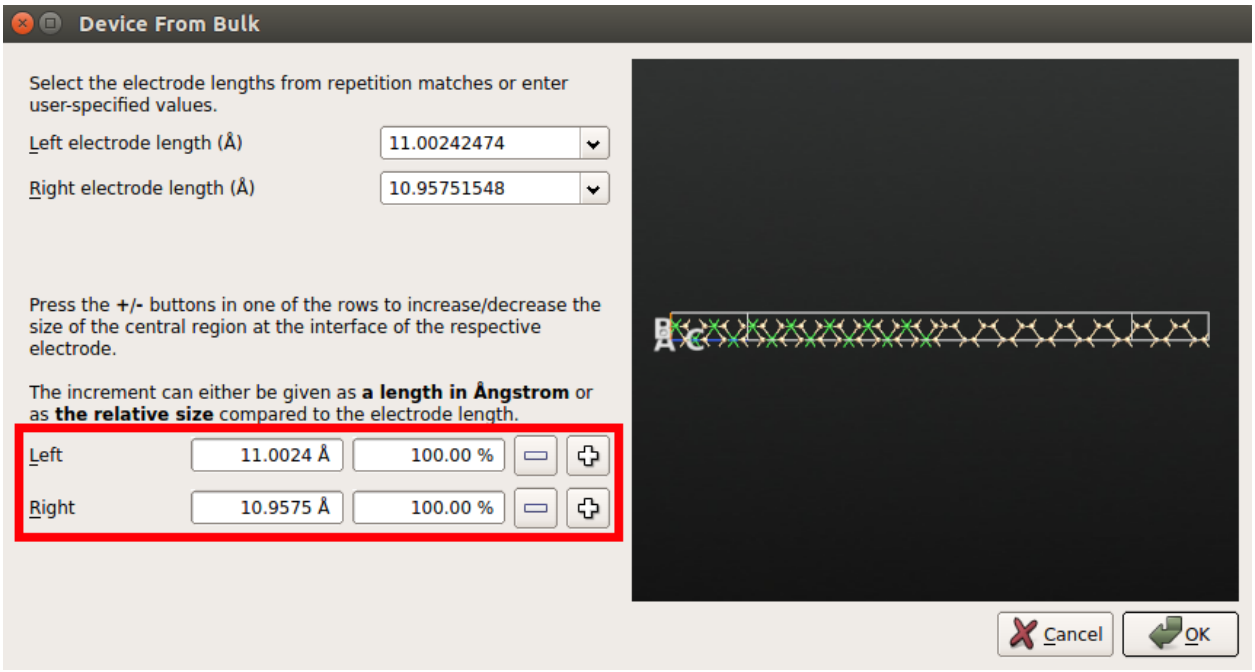
Note: You can learn how to create an interface from the tutorials *Building a Si-Si3N4 Interface*, *Graphene–Nickel interface* and *Building an interface between Ag(100) and Au(111)*.

---

3. Use *Add* → *From Files* to add the newly downloaded interface structure to the **Stash**.

4. Go to *Device Tools* → *Device From Bulk* to create the device configuration from the bulk configuration.

5. Do not modify the electrode lengths but increase the size of the central region on the left and right side by 100% compared to the size of left and right electrodes, respectively.



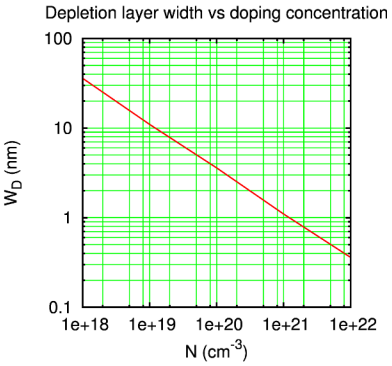
The screening region

What should be your doping concentration? In principle, you can use the experimental one. However, you need to be very careful about another quantity: the width of the depletion layer, usually denoted as W_D, which is related to the screening length of the semiconductor.

The width of the depletion layer depends on:

- the dielectric constant of the semiconductor;
- the doping concentration (number of carriers);
- the potential barrier at the interface;
- the applied voltage.

The plot below shows typical values of W_D for a metal-semiconductor junction (as reported in[1] pag. 119) as a function of the doping concentration N.



For the purpose of your simulations you need to ensure that the silicon part in the central region is larger than the width of depletion layer. Throughout this tutorial you will use doping concentrations ranging from 10^{19} cm^{-3} to 10^{20} cm^{-3}. This means that you will need a silicon region of about 30 Å to 100 Å wide. A good way to check if your system is large enough is to plot the Electrostatic Difference Potential along the device (see below).

Note: The screening length of a metal is much smaller that that of a semiconductor, only few atomic layers. Therefore, you can keep the $NiSi_2$ side much shorter than the Si side to save computational time.

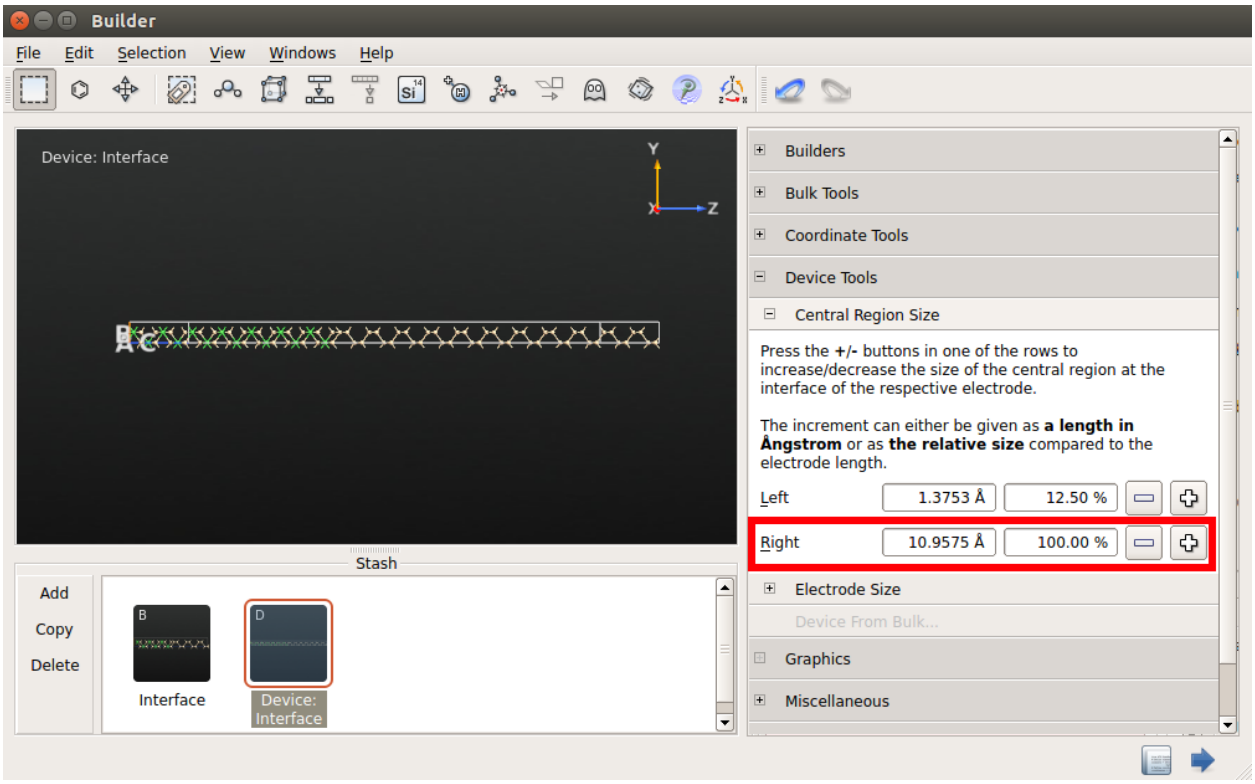
Note: In this tutorial you will use a highly doped device. The electronic transport properties of this device are significantly different from those a device with a much lower doping concentration, e.g. 10^{17} cm^{-3} or 10^{18} cm^{-3}. As you just learned, if you want to simulate a device with a lower doping concentration, you will also need a much longer device.

---

[1] E.ăKasper and D.ăJ. Paul. *Silicon Quantum Integrated Circuits*. Springer-Verlag Berlin Heidelberg, 2005. doi:10.1007/b137494.

Increase the length of the central region

1. Select again the device structure from the **Stash**.
2. Click on *Device Tools* → *Central Region size* and increase the dimension of right side (silicon) by 100% compared to the electrode length.



3. Send the structure to the **Script Generator** using the button to calculate some interesting properties of the undoped device.

Set-up the calculation for the undoped device

Once you have sent the structure to the **Script Generator**, you are ready to set-up the calculation. Add the following blocks to the script by double-clicking them:

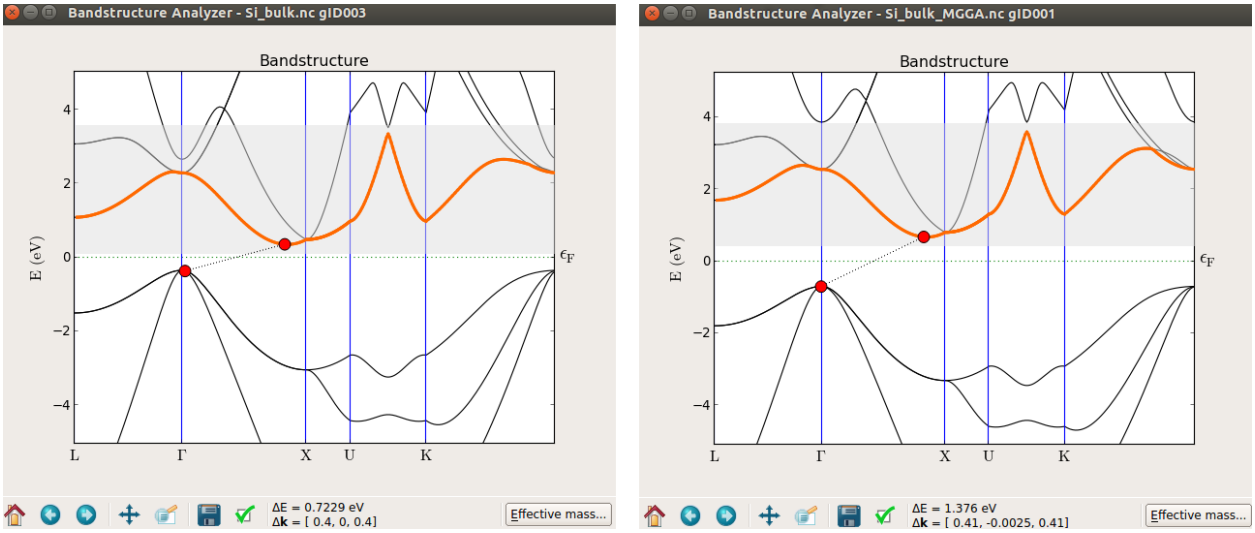
1. **New Calculator**. Double-click on it to modify the following parameters:

- change the exchange correlation parameter to MGGA.
- *k-point sampling*: 5x5x100 k-point sampling.
- *SingleZetaPolarized* basis set for both Si and Ni atoms.
- You need to set manually the TB09-MGGA c parameter in the **Editor**. Locate the exchange-correlation block in your python script and modify it as follows:

```
exchange_correlation = MGGA.TB09LDA(c=1.09368541059162)
```

Attention: We have obtained the c parameter self-consistently from a single-point calculation performed using the TB09-MGGA functional on the LDA-optimized structure of bulk silicon. If needed, you can obtain more details about how to obtain the c parameter or how to fit it from the tutorial *Meta-GGA and 2D confined InAs*. We have also compared the band structure of silicon at LDA and TB09-MGGA level of theory:

Figure 1: Band structure of bulk silicon computed using LDA (left) and TB09-MGGA (right).



From the picture it can be seen that the band structures are similar but the band-gap obtained using TB09-MGGA is closer to the experimental value (1.17 eV).

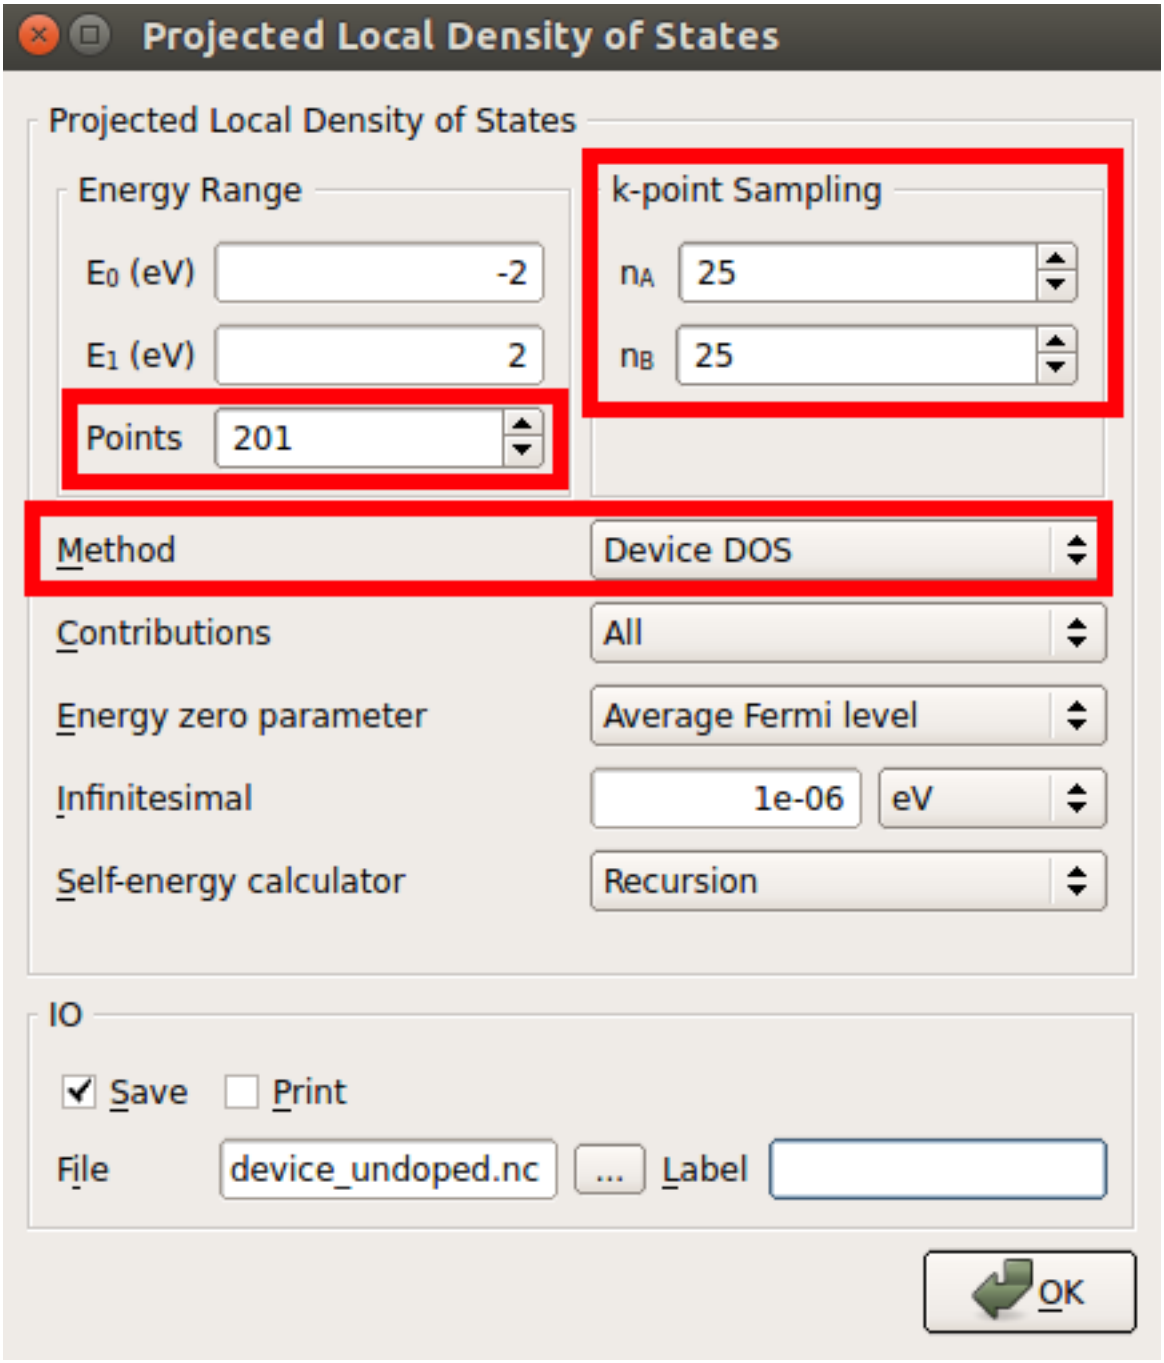
2. **Analysis**. In the menu that appears, choose the following analysis objects and modify the default parameters as shown below:

- **ElectrostaticDifferencePotentials**
- **ElectronDensity**
- **ElectronDifferenceDensity**.
- **ProjectedLocalDensityOfStates.**

– 25x25 k-points sampling

– 201 energy points

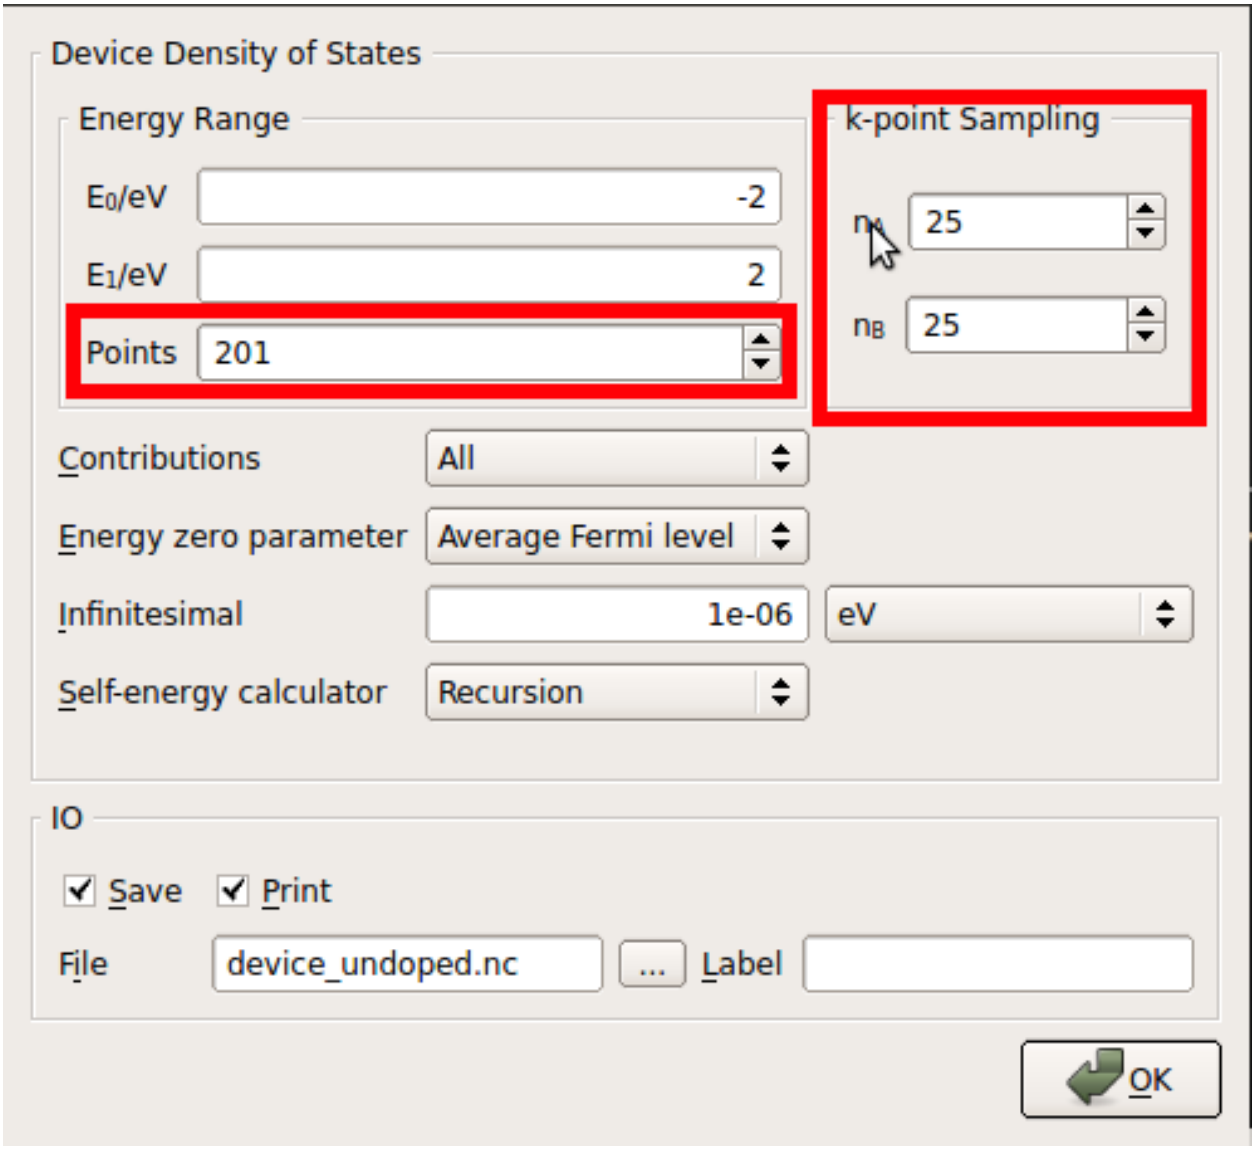
– Choose the *Device DOS* method.



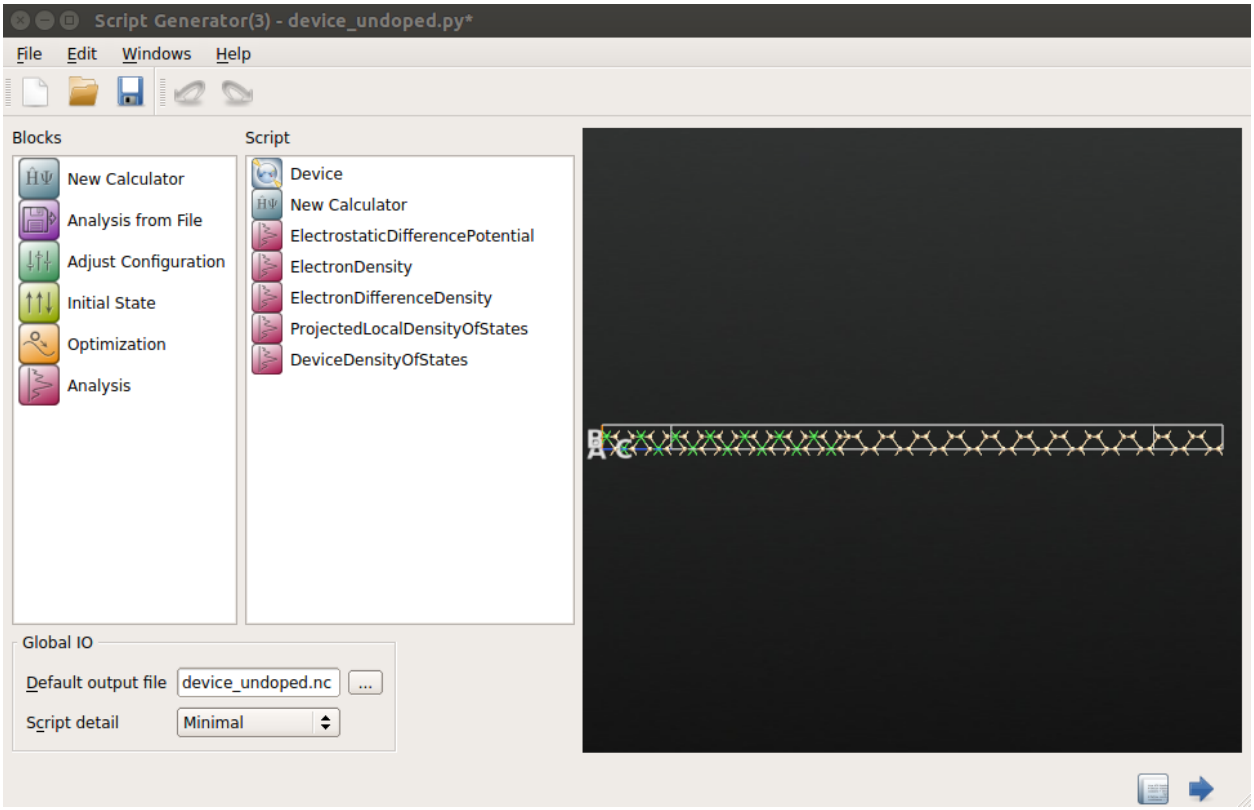
•**DeviceDensityOfStates.**

–25x25 k-points sampling

–201 energy points.



3. Change the name of the default output file to `device_undoped.hdf5` and save the script with the same name, `device_undoped.py`. The **Script Generator** panel should look as in the figure below.

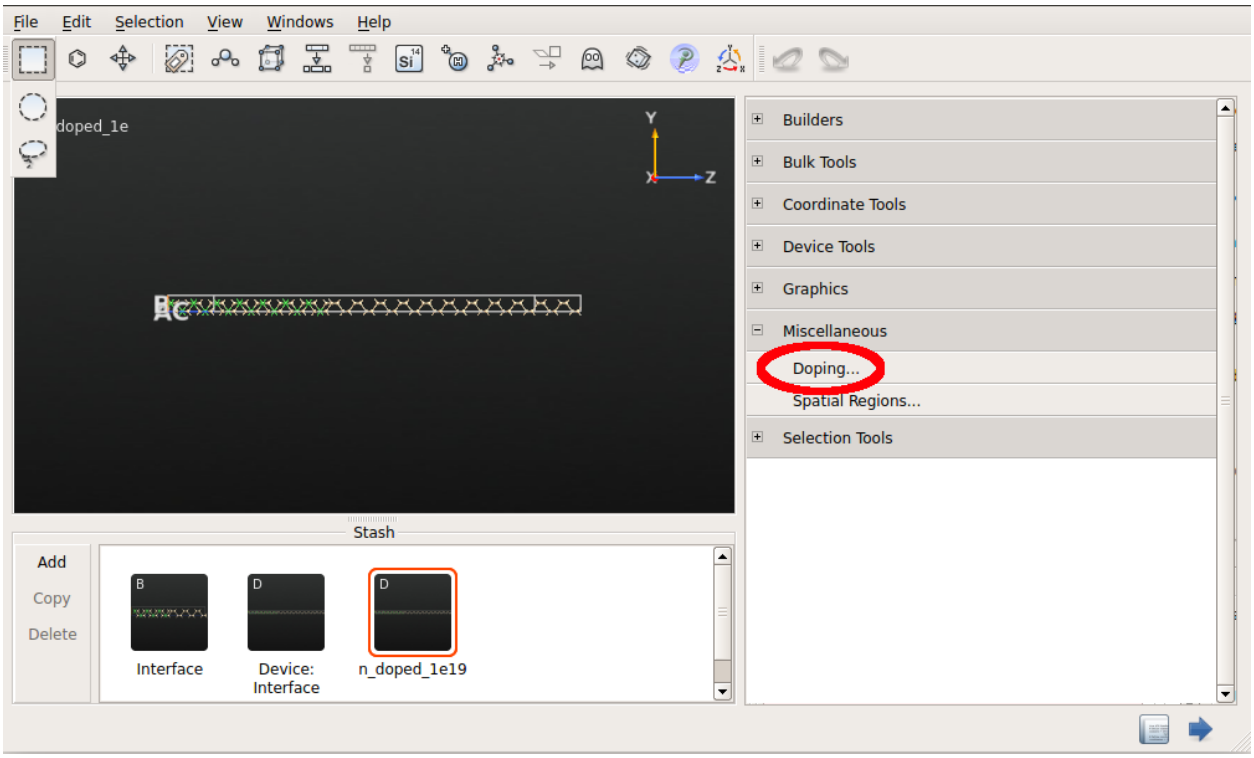


4. Send the script to the **Job Manager** and run it. The entire job will take around two hours by using 4 MPI processes. The calculation of each DOS takes around four hours on a single processor.

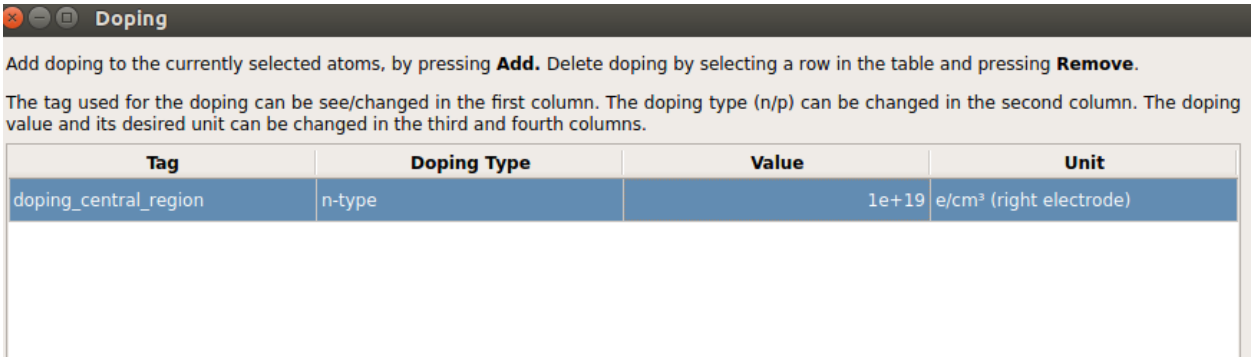
Note: The DOS calculations take quite a lot of time, especially with a 25x25 k-points sampling. You can reach reasonable good results also with a smaller mesh, e.g. 15x15 k-points. You can also run the DOS analysis at a later stage by reading the converged device configuration.

Dope the device

1. In the **Stash**, copy and paste the device configuration and rename it as `n_doped_1e19`.
2. Select the semiconductor atoms using the mouse by drawing a rectangle.
3. Go to *Miscellaneous* → *Doping*.



4.In the **Doping** panel that shows up set the doping as shown in the figure below.



5.Close the **Doping** panel and send the structure to the **Script Generator**.

6.Set up the calculation as for the undoped device and run the script.

7.Repeat the same steps for the p-type doped (10^{19} cm^{-3} and 10^{20} cm^{-3}) devices.

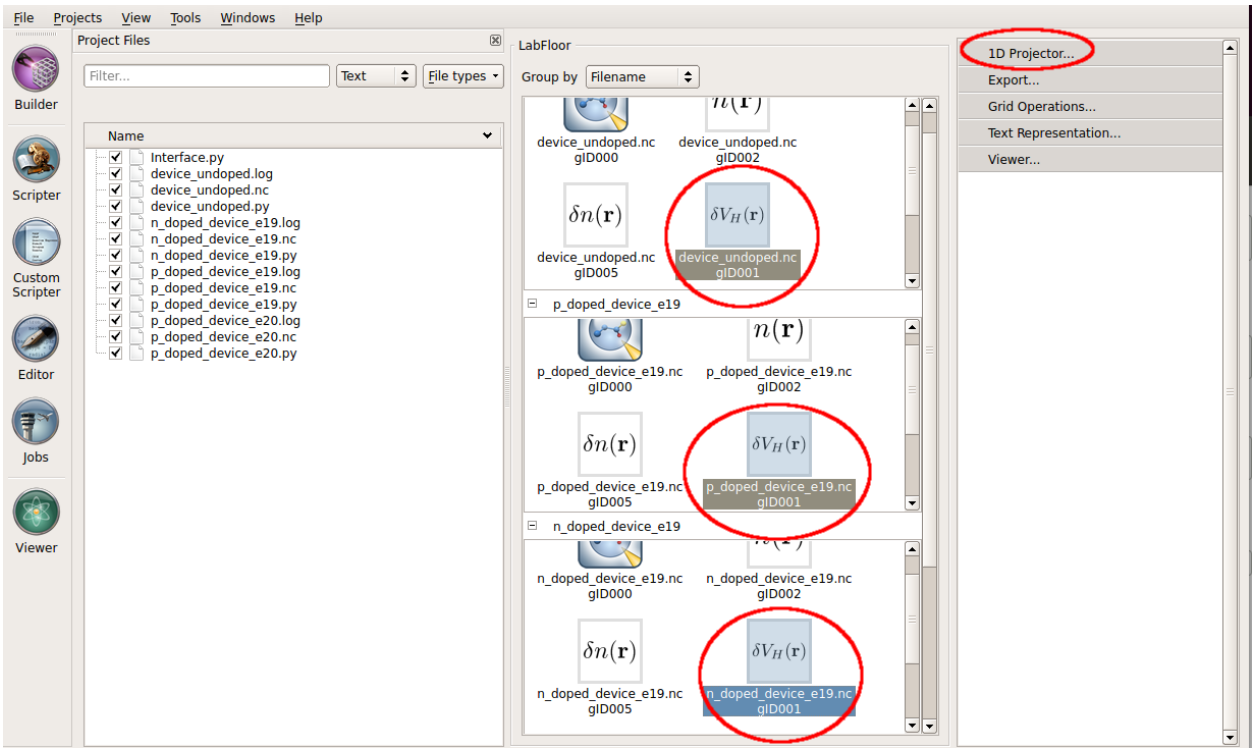
Analysis of the results

Once the calculations are finished, we are ready to analyze and compare the results obtained from the four calculations above.

Electrostatic difference potential

The electrostatic difference potential (EDP) corresponds to the difference between the electrostatic potential of the self-consistent valence electronic density and that obtained from a superposition of atomic valence electronic densities (see also the Reference Manual, *ElectrostaticDifferencePotential*). The analysis of the averaged EDP along the C axis of the device allows to see if the device is long enough, i.e. if the potential drop due to the interface is fully screened in the electrode regions.

1. In the **LabFloor**, select the four *Electrostatic Difference Potentials* objects obtained for the undoped and the three doped devices by holding Ctrl, and click on the **1D Projector** tool.



2. In the window that shows up, plot the average of the three potentials along the C direction as shown in the figure below. Right click in the graph and choose **Figure options** to change the legend.

This plot shows that the device is not long enough for the undoped device and for those at a doping of 10^{19} cm^{-3}. (see below the convereged EDP calculated for the longer device at an n-type doping of 10^{19} cm^{-3}). The EDP of the p-type doped device at a doping of 10^{20} cm^{-3} is the only one showing the correct behaviour: it can be seen that the EDP it is flat in the electrode extension region (close to c = 1). The interface is located around the fractional coordinate c = 0.35, although it is better to say that the silicon atoms in contact with the Ni atoms are located at this coordinate since the interface is not simply a infinite thin 2D plane but correspond to a thick region of your device.

Electron Difference Density

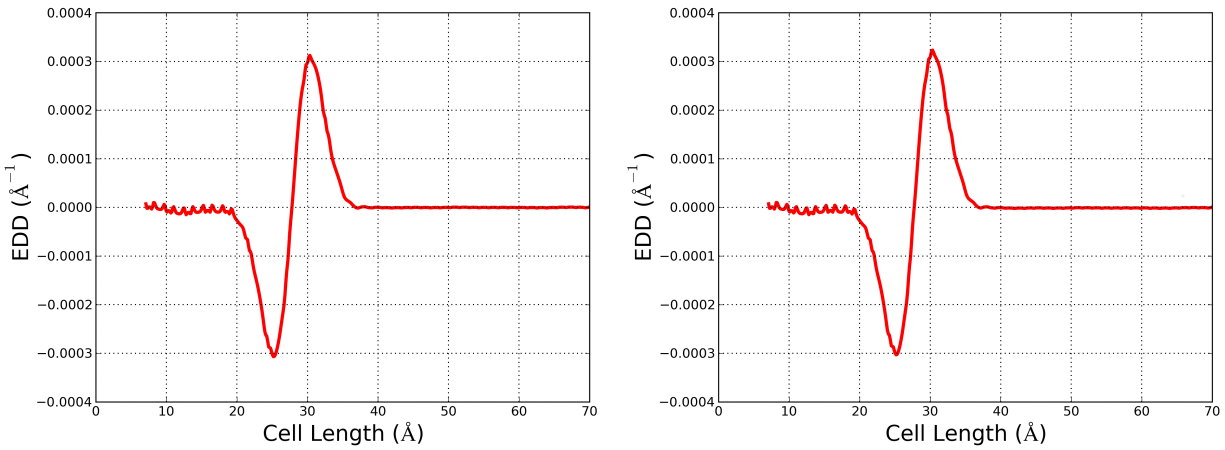
Electron Difference Density (EDD) is the difference between the self-consistent valence electronic density and the superposition of the atomic valence electronic densities.

1. Use the script provided (download the script here: `edp_macro_avg.py`) to plot the macroscopic average of the EDD.
2. Write the following commands in the terminal:

```
atkpython edp_macro_avg.py file.hdf5
```

where `file.hdf5` is the name of one of the HDF5 output files obtained from the device calculations.

Figure 2: Macroscopic average of the EDD of the undoped device (left) and of the n-type doped device (right).



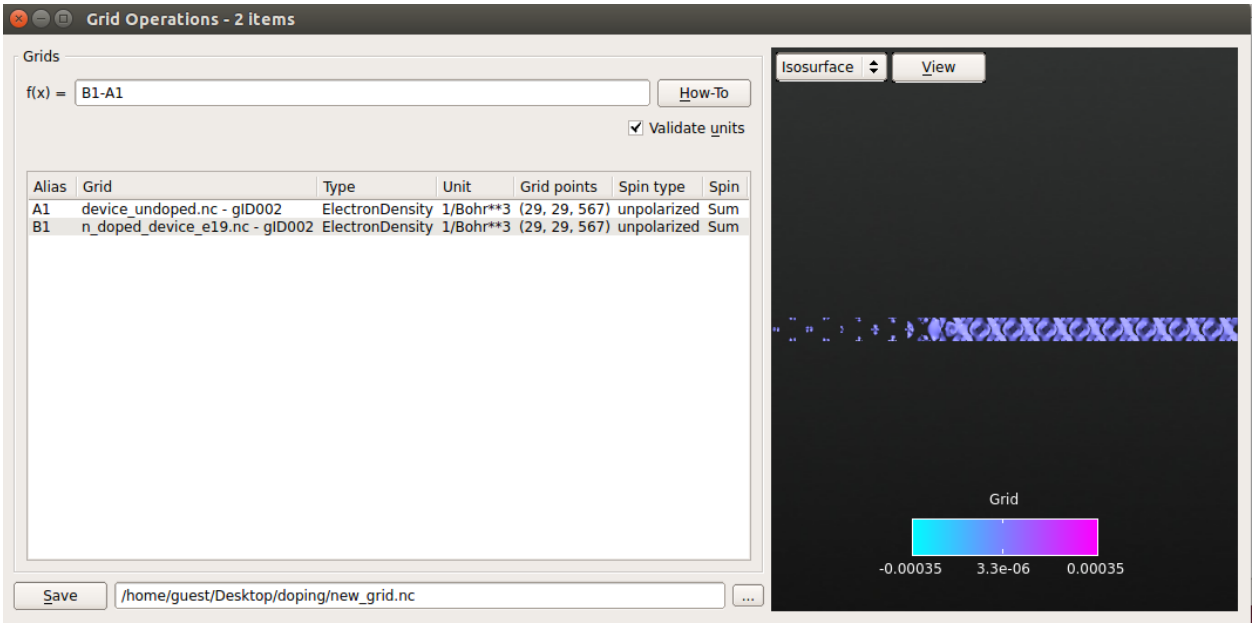
These two plots show the presence of an interfacial dipole which changes (although the change is small) unpon changing the doping in the semiconductor.

Electron density difference (doped - undoped)

You can analyze the difference in electron density between two device configurations in the following ways:

3D Analysis

1. Select the **ElectronDensity** objects of the following configurations from the **LabFloor**:
   - undoped device.
   - n-doped device (10^{19} cm^{-3})
2. Click the **Grid Operation** plug-in on the left-hand side of the **LabFloor**.
3. In the formula editor, insert B1-A1 and click *View* to visualize the isosurface of the electron density difference.



4.Save the generated density difference in a `new_grid.hdf5` file.

1D Analysis

Use the provided script to plot the macroscopic average of difference between the n-type doped and the undoped configurations.

1.Open the script and modify the line:

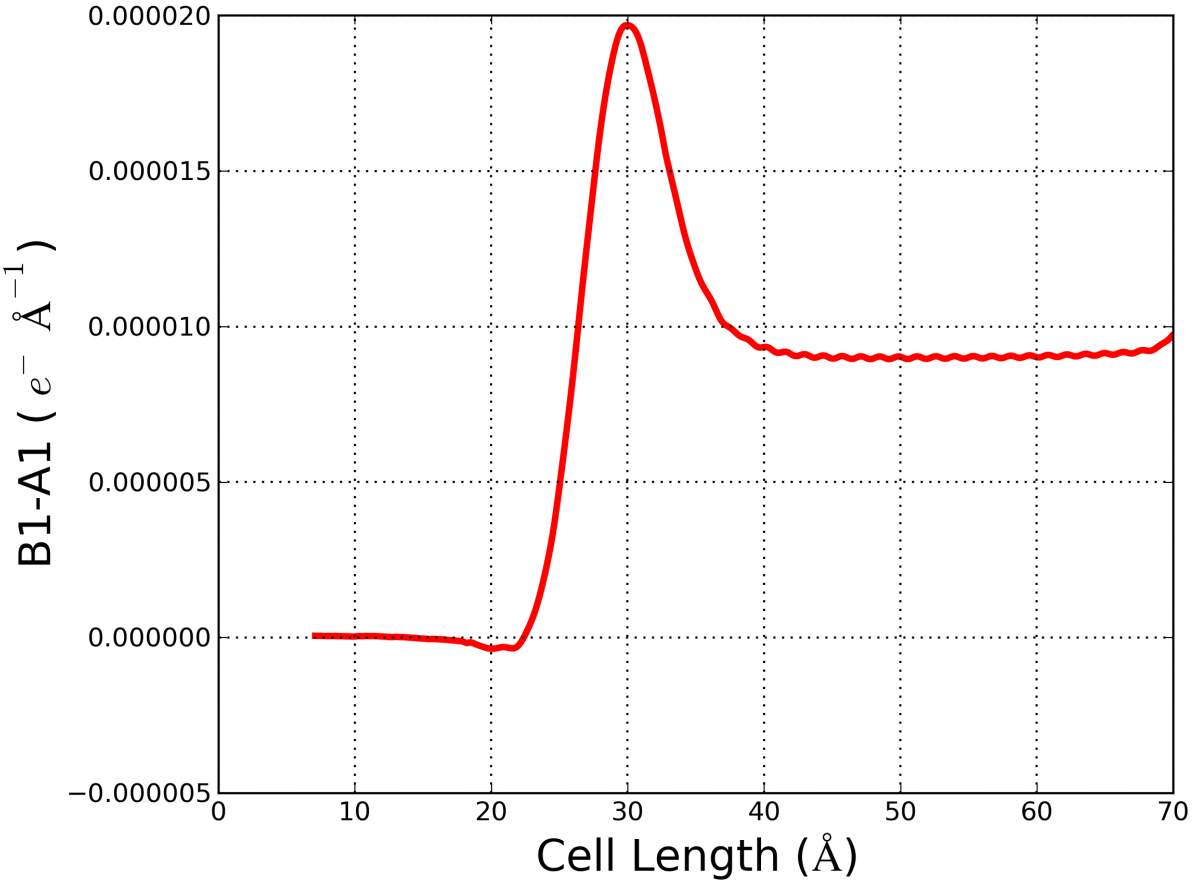
```
ax.set_ylabel(r'EDD ($\AA^{-1}$)', fontsize=20)
```

as follows:

```
ax.set_ylabel(r'B1-A1 ($\AA^{-1}$)', fontsize=20)
```

2.Run the script as shown previously:

```
atkpython edp_macro_avg.py new_grid.hdf5
```



The plot shows the difference B1-A1 between the electronic densities of the n-type doped (B1) and undoped (A1) devices. B1-A1 > 0 e^- Å $^-$ in the semiconductor region due to the extra electrons added to the silicon in the n-type doped device. Furthermore, the value of B1-A1 increases when approaching the interface, which can be understood taking into account the change of the interfacial dipole due to doping.

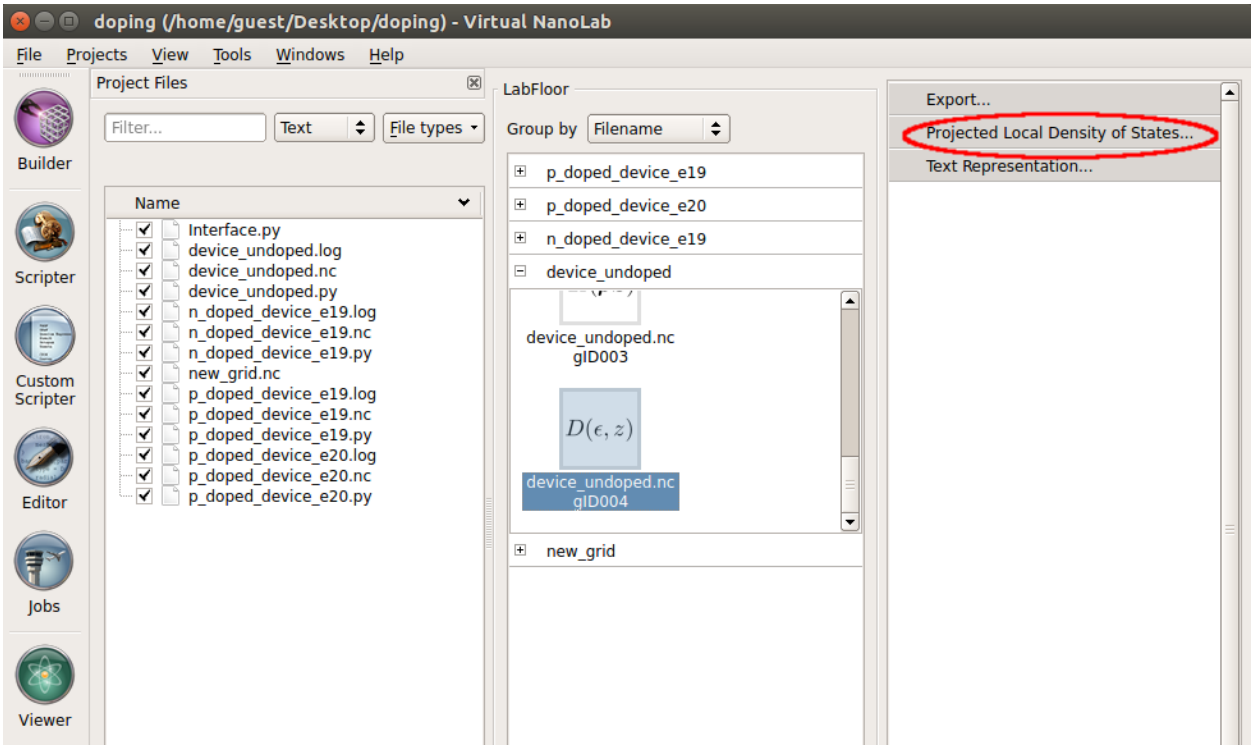
Density of states (DOS) analysis

In this tutorial we have computed two DOS analyses.

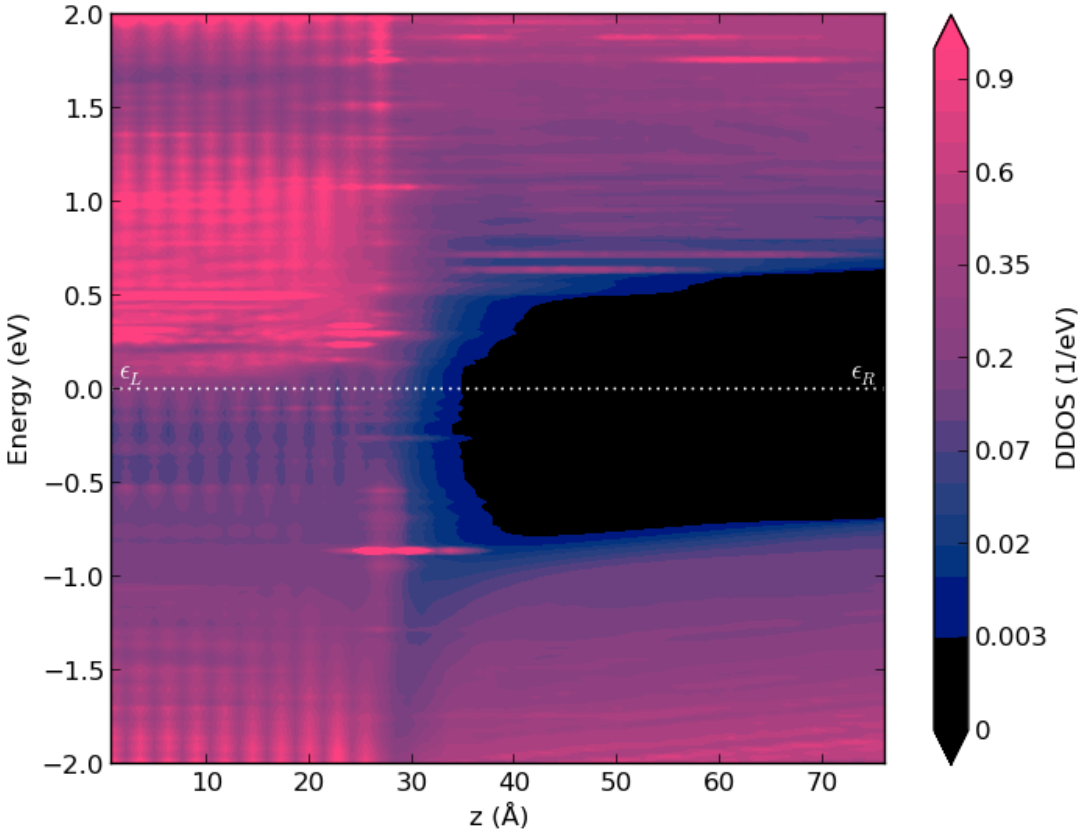
Projected Local Density Of States

1.Select the *Projected Local Density Of States* object of the undoped device from the **LabFloor**.

2.Click the **Projected Local Density of States** plug-in:



You will obtain the following plot:

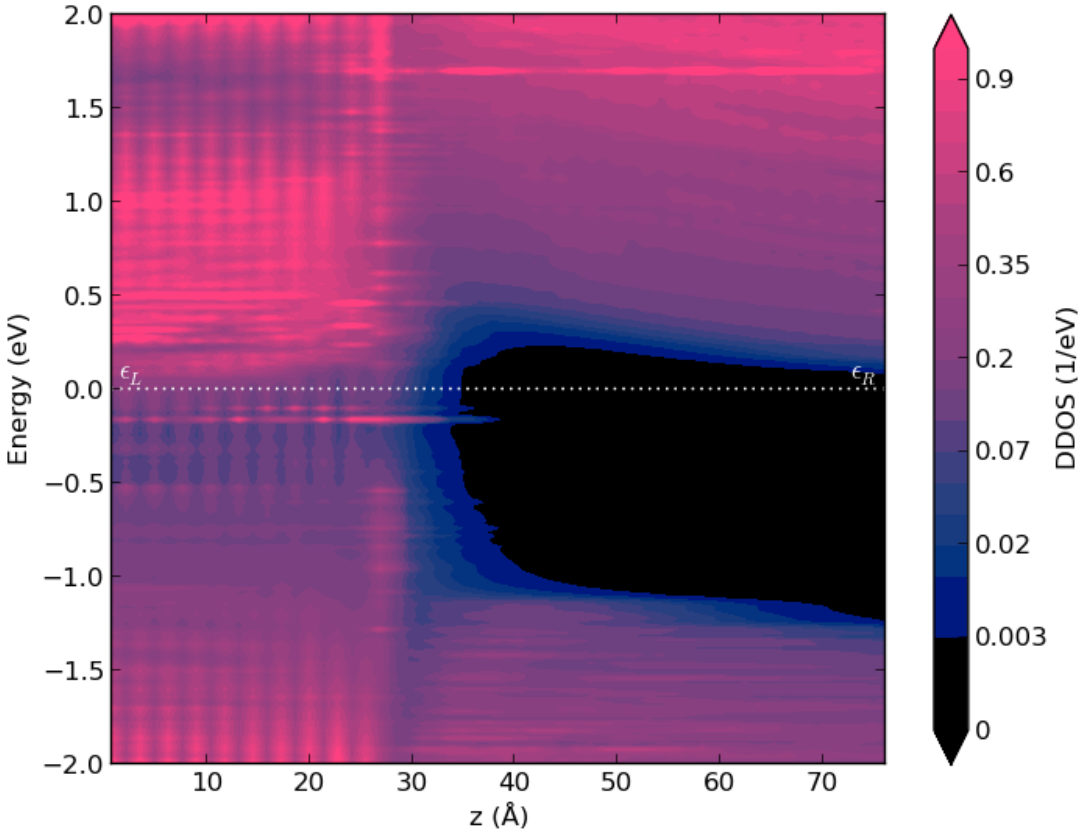


The abscissa indicates the Cartesian coordinate of the central region along the C direction. In this case, the interface is located around 27 Å. The energy on the Y-axis is relative to the Fermi energy. The color bar indicates the DOS amplitude.

It is clear from this plot that:

- The left side of the device is metallic, $NiSi_2$;
- The right side is a semiconductor with a band gap that resemble that of bulk undoped Si;
- There is a wide region of silicon atoms which show gap states induced by the metal-semiconductor interface. These are called metal-induced gap states (MIGS).

3. Follow the same procedure to plot the projected local DOS of the n-doped device.

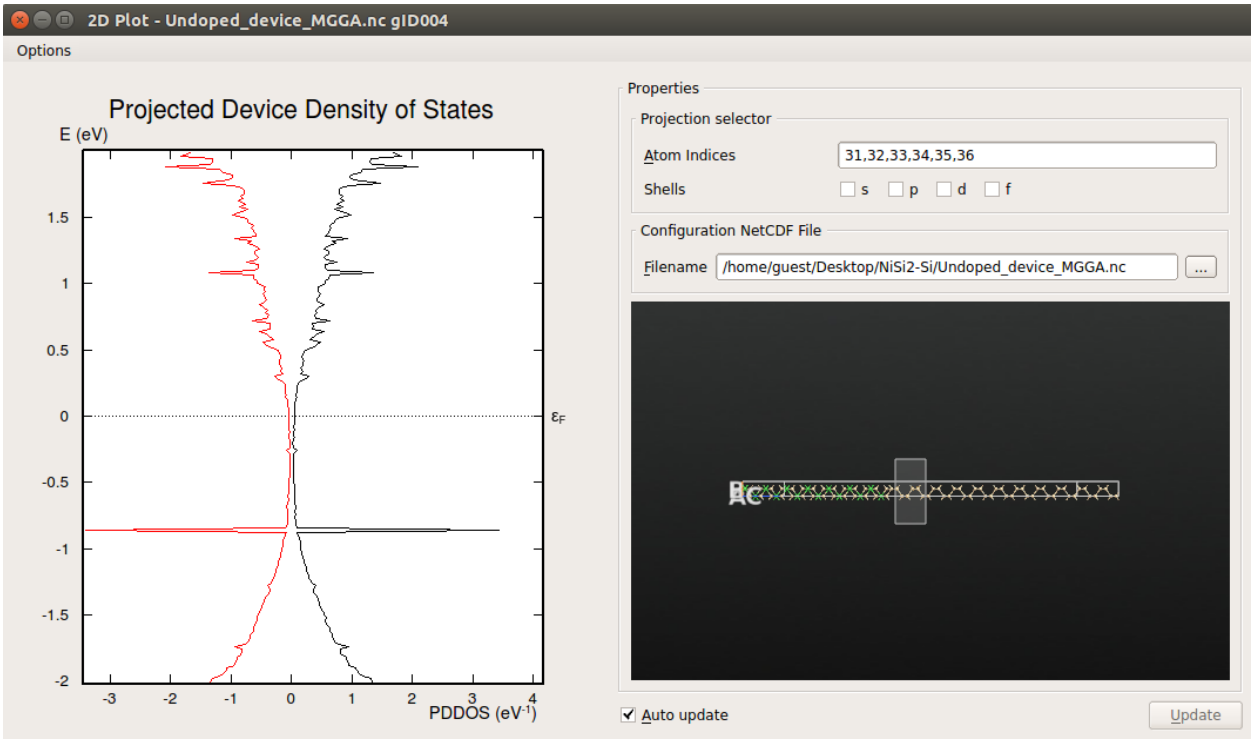


Note that in this case the Fermi level lies at the bottom of the silicon conduction band due to the doping of the semiconductor.

Device Density Of States

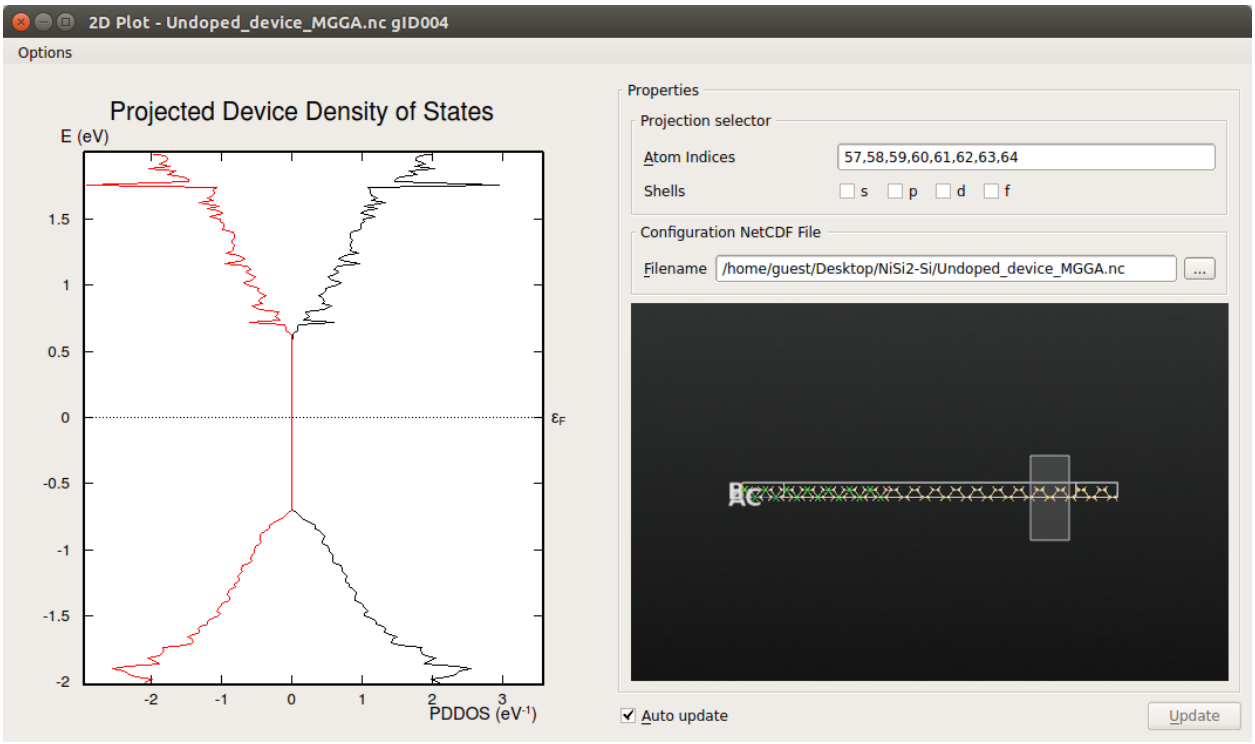
This tool allows the analysis of the density of states projected onto the atomic sites of the device.

1. Select the *Device Density Of States* object of the undoped device in the **Labfloor**.
2. Click the **2D Plot** plug-in and the window that appears will show the 2D plot of the total density of states together with a 3D view of the device.
3. Navigate to the 3D view and select the atoms close to the interface by drawing a rectangle with the mouse as shown below.



The 2D plot now shows the projected density of states onto the selected atoms. It is possible to see the presence of MIGS around the Fermi level.

4.Select the silicon atoms close to the electrode as shown below:



It can be seen that close to the silicon electrode the MIGS have disappeared and the electronic structure presents a band-gap similar to that calculated for bulk silicon, in agreement with the results obtained from the analysis of the projected local DOS.

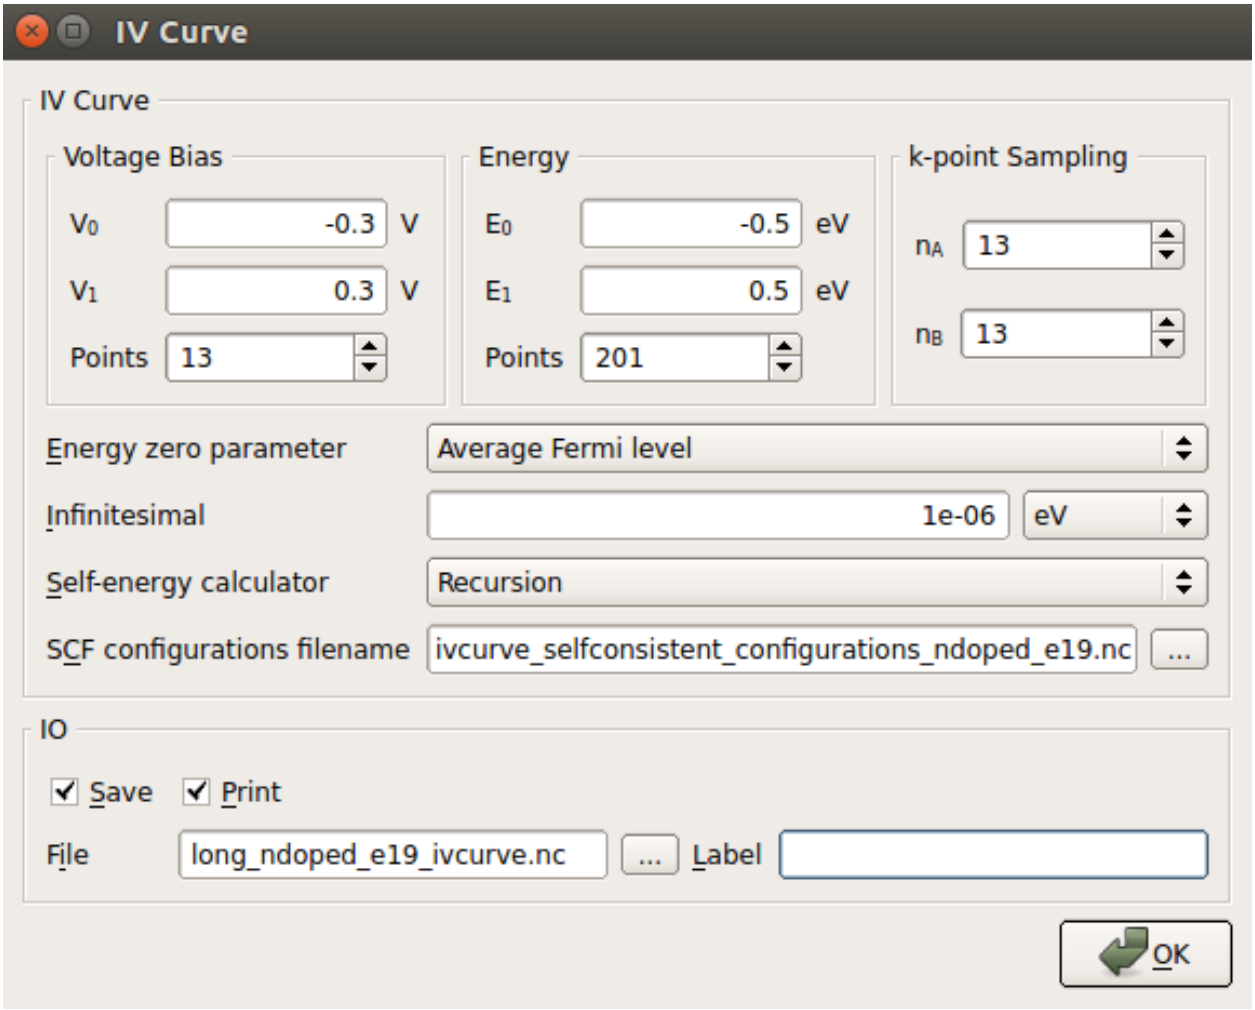
Finite-bias calculations

In this section we will calculate the IV curve for a n-type doped device (10^{19} cm^{-3}). As we have already mentioned, the device used above is not long enough for this doping concentration. In this section, we will perform the finite-bias calculations using a 100 Å long device. We have increased the lenght of the device following the steps described in the *Increase the length of the central region* section. You can download the structure here (`long_ndoped_e19_ivcurve.py`).

Set up the IV curve calculation

1. Send the structure to the **Script Generator** and add the following blocks to the script:

- **New Calculator** : Set the parameters as for 0 V_{bias} calculations.
- **IV curve**: Change the following default parameters as in the figure below:



It is worth adding some comments regarding the meaning of the most important parameters:

– *Voltage Bias* : 13 different calculations will be performed at V_{bias} = 0.0, -0.05, -0.1, -0.15, -0.2, -0.25, -0.3, 0.05, 0.1, 0.15, 0.2, 0.25 and 0.3 V, in this exact order. V_{bias} is defined as V_L - V_R.

Note: Each calculation will use the self-consistent configuration of the previous one as starting guess. This procedures improves quite a lot the convergence.

–*Energy* : These parameters refer to the enery range and the number of points within this range at which the transmission spectra will be calculated at each bias voltage.

Warning: The convergence of the energy range is very important when calculating IV curves! Check the *Transmission spectrum convergence* and The *IV curve object analysis* sections.

–*k-point Sampling* : This is the k-point mesh used to calculate the transmission spectra. It must correspond to a sampling for which the transmission curve is converged. In general a greater k-point sampling will be needed with respect to the one used for the SCF part.

Warning: The convergence of the k-point mesh can affect the calculated current! In this tutorial we have considered that at 13x13 the transmission is converged, check the *Transmission spectrum convergence* section.

–*IO File name* : Change the default name if you are going to do more than one IV curve. This is the file in which all the converged configurations will be stored. As you will learn in the *Post analysis of finite-bias calculations* section, you can use this converged states to:

∗re-calculate all, or selected transmission spectra with different parameters (k-point sampling, energy range,)

∗perform additional analysis at any specific bias (DOS, electron density, effective potential,)

∗extend your bias range by restarting from a well converged finite bias calculation.

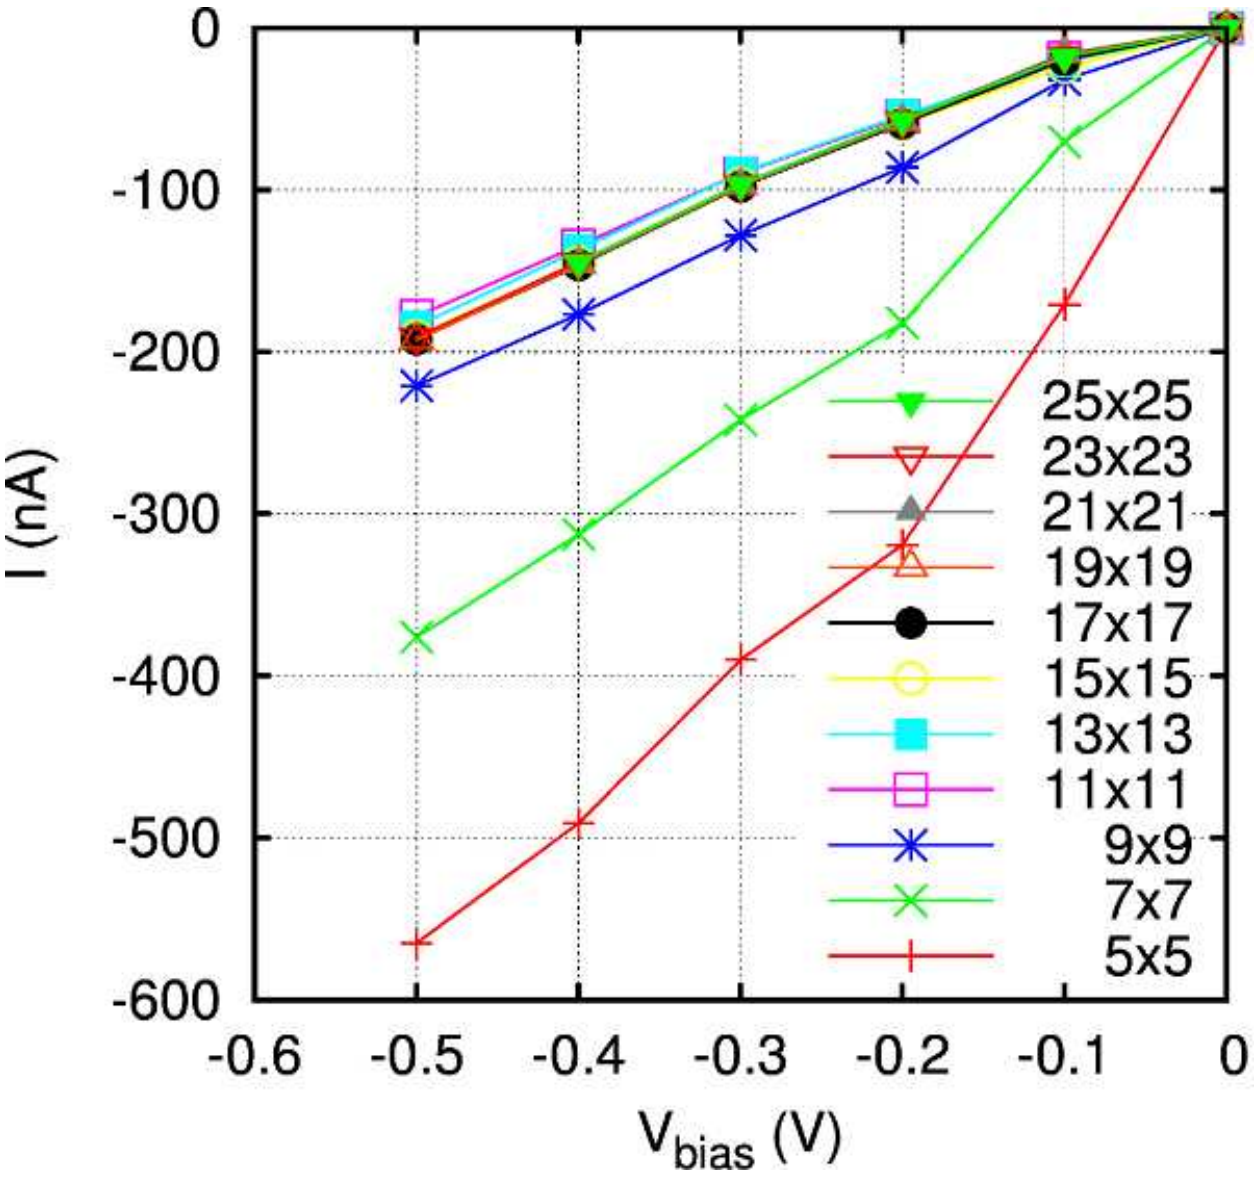
2.Once you have set all the parameters, you are ready to send the script to the **Job Manager** and run the calculation. This calculation will take around ten hour using 4 MPI processors.

Transmission spectrum convergence

Two parameters are very importat to determine the convergence of the transmission spectrum:

•**Number of energy points:** The first parameter you can tune to improve the balance between the precision of your transmission and computational efficiency is the number of energy points used to evaluate the transmission spectrum. Ideally, the range of the transmission spectrum should span at least the entire region where the spectral current is finite. In the present case the minimum range would be between +0.1 eV and +0.4 eV (see below). However, it is often safer to consider a larger and symmetric energy range.

•**K-points sampling:** The second and most important parameter to consider is the k-point sampling used for the evaluation of the transmission spectra. As already mentioned, you usually need more k-points than for the DFT calculation, since the Greens functions (which determine the transmission) have a stronger variation with k than the Fourier components of the electron density do. The plot below shows the IV curves at negative bias for the n-type doped device (at 10^{20} cm^{-3} doping concentration) calculated using different k-points samplings for the evaluation of the transmission spectra. In general, it is enough to converge the current at a specific applied bias within the range considered.



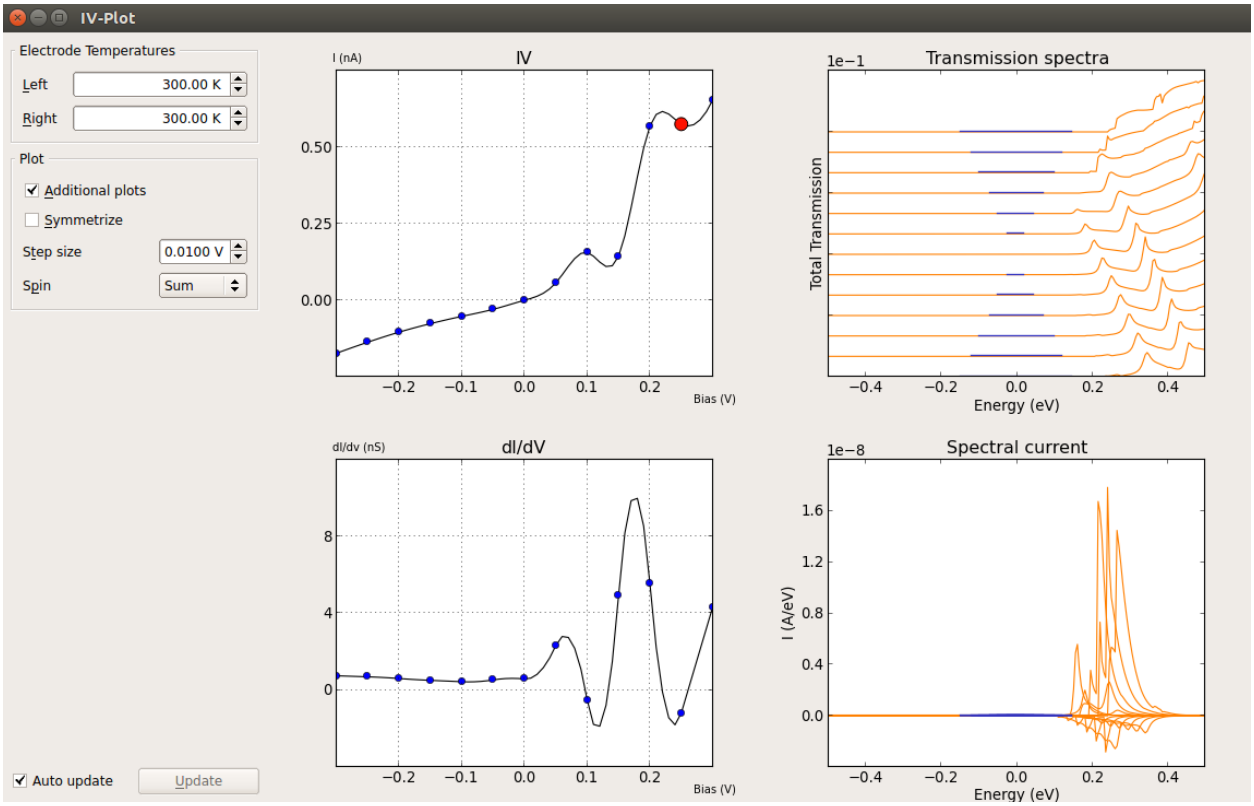
From this plot we can deduce that a 13x13 k-points mesh is good enough to give converged results, since the IV curve obtained at this mesh is very close to the one obtained at the highest sampling, 25x25.

Warning: This assessment have been done for n-type doped device with a concentration of 10^{20} cm^{-3}. For a more rigorous study, an assessment for the device doped at 10^{19} cm^{-3} should be done.

IV curve object analysis

Once the IV curve calculation are finished we are ready to analyse the **IVCurve** object. You can find it loaded in the **LabFloor**.

- Select the **IVCurve** object and click the **IV-plot** plug-in.
- You will find the IV curve plot in the panel that shows up. Click on *Additional Plots* and you will get the dI/dV, transmission spectra and spectral current plots.



Important: The spectral current is the energy resolved current:

$$I(E) = e/h[T(E, \mu_R, \mu_L)(f(E - \mu_R)/(k_B T_R) - f(E - \mu_L)/(k_B T_L))]$$

This is the quantity which is integrated to get the current at a given bias. As such, it is good practice to check that the energy range set for the evaluation of the transmission spectra spans the entire region where the spectral current differs from zero. You can refer to the *TransmissionSpectrum* entry in the Reference Manual for more information on how the current is evaluated in QuantumATK.

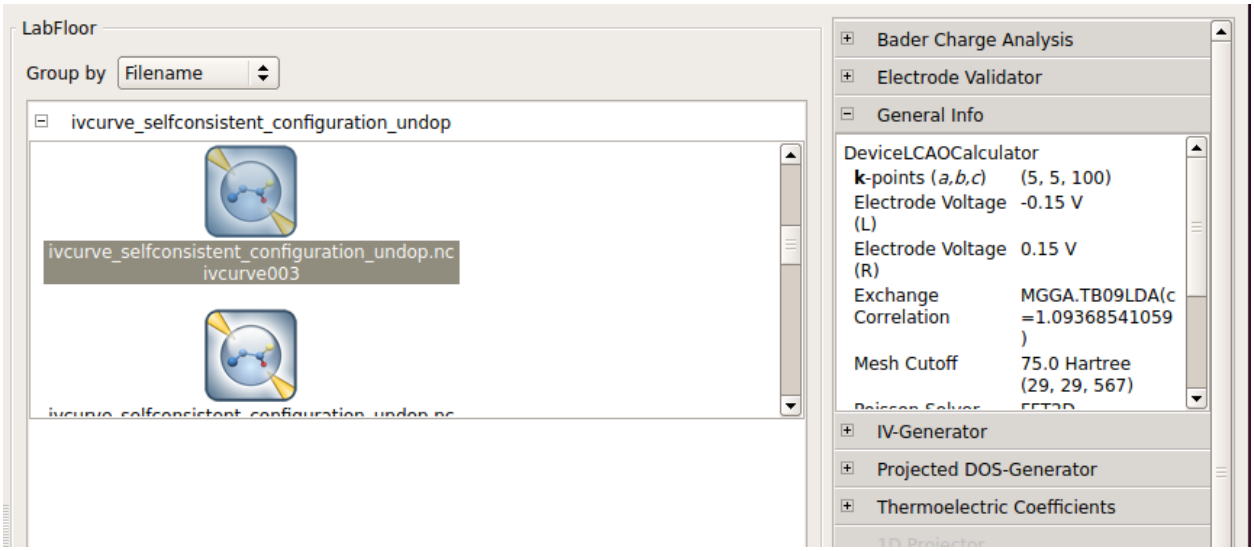
Note: You can right-click on any of the plot windows to export the data and use your favourite utility to plot your results.

Post analysis of finite-bias calculations

As we have already mentioned, using the selfconsistent configurations (stored in the `ivcurve_selfconsistent_configurations.hdf5` file) it is possible to perform further analysis at any specific bias. In this section we will explain how to inspect this objects and how to set-up the script for the additional analysis of a configuration.

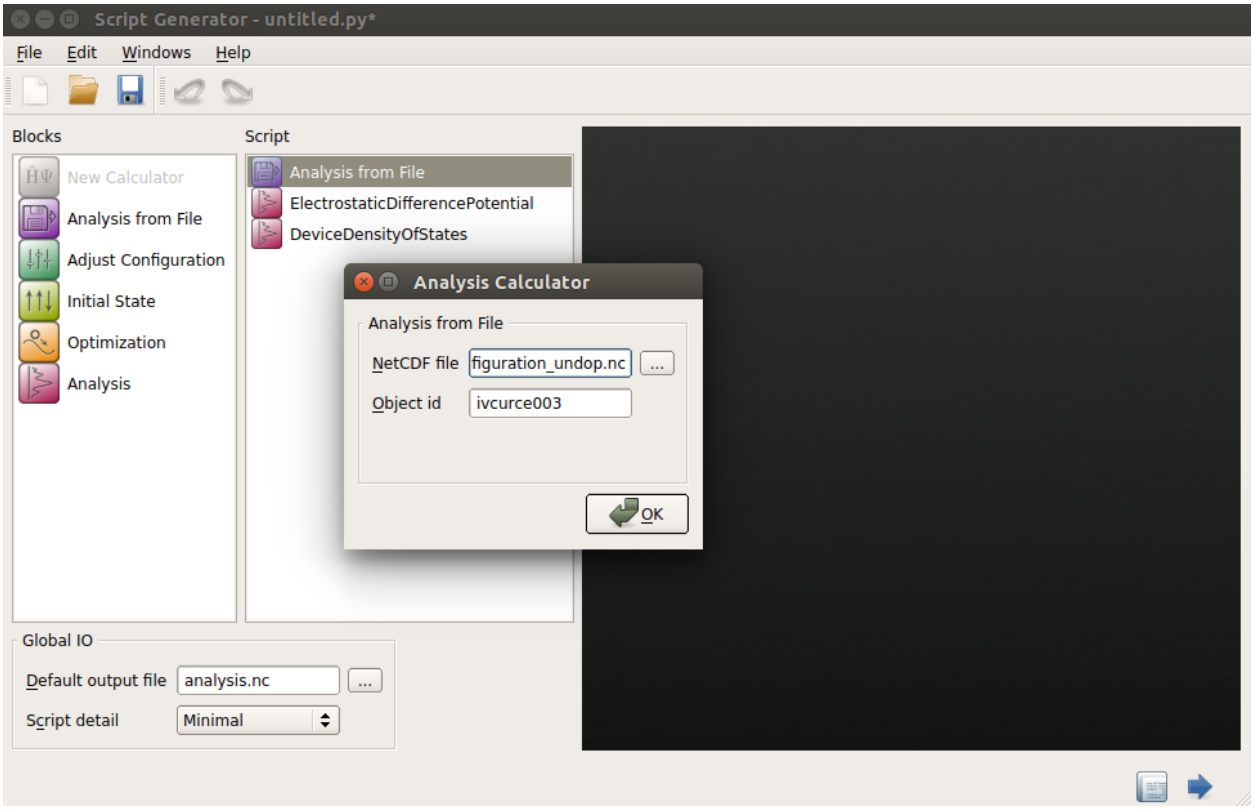
Analysis of a single self-consistent configuration

1. Select a self-consistent configuration and click on the **General info** tab. In the panel that opens up, you can check the details of the self-consistent configurations. Once you have identified the configuration you are interested in, you are ready to set up the script.



2. Go to **Script Generator** and add the **Analysis from File** block.

3. Double-click the **Analysis from File** block to open it and insert the name of the HDF5 file and the Object ID of the self-consistent configuration you want to analize.



4. Add the analysis blocks you need to the script and once you have set the parameters of these additional blocks, send the script to the **Job Manager** to run it.

Analysis of multiple self-consistent configurations

Here we will show how to perform an additional evaluation of the EDP at different bias voltages starting from the self-consistent configurations obtained previously.

1. Identify the self-consistent configurations you want to analyze using the **General info** tab as explained in the previous section.

2. Use the provided script (`loop.py`) to perform the analysis you want for multiple self-consistent configurations in the same calculation. Select the self-consistent configurations by including the relevant Object IDs in the id_list in the script.

```
id_list = [
      'ivcurve000',
      'ivcurve001',
      'ivcurve002',
      'ivcurve003',
      'ivcurve004',
      'ivcurve005',
      ]
for id_item in id_list:
   # Read the DeviceConfiguration
   configuration = nlread('ivcurve_selfconsistent_configurations.nc', object_id="%s" %id_
↪item)[0]

```

(continues on next page)

(continued from previous page)

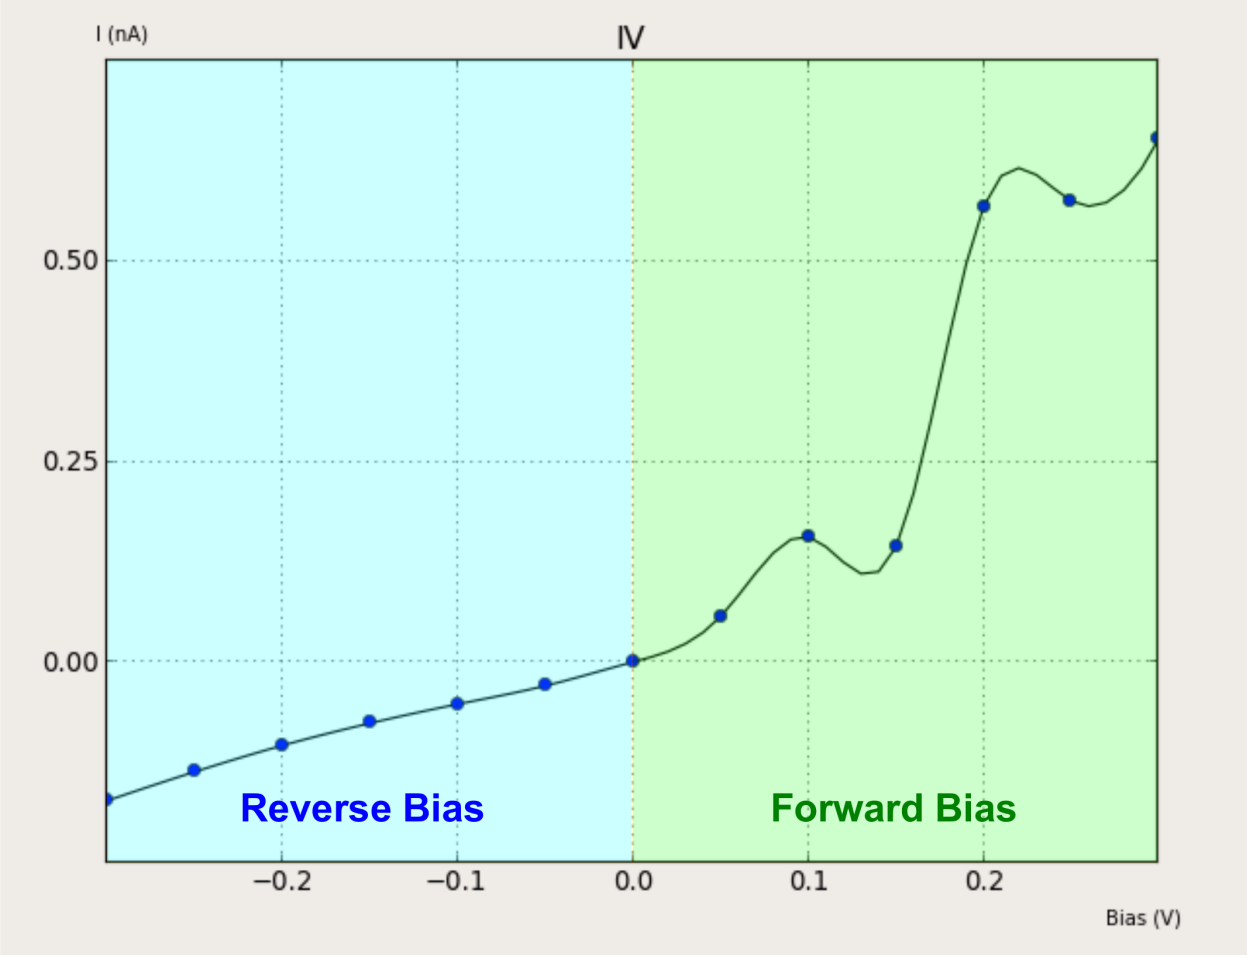
```
# ------------------------------------------------------------
# Electrostatic Difference Potential
# ------------------------------------------------------------
electrostatic_difference_potential = ElectrostaticDifferencePotential(configuration)
nlsave('analysis.nc', electrostatic_difference_potential)
```

3.Send the sript to the **Job Manager** and run the calculation.

Analysis of the IV curve

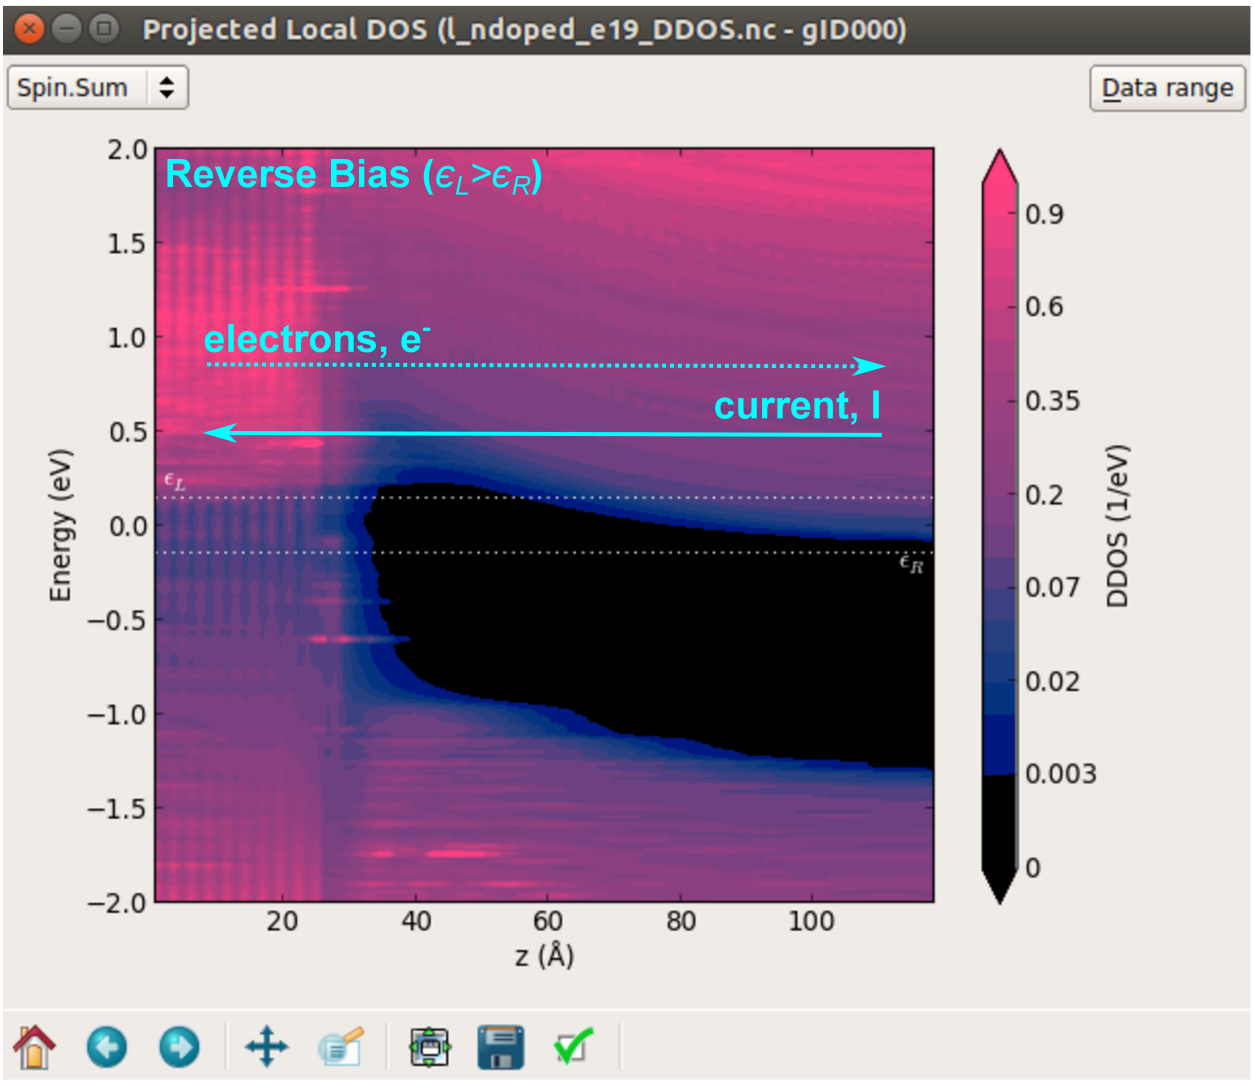
In this section we are going to analyze the EDP of several self-consistent configurations at different V_{bias} and the projected local DOS of the self-consistent configurations at -0.3 V and 0.3 V. You can perform these analyses following the steps described above. You can download the required scripts here (`l_ndoped_e19_EDP.py` `l_ndoped_e19_DDOS.py`).

The IV curve obtained can be divided in two regions, Forward Bias (V_{bias} > 0 V) and Reverse Bias (V_{bias} < 0 V):



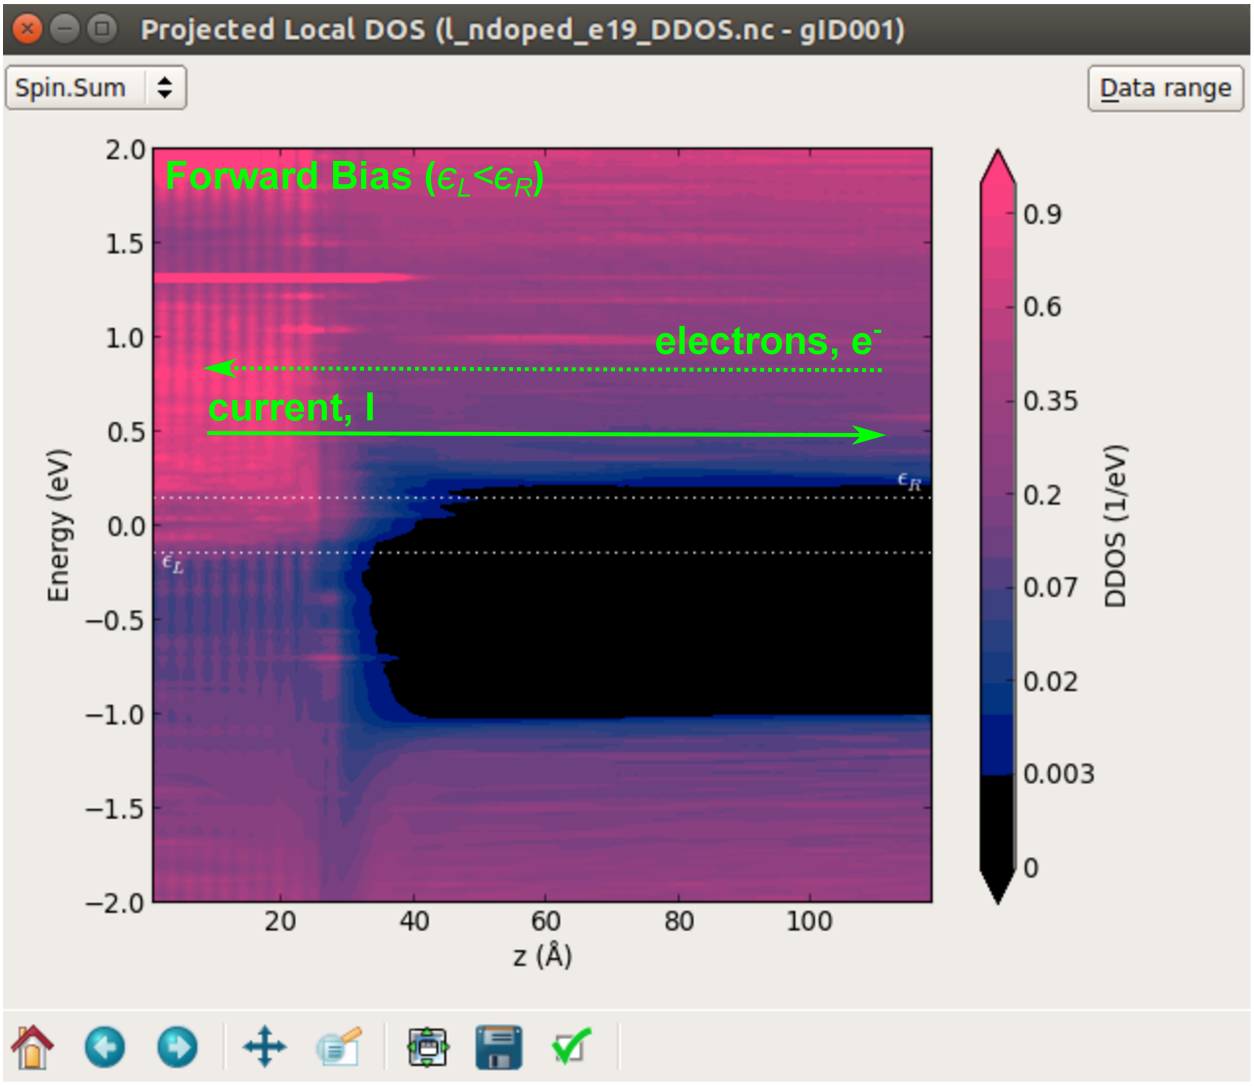
The IV curve shows that the reverse bias current is lower than the forward bias current. This can be undertood looking to the projected local DOS plots.

The figure below shows the projected local DOS at -0.3 V.



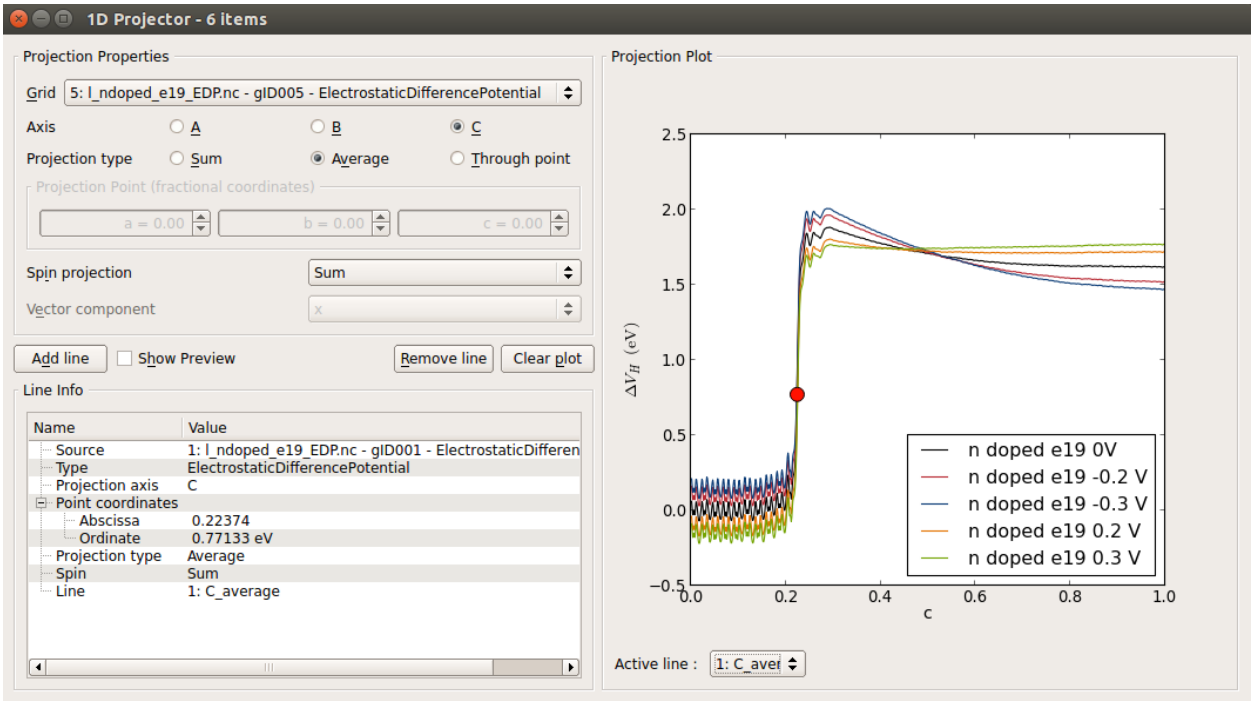
In reverse bias conditions, the chemical potential of the left electrode is higher in energy than that of right electrode. Consequently, there will be a net flow of electrons from the left to the right electrode, so that the current will propagate in the opposite direction. However, the electrons have to overcome a potential barrier at interface due to the presence of the depletion region, and consequently the current will be low.

In the next plot we show the projected local DOS at 0.3 V.



It can be seen that in forward bias conditions, the chemical potential in the right electrode is larger than that of the left electrode. Consequently, there will be a net flow of electrons from the right to the left electrode, so that the current will propagate in the opposite direction. However, at difference with the reverse bias case, here the electrons do not have to overcome any potential barrier, so that the current will be higher.

Finally, in the figure below the EDP along the the C axis of the long n-type doped device at different V_{bias} is shown:



Notice how applying a bias has also an effect on the EDP and on the width of the depletion region.

Warning: In the above plot, the EDP profiles are relative to $(\mu_L + \mu_R)/2$, which is how the potential are defined in the calculation. For a more intuitive picture, one should plot the EDP profiles relative to μ_L.

3.2.7 Bi_2Se_3 topological insulator

Version: 2016.2

Topological insulators are electronic materials that have a bulk band gap like an ordinary insulator, but still support conducting states on their surface. It can be shown that these states are topologically protected due to a non-trivial topological index of the material and cannot be removed by any distortions. The 2D energy–momentum relation of these surface states has a Dirac cone structure similar to that of graphene. Topological insulators therefore constitute a new class of quantum matter governed by exotic physics that may some day be exploited in electronic devices. Refs.[1] and[2] provide recent reviews of this highly active field of research.

In this tutorial you will learn how to use ATK-DFT to study the Bi_2Se_3 compound, which is a 3D strong topological insulator. Nonequilibrium Greens function DFT calculations were recently reported for a Bi_2Se_3 thin film connected to leads in a two-terminal device setup[3]. However, this tutorial focuses on bulk calculations and properties of the surface states. In particular, you will:

•Use the QuantumATK Crystal Builder to construct the Bi_2Se_3 crystal structure.

[2] Xiao-Liang Qi and Shou-Cheng Zhang. Topological insulators and superconductors. *Rev. Mod. Phys.*, 83:1057–1110, Oct 2011. doi:10.1103/RevModPhys.83.1057.

[3] Po-Hao Chang, Troels Markussen, Soren Smidstrup, Kurt Stokbro, and BranislavăK. Nikolic. Nonequilibrium spin texture within a thin layer below the surface of current-carrying topological insulator Bi2Se3: A first-principles quantum transport study. *Phys. Rev. B*, 92:201406, 2015. doi:10.1103/PhysRevB.92.201406.

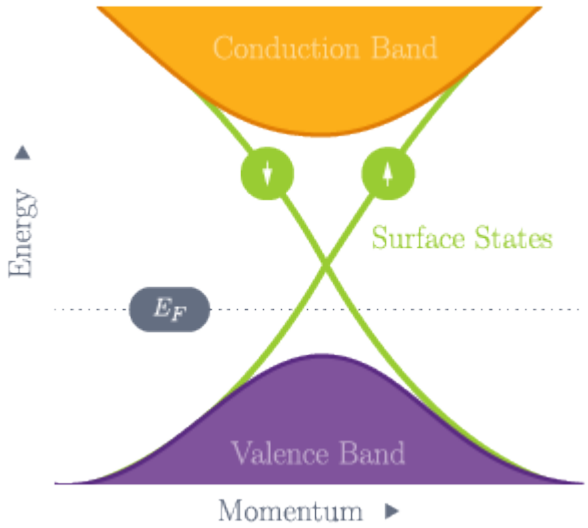

Fig. 3.28: The valence and conduction bands of a topological insulator are separated by a non-zero band gap, but bands due to surface states cross the band gap and lead to electronic conduction at the surface of the material.

•Investigate the bulk Bi_2Se_3 band structure with and without the SOC.

•Construct a Bi_2Se_3 slab configuration and compute the SOC band structure, which exhibits the surface states mentioned above.

•Compute the density of states (DOS) around the Fermi energy, which nicely illustrates the Dirac cone inside the bulk band gap.

•Investigate the surface state penetration depth into the material.

•Plot the spin-resolved Fermi surface of surface states, and investigate how the in-plane spin orientation varies on the Fermi surface.

•Calculate the topological invariants for Bi_2Se_3.

Note: It is essential to include the spin-orbit coupling (SOC) to correctly describe the electronic structure of a topological insulator.

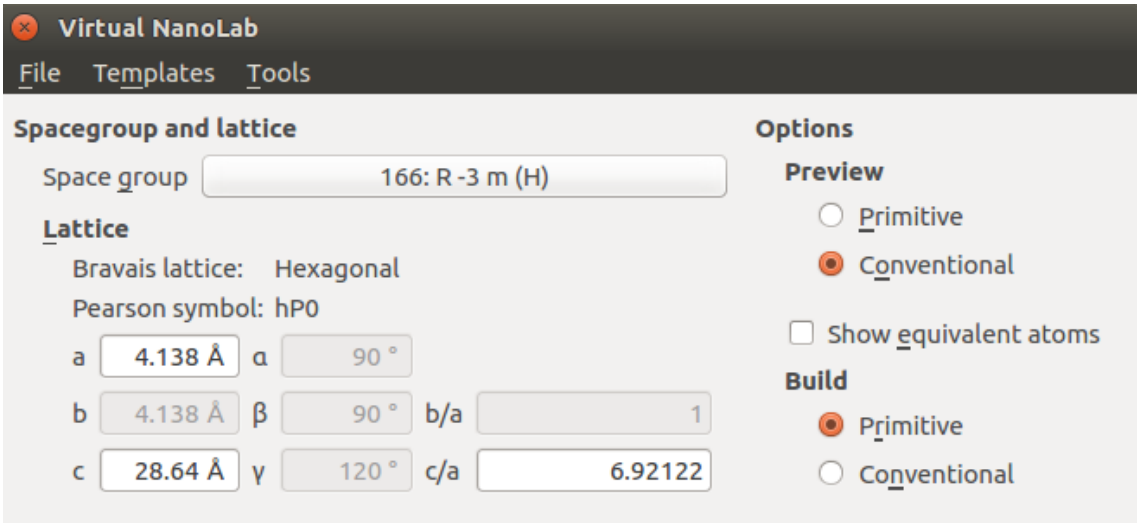
Build the Bi_2Se_3 crystal

Open the QuantumATK Builder and click *Add* → *From Plugin* → *Crystal Builder*. As described in[4], the Bi_2Se_3 crystal is rhombohedral and belongs to space group $R\bar{3}m$. It has lattice constants a=4.138 Å and c=28.64 Å, and internal coordinates μ=0.399 for Bi sites and ν=0.206 for Se sites. The basic Bi_2Se_3 unit cell, called a quintuple layer (QL), contains 5 atoms: One Se atom at coordinate (0, 0, 0), Bi atoms at internal coordinates $(\pm\mu, \pm\mu, \pm\mu)$, and Se atoms at $(\pm\nu, \pm\nu, \pm\nu)$.

[4] Wei Zhang, Rui Yu, Hai-Jun Zhang, XiăDai, and Zhong Fang. First-principles studies of the three-dimensional strong topological insulators Bi2Te3, Bi2Se3 and Sb2Te3. *New Journal of Physics*, 12(6):065013, 2010. doi:10.1088/1367-2630/12/6/065013.

Lattice

In the Crystal Builder, choose the *Trigonal* space group number 166 with *Hexagonal* setting, and enter the lattice parameters:



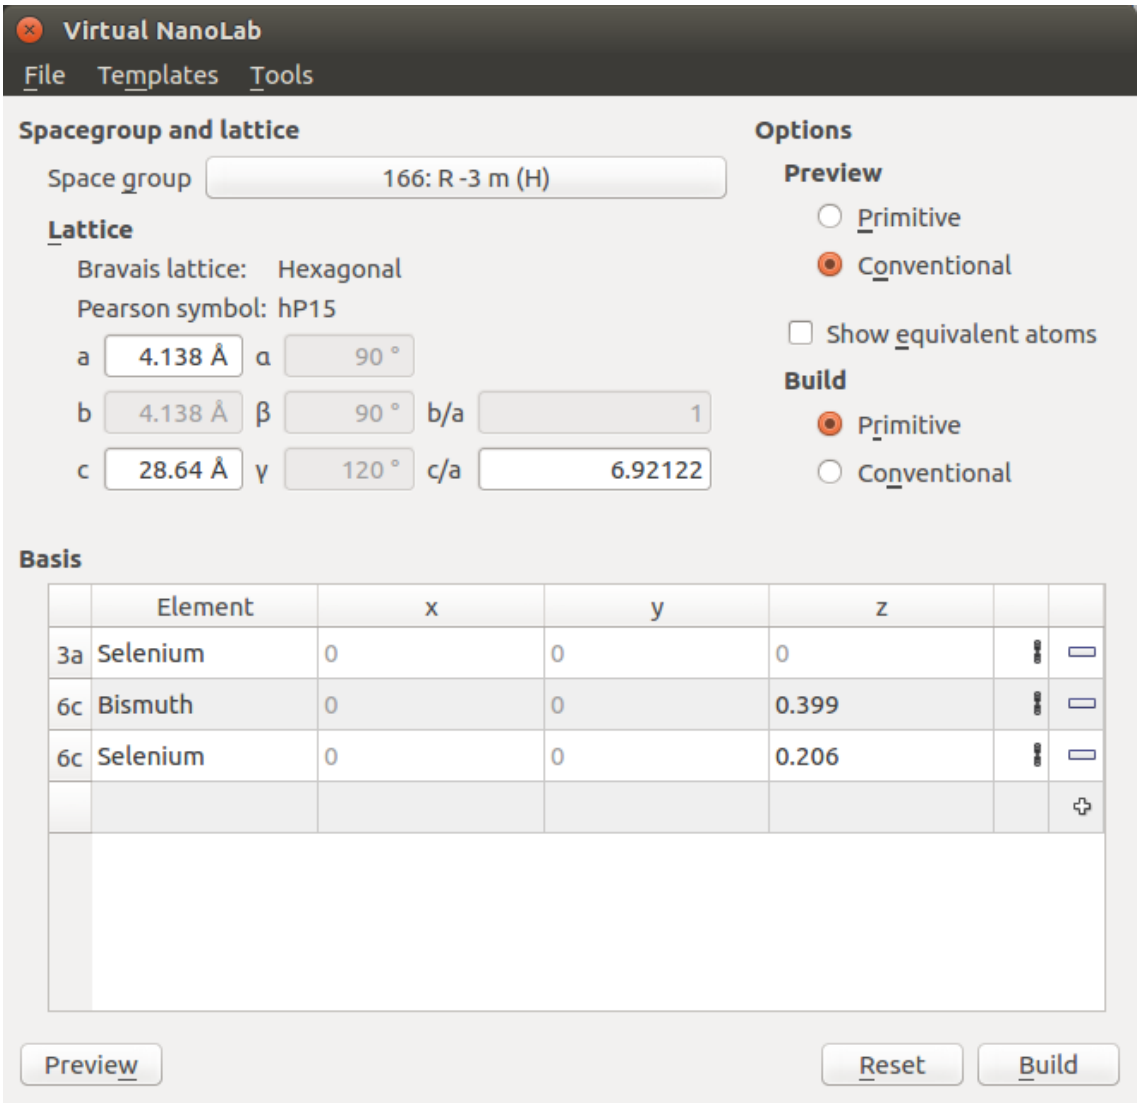
Basis

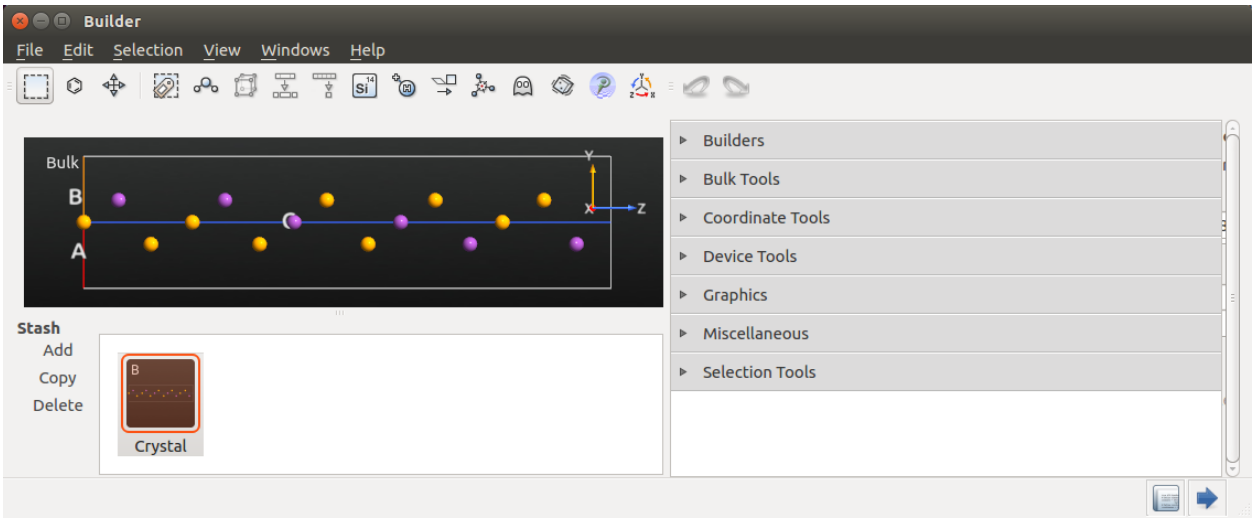
Then specify the atomic basis with which to decorate the lattice, i.e. enter the internal coordinates of the unique sites of the Bi_2Se_3 crystal and the elements that should be at those sites:

1. Click the icon and select site *3a: (0,0,0)*, and change the element from hydrogen to selenium.

2. Use the same procedure twice for specifying the remaining sites, but choose *6c: (0,0,z)* for the site type, and enter the internal coordinates z=0.399 for bismuth and z=0.206 for selenium.

   The Crystal Builder window should now look like illustrated below. Click *Build* to build the bulk configuration – it will then appear in the Builder Stash.





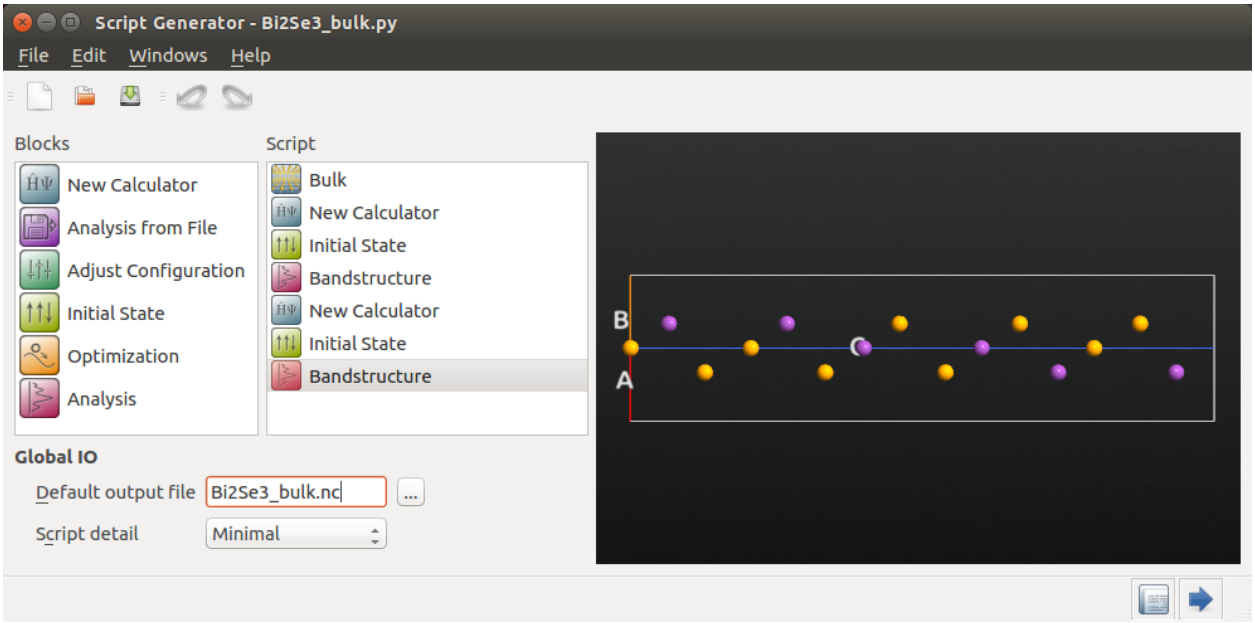
You have now built the Bi_2Se_3 bulk configuration with 3 QLs and 15 atoms in total. Continue to the next section to start doing some DFT calculations for this material. If needed, you can also download the bulk configuration here:

`Bi2Se3_bulk_configuration.py`

Bi_2Se_3 bulk band structure

Send the bulk configuration to the Script Generator, and set up a Python script that uses ATK-DFT to calculate the band structure with and without the spin-orbit coupling. The script should first calculate the self-consistent GGA state and perform band structure analysis, and then use that state as an initial guess for the self-consistent SOGGA state, again followed by band structure analysis.

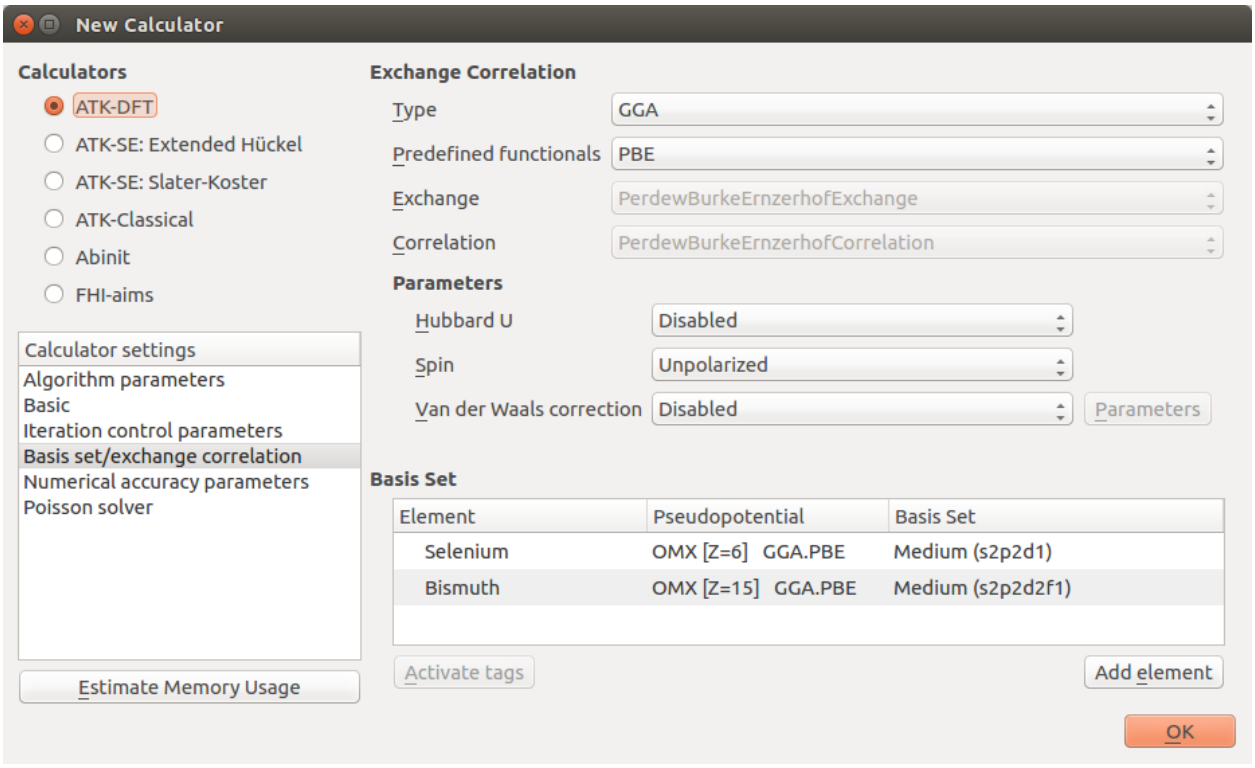
The Script Generator now contains the bulk configuration. Add the New Calculator, *Analysis* → *Bandstructure*, and Initial State blocks, as illustrated below. Also change the default output file to `Bi2Se3_bulk.nc`.

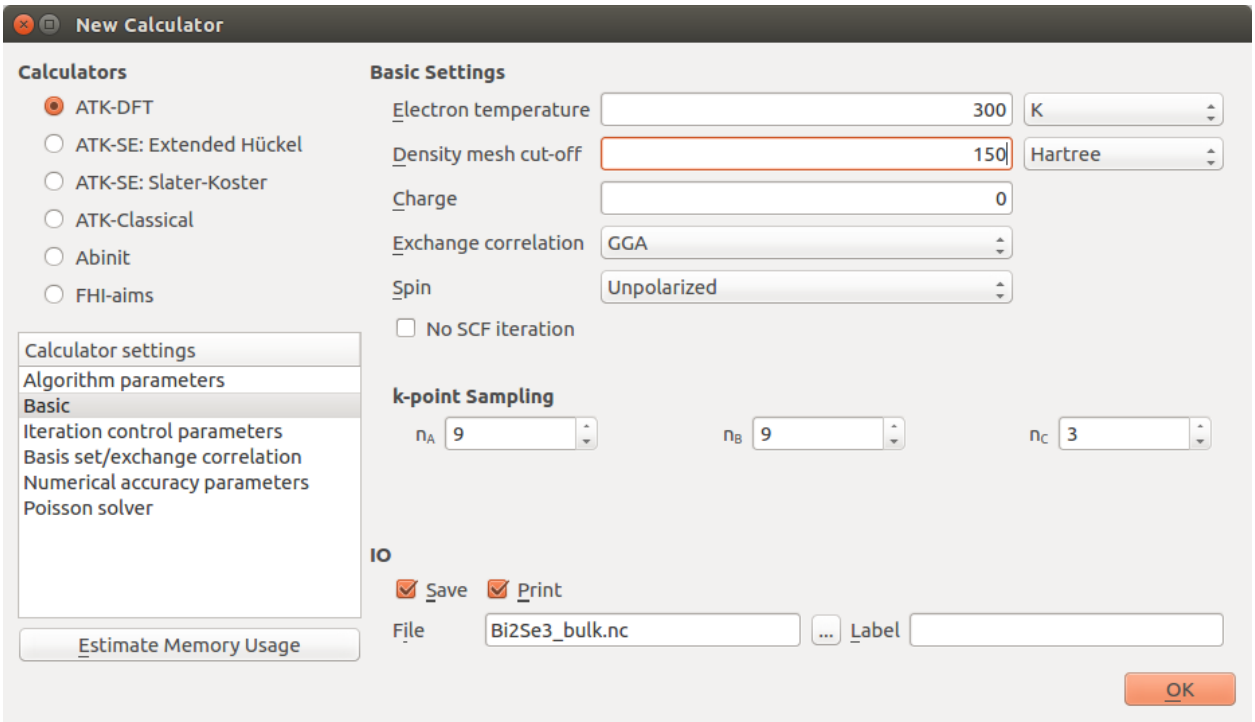


GGA calculation

Open the first New Calculator block to edit it:

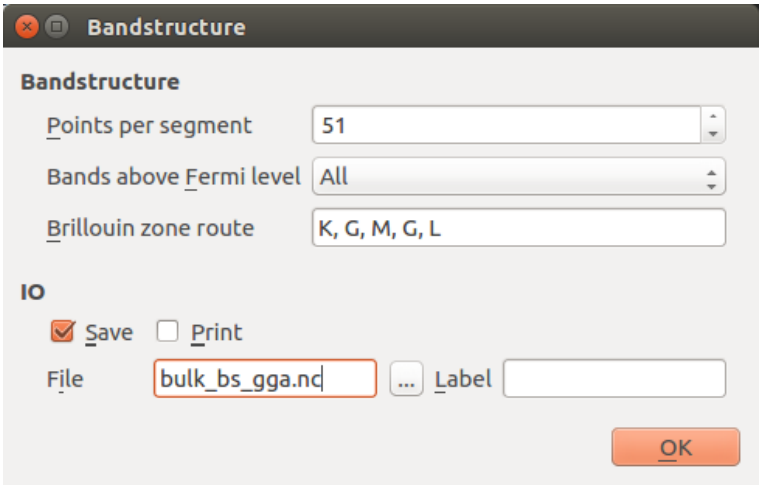
- Make sure to choose the ATK-DFT calculator.
- In the *Basis set/exchange correlation* settings, choose *GGA* and change the pseudopotentials to the *OMX* family with *Medium* basis sets for both Se and Bi.
- In the *Basic settings* tab, increase the density mesh cut-off to 150 Hartree, and set up a 9x9x3 k-point grid. Click *OK* to save the settings.





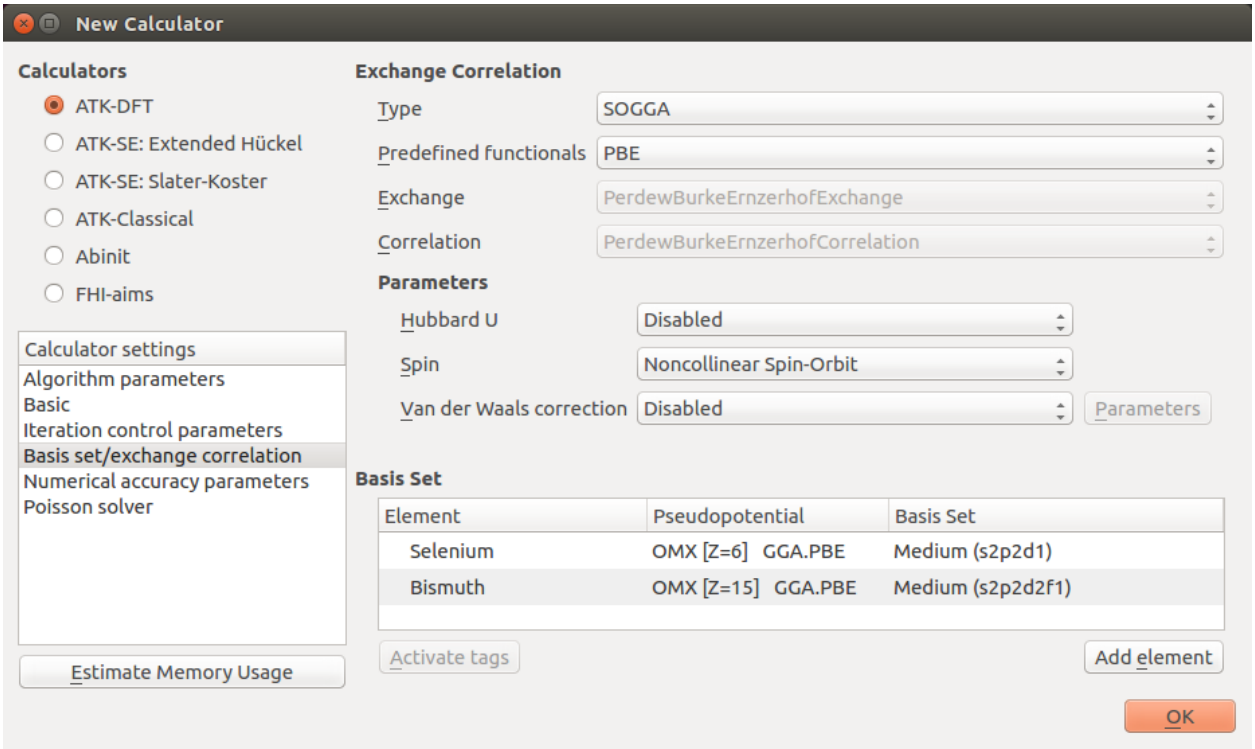
Then open the first Bandstructure block and edit it:

- Increase *points per segment* to 51 to get a nicely resolved band structure.
- Change the Brillouin zone route to *K, G, M, G, L*.
- Change the IO file to `bulk_bs_gga.nc`.

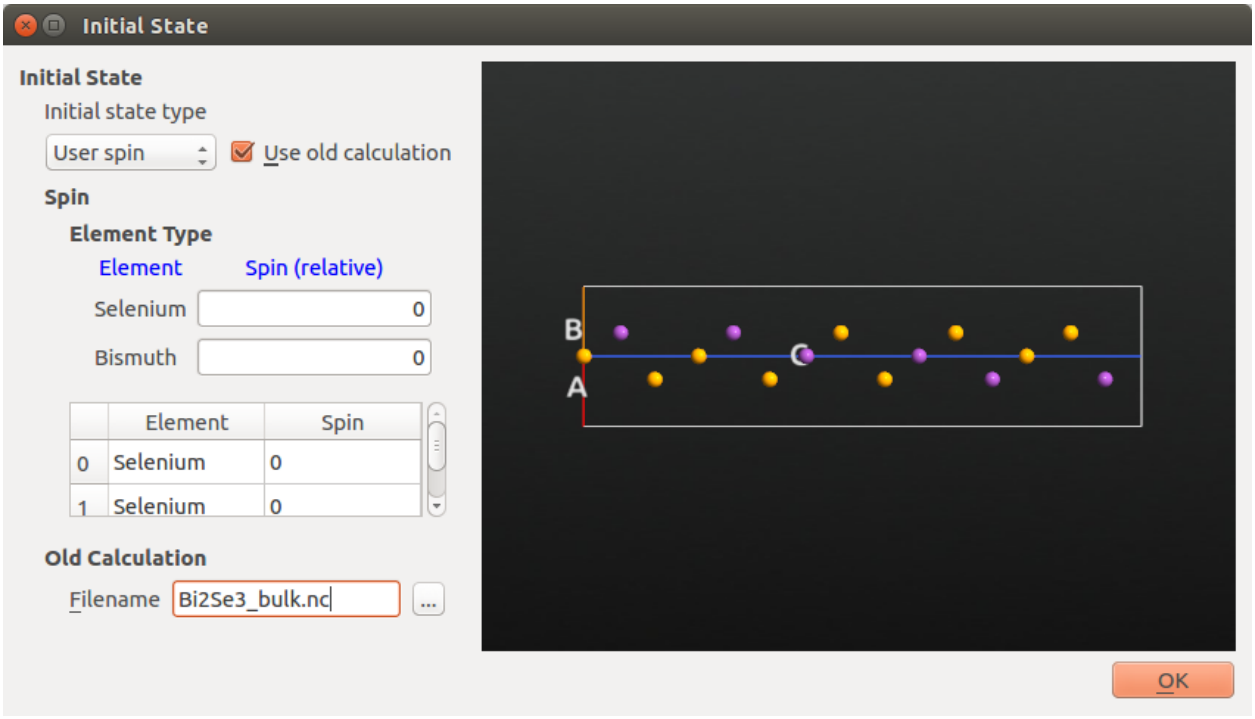


SOGGA calculation

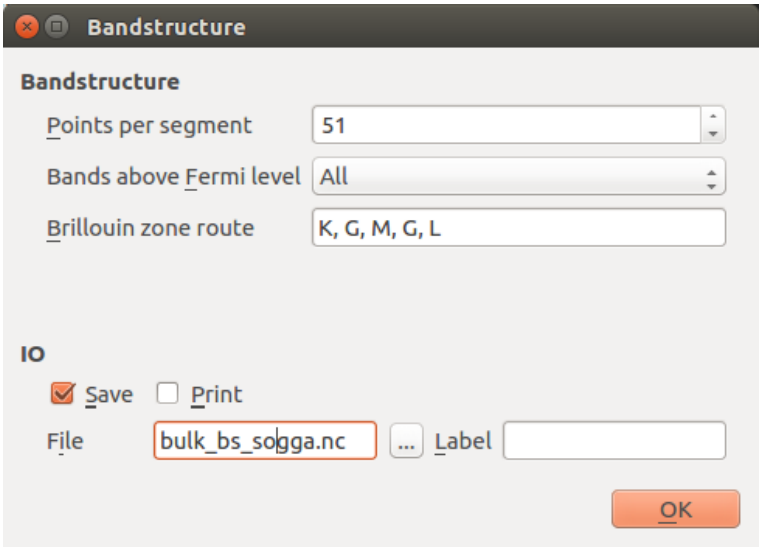
Open the second New Calculator block, and edit it such that the settings are identical to those in the first calculator, but set the *Spin* parameter to *Noncollinear Spin-Orbit* in order to do a SOGGA calculation. Remember to also set the pseudopotentials, density cut-off, and k-points.



Next, open the second Initial State block, and select *User spin* for *Initial state type*, tick the *Use old calculation* option, and enter the file name `Bi2Se3_bulk.nc` from which the GGA state should be read.



Finally, set up the second Bandstructure block identically to the first one, but use `bulk_bs_sogga.nc` for the IO file.



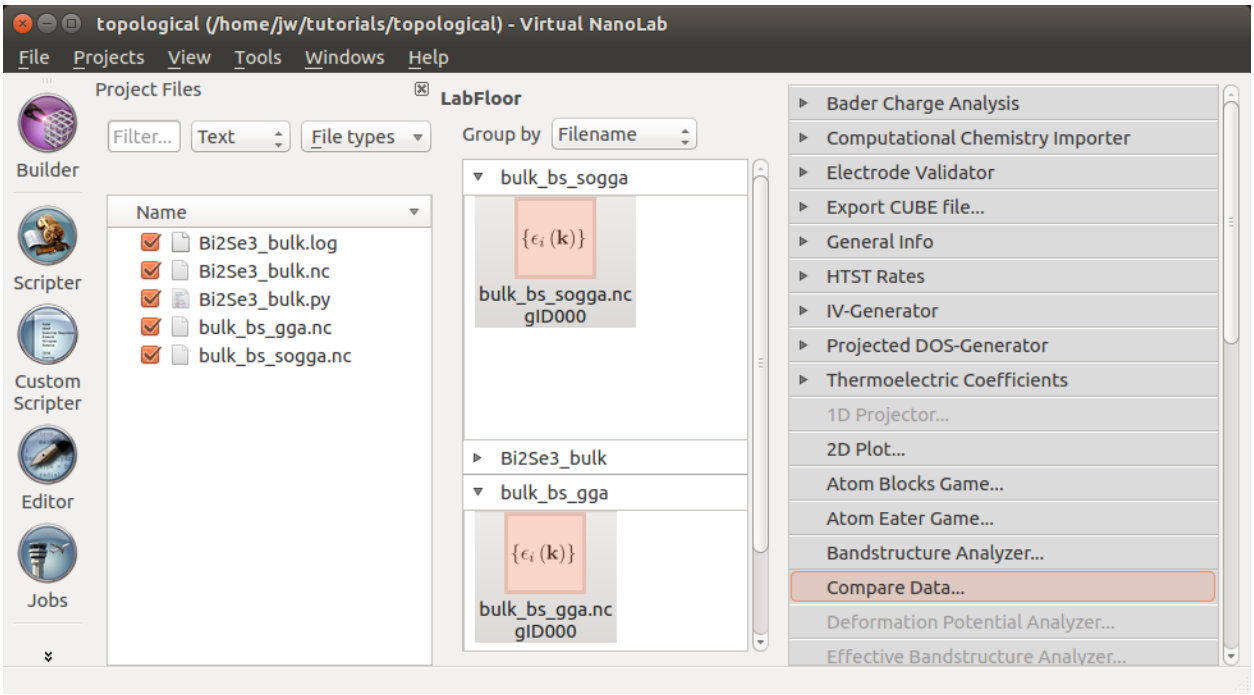
Results

The Python script is now ready. Save it as `Bi2Se3_bulk.py`. If needed, you can also download it here: `Bi2Se3_bulk.py`

Execute it using the Job Manager or in a Terminal. The job will take a while, but the wall time can be brought down to around 40 minutes if executed in parallel with 2 MPI processes on 2 CPUs. Note that this requires in total about 15 GB of available memory!

Tip: The tutorial *Basic QuantumATK Performance Guide* offers tips on QuantumATK performance, including how to deal with memory issues.

Once the calculation has finished, the QuantumATK **LabFloor** contains three sets of data: *Bi2Se3_bulk*, *bulk_bs_gga*, and *bulk_bs_sogga*. The last two contain the GGA and SOGGA band structures. Highlight both band structure objects, and use the **Compare Data** plugin to plot both of them.



The plot is shown below. Including spin-orbit coupling in the calculations (SOGGA) has a significant impact on the band structure, and widens the direct band gap at the Γ-point However, we do not see any bands crossing the Fermi level (the smallest SOGGA band gap is 0.3 eV), so the Bi_2Se_3 bulk material is an insulator.

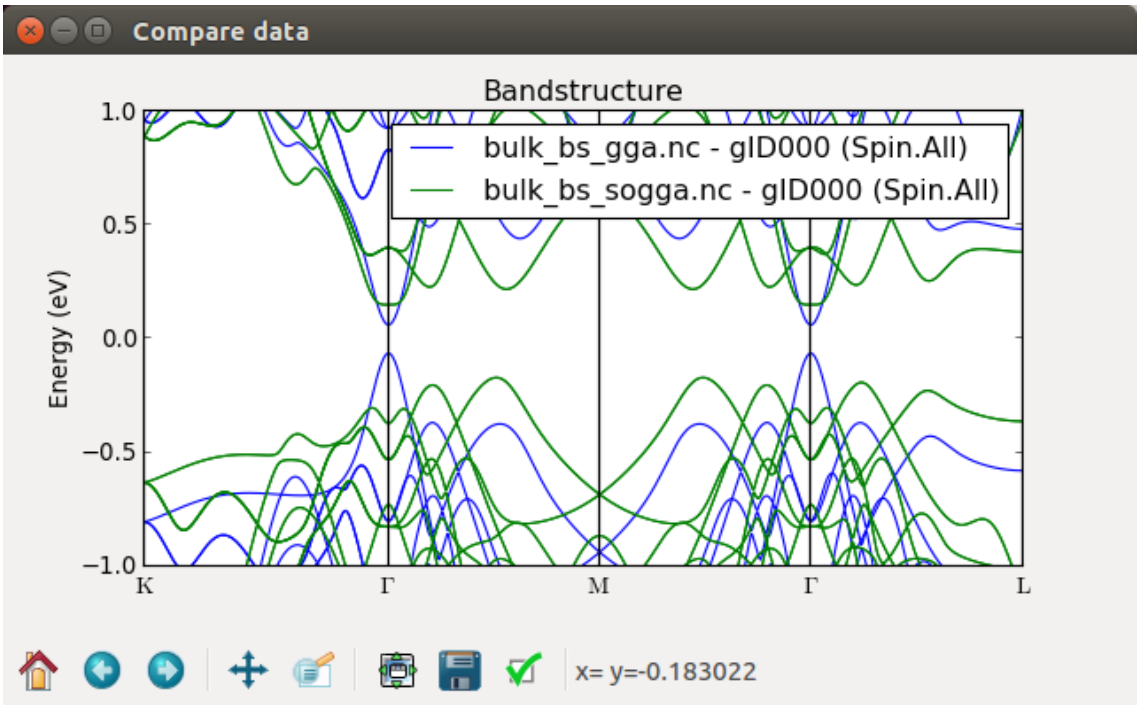


Fig. 3.29: Comparison of the GGA (blue) and SOGGA (green) band structures of bulk Bi_2Se_3.

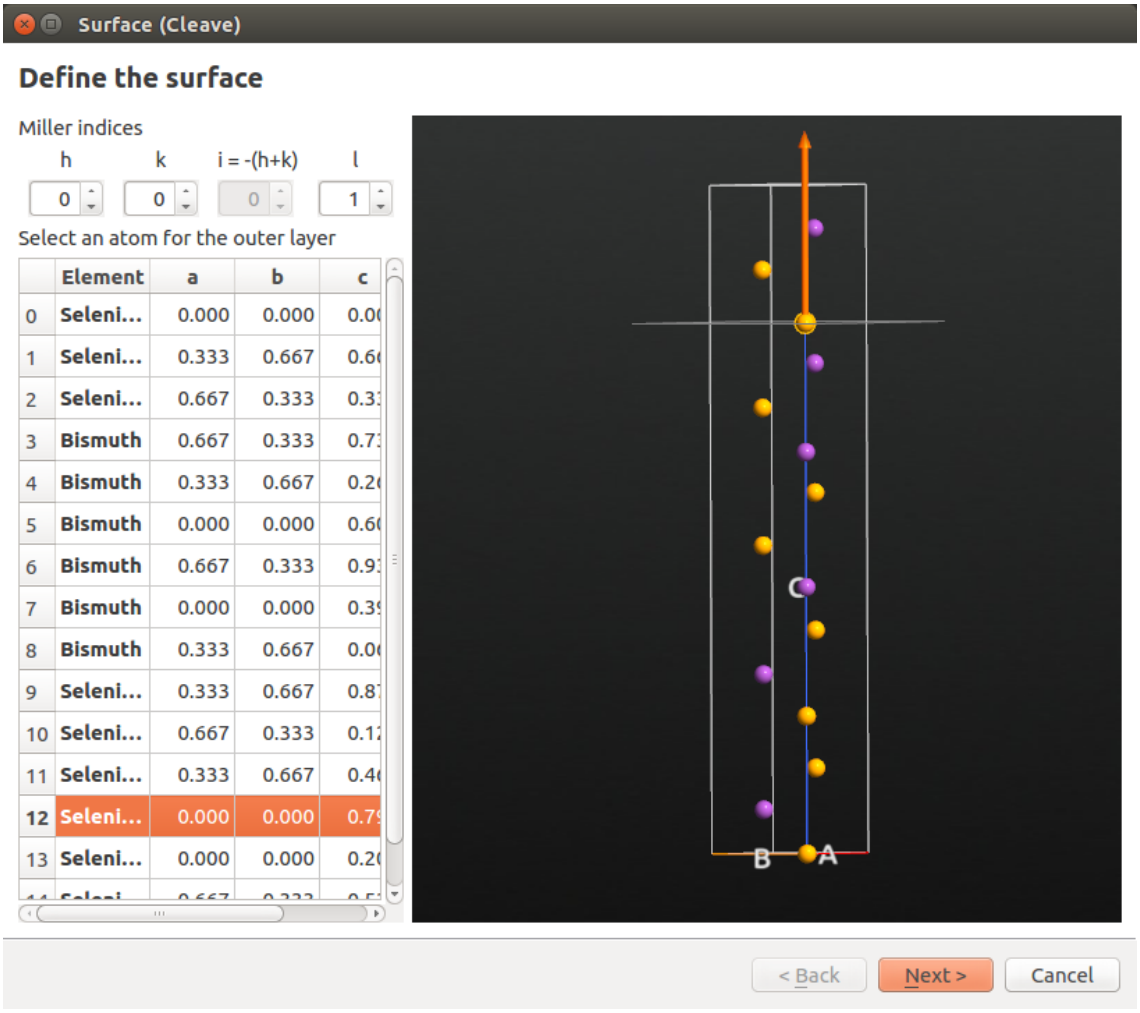
Bi2Se3 surface: Spin-orbit band structure

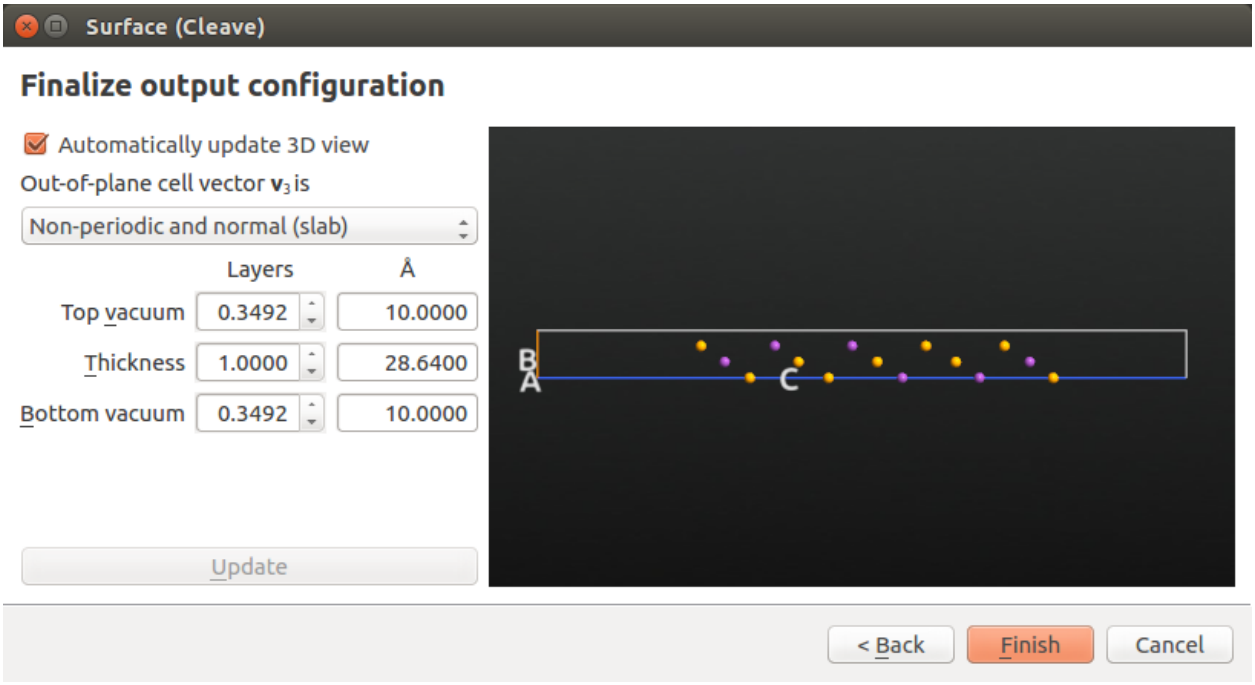
You will now create a Bi_2Se_3 slab configuration, and compute the SOGGA band structure, which will exhibit the topologically protected surface states crossing the band gap around the Γ-point.

Constructing the surface

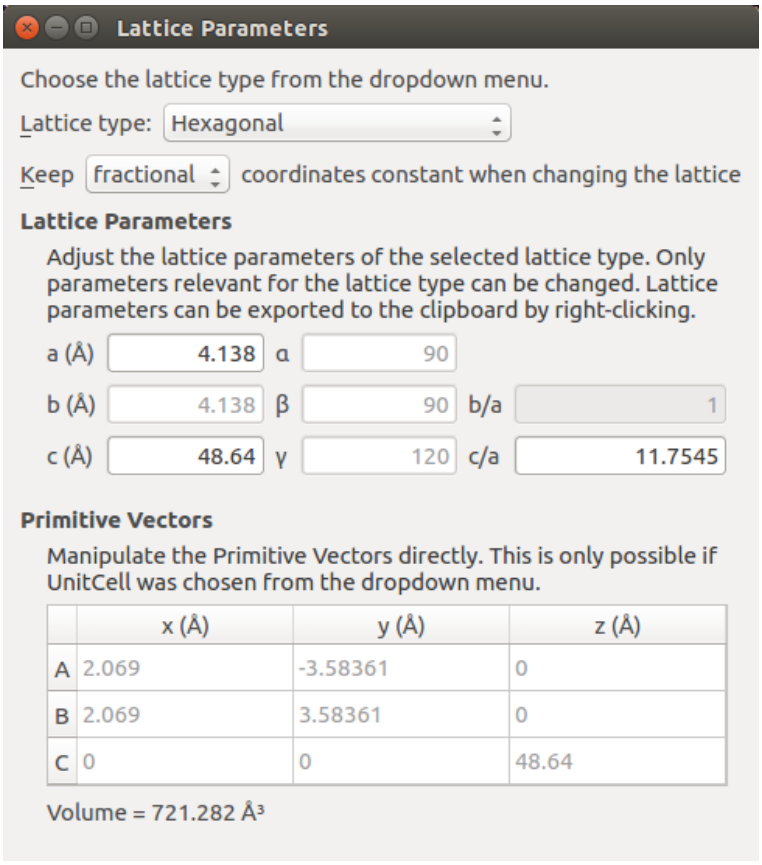
Back in the **Builder**, highlight the Bi_2Se_3 bulk configuration (named Crystal), and open the *Builders* → *Surface (Cleave)* plugin. Choose Miller indices (0001), and select selenium atom #12 as the top atom in the slab. Then click *Next*.



Leave settings at defaults in the Define surface lattice options window. In the Finalize output configuration options, choose a *Non-periodic and normal (slab)* out-of-plane cell vector, and enter 10 Å for both top and bottom vacuum. Then click *Finish*.



The slab configuration, named Crystal (0001), has now appeared in the Stash. As a final touch, highlight the item and use the *Bulk Tools* → *Lattice Parameters* plugin to convert the lattice type to *Hexagonal* while keeping the fractional coordinates constant:

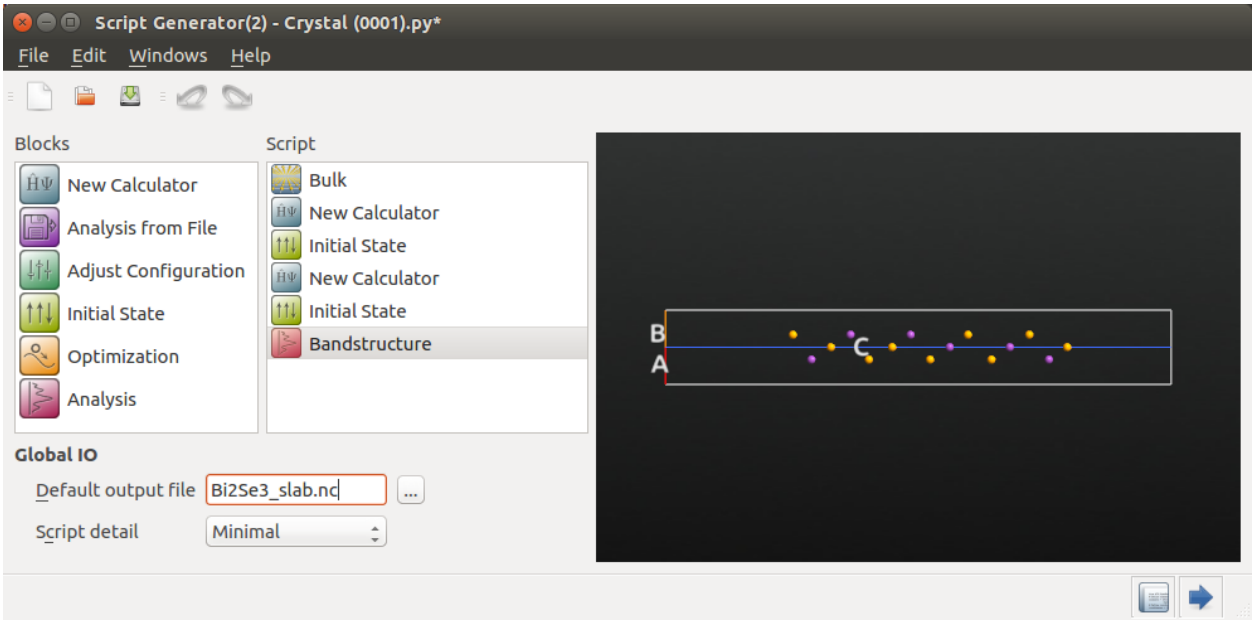


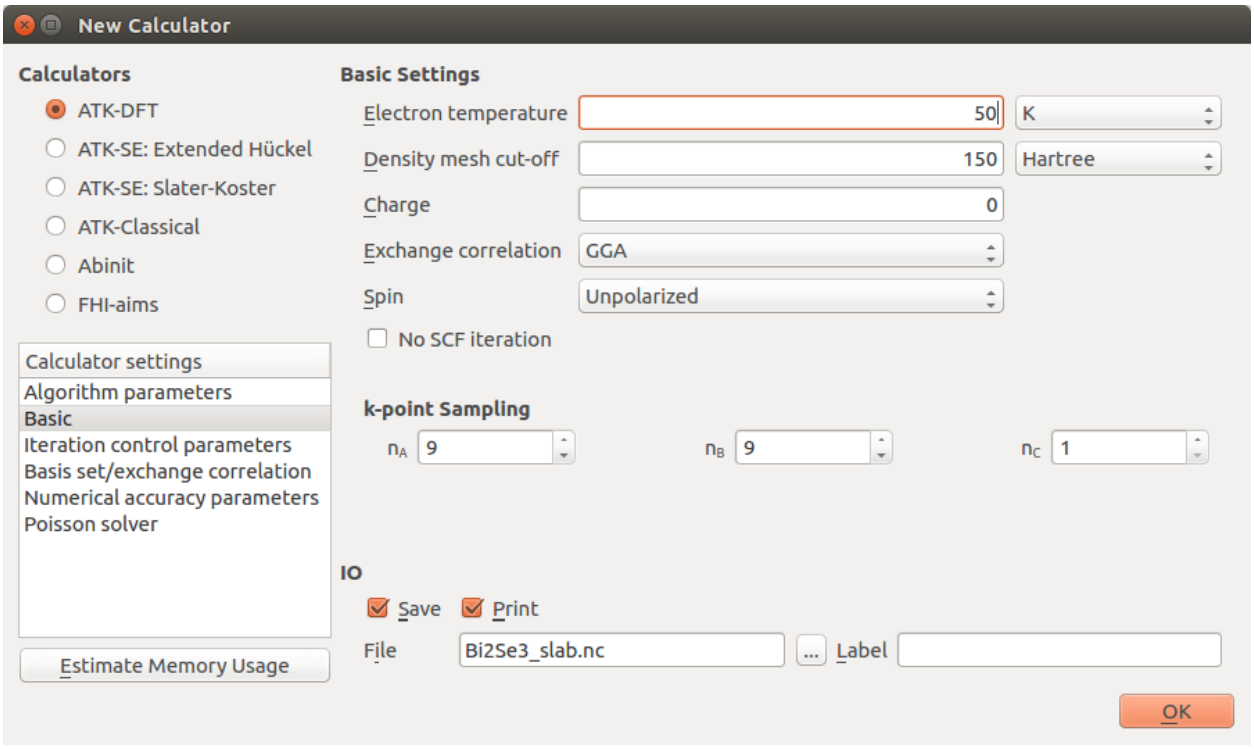
DFT-SOGGA calculations

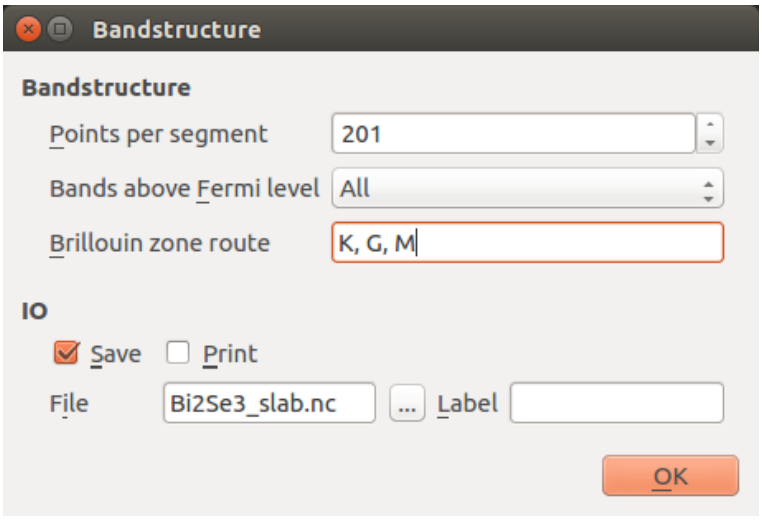
You can now send the slab configuration to the **Script Generator**, and set up the SOGGA band structure calculation similarly to what you did above for the bulk, but with slight changes:

- You will not need the GGA band structure analysis.
- Use `Bi2Se3_slab.nc` as default output file.
- Use a 9x9x1 k-point grid (the slab is not periodic along the C-direction).
- Decrease the electron temperature from 300 to 50 K. This will improve the DFT description of electron occupations close to the Fermi level.
- Use 201 points per segment for the SOGGA band structure analysis, and the *K–G–M* Brillouin zone route.

Alternatively, you can simply skip the above and go directly to the next section to use a pre-made Python script with a few additional features.







Convenient Python script

Click here: `Bi2Se3_slab.py` to download a Python script that was made using the procedure outlined above, but also has a few extra features:

- The MemoryUsage functionality is used to estimate the memory required for the GGA and SOGGA calculations immediately before they are executed.
- The SOGGA calculator is constructed as a copy of the GGA calculator, and is then modified accordingly.
- A special density mixing algorithm is used for the non-collinear calculation.

Run the calculation using the Job Manager or in a Terminal. The job will take roughly 30 minutes if executed in 2

parallel MPI processes on 2 CPUs.

Hint: If you look at the log file during the calculation, you will see that the estimated peak memory requirements are 756 MB per MPI process for the GGA calculation, and 3.8 GB per MPI process for the SOGGA calculation. These are estimates, and in practice you should expect the full calculation to require almost 5 GB per MPI process.

```
GGA:
+-------------------------------------------------------+
| Memory usage estimate                                 |

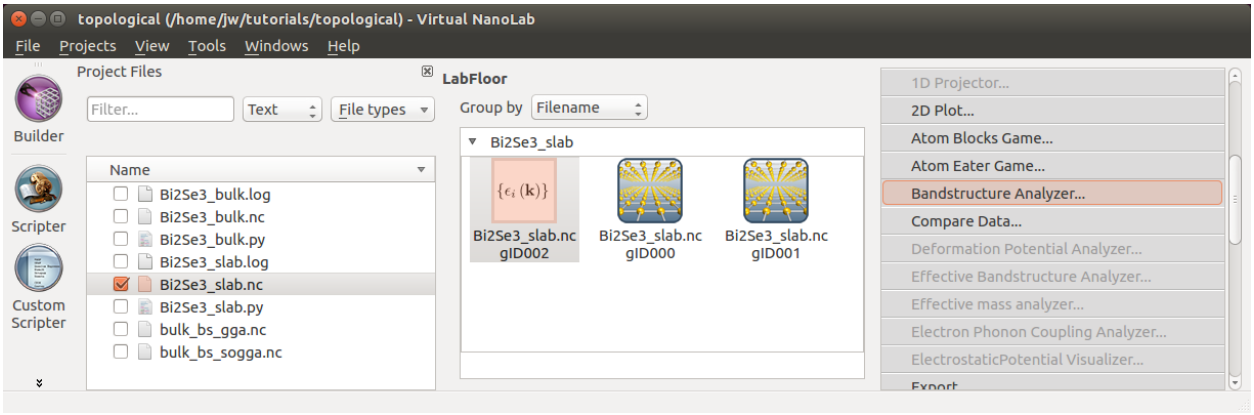
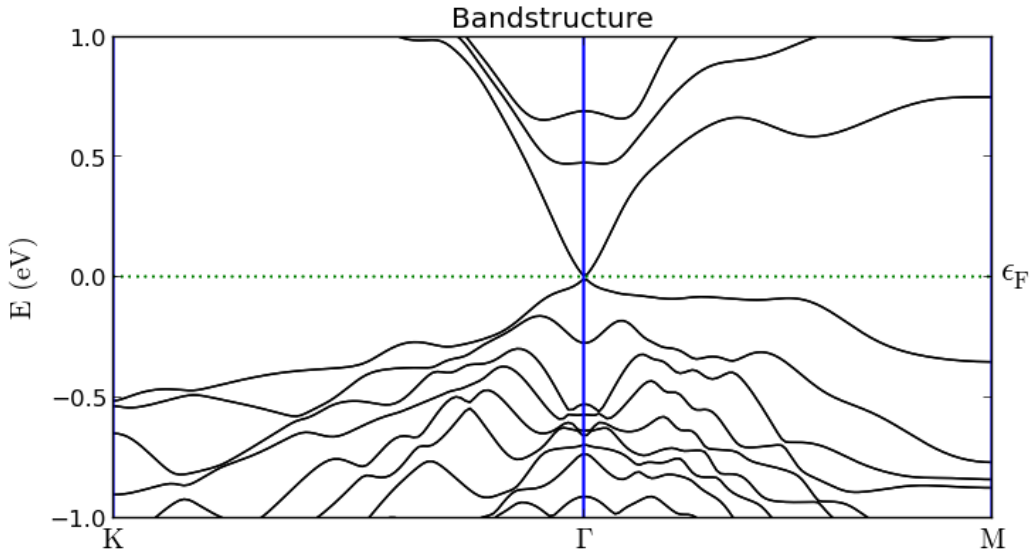
```

Results

The QuantumATK **LabFloor** should now contain the results of the calculation. Select the band structure object, and use the **Bandstructure Analyzer** to plot it.



The calculated band structure of the Bi_2Se_3 slab is shown below. Bands are now present around the Fermi level at the Γ-point – these are surface states. There are four such surface states crossing the Fermi level (indicated by red dots); bands 142 and 143 form a single degenerate band immediately below the Fermi energy, while bands 144 and 145 form a degenerate band above E_F. The bulk valence bands are below those surface states (indicated by blue dot). It is clear that the dirac cone is located inside the bulk band gap. There is a tiny gap between the valence and conduction surface bands of size 7 meV. This is a finite size effect from the use of a slab model, which arise from the interaction of the surface bands on opposite sides of the slab. For a larger slab the gap will be reduced.



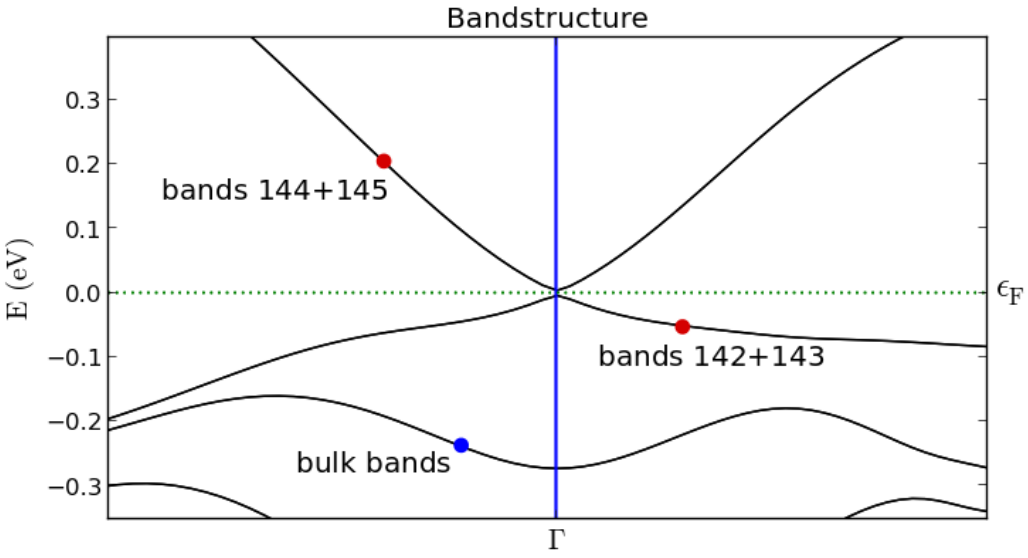


Fig. 3.30: SOGGA bandstructure of the Bi_2Se_3 slab configuration. The bottom panel is a zoom-in on the topologically protected Dirac cone. Both surface state bands (red dots) are both doubly degenerate and are located above the bulk valence bands (blue dot).

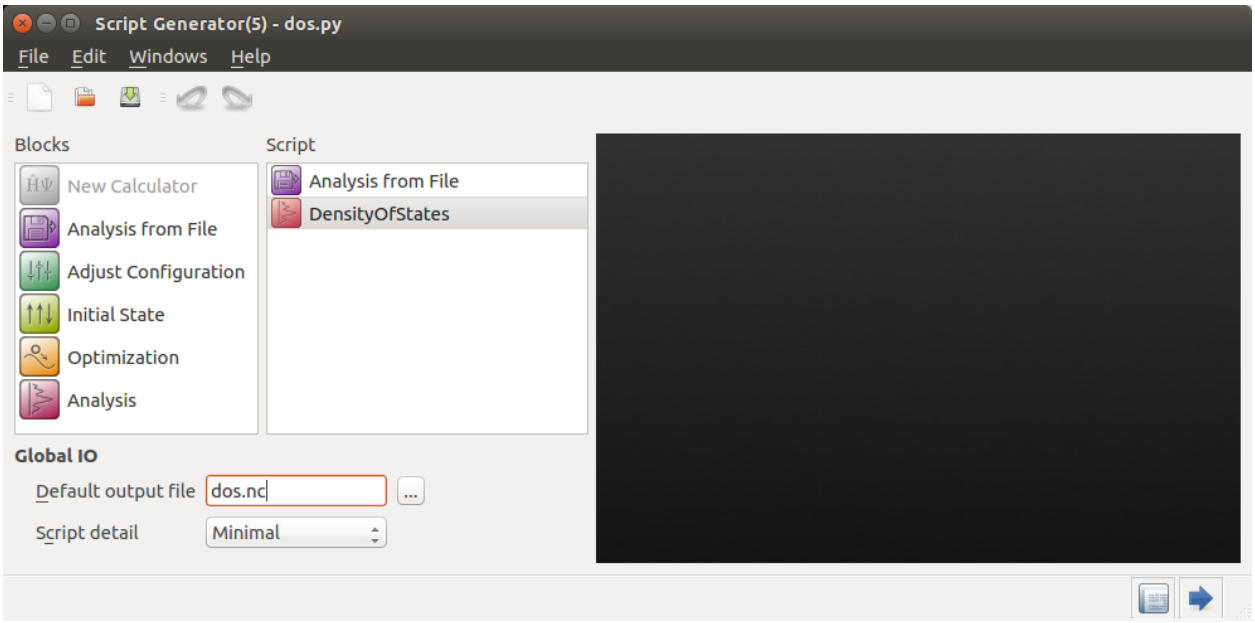
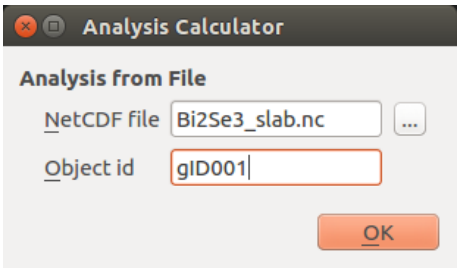
DOS analysis: Dirac cone finger print

As stated in the introduction, the electronic structure of the surface states close to the Fermi level resembles that of a Dirac cone, where the electron momentum depends linearly on the energy. Since the surface states are the only states present inside the bulk energy gap, we should expect the electronic density of states close to E_F to be linear. It is easy to compute and plot the DOS as a post-SCF analysis:

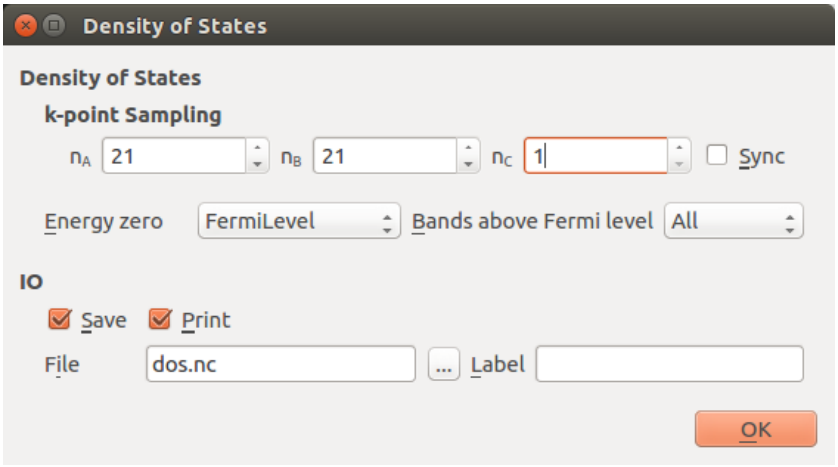
Open the **Script Generator** and add the Analysis from File and *Analysis* → *DensityOfStates* blocks. Change the default output file to `dos.nc`.



Open the first block, and point to the `Bi2Se3_slab.nc` file and Object id *glD001*, which is the self-consistent SOGGA state.



Then open the DensityOfStates analysis block, and set up a dense k-point sampling along k_x and k_y, 21x21x1. You will need to uncheck the *sync* option. Remember: It is important in this case to sample the Γ-point, so we use use an odd k-grid.



Save the script as `dos.py` and run it. You can also download it here: `dos.py`.

Then locate the DOS object on the **LabFloor**, and use the **2D Plot** plugin to visualize it. With a bit of zooming you should be able to see the expected linear dependence of the DOS on energy, as illustrated below. The sharp increase in DOS at E=0.47 eV are due to the lowest bulk conduction bands.

Penetration depth of surface states

An essential feature of the topologically protected surface states close to the Dirac point is that they are highly localized to the surface region. The penetration depth into the bulk material may be as small as 2–3 nm[Page 549, 4]. Moreover, the degenerate surface states observed in a band structure calculation are in each specific k-point composed of states with opposite spin and localized on opposite sides of the slab.

You will now investigate this by performing a **BlochState analysis** in a specific k-point on the Dirac cone for bands 144 and 145. You will then project both Bloch states onto the C-axis of the Bi_2Se_3 slab unit cell, and plot the magnitude and direction of the non-collinear spin vectors as a function of the C-coordinate.

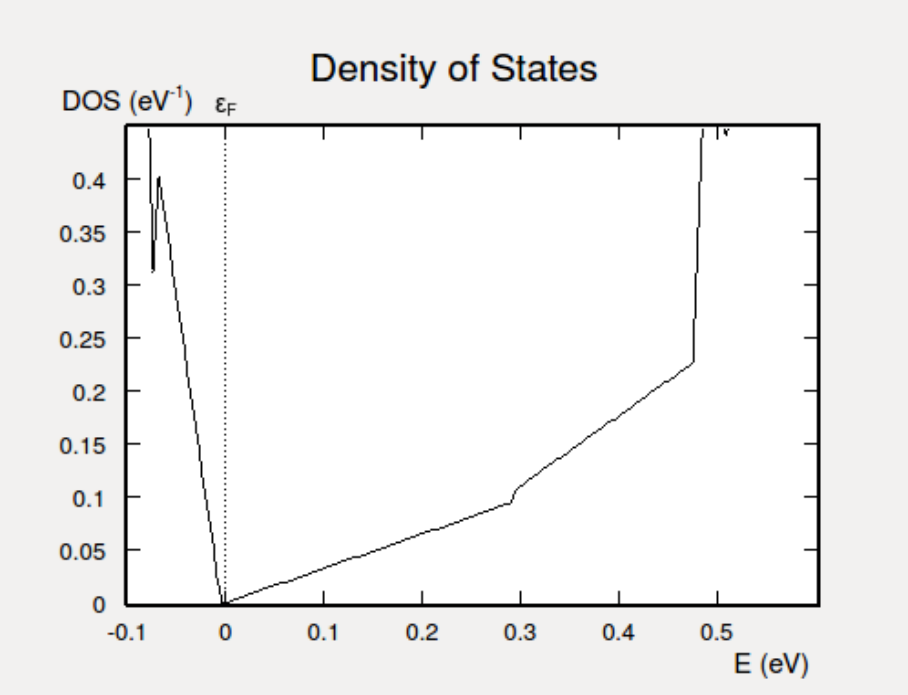


Fig. 3.31: Electronic DOS for the Bi_2Se_3 slab. Due to the Dirac cone, the DOS depends linearly on the energy in the vicinity of the Fermi level.

Calculations

You will need the following two scripts: `bloch_states.py` and `spinVector.py`. Download the scripts and execute the first one (`bloch_states.py`) using the Job Manager or in a Terminal. It reads in the SOGGA state from `Bi2Se3_slab.nc`, performs the two BlochState analyses for k-point [0, 0.04, 0], and then computes the length r and polar angles θ and ϕ for both Bloch states and plots them.

The resulting figure is shown above. Orange and purple dots at the bottom indicate the position of the Se and Bi atoms, respectively. The two states are clearly localized on opposite sides of the slab (red curves) and have very little overlap in the middle of it. The polar angle ϕ is 270ř for both states (blue curves), but the in-plane angle ϕ is 120ř for band 144 and rotated by 180ř to 300ř for band 145 (green curves). The two spin states therefore point in opposite directions!

Fermi surface and spin directions

Finally, it is interesting to study the Fermi surface of the Bi_2Se_3 slab in the vicinity of the Dirac cone. This is easily done by sampling the band structure on a dense k-grid centered at the Γ-point.

Download and execute this pre-made script: `fermi_surface.py`. It reads in the SOGGA state from `Bi2Se3_slab.nc`, performs band structure analysis in all points on a $k_x \times k_y$=51×51 grid, and creates a contour plot of the eigen-energies of the surface state in energy band 144.

Note: For users of QuantumATK 2017: Use instead the script `fermi_surface_2017.py`.

The resulting plot is illustrated above. As expected for a Dirac cone, the Fermi surface is circular close to the apex (red dot), but in this case it turns more hexagonal in shape for higher energies.

The Python script has also extracted the contour corresponding to E_F=0.15 eV and computed the Bloch state for every

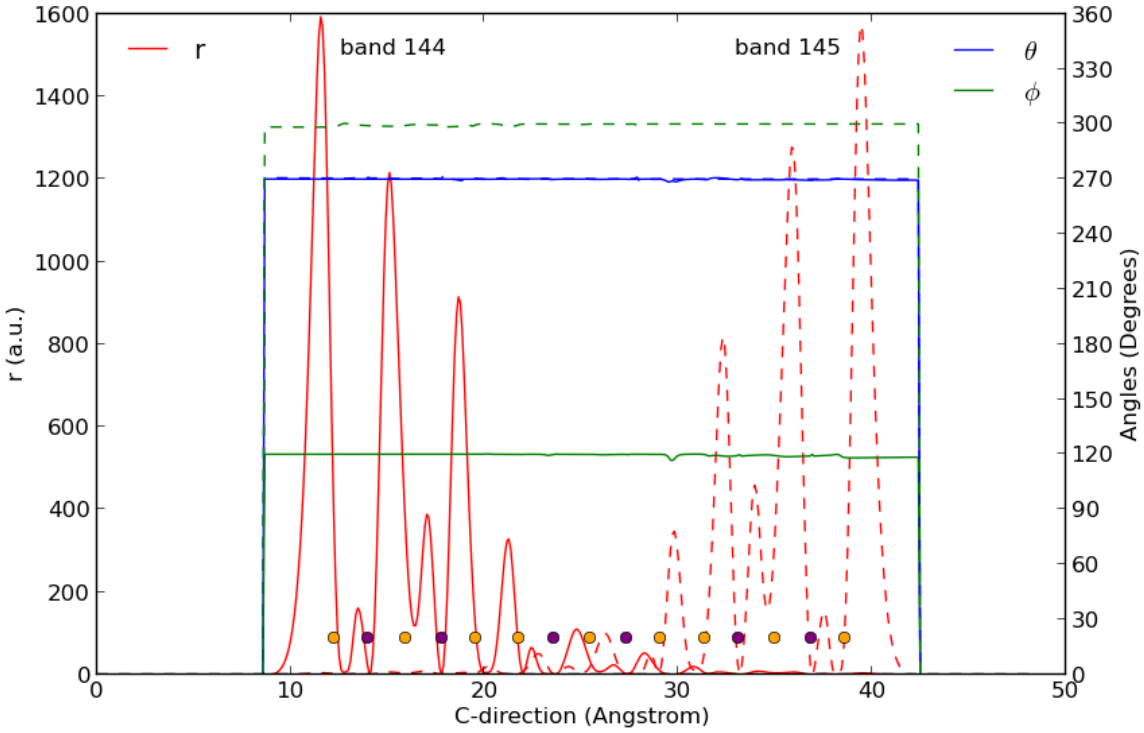

Fig. 3.32: Surface Bloch states in bands 144 and 145 evaluated in k-point [0, 0.04, 0]. The states are projected onto the C-direction. The states are localized on opposite sides of the slab configuration, and their spin directions are opposite.

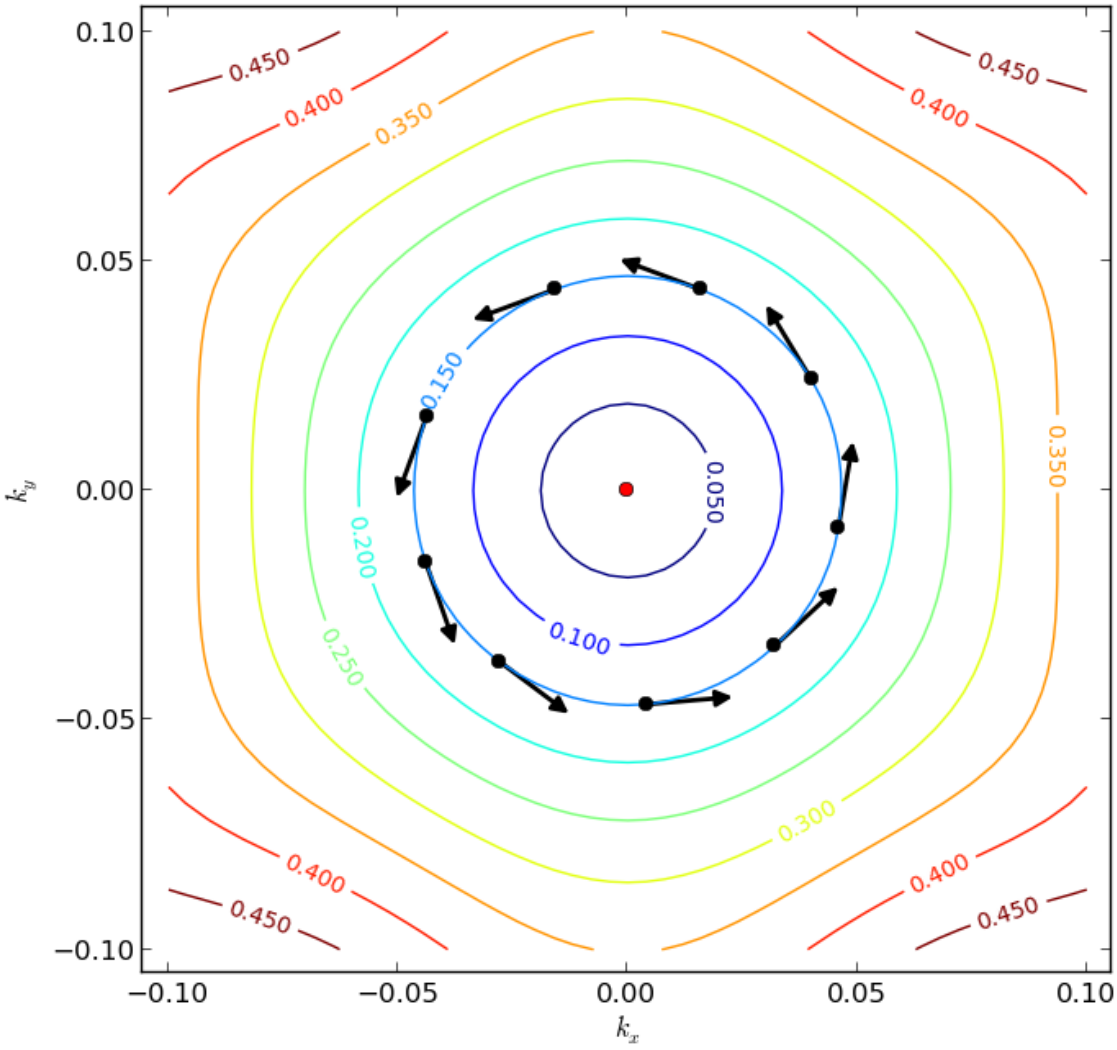

Fig. 3.33: Fermi surfaces on the Dirac cone centered at the Γ-point. The arrows indicate how the in-plane spin direction varies as an electron circles around the Dirac point.

10th (k_x, k_y) point around that contour. In each point, an arrow indicates the in-plane spin orientation (ϕ). It is clear that the spin rotates by 2π as it circles around the Dirac point.

The reason for this is simple: Time-reversal symmetry requires that states at momenta **k** and -**k** have opposite spin. However, the Dirac cone for surface states originating from a *single* surface is *not* spin degenerate. The spin must therefore rotate with **k** as it goes around the Fermi surface. See Ref.[Page 548, 1] for more details.

Topological Invariants

The properties of a 3-D topological insulator is determined by four topological invariants[5],[6],[7], which describe properties of the band structure at special k-points, i.e. the Γ-point and the Brillouin zone edges.

The first topological invariant describes the difference in the wavefunction symmetry at the different special k-points. This invariant distiguishes strong topological insulators, and when present, the system will have topologically protected surface bands. The topological invariant is robust towards atomic disorder and any time-invariant perturbation cannot remove the surface bands.

For a system with inversion symmetry the topological invariants can be calculated from the symmetry of the Bloch function at 8 special Brillouin zone points[8],

$$\Gamma_{i=(n_1,n_2,n_3)} = \frac{1}{2}(n_1\mathbf{b_1} + n_2\mathbf{b_2} + n_3\mathbf{b_3}),$$

where $\mathbf{b_i}$ are the reciprocal lattice vectors and $n_i = 0, 1$.

Let $\psi_{i,n}$ be the nth occupied Bloch function at Γ_i, then we define the symmetry function

$$\delta_i = \Pi_n \sqrt{\langle\psi_{i,n}|\Theta|\psi_{i,n}\rangle}$$

where Θ is the inversion operator. Once the symmetry functions are known the strong topological invariant, ν_0, is given by

$$(-1)^{\nu_0} = \Pi_{i=1}^{8}\delta_i.$$

There are three weak invariants, ν_1, ν_2, and ν_3, given by products of four δ_is, for which Γ_i reside in the same plane:

$$(-1)^{\nu_k} = \Pi_{n_k=1,n_{j\neq k}=0,1}\delta_{i=(n_1,n_2,n_3)}.$$

The weak invariants are not robust towards atomic disorder, and do not guarantee the existence of metallic surface bands.

Python script for the calculating the topological invariants

Download the script `TopologicalInvariant3D.py`, which implements the equations given above for calculating the topological invariants. The script will only work for systems with inversion symmetry. An example of usage is given with the python script below.

[5] Liang Fu, CharlesăL Kane, and EugeneăJ Mele. Topological insulators in three dimensions. *Physical Review Letters*, 98(10):106803, 2007. doi:10.1103/PhysRevLett.98.106803.

[6] JoelăE Moore and Leon Balents. Topological invariants of time-reversal-invariant band structures. *Physical Review B*, 75(12):121306, 2007. doi:10.1103/PhysRevB.75.121306.

[7] Rahul Roy. Topological phases and the quantum spin Hall effect in three dimensions. *Physical Review B*, 79(19):195322, 2009. doi:10.1103/PhysRevB.79.195322.

[8] Liang Fu and CharlesăL Kane. Topological insulators with inversion symmetry. *Physical Review B*, 76(4):045302, 2007. doi:10.1103/PhysRevB.76.045302.

```
from TopologicalInvariant3D import topologicalInvariant3D

bulk_configuration = nlread('Bi2Se3_bulk.nc', BulkConfiguration)[-1]

print '-----------------------------------'
print 'Topological Invariants = ', topologicalInvariant3D(bulk_configuration)
print '-----------------------------------'
```

which when run will produce the output

```
-----------------------------------
Topological Invariants =  [1 0 0 0]
-----------------------------------
```

We see that Bi_2Se_3 is a strong 3D topological insulator, because $\nu_0 = 1$, while the three weak invariants are all 0.

You can now easily screen a range of 3D materials with inversion symmetry for their topological indices to figure out if they are strong or weak topological insulators.

Note: For users of QuantumATK 2017 and later: The script `TopologicalInvariant3D.py` will **not** work with QuantumATK 2017 and later versions. Download instead the script `TopologicalInvariant3DATK2017.py` and use it like this:

```
from TopologicalInvariant3DATK2017 import topologicalInvariant3D

bulk_configuration = nlread('Bi2Se3_bulk.nc', BulkConfiguration)[-1]

print '-----------------------------------'
print 'Topological Invariants = ', topologicalInvariant3D(bulk_configuration)
print '-----------------------------------'
```

3.2.8 Effective band structure of random alloy InGaAs

Version: 2015.1

Random alloys are becoming technologically important materials. For example, SiGe is one of the best known thermoelectric materials, and InGaAs is a prime candidate to substitute or complement silicon in future CMOS devices. Simulations of both thermoelectric elements as well as transistor devices often refer to band structure parameters such as band gaps and effective masses.

In this tutorial, you will lean how to setup the structure of a random alloy and calculate the so-called effective bandstructure. The tutorial will focus on $In_{0.53}Ga_{0.47}As$ and calculations will be performed with DFT using the TB09-MGGA exchange-correlation functional, in order to obtain accurate band gaps.

Note: In a normal band structure, each band is a line with zero width/broadening in both the E- and **k**-directions:

Blochs theorem applies and the wavenumber **k** is a good quantum number. In a disordered alloy, Blochs theorem strictly does not apply, and one cannot *a priory* know if **k** is still a good quantum number or if the whole concept of a band structure is well defined.

In QuantumATK 2015 it is possible to calculate effective band structures of random alloys, following the method described in Refs.[1][2][3]. The purpose is to investigate whether or not the random alloy band structure is well defined, and if it is reasonable to extract band parameters.

Methodology

In the calculation of effective band structures, one considers a large super-cell containing many atoms. Here we consider a 3x3x3 repetition of the primitive FCC unit cell with 64 atoms. We model $In_{0.53}Ga_{0.47}As$ as InAs with some of the indium atoms replaced at random with gallium atoms. The In/Ga ratio is kept fixed at 0.53/0.47 in all calculations.

From the band structure of the super-cell containing more than 500 electronic bands, one can unfold the band structure such that it only contains bands corresponding to the primitive cell. In the unfolding procedure, one calculates a spectral weight $| \langle e^{i\mathbf{k}\cdot\mathbf{r}} \mid \psi_{j,K} \rangle |$, where $\mid \psi_{j,K} \rangle$ is an eigenstate of the super-cell at k-point K. If the super-cell is simply a copy of a simple unit cell (e.g. a super-cell of InAs), the spectral weights will either be 0 or 1, and the band unfolding can be done explicitly. However, in the case of a disordered alloy, such as $In_{0.53}Ga_{0.47}As$, the band weights can be any real number between 0 and 1.

Band structures of InAs

You will first calculate the normal band structure of a InAs, using the primitive (1x1x1) unit cell. Then a 3x3x3 InAs configuration is created, and you will show that the effective band structure of this repeated super-cell reproduces that of the primitive cell.

1x1x1 InAs

•Open the **Builder** and go through the following steps:

–Use the *Add* → *From Database* tool to create the InAs bulk configuration.

–Use the *Bulk Tools* → *Lattice Parameters* tool to change the lattice constant to the room temperature value:

∗Choose keep *fractional*;

∗Type in a = 6.058 Å.

–Click *OK* and send the configuration to the **Scripter** .

[1] V.ăPopescu and A.ăZunger. Effective Band Structure of Random Alloys. *Phys. Rev. Lett.*, 104:236403, Jun 2010. doi:10.1103/PhysRevLett.104.236403.

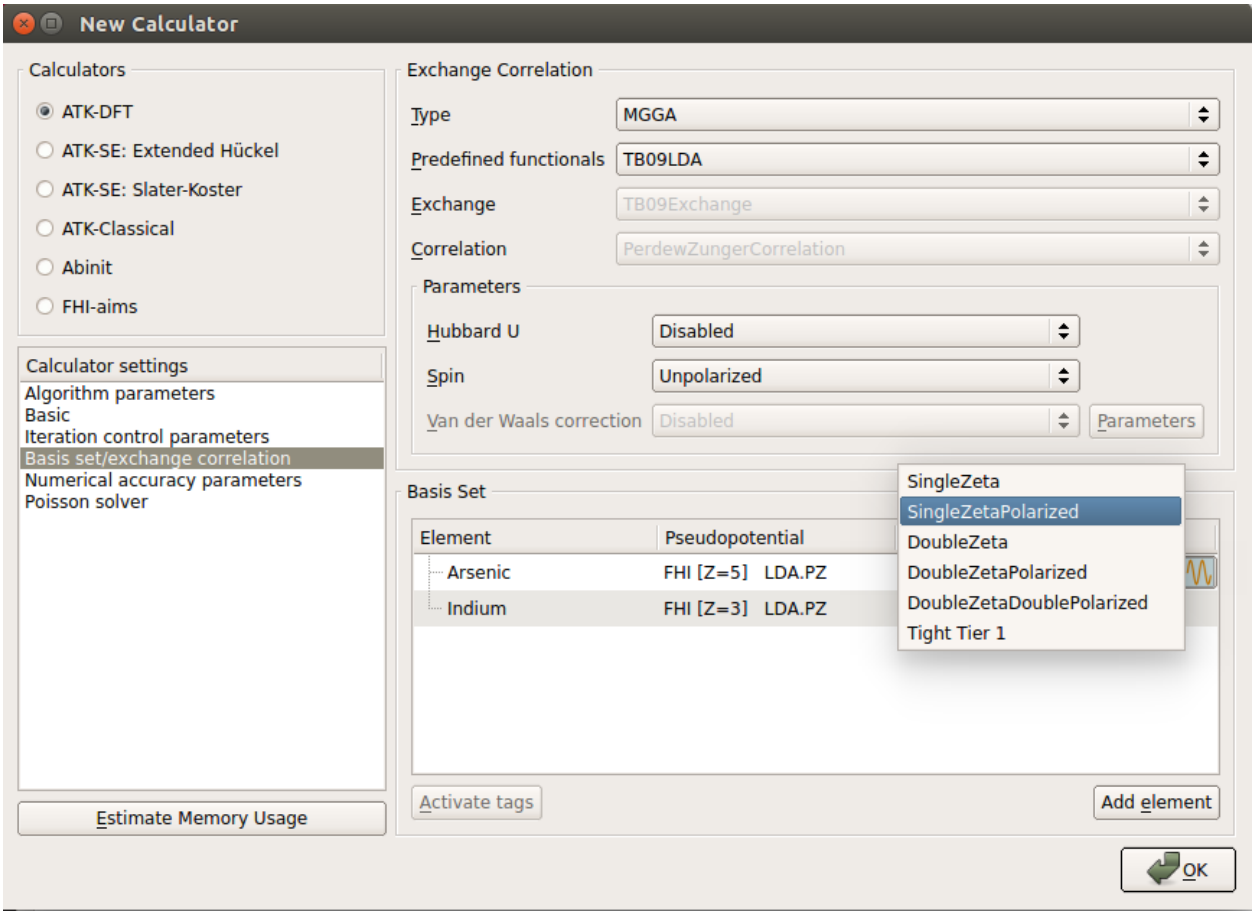
- In the **Scripter** add a New Calculator block. Then open and edit it:

  - Select the *ATK-DFT* calculator.
  - Use *MGGA* for exchange-correlation potential.
  - Set up a 9x9x9 grid for k-point sampling.
  - Use a *SingleZetaPolarized* basis set to speed up calculations.



•Next, add an *Analysis → Bandstructure* block. Open it and set the Brillouin zone route to L, G, X.

•Change the Default output file name to `InAs_1x1x1.hdf5`.

•Transfer the script to the **Editor** in order to specify the TB09-MGGA c-parameter. Locate the line

```
exchange_correlation = MGGA.TB09LDA
```

and change it to

```
exchange_correlation = MGGA.TB09LDA(c=0.91)
```

•Run the calculation using the **Job Manager** or in a Terminal. It takes about eight minutes to complete the simulation.

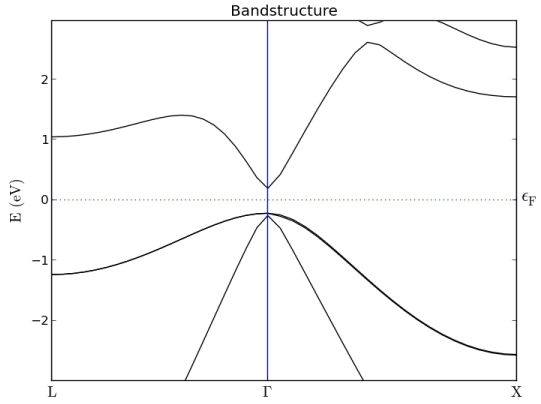
Note: You can learn more about the TB09-MGGA exchange-correlation potential and the TB09-MGGA c-parameter from the tutorial *Meta-GGA and 2D confined InAs*.

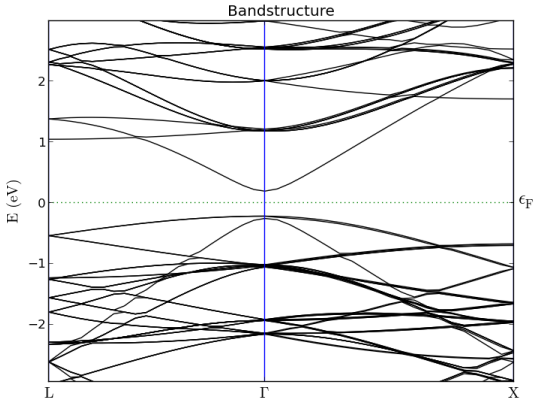
3x3x3 InAs

- Back in the **Builder** , repeat the 1x1x1 InAs configuration 3 times in each direction using the *Bulk Tools* → *Repeat* tool.
- Send this configuration to the **Scripter** and repeat the procedure outlined above to set up a script, buth with the following changes:
  - The k-point sampling in the calculator should be 3x3x3.
  - The default output file name should be `InAs_3x3x3.hdf5`.
- Use again the **Editor** to explicitly set the TB09-MGGA c-parameter, and run the calculation.

Results

The band structures for the 1x1x1 (left) and 3x3x3 (right) InAs configurations are shown below. The 3x3x3 band structure is folded at the zone boundaries, which makes it hard to locate the valleys corresponding to the X- and L-valley minima of the 1x1x1 configuration.

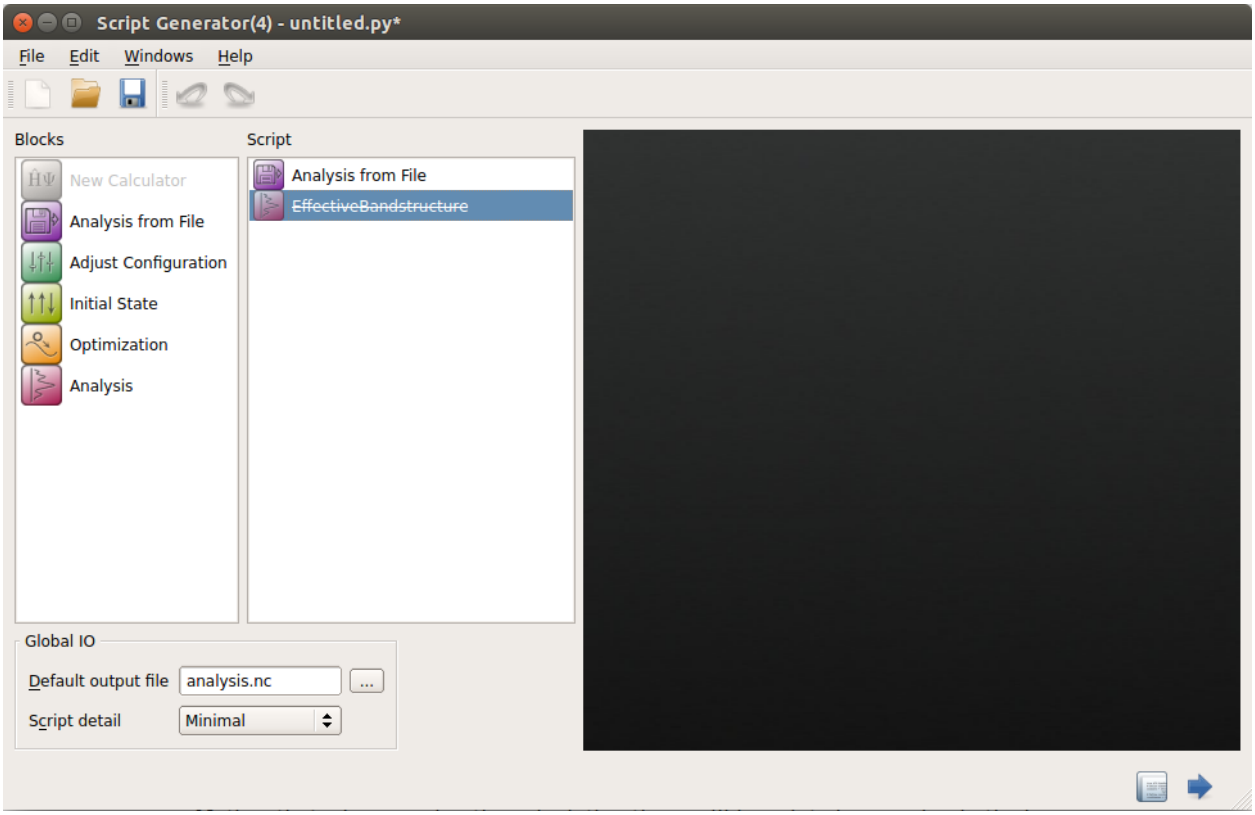




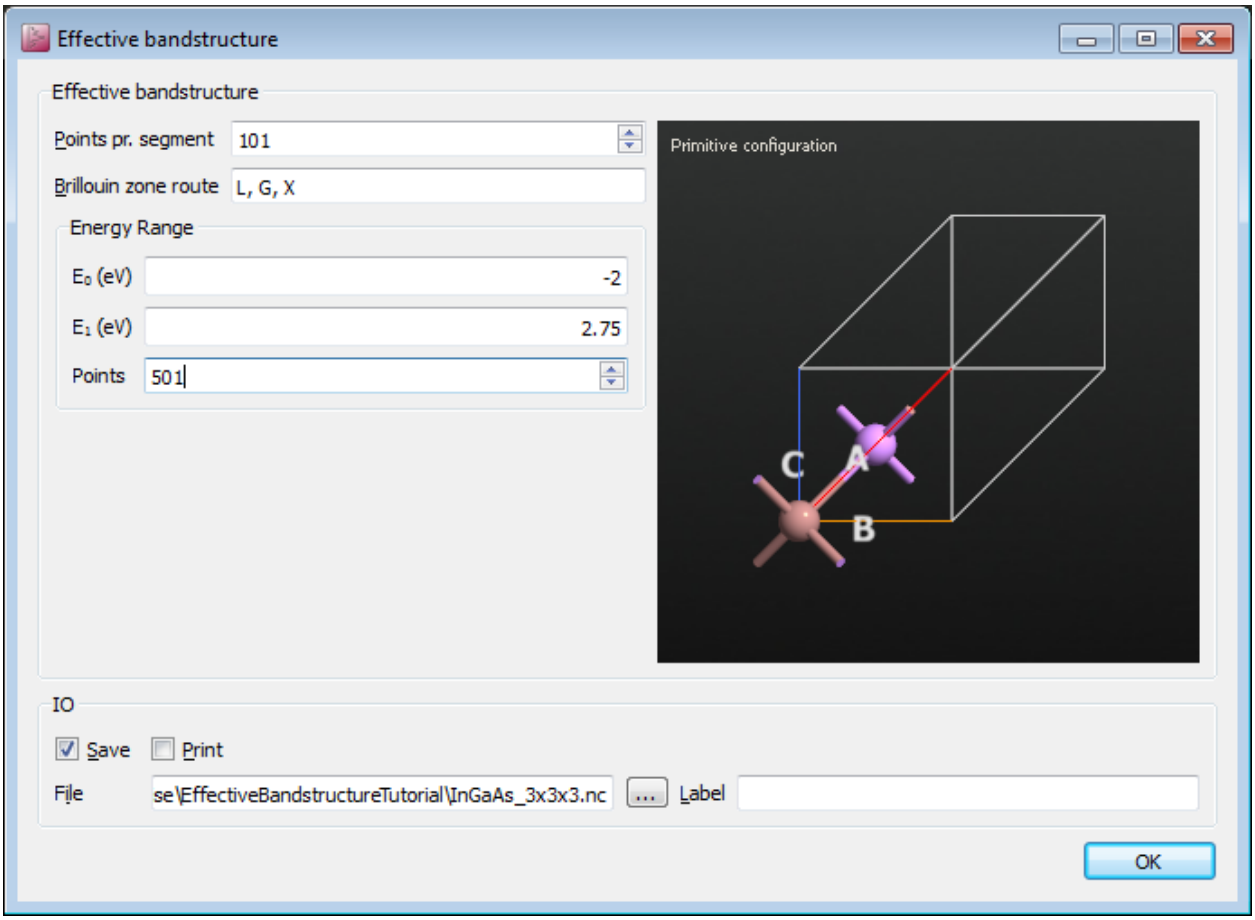
Effective band structure of 3x3x3 InAs

Open a new **Scripter** window, and follow these steps:

- Add the Analysis from File block, open it, and select the existing HDF5 file `InAs_3x3x3.hdf5`.
- Add also the *Analysis* → *EffectiveBandstructure* block. It will be crossed over, indicating that the block needs further editing.



- Open the EffectiveBandstructure block and start editing it.
- Select a 1x1x1 InAs configuration, either from the **Builder** or from the **LabFloor**, and drag it to the black area named Primitive configuration.
- Apply the following settings:
  - Points pr. segment: 101
  - Brillouin zone route: L, G, X
  - E0: -2.0 eV
  - E1: 2.75 eV
  - Points: 501



•The script is now done, so save it and run the calculation. It takes about three minutes to complete on a laptop.

Note: When running the calculation the folllowing warning will appear in the log file:

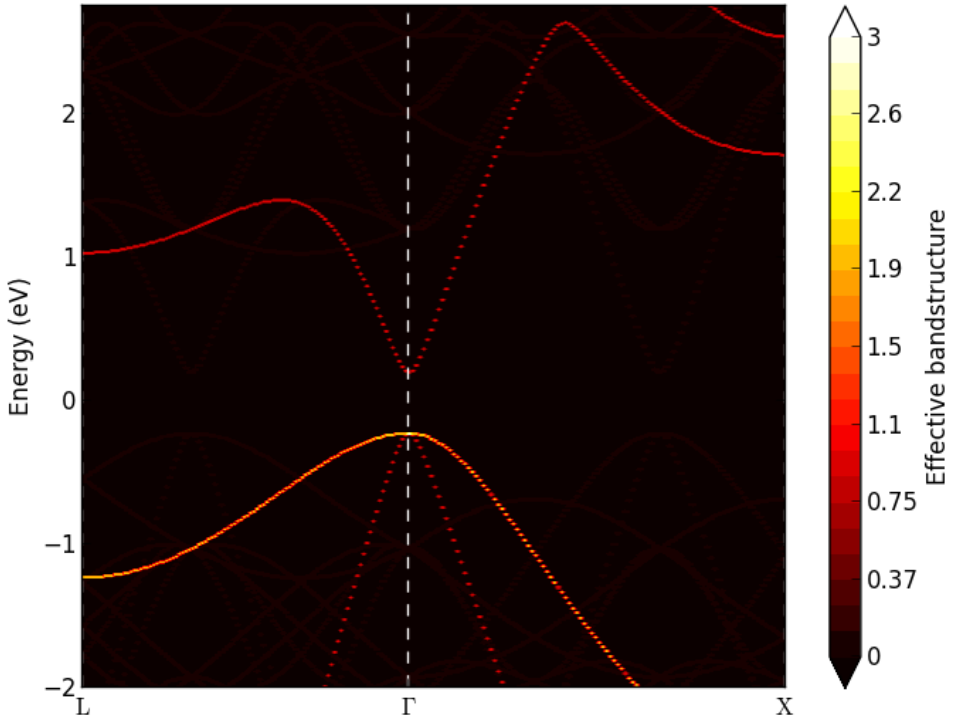
```
Warning: The calculation did not converge to the requested tolerance!
```

This is perfectly OK. A single SCF iteration is executed to obtain the basis functions in the primitive cell, which are used in the effective band structure calculation.

•The EffectiveBandstructure object will now have appeared on the **LabFloor**. It looks like this:

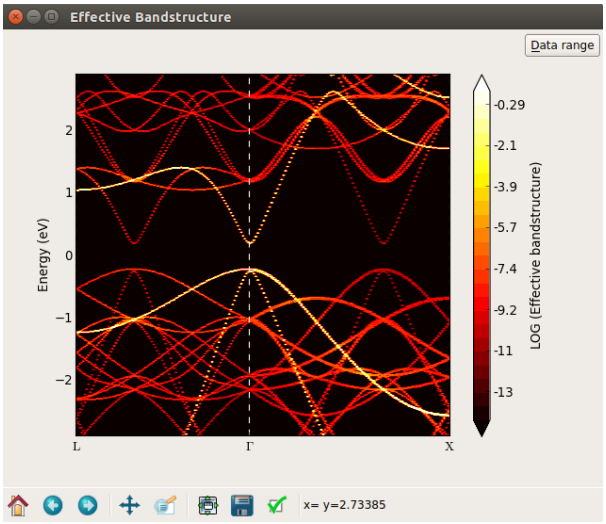
$$\epsilon(E, \mathbf{k})$$

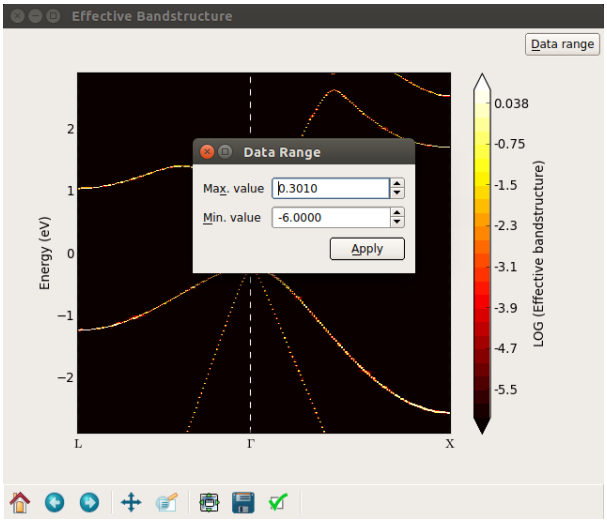
•Select the object and use the **Effective Bandstructure Analyzer** plugin to visualize it. Compare the figure (shown below) with the normal band structure plot of the 1x1x1 InAs shown above.



The analyzer shows a band density map of the **k**,E(**k**) plane. Each band will add a weight between 0 and 1 to the band density. At the Γ-point there are three degenerate valence bands, and the band density becomes 3 (bright yellow in the figure above). The conduction band has a weight of 1.

In order to see all the bands with a weight close to 0, you can plot the band density on a logarithmic scale. Right-mouse click on the plot and select *Log scale* in the bottom of the menu, and the plot is shown as the left figure below. A lot of bands appear in red color. By inspecting the colorbar you notice that these bands have weights around 10^{-9}, which is essentially just numerical noise. Try to adjust the Data range (upper right corner) and set the minimum value to -6. The noise bands now disappear, as shown at the right figure below.





Important: So far, you have seen that the effective bandstructure works, and give what we expect: The effective band structure of the 3x3x3 repeated InAs is the same as the normal bandstructure of the simple 1x1x1 InAs.

In the next section you will learn how to setup a random InGaAs alloy – a system where the normal bandstructure cannot be calculated for a simple 1x1x1 configuration, and where it is not *a priori* obvious if the whole concept of a band structure is well-defined or not.

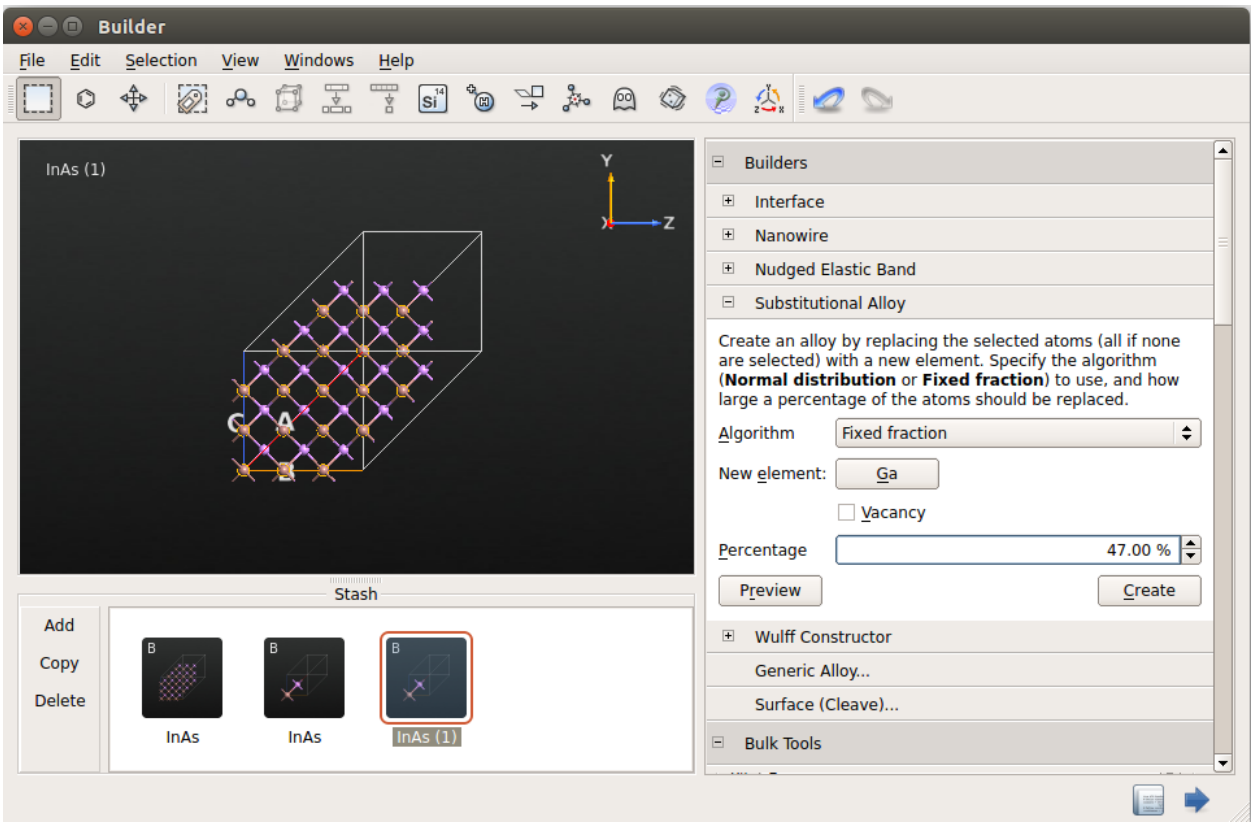
$In_{0.53}Ga_{0.47}As$ random alloy

You will now set up a $In_{0.53}Ga_{0.47}As$ random alloy structure and calculate the effective bandstructure. We shall also consider the sample averaged effective band structure, and analyze the consequences of finite band broadening.

Random alloy

Open the **Builder** to create the alloy configuration:

- Add a new InAs configuration, and change the lattice constant to 5.8687 Å, which is the experimental value for $In_{0.53}Ga_{0.47}As$.
- Right-click the new Stash item and copy it (you will need the copy later on for calculating the effective bandstructure).
- Repeat the InAs configuration 3 times in each direction.
- Next, select all the indium atoms by using the *Select* → *By Element* tool, and open the *Builders* → *Substitutional Alloy* plugin. Apply the following settings:
  - Algorithm: *Fixed fraction*
  - New element: *Ga*
  - Percentage: *47%*
- Then click *Create*.



In the new configuration, approximately 47% of the indium atoms have been substituted with gallium atoms in a random way. Transfer this $In_{0.53}Ga_{0.47}As$ random alloy configuration to the **Script Generator** .

Effective band structure calculation

- Add a **New Calculator** block with the same settings as used for InAs:

  – MGGA exchange correlation.

  – 3x3x3 k-point sampling.

  – SingleZetaPolarized basis set.

- Add the *Analysis* → *EffectiveBandstructure* block, and open it for editing.

- Drag-and-drop the copied 1x1x1 InAs configuration with the 5.8687 Å lattice constant from the **Builder** onto the black area.

- Apply these settings:

  – Points pr. segment: 101

  – Brillouin zone route: L, G, X

  – E0: -2 eV

  – E1: 2.75 eV

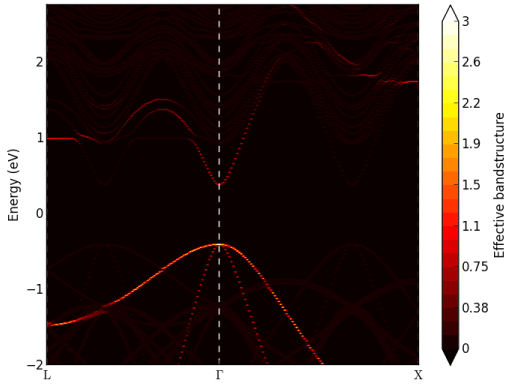
  – Points: 501

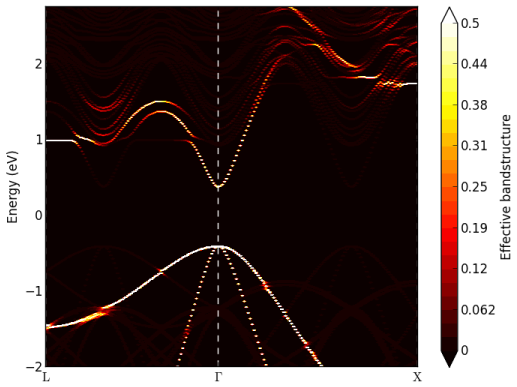
•Transfer the script to the **Editor** and add the TB09-MGGA c-parameter. For $In_{0.53}Ga_{0.47}As$ with a SingleZetaPolarized basis set, you should use c=1.01 to get approximately the experimental band gap of 0.74 eV.

•Run the job using **Job Manager** or in a Terminal. It takes about 10 minutes to complete the job.

Results

Investigate the calculated effective band structure using the **Effective Bandstructure Analyzer**. It should be similar to the figure on the left below. The bands are no longer weighted at either 0 or 1, but with a value in between. In particular around the L- and X-point conduction band minima, there are clear deviations from the simple band structure seen for InAs. Try to adjust the data range and set the maximum value to 0.5. Then some of the bands become more visible, as shown below on the right. Near the Γ-point, both the valence band and conduction bands are well-defined, and the effect of the random disorder seems to be rather limited.





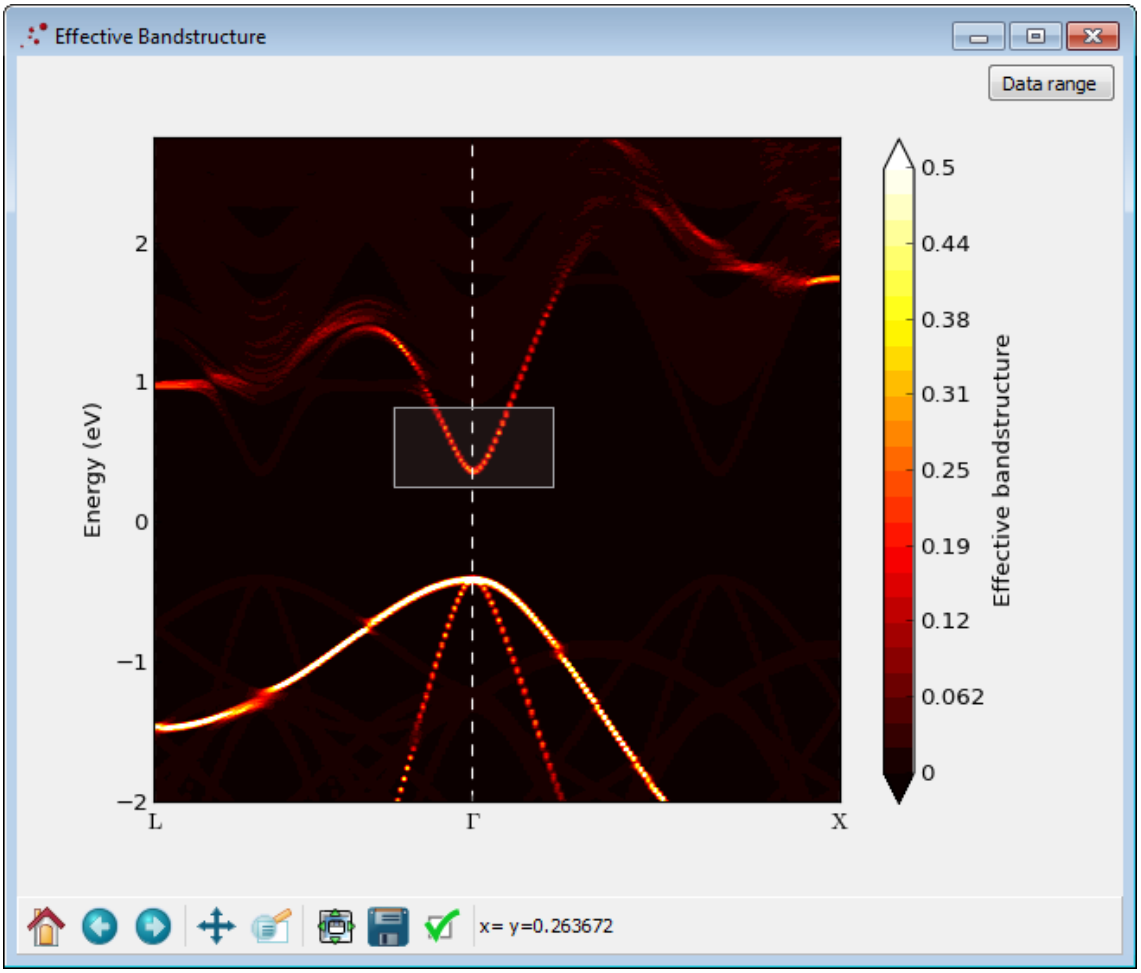
Note: The resulting effective bandstructure is not necessarily exactly the same as in the figure above due to the random alloy generation.

Sample averaged effective band structure

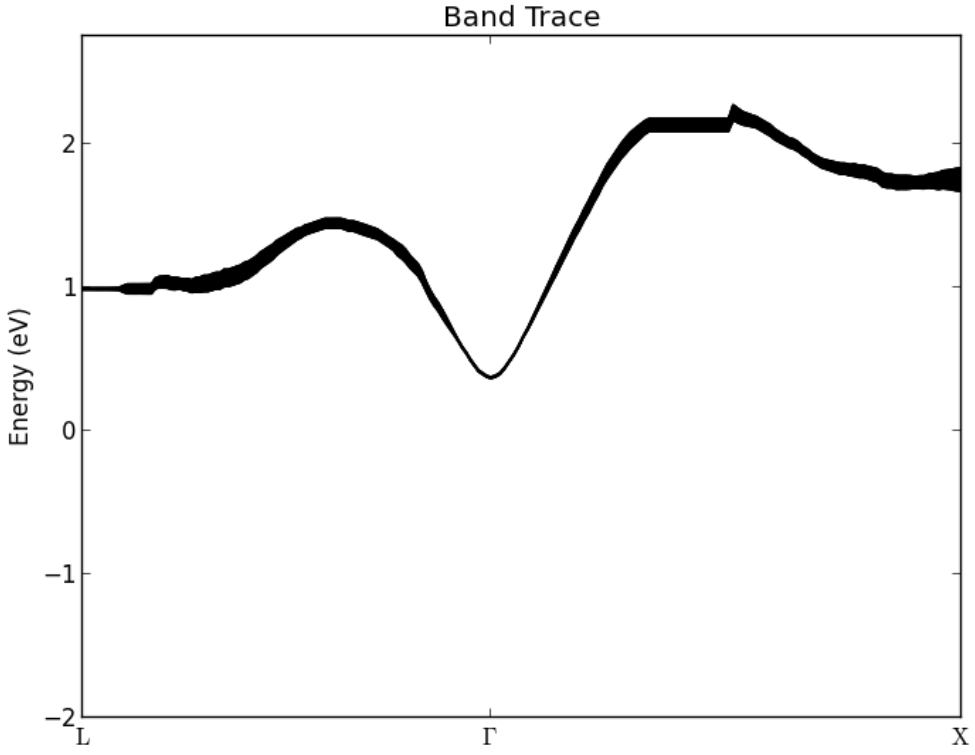
A quantitatively more reliable effective band structure should be obtained by repeating the above procedure a number of times to create different random configurations. Some python scripting can help to finish the task elegantly and efficiently.

Download the Python script `ingaas_ebs.py`, which creates a number of random $In_{0.53}Ga_{0.47}As$ alloys and performs the effective band structure calculation for each of them. You can then average over the results. The default number of generated alloys (`number_of_runs`) is 10. You will get even better results by increasing that number.

Run the script, and observe the EffectiveBandstructure objects appear in the file `InGaAs_3x3x3.hdf5` on the **LabFloor**. Mark all the generated data objects and click the **Effective Bandstructure Analyzer**. The analyzer will now show the average of all the effective band structure densities. Try to adjust the colours by changing the data range and maximum value:



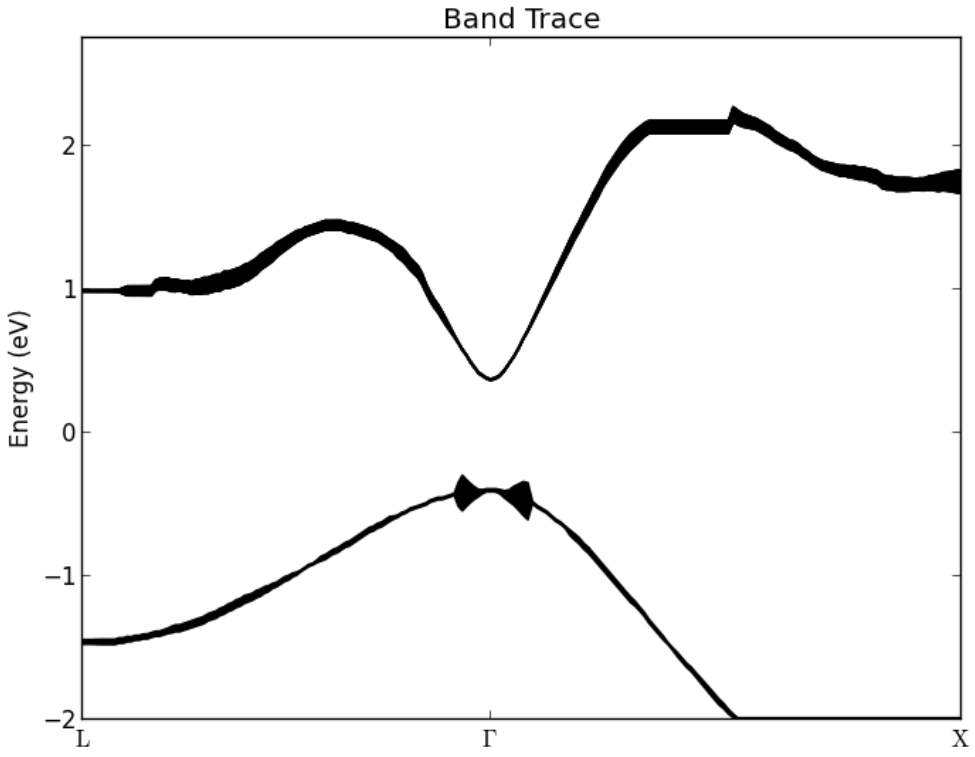
It is possible to trace the most significant bands with the heighest weight: Draw a box with the mouse like shown in the figure above. A progress bar will appear in the bottom of the window signalling that the effective band structure data is being analyzed for band tracing. After a little while a new window will appear, like the one shown below. The figure shows the traced bands plotted with a finite with. The center of the line is identified as a band. It can be exported to a text file by right-clicking on the figure and choosing *Export data*.



Tip: The band is calculated in the following way:

1. For each **k**, the band density is first smoothed by performing a convolution with a Lorentzian function (the broadening in energy is 0.2 eV).
2. The peaks of this smoothed band density is found.
3. A band is formed by selecting the peak energies closest to the peak energy found at the previous k-point (or, for the first k-point, closest to the center of the box you draw).
4. Proceed to the next k-point and repeat the process.

The width is calculated as the second moment of the raw data (i.e. not smoothed) in an interval of -0.15–0.15 eV around the peak energy. The maximum width is thus 0.3 eV. Note that if two or more bands are close to each other, the calculated width will be slightly wrong, since the density from the other bands will contribute to the width. Try to draw a box around the highest valence band. The Band Trace figure will be quickly updated to appear like the figure below. Close to the Γ-point the senond-highest valence band erroneously contribute to the width of the first one.



Finite broadening

Contrary to a normal band structure, the effective bands will have a finite broadening. If the broadening is small, the band structure is well-defined; if the broadening is large, the concept of bands is no longer valid. The average effective band structure of an $In_{0.53}Ga_{0.47}As$ random alloy, as shown in the figure above, is well-defined close to the Γ-point. However, the conduction band is not well-defined around the L- and X-valley minima, where the bands have a finite broadening of $w \approx 0.06$ eV.

The well-defined effective band structure around the Γ-point can be understood in terms of the long wavelength present there. The local random variations are not seen by a long wavelength electron. On the contrary, at the X and L points, the wave functions vary on the atomic scale, and are affected by the disorder.

Analysis and consequences of finite band broadening

One can interpret the finite band broadening in terms of a life-time $\tau = \hbar/w = 11$ fs. Together with an approximate longitudinal effective mass m_l=1.5 m_e and transverse effective mass m_t=0.2 m_e, both obtained from virtual crystal approximation (VCA) calculations, we can estimate the effective mean free path (MFP) as:

$$\mathrm{MFP} = v_k \tau,$$

where the band velocity $v_k = 1/\hbar \cdot \partial E(k)/\partial k$. Assuming a parabolic band $E(k) = \hbar^2 k^2/2m$ around the valley minima, the mean free path as a function of energy, relative to the X- or L-valley minimum, is then:

$$\mathrm{MFP} = \frac{\hbar}{\omega}\sqrt{\frac{2E}{m}}.$$

At the valley minima, the mean free path vanishes, and at a constant energy surface of 0.01 eV above the X- or L-valley minima we obtain estimated mean free paths of 1.5 nm and 0.5 nm in the transverse and longitudinal directions, respectively. Clearly, the random disorder will be a limiting factor for transport in these valleys. The MFP vs. energy can be plotted with the python script `mean_free_path.py`.

Final comments

For scientific use we recommend to use even larger super-cells, e.g. 4x4x4 or even larger, which will be more like a real random alloy. The relatively small 3x3x3 cell used in this tutorial was chosen to make the calculations relatively fast. The small cell size might affect the results in a quantitive manner, but we do expect the main conclusions to remain unchanged.

Since the effective band structure close to the Γ-point has a narrow broadening, it is reasonable to assume that Blochs theorem applies here and that the random disorder has a small effect on the transport properties. In this case, more efficient studies of the band structure of random alloys can be performed with the virtual crystal approximation as explained in the tutorial *Virtual Crystal Approximation for InGaAs random alloy simulations*.

3.2.9 Complex bandstructure of Si(100)

Version: 2015.1

Downloads & Links

`si_100_cbs.py` `3D_plot.py` `2D_plot.py` *`ComplexBandstructure`*

In this tutorial you will calculate the complex bandstructure of a silicon crystal along the (100) direction.

In particular you will:

1. create the Si(100) surface;
2. set up and run the calculation;
3. plot the complex bandstructure (3D and 2D).

Background

In a periodic solid the eigenstates $\psi_{n\mathbf{k}}$ of the Schrödinger equation $H\psi_{n\mathbf{k}} = E_{n\mathbf{k}}S\psi_{n\mathbf{k}}$, ($S$ is the overlap matrix) can be written as $\psi_{n\mathbf{k}}(\mathbf{r}) = e^{-i\mathbf{k}\cdot\mathbf{r}}U_{n\mathbf{k}}(\mathbf{r})$, where $U_{n\mathbf{k}}(\mathbf{r})$ is a periodic function with the same periodicity as the crystal itself. In a usual bandstructure calculation, the wave vector $\mathbf{k}$ is a real number, and by solving the Schrödinger equation above for various fixed values of $\mathbf{k}$ (typically located along different symmetry lines in the first Brillouin zone) an eigenproblem is defined, from which the eigenenergies $E_{n\mathbf{k}}$ (i.e. the bandstructure) can be determined.

When calculating the complex bandstructure another approach is taken[1]. Instead the energy E is fixed, and the values of $\mathbf{k}$ which solve the Schrödinger equation are sought. Such solutions will be found with both real and complex $\mathbf{k}$; the

[1] Yia-Chung Chang and J.ăN. Schulman. Complex band structures of crystalline solids: An eigenvalue method. *Phys. Rev. B*, 25:3975–3986, Mar 1982. doi:10.1103/PhysRevB.25.3975.

solutions with a real $\mathbf{k}$ are the usual Bloch states, while the solutions with an imaginary part are exponentially decaying in one direction and increasing in the other. Such solutions cannot exist in a bulk material, and so they are normally ignored in a bandstructure calculation. They may however exist at a surface or interface, and they give information about how electronic states decay in the material, for instance through a thin tunneling barrier.

Note: You will primarily use the graphical user interface QuantumATK for setting up and analyzing the results. If you are new to QuantumATK, it is recommended to go through the Basic QuantumATK Tutorial.

The calculations in this tutorial will be performed using the semi-empirical models of QuantumATK. A complete description of all the parameters, and in many cases a longer discussion about their physical relevance, can be found in the ATK Reference Manual. In particular, the Reference Manual entry for complex bandstructure calculations is of relevance: `ComplexBandstructure`.

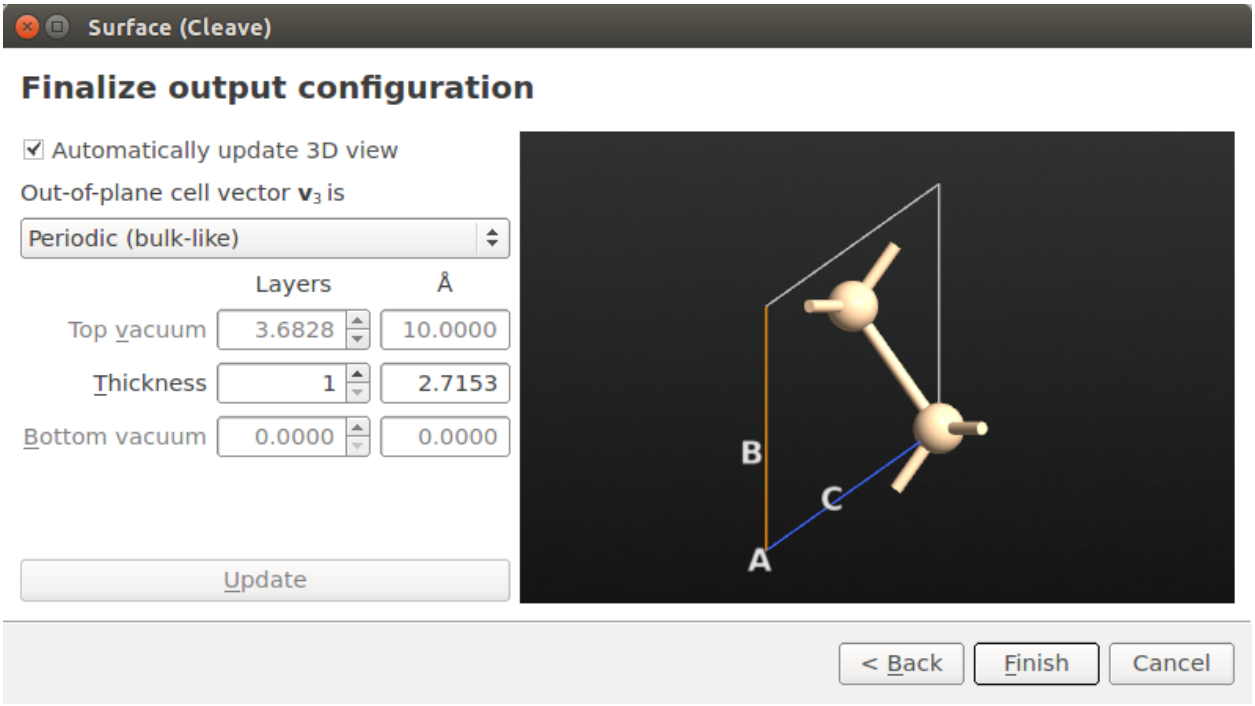
Si(100) surface

Start QuantumATK and create a new project named ComplexBandstructure. Then click *Open* and launch the **Builder** via the icon on the toolbar.

In the Builder, click *Add* → *From Database* and locate the Silicon (alpha) structure. Double-click the line to add the structure to the Stash, or click the icon in the lower right-hand corner.

Unfold *Builders* from the plugin panel and open the Surface (Cleave) tool, and follow the next steps to set up the Si(100) surface:

1. Keep the default Miller indices (100) and click *Next*.
2. Keep the default lattice vectors and click *Next*.
3. Select *Periodic (bulk-like)* for the out-of-plane cell vector.
4. Set the thickness of the surface to 1 layer.
5. Click *Finish* to add the Si(100) surface structure to the Stash.



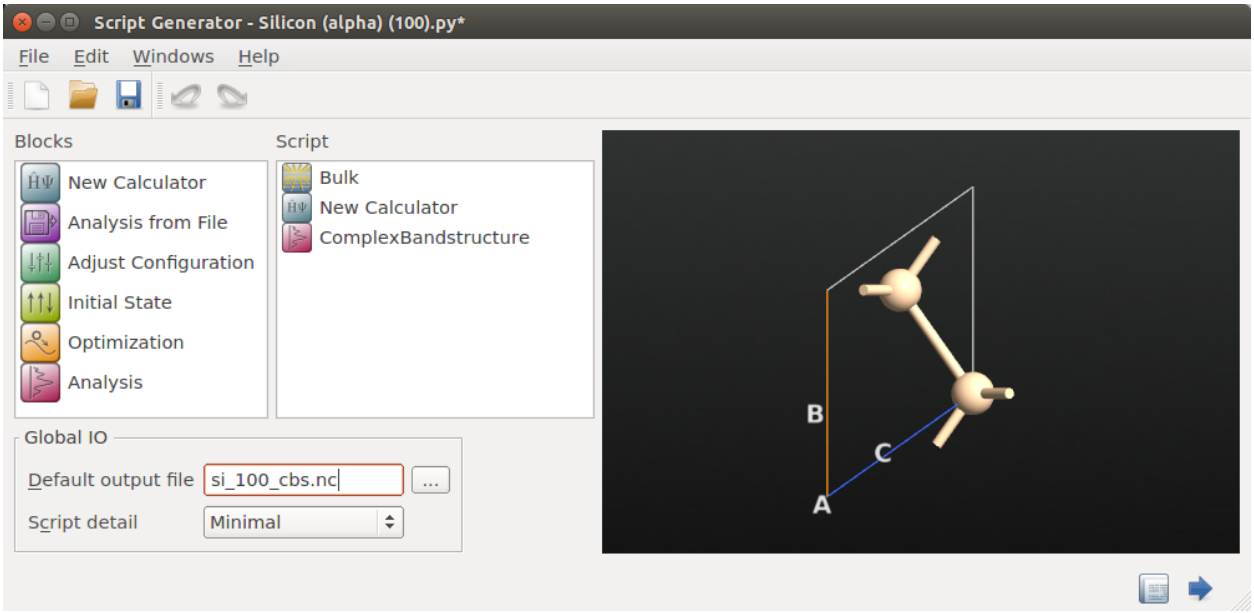
With these settings we use a surface representation with a minimum number of layers in order to reduce the calculation time and avoid zone folding.

Note: The cleave plane – in the present case (100) – is always spanned by the two first unit cell vectors, and $\mathbf{B}$. In the electrode mode, the normal to this plane coincides with $\mathbf{C}$, the third unit cell vector, but in the bulk-like mode this is not the case. In QuantumATK the complex bandstructure is always computed along the third reciprocal vector, $\mathbf{g}_C$, which is of course parallel to $\mathbf{A} \times \mathbf{B}$. With the present geometry you will therefore obtain the complex bandstructure along (100).

Complex bandstructure calculation

Send the structure to the **Script Generator** using the icon in the lower right-hand corner of the Builder and follow the next steps:

1. Add a New Calculator block.
2. Add the *Analysis* → *ComplexBandStructure* block.
3. Change the default output filename to `si_100_cbs.hdf5`.

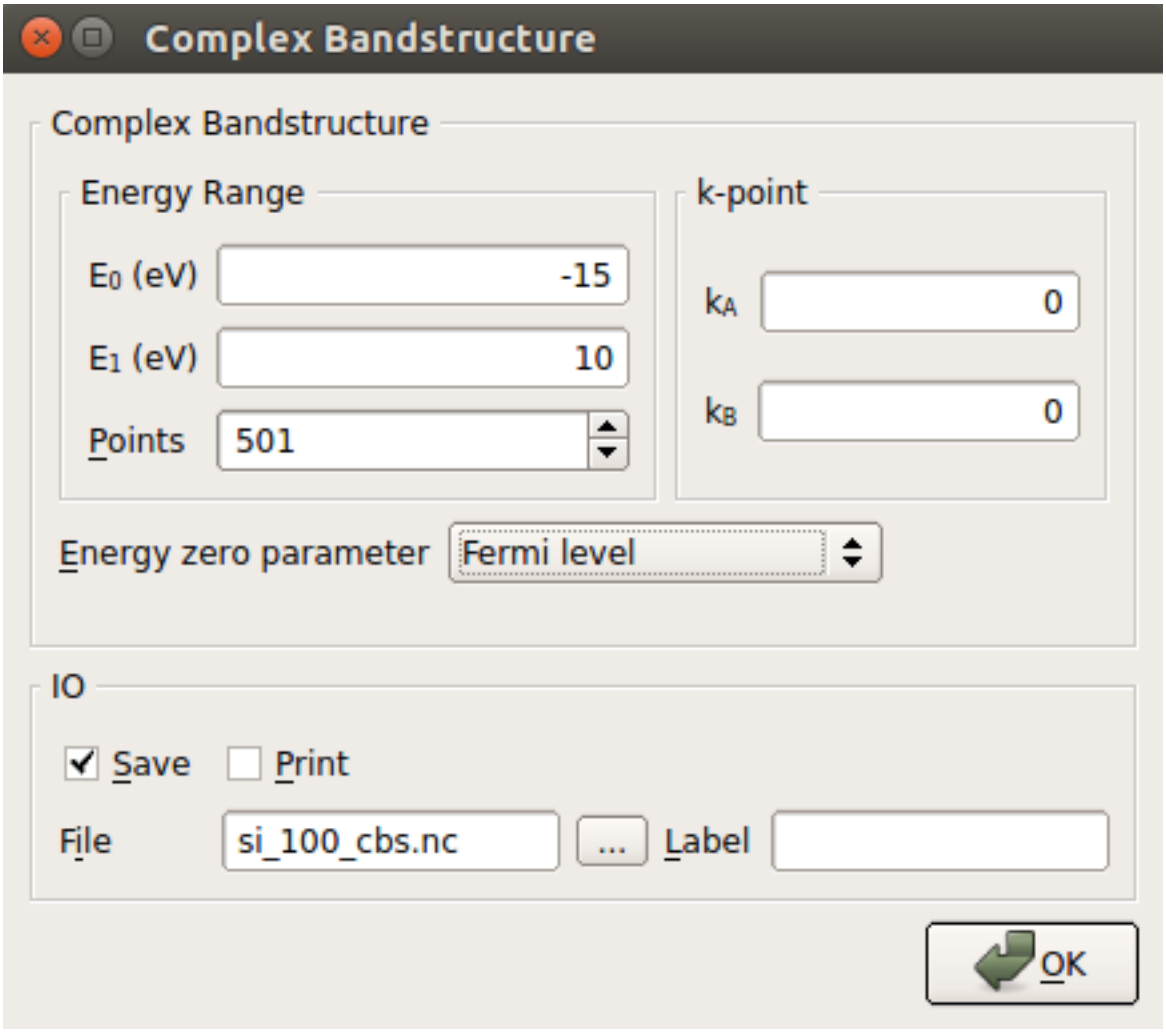


Next, open the inserted New Calculator block (double-click it), and set up a tight-binding calculation:

1. Select the *ATK-SE: Extended Hückel* calculator.
2. Set the k-point sampling to 5x5x5.
3. Under Huckel Basis set, select the *Cerda.Silicon [diamond GW]* basis set. This basis set has been fitted to GW calculations, and gives an excellent description of the bandstructure, including the size of the band gap.
4. Close the dialogue by clicking *OK*.

Next, open the ComplexBandstructure analysis block, and edit it:

- Set the energy range to -15 to 10 eV with 501 points.



Note: The projection of **k** on the cleave plane is kept constant in the complex andstructure calculation, and the value of the projection is specified by the (k_A, k_B) parameters, which are given in units of the two first reciprocal lattice vectors, $\mathbf{g}_A$ and $\mathbf{g}_B$. Therefore, the obtained solutions will lie along the third reciprocal lattice vector, $\mathbf{g}_C$, which is parallel to the cleave plane normal. A new set of solutions $k_C + i\kappa_C$ is obtained for each value of (k_A, k_B).

Please note that k_C is therefore the *real* part of the complex bandstructure, while $kappa_C$ is the *complex* part.

You have now finished the Python script. Save it as `si_100_cbs.py` and send it to the **Job Manager** for execution.

It should only take a few minutes for this small system. If needed, you can also download the script here: `si_100_cbs.py`.

Tip: This type of calculation parallelizes extremely well, so for larger structures it is warmly recommended to execute the script in parallel.

Analysing the results

The file `si_100_cbs.hdf5` should now have appeared on the QuantumATK **LabFloor**. It contains the saved Hückel calculation and the ComplexBandstructure analysis object:

ComplexBandstructure

$\mathbf{k}_\perp(\epsilon, \mathbf{k}_\parallel)$

Select that analysis object and click **Show 2D Plot** tool from the right-hand side plugins panel. A window with a plot of the complex bandstructure pops up. Zoom in a bit to filter out the solutions with large values of the complex part κ_C, since these are not really relevant:

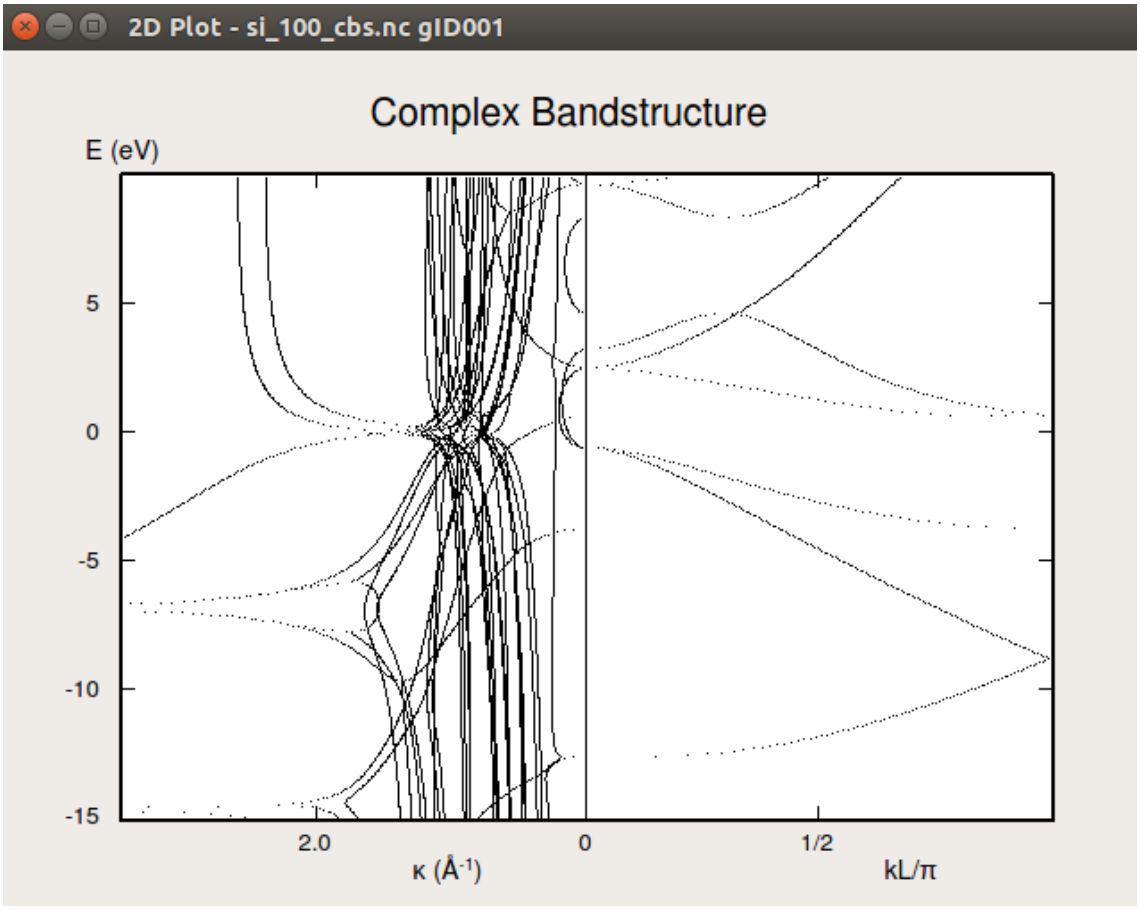


Fig. 3.34: Si(100) bandstructure. The right-hand part of the plot shows the *real* bands – note the indirect band gap of ~1.2 eV. The left-hand part of the plot shows the *complex* bands, plotted against the imaginary part, κ_C. The bands with a small imaginary part are the most important ones, since they are less damped if you should try to tunnel electrons through a thin slice of silicon in the (100) direction.

Note: In the plot above, the solutions κ_C are given in reciprocal Cartesian coordinates, to make it easier to compare different structures. For the real part of the bandstructure, on the other hand, the solutions k_C are normalized by L, the layer separation perpendicular to the cleave plane. In the case of a fcc crystal cleaved along (100), the layer separation is $L = a/2$, where a is the lattice constant. The layer separation can be extracted from the ComplexBandstructure object using the *layerSeparation()* method, see `ComplexBandstructure`.

3D and 2D visualizations

In the complex part of the bandstructure, the solutions actually have a real part too. Thus, they could be visualized in a three-dimensional plot, $(x, y, z) = (k_C, \kappa_C, E)$. This is possible with the following script. Open the QuantumATK **Editor** and copy-paste the script and save it as `3D_plot.py`. Make sure that the indentation is correct. Alternatively, you can simply download it here: `3D_plot.py`.

```
from QuantumATK import *
from mpl_toolkits.mplot3d import Axes3D
import matplotlib.pyplot as plt
import math

# Read the complex bandstructure object from the NC file
cbs = nlread('si_100_cbs.nc', ComplexBandstructure)[-1]
energies = cbs.energies().inUnitsOf(eV)
k_real, k_complex = cbs.evaluate()
L = cbs.layerSeparation()

fig = plt.figure()
ax = fig.add_subplot(111, projection='3d')

# First plot the real bands
kvr = numpy.array([])
e = numpy.array([])

# Loop over energies, and pick those where we have solutions
for (j, energy) in enumerate(energies):
    k = k_real[j]*L/math.pi
    if len(k)>0:
        e = numpy.append(e,[energy,]*len(k))
        kvr = numpy.append(kvr,k)

# Plot the bands with red
ax.scatter([0.0,]*len(kvr), kvr, e, c='r', marker='o', linewidths=0, s=10)

# Next plot the complex bands
kvr = []
kvi = []
e = []

# Again loop over energies and pick solutions
for (j, energy) in enumerate(energies):
    if len(k_complex[j])>0:
        for x in numpy.array(k_complex[j]*L/math.pi):
            kr = numpy.abs(x.real)
            ki = -numpy.abs(x.imag)
            # Discard rapidly decaying modes which clutter the plot
            if ki>-0.3:
                e += [energy]
                kvr += [kr]
                kvi += [ki]

```

(continues on next page)

(continued from previous page)

```
# Plot the complex bands with blue
ax.scatter(kvi, kvr, e, c='b', marker='o', linewidths=0, s=10)

# Put on labels
ax.set_xlabel('$\kappa$ (1/Ang)')
ax.set_ylabel('$kL/\pi$')
ax.set_zlabel('Energy / eV')

plt.show()
```

Execute the script using the **Job Manager** or from a Terminal. The plot will resemble the figure below, but your points will be more scattered, since the figure below was produced from a Hückel calculation with 10,001 energy points instead of 501.

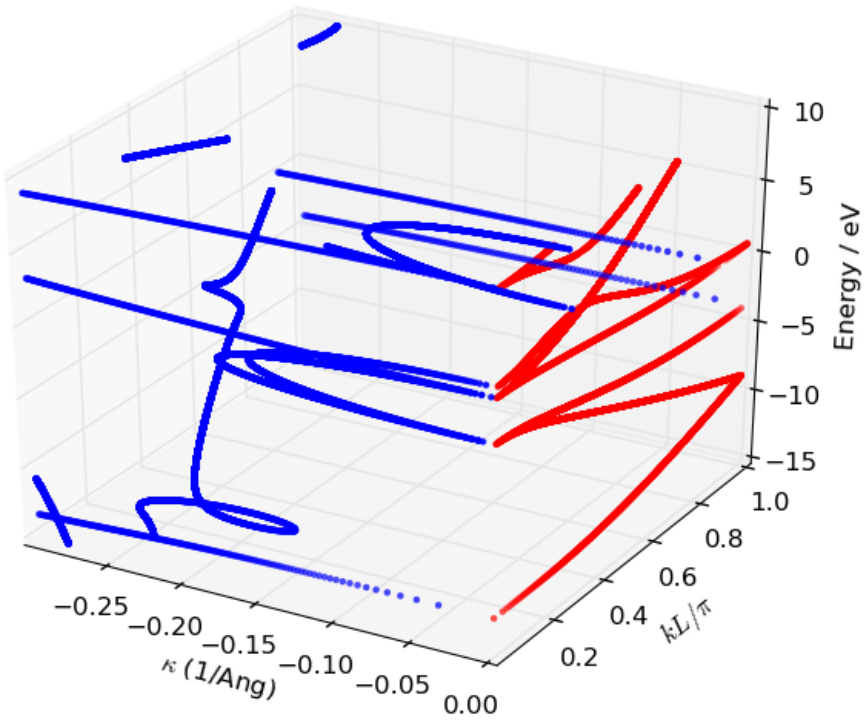

Fig. 3.35: 3D visualization of the complex bandstructure of Si(100). The real bands are plotted with red dots and the complex part in blue. Note how the complex bands connect with the real bands.

Another way to visualize the real part of the complex bandstructure is using colors. The script `2D_plot.py` does this (you can see the script below). It is a bit complicated towards the end, but that part is just for placing the colorbar, and could be omitted.

The forest of complex bands with a rather large value of κ are not usually seen in tight-binding simulations. However,

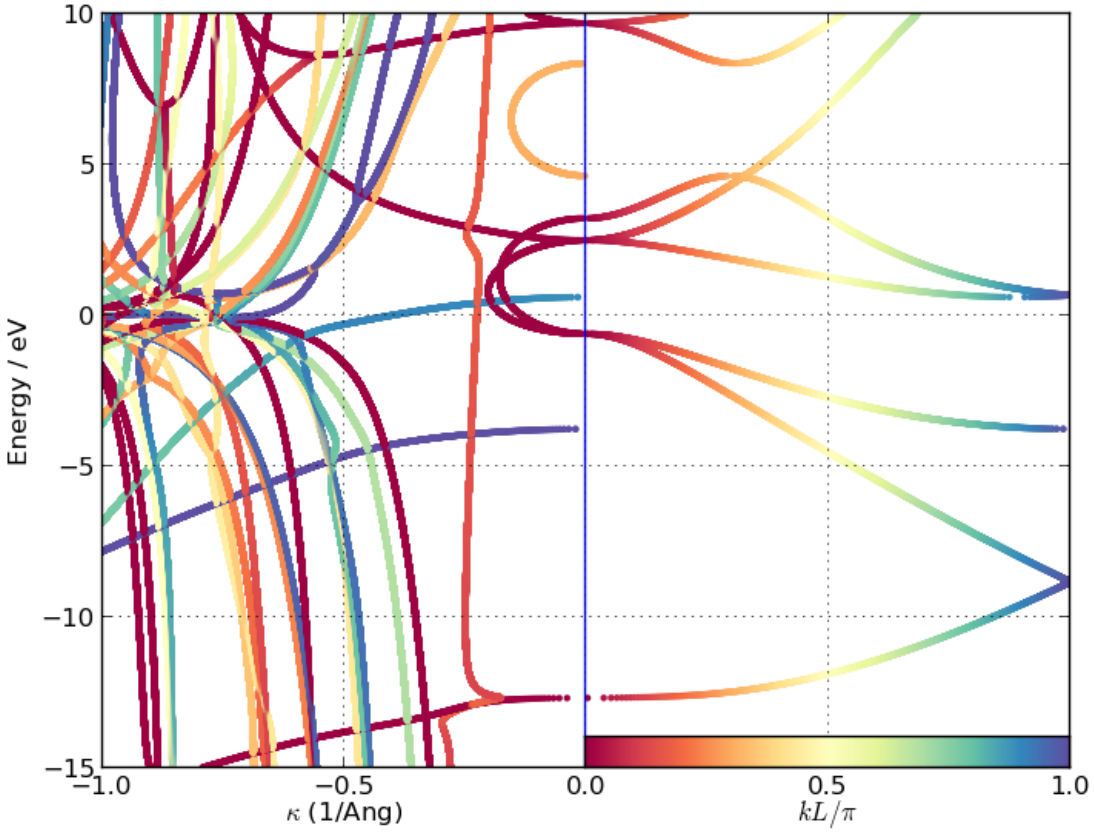

Fig. 3.36: 2D visualization of the complex bandstructure. Note how the color-coding of the k-values applies both to the real and the complex parts of the bandstructure, which makes it easier to see where the complex bands are attached to the real ones.

for DFT and Hückel, the basis sets are larger, so there are more complex bands as well, connecting unoccupied levels with various valence bands.

```
from QuantumATK import *
import matplotlib.pyplot as plt
import math

# Read the complex bandstructure object from the NC file
cbs = nlread('si_100_cbs.nc', ComplexBandstructure)[-1]
energies = cbs.energies().inUnitsOf(eV)
k_real, k_complex = cbs.evaluate()

ax = plt.axes()
cmap="Spectral"

# First plot the real bands
kvr = numpy.array([])
e = numpy.array([])
for (j, energy) in enumerate(energies):
    k = k_real[j]*cbs.layerSeparation()/math.pi
    if len(k)>0:
        e = numpy.append(e,[energy,]*len(k))
        kvr = numpy.append(kvr,k)

# Plot
ax.scatter(kvr, e,
           c=numpy.abs(kvr),
           cmap=cmap, marker='o', linewidths=0, s=10)

# Next plot the complex bands
kvr = numpy.array([])
kvi = numpy.array([])
e = numpy.array([])

for (j, energy) in enumerate(energies):
    if len(k_complex[j])>0:
        kr = [numpy.abs(x.real) for x in k_complex[j]]
        ki = [numpy.abs(x.imag) for x in k_complex[j]]
        e = numpy.append(e,[energy,]*len(kr))
        kvr = numpy.append(kvr,kr)
        kvi = numpy.append(kvi,ki)

# Plot with color depending on the imaginary part (corresponding to real k-points)
sc = ax.scatter(-kvi, e,
                c=kvr,
                cmap=cmap, marker='o', linewidths=0, s=10)

# Put on labels and decorations
ax.axvline(0,color='b')
ax.grid(True, which='major')
ax.set_xlim(-1, 1)
ax.set_ylim(-15, 10)
ax.annotate('$\kappa$ (1/Ang)', xy=(0.25,-0.07), xycoords="axes fraction", ha="center")
```

(continues on next page)

(continued from previous page)

```
ax.annotate('$kL / \pi$', xy=(0.75,-0.07), xycoords="axes fraction", ha="center")
ax.set_ylabel('Energy / eV')

# Add a colorbar
fig = plt.gcf()
x1, x2, y1, y2 = 0., 1, ax.get_ylim()[0], ax.get_ylim()[0]+1
trans = ax.transData + fig.transFigure.inverted()
ax_x1, ax_y1 = trans.transform_point([x1, y1])
ax_x2, ax_y2 = trans.transform_point([x2, y2])
ax_dx, ax_dy = ax_x2 - ax_x1, ax_y2 - ax_y1
cmap_axes = plt.axes([ax_x1, ax_y1, ax_dx, ax_dy])
a = numpy.outer(numpy.arange(0,1,0.01),numpy.ones(10)).transpose()
cmap_plt = plt.imshow(a,aspect='auto',cmap=plt.get_cmap(cmap),origin=(0,0))
ax = plt.gca()
ax.set_xticks([])
ax.set_yticks([])
ax.set_xticklabels([])
ax.set_yticklabels([])

plt.show()
```

Hint: You may note that there are gaps in the visualizations. The reason is that, unlike a normal bandstructure plot, the data is not plotted with lines, but with dots. In a standard bandstructure plot you can – with some level of confidence – define bands, which continuously run between the symmetry points (only band crossings can create some small problems). In the present case, the number of solutions is first of all different at each energy (particularly on the complex side), and depending on the density of the energy sampling, you may not hit a particular band close to points where the bands are very flat (heavy effective mass). This can to some extent be alleviated by increasing the number of energy points.

3.2.10 InAs p-i-n junction

Version: 2017

The purpose of this tutorial is to show how to set up and perform calculations for a device based on an InAs slab. You will define the structure of a H-passivated InAs slab along the (100) direction, and set up a p-i-n junction.

The underlying calculation engine for this tutorial is ATK-SE. A complete description of all the parameters, and in many cases a longer discussion about their physical relevance, can be found in the ATK-SE section of the *ATK Reference Manual*.

Tip: For more basic properties of InAs slabs, see this tutorial: *Meta-GGA and 2D confined InAs*

Setting up the device geometry

Creating a passivated InAs slab

Start QuantumATK and launch the **Builder** by pressing the icon on the toolbar.

•In the builder, click *Add* → *From Database*.

•Type InAs in the search field and double-click on the row with InAs.

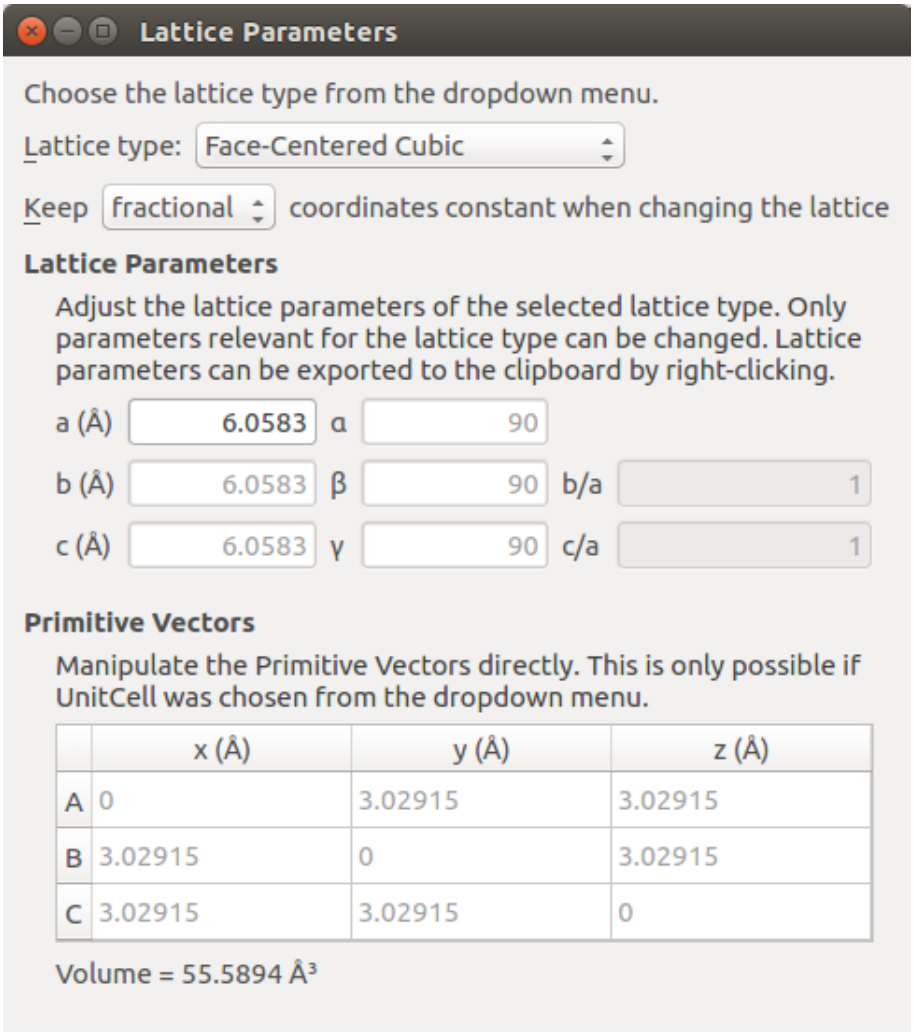
•Click the icon in the lower right-hand corner of the **Database** window to add the structure to the **Stash** in the **Builder**.

The next step is to change the lattice constant to the experimental room temperature lattice constant, a = 6.0583 Å[1].

•In the panel to the right open *Bulk tools* → *Lattice Parameters*.

•Set *Keep fractional coordinates*.

•Set a = 6.0583 Å.



[1] New Semiconductor Materials - Characteristics and Properties. InAs. http://www.ioffe.rssi.ru/SVA/NSM/Semicond/InAs/index.html. Accessed: 2017-05-31.

We now have a bulk configuration with the correct lattice parameter, and the next step is to create a slab with the right orientation. Open *Builders* → *Surface (Cleave)* to cleave the crystal. In this case, along the (100) direction.

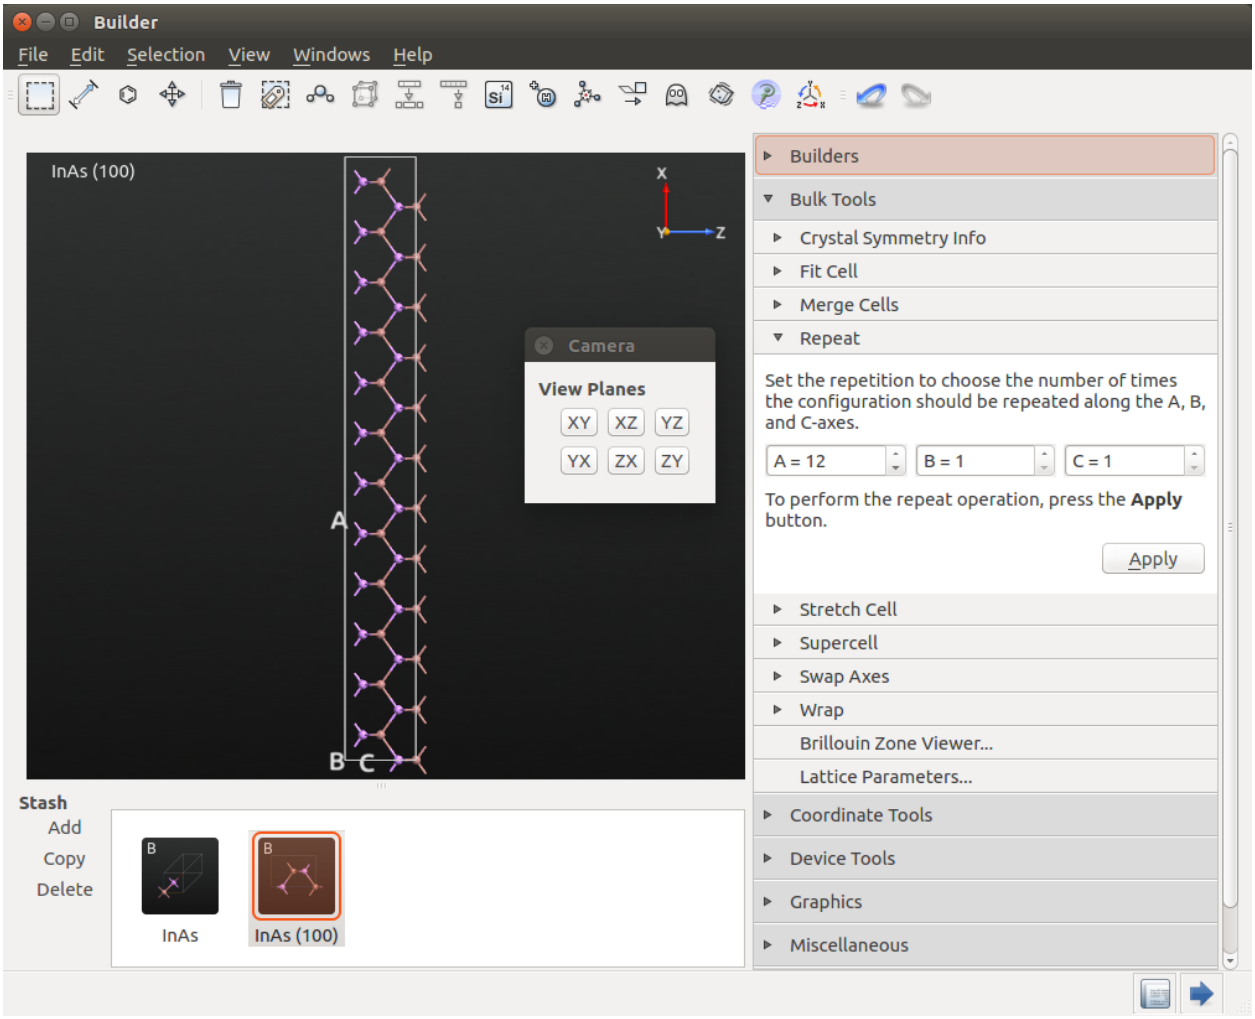
•Keep the default (100) cleave direction, and press *Next* >.

•Keep the default surface lattice, and press *Next* >.

•Keep the default settings on the last page, and press the *Finish* button to add the cleaved structure to the **Stash**.

•Open *Bulk Tools* → *Repeat* and enter A = 12, B = 1, and C = 1, and press *Apply*.

To get a good look at the structure, click on the viewplane icon and choose *ZX*. You should now see the following:



At this point you should register the volume of this InAs cell. Open *Bulk Tools* → *Lattice Parameters*. The volume is printed in the **Lattice Parameters** window: 1334.15 Å^3. You will need this value in the next section when we set up the doping of the p-i-n device.

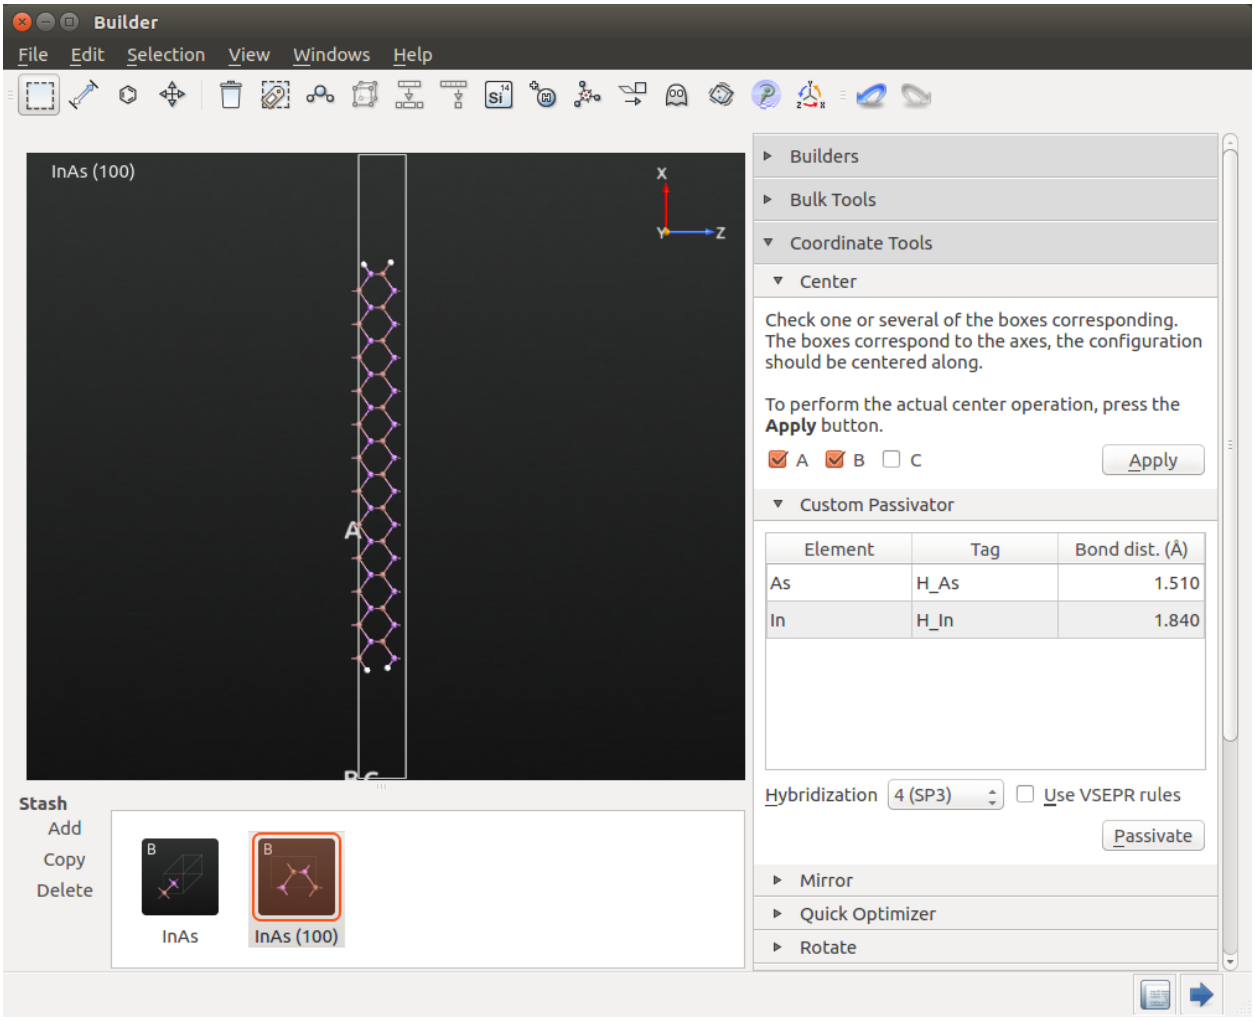
To finalize the setup, perform the following steps:

•Open *Bulk Tools* → *Lattice Parameters*. Select *Keep Cartesian*, and set the length of the *A* vector to 80 Å.

•Open *Coordinate Tools* → *Center* and center the structure in the *A* and *B* directions.

•Open *Coordinate Tools* → *Custom Passivator*. Select Hybridization *4(SP3)*, and passivate the structure.

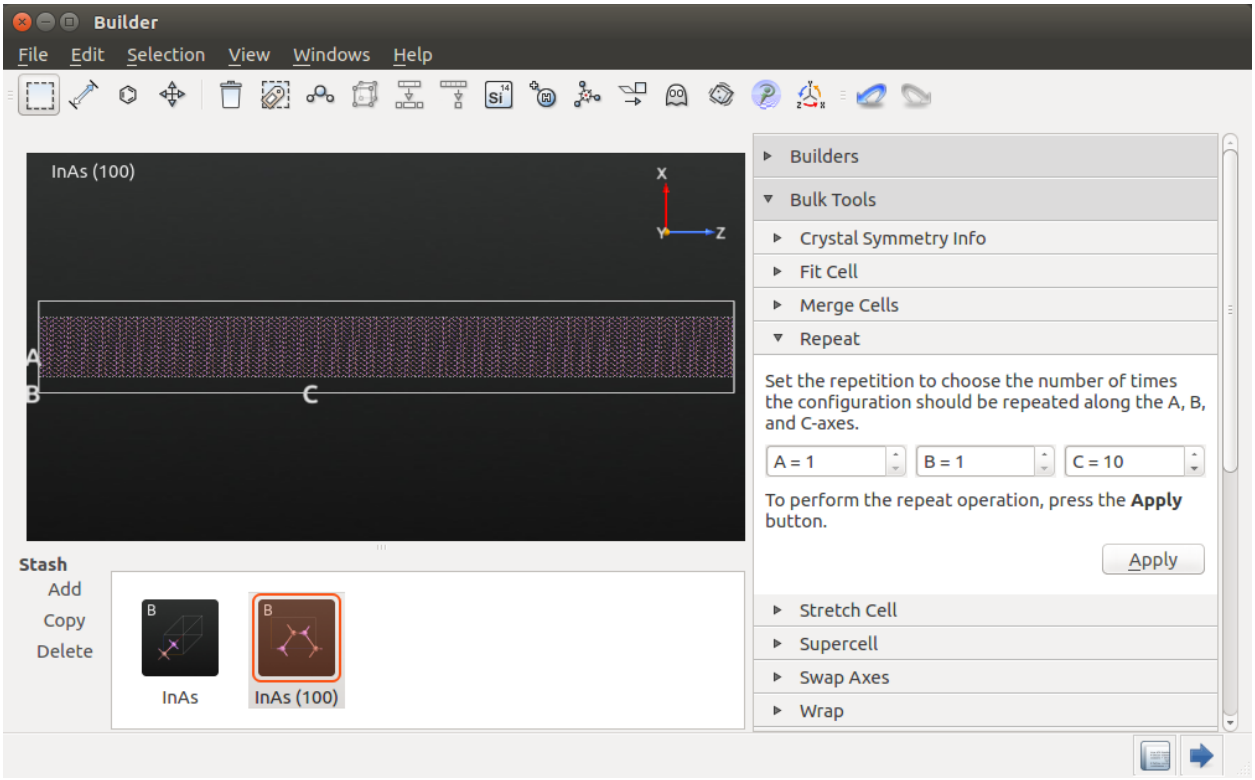
Your structure should now resemble the one shown below.



Warning: In previous versions of QuantumATK (2016 and earlier), we have identified a bug which caused some of the H atoms to miss their tags in some cases. If you use a version where this bug might apply, please check the tags of the H atoms, and manually apply the correct tag to any that are missing. We need these tags later when applying compensation charges and doping.

Creating the FET device geometry from the slab

We will make a 60 nm long device, thus the unit cell must be repeated 100 times along C. Therefore, open the *Bulk Tools* → *Repeat* panel, set A = 1, B = 1 and C = 10, and press *Apply* twice. Your structure should now look like this:



Warning: The repeat panel remembers your settings from last time, so remember to change the value for *A* back to 1. If you forgot this, you can use the undo button .

Adding dielectric regions and gates

The next step is to add 1 nm thick dielectric regions on both sides of the device with a double gate in the center.

•Open *Miscellaneous* → *Spatial Regions*.

•Right-click in the white area of the widget and click *Insert region* to insert a new spatial region. You can also click on the icon below the white area.

•Change the spatial region into a dielectric region and set the dielectric constant to 3.9. Define in fractional coordinates:

–*a*: 0.0375–0.165,

–*b*: 0–1,

–*c*: 0–1.

•Add another dielectric region with dielectric constant 3.9. Define in fractional coordinates:

–*a*: 0.8375–0.9625

–*b*: 0–1

–*c*: 0–1.

•Add a metallic region with value 0.0 Volt. Define in fractional coordinates:

–*a*: 0–0.0375

–*b*: 0–1

–*c* :0.33–0.67.

•Add another metallic region with value 0.0 Volt. Define in fractional coordinates:

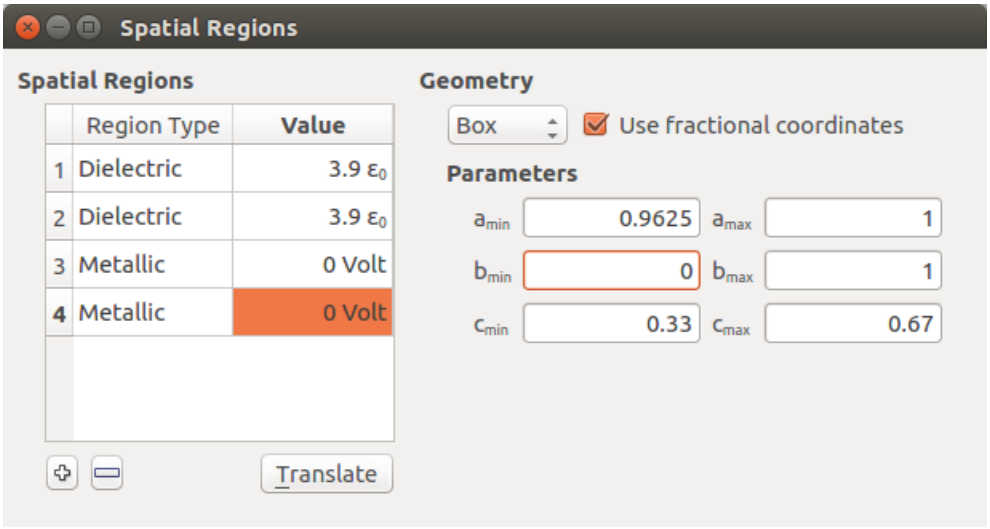
–*a*: 0.9625–1,

–*b*: 0–1

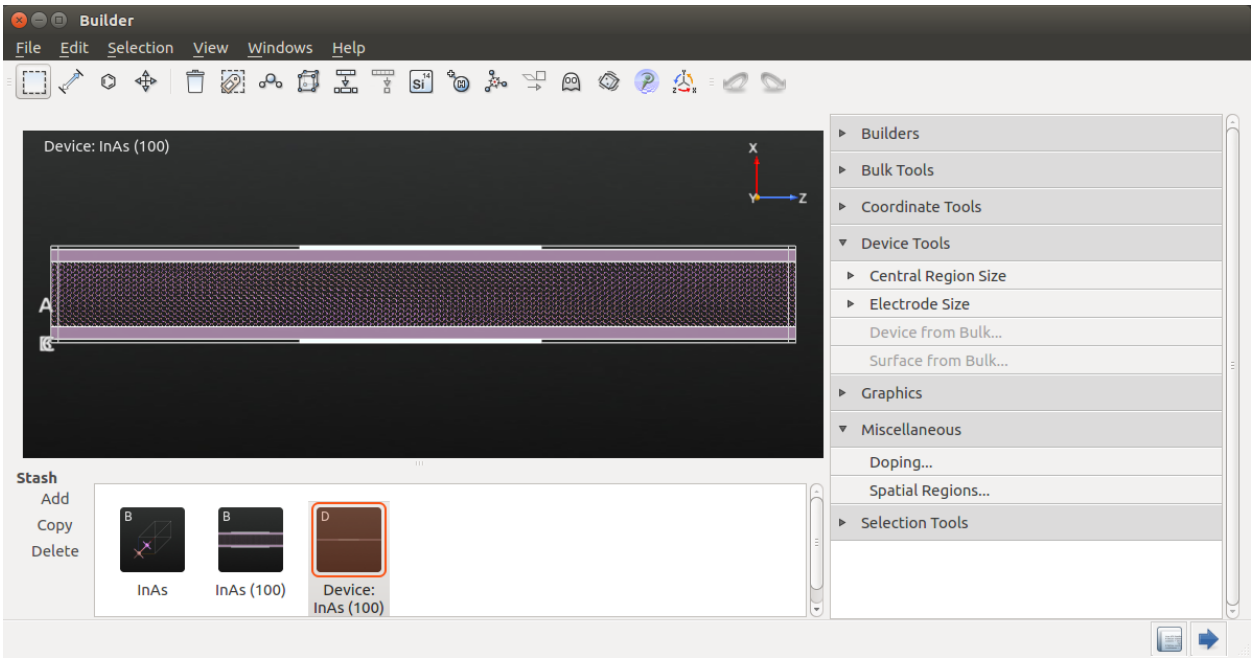
–*c*: 0.33–0.67.

Note: Note that you can switch between fractional and cartesian coordinates, if you prefer a particular representation of coordinates.

At the end, the widget should look like this, and you can close it:



Finally, transform the structure into a device configuration by opening *Device Tools* → *Device From Bulk*. Accept the default suggestion for the electrode lengths of a = 6.0583 Å. The dielectric regions are automatically extended to the electrodes as well.



Warning: In previous versions of QuantumATK (2016 and earlier), this extension was not done automatically. If you use an older version, you can add the dielectric regions to the electrodes in the script, by inserting the contents of this file somewhere after the two electrodes have been defined: `dielectric-regions.py`

Adding doping to the configuration

Finally, we add the doping to the configuration, which includes both regions of In and As atoms, as well the passivating hydrogen atoms. As InAs is a III-V material, the passivating hydrogens should have fractional charges, as explained in this tutorial: *Meta-GGA and 2D confined InAs*.

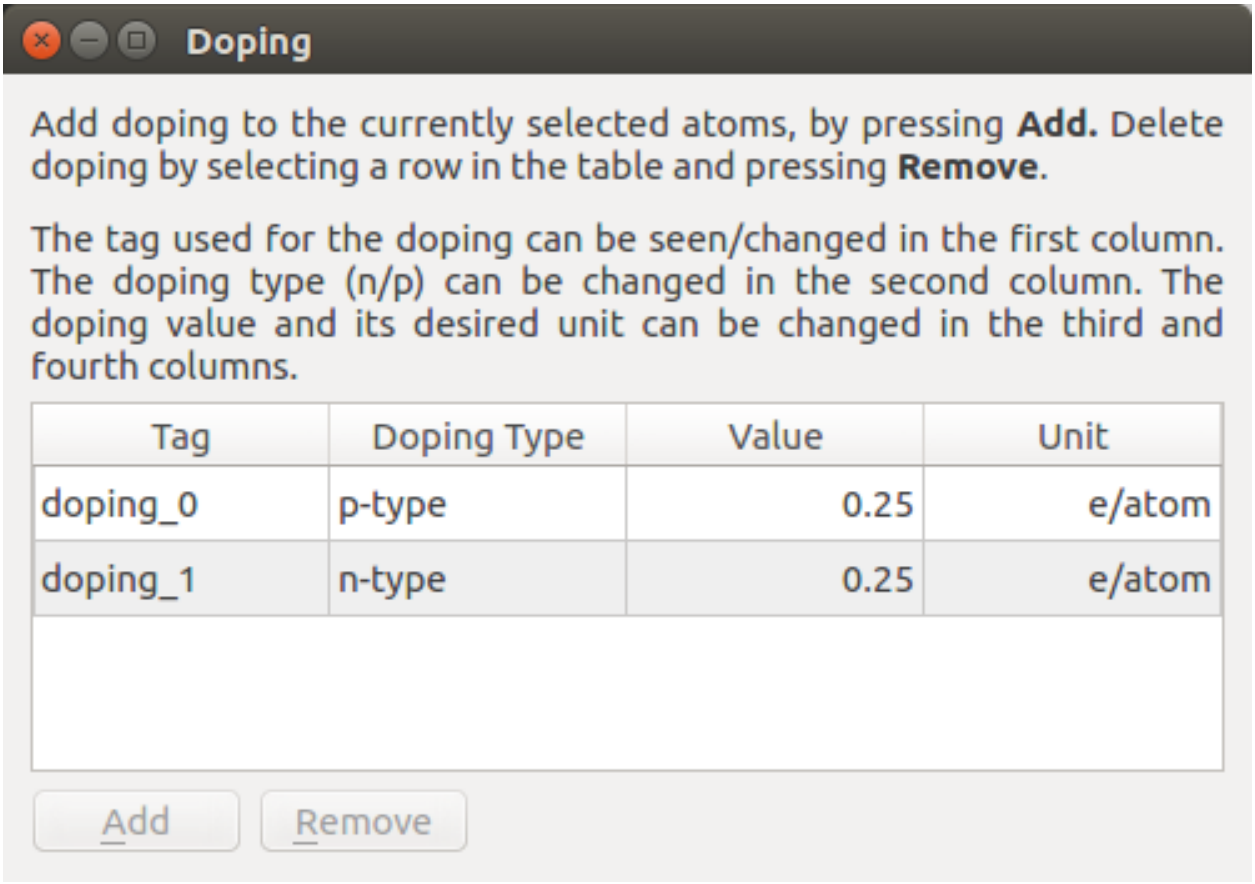
Note: The doping can also be applied via a script. Send the device configuration to the **Editor**, and append the contents of this script at the end: `add-doping.py`. You have now created the device, and are ready to set up the actual calculations.

Adding fractional charges to the H atoms

To add the correct fractional charges to the H atoms, go to the panel on the right, and select *Selection Tools* → *Tags*.

- Click on *H_As*, which will select the H atoms bonded to As atoms.
- Open *Miscellaneous* → *Doping*, click **Add**, change the **Unit** to *e/atom* and the **Doping Type** to *p-type*.
- Double-click on the number under **Value** and type 0.25 to apply a fractional charge of -0.25 electron to these H atoms.

Now, go back to *Selection Tools* → *Tags* and select *H_In*. Repeat the process above, but choose *n-type* to apply a charge of +0.25 electron instead. The doping widget should now look like this:



Tip: When using the doping widget, QuantumATK automatically assigns a tag to each atom, and you can easily edit these tags to make them more meaningful for your application.

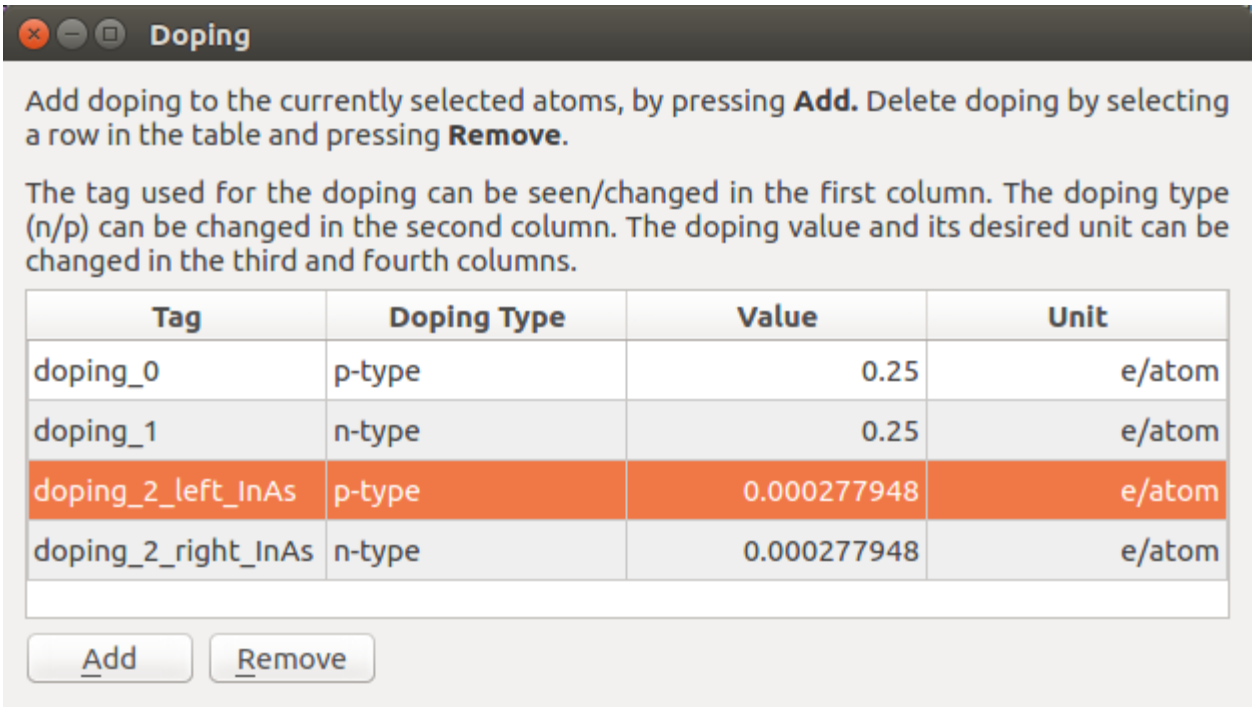
Adding p-type and n-type doping to InAs

Secondly, we dope the InAs with p-type doping at one end and n-type at the other, with an intrinsic region in the middle. Here, we will also use the doping widget, which can handily apply a doping with a specific volume concentration. However, because we already have vacuum in the configuration, we cannot use this feature, as it would be based on a too large volume. We would like a doping concentration of 10^{19} per cm^3, and with the 48 atoms and 1334.15 Å^3 volume of the un-repeated slab, this works out to a doping value of 0.0002779479 e/atom, irrespective of the vacuum.

First, we will apply the p-type doping to the left side of the device. We will use the gate to define the intrinsic region, so zoom in on the left side of the device so that you can still see the whole electrode and the edge of the gate.

Tip: If you hold down the `shift` key and the right mouse button at the same time, you can move the configuration around the window. This is very useful in this case. See also the *Mouse and key operations* section of the *Builder Manual*.

Now select all the In and As atoms to the left of the gate, while not hitting any H atoms. Open the doping widget again, and apply a p-type doping of 0.0002779479 e/atom. Do the same to the right of the gate, but instead selecting n-type here. The doping widget should now look like this:



The device is now finished, and you are ready to begin calculations. You can download the full geometry here: `full-device.py`.

Running the calculations

Send the updated script from the **Editor** to the **Script Generator**.

1. Add a **New Calculator**

- Select the *ATK-SE: Slater-Koster* calculator
- Set the *k-point sampling* to 1, 11, 100 and uncheck the *No SCF iteration* box.
- **Iteration control parameters**: set the number of *history steps* to 10. This will slightly improve the convergence for this system and it will reduce the memory consumption.
- **Device algorithm parameters**: Set the *Self energy* method to *Sparse Recursion* for calculating both equilibrium and non-equilibrium contour integrals.
- **Poisson Solver**: Select the *[Parallel] Conjugate Gradient* method and *Neumann* boundary conditions in the A-direction, where the gates are located.
- **Slater-Koster basis set**: Select the *Bassani.InAsH* basis set.

2. Add an **ElectrostaticDifferencePotential** object.

3. Add a **ProjectedLocalDensityOfStates** object.

- Choose *Device DOS* as the **Method**
- Set the k-point sampling to 1, 15.

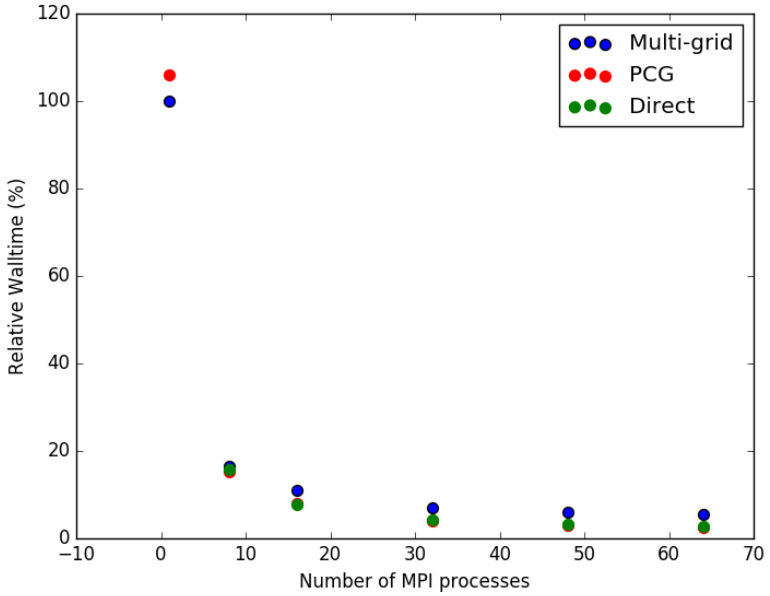
4. Set the output filename to `InAs_5nm_pin.nc`

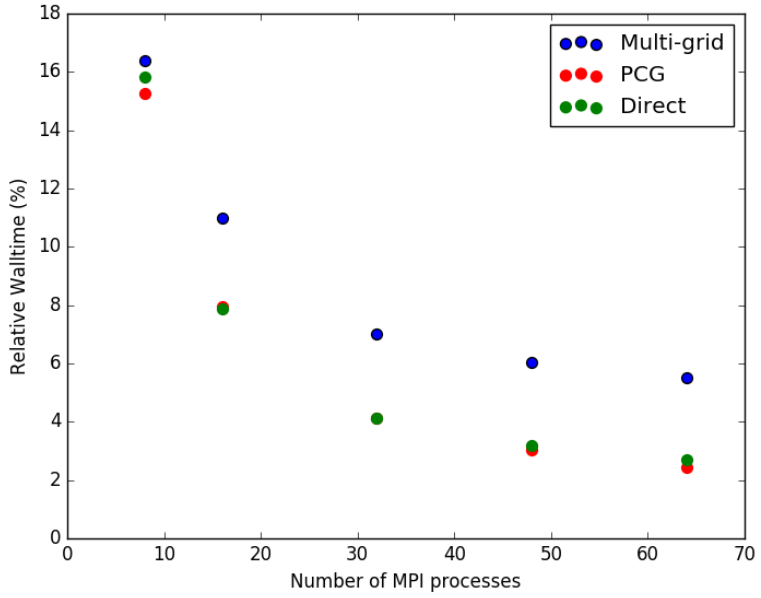
5.Run the script.

You can also download the full script here: `full-script.py`.

Choice of the Poisson Solver

For this system, the choice of Poisson solver is quite important, and is directly related to the number of cores or MPI processes the script will be run on. In this case threading is less efficient than MPI parallelization, so we will not treat it here. See figures below for an overview of the performance for the three methods when running on different numbers of cores. First is the timing relative to the Multi-grid method in serial, and second is the exact same figure, but with the serial data-points omitted. The index number (equivalent to 100 %) is 67,532 seconds, or a little less than 19 hours.





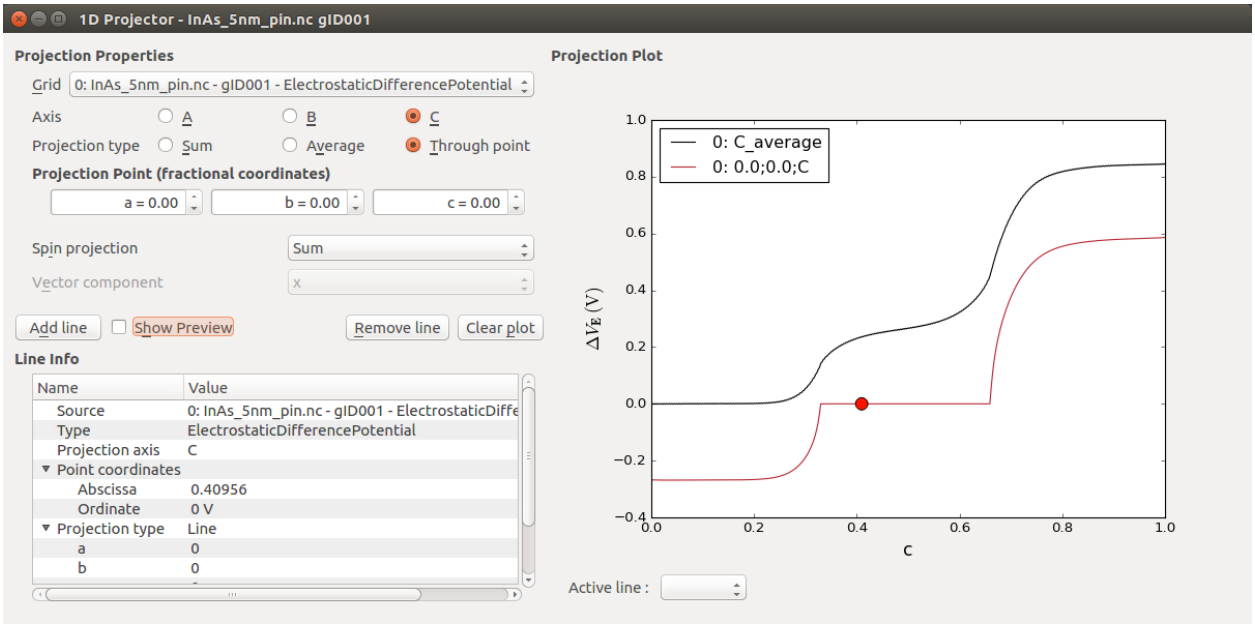
To summarize, one should use the Multi-grid solver if running in serial and either the Parallel Conjugate Gradient or the Direct method if running in parallel. However, the memory footprint of the PCG method is much smaller than for the Direct solver, so in most cases PCG will be preferable of the two.

Analysis of the results

You can now plot the electrostatic potential. From the **LabFloor**, select the *ElectrostaticDifferencePotential* object contained in the file `InAs_5nm_pin.nc`. Afterwards, use the 1D Projector on the right-hand side and plot the average potential along the C axis.

In the calculation, you have used a gate potential of zero volt. Since you use Neumann boundary conditions you have an arbitrary vacuum level. To see the vacuum level of the left or the right electrode, plot the electrostatic potential at the edge. As **projection type** select *through point* and use the *0, 0, 0* fractional coordinates. This will now be added as a red line, in addition to the black line showing the average.

You can inspect the potential at the edge of the cell (edge of the vacuum region), in addition to the average plotted previously. From the plot you can extract the two vacuum levels, left = -0.28 V, right = 0.58 V.



The zero energy reference for this vacuum level is defined by the construction of the basis set. In the next section, you will learn how to align the vacuum level with the Fermi level and the band edges of your device. By doing so you will be able to calculate the work function of your metal gate and finally tune it to match the work function of a gold gate, for example.

Finally, it is worthwhile to plot the electrostatic potential directly on top or your device configuration. Select the *ElectrostaticDifferencePotential* object and click on the **Viewer** (or drag and drop it on top of the Viewer icon:).

Here, you can choose to plot it as an isosurface or as a cut plane. The figure below shows a 3D view of a cut plane along the *CA* plane where you can nicely see the atomic resolution of the electrostatic potential of your 60 nm InAs device.

Tip: If you wish to re-create the figure, you need to do the following:

1. Drop the *ElectrostaticDifferencePotential* object on the Viewer and choose *Cut plane*.
2. Click on *Properties* on the right.

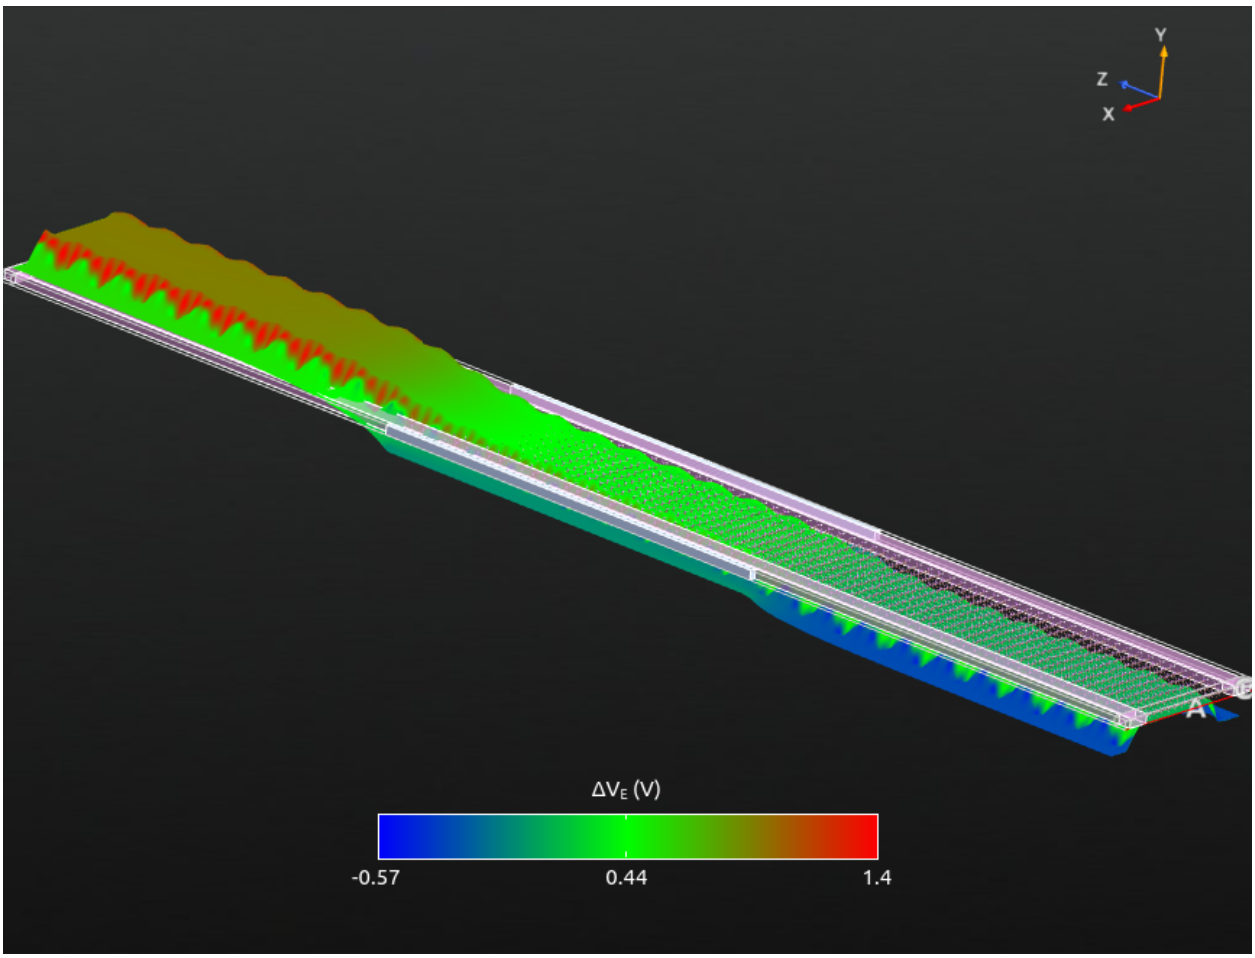


Fig. 3.37: 3D view of the ElectrostaticDifferencePotential across the device.

3.Under **Surface Properties** change the value of *3D* to 0.03.

4.In the bottom left, click the button *AC*.

5.On the lab floor, locate the *DeviceConfiguration* object, and drag it onto the cut plane window.

6.Use the mouse to re-orient the figure to your liking.

Defining the work function of the metal gate

Note: In the following, gate usually refers to the entire gate region, and the gate voltage is thus applied to both metallic regions.

In order to calculate the metal gate work function you will need to align the vacuum levels extracted in the previous chapter with the Fermi level and the band edges of your InAs device. As described in the first section, you need to perform this operation since these levels are not related to each other within the definition of this Slater-Koster basis set.

At zero applied voltage between the left and right electrodes, the Fermi levels will coincide and the band diagram of the whole system corresponds to the one shown in the following figure.

The choice of your zero energy reference is quite arbitrary. In the following, you will consider the Fermi level at zero bias to coincide with the zero energy in the scheme above, $E_F = 0$ eV. In order to set the vacuum levels, and in particular the left electrode vacuum level, you need to know:

1.The positions of the band edges, valence band maximum (VBM) and conduction band minimum (CBM), see the next section: *Band gap and band edges*.

2.The electron affinity (E_{aff}) defined as the energy difference between the CBM and the vacuum level. This can be computed in a manner similar to the metal work function, as described in this tutorial: *Greens function surface calculations*.

As a first approximation you could use the values reported in the literature for InAs which are: 4.55 eV[2] and 0.451 eV at 0 K[Page 595, 1] for the electron affinity and band gap of InAs, respectively. However, the band gap and the electron affinity of your device can be quite different from the bulk value due to finite size effects. Here, you will instead use a calculated value of the electron affinity for a 2d-InAs slab of 5.09 eV, and you will determine the band edges and band gap of your gated device.

Band gap and band edges

You can easily plot the density of states across your device from the *DeviceDensityOfStates*, *LocalDeviceDensityOfStates* or *ProjectedLocalDeviceDensityOfStates* analysis objects available in QuantumATK. Here you will use the *ProjectedLocalDeviceDensityOfStates* tool available from the QuantumATK 2015 release, and which we already calculated previously. Select this object on the LabFloor and click on the *Projected Local Density of States* plugin on the right-hand side to open the corresponding window. In order to highlight the band gap and band edges, the figure above has been created by narrowing the data range for the DDOS values to 0-0.02 1/eV Å^3 (click on the *Data range* button in the upper right corner).

This plot nicely shows the electronic structure across the full length (about 60 nm) of your device. In particular, you can immediately see the band bending due to different doping types in the left and right parts of the device.

From this plot, you can extract the band gap of 0.68 eV by zooming in on the p-doped region, where the position of the VBM is exactly on the Fermi level.

Tuning the work function of the metal gate

You now have all the ingredients to define the electronic structure of your device and align the Fermi levels, vacuum levels and band edges.

From your actual set-up you thus have a metal gate with an intrinsic work function of 5.5 eV. This can be calculated as: $E_G + E_{aff} - E_{vac,left}$. Note that the value for the vacuum level from earlier needs to be multiplied by -*e* before being inserted here. This value may correspond to the work function of Pt, 5.12/5.93 eV as reported in the CRC Handbook[3].

You can now tune the work function of your metal gate by applying a gate voltage to adjust to your experimental conditions. In particular, you can lower or increase the metal gate work function by applying a positive or negative gate bias, respectively.

For example, in case of a gold gate, with a work function of 5.28 eV[Page 608, 3], you will need to apply a +0.21 V gate voltage to have the correct energy reference for a grounded gold left electrode.

In the next chapter you will perform the gate scan at finite bias.

Performing a gate scan

You will now apply a source-drain voltage, V(SD), of -0.5 V and perform a gate scan. To this end use this script: `gatescan.py`, which uses the converged zero bias calculation as a starting point to generate converged calculations at each bias. Again, you can get a good speed up by parallelizing over several MPI processes.

You can now analyze the behavior of the electrostatic difference potential as a function of the gate bias. From the figure below you can see that the effect of applying a positive gate voltage is to shift up the potential at the metal gates.

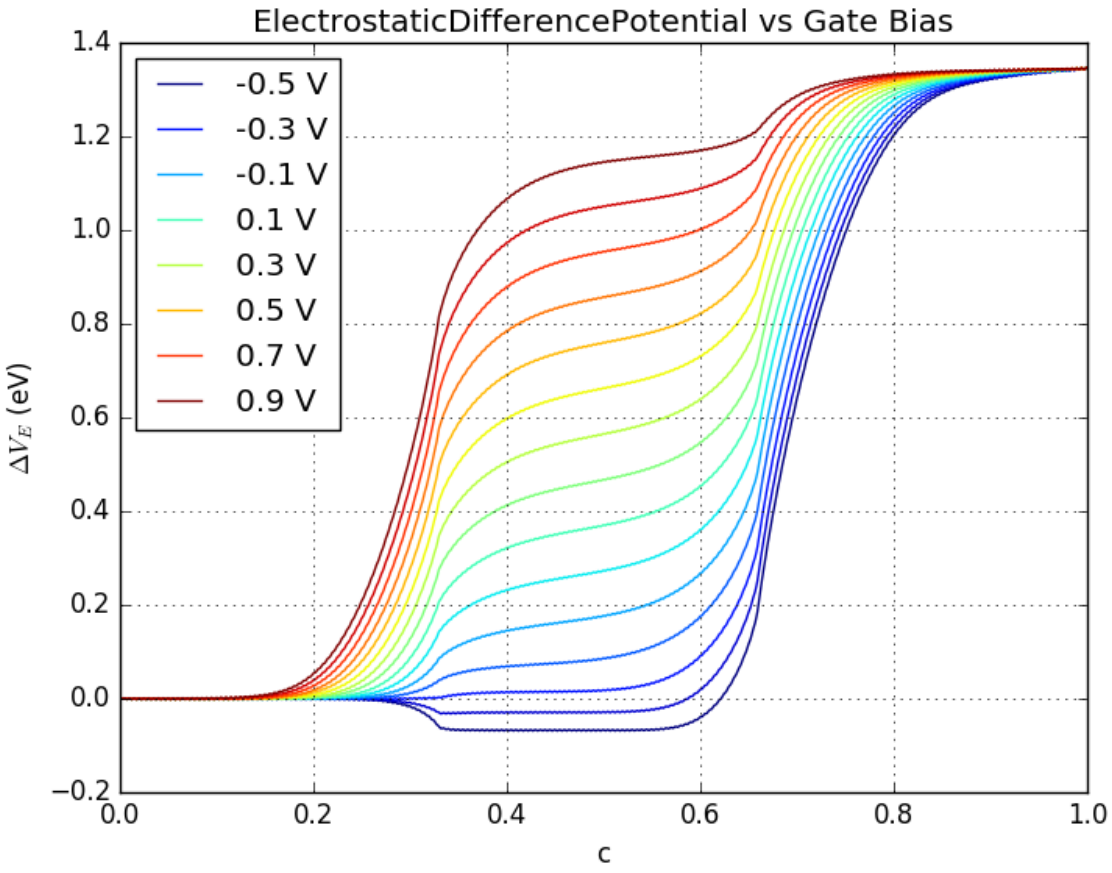

Fig. 3.38: ElectrostaticDifferencePotential vs gate bias between -0.5 and 0.9 V. You can recreate the plot with this script: `plot-gatescan-edps.py`.

You can now calculate the transmission spectra for the converged configurations. This script will calculate the transmission spectrum at each gate voltage: `transmission.py`. This calculation can be performed with high parallelization. We will return to these results after a small detour to look at a system where there is a smaller doped region on the right side, towards the *Drain*.

Simulating a drain underlap

You will now simulate a system where there is a drain underlap, i.e. the atoms 10 nm to the right of the central gate are not doped. In the following figure, this situation is shown, by comparing sketches of the doped areas in both the normal p-i-n case and with a drain underlap.

Fig. 3.39: Structure of the gated InAs p-i-n device and of the same device with a drain underlap of 1 nm. Source (S), drain (D) and gates (G) are indicated.

In the calculation, the drain underlap is created by only adding a compensation charge for the last 860 atoms. You can set up this system in several ways:

- If you are using the script you can set `n_central_right = 860`.
- Using the direct procedure of selection in the Builder is a little harder in this case, because we do not have the gate to use as guideline for the edge of the region. On the other hand, it is not that important to hit exactly in the middle in this case.
- You can also manually modify the tags for the n-doping in the script and delete the first half of the indexes (should be 3484 to 4344).

Also change the output filename to `InAs_5nm_pin_du.nc`. Once the calculation is finished, you can repeat the gatescan with the calculation of the electrostatic difference potential and transmission spectra as explained in the previous section.

Analysis of the results

We can now plot the I-V curve for both the regular p-i-n junction, and the system with a drain underlap, using an applied gate voltage from -0.5 V to 0.9 V. In the figure, the gate voltage is shifted to account for the work function of the metal gate, as explained previously. We also calculate the subthreshold slope, as indicated by the dashed black lines. We get values of 58 mV/dec for the regular device and 43 mV/dec for the device with a drain underlap. You can generate the plot yourself with the following script: `plot-iv-curve.py`

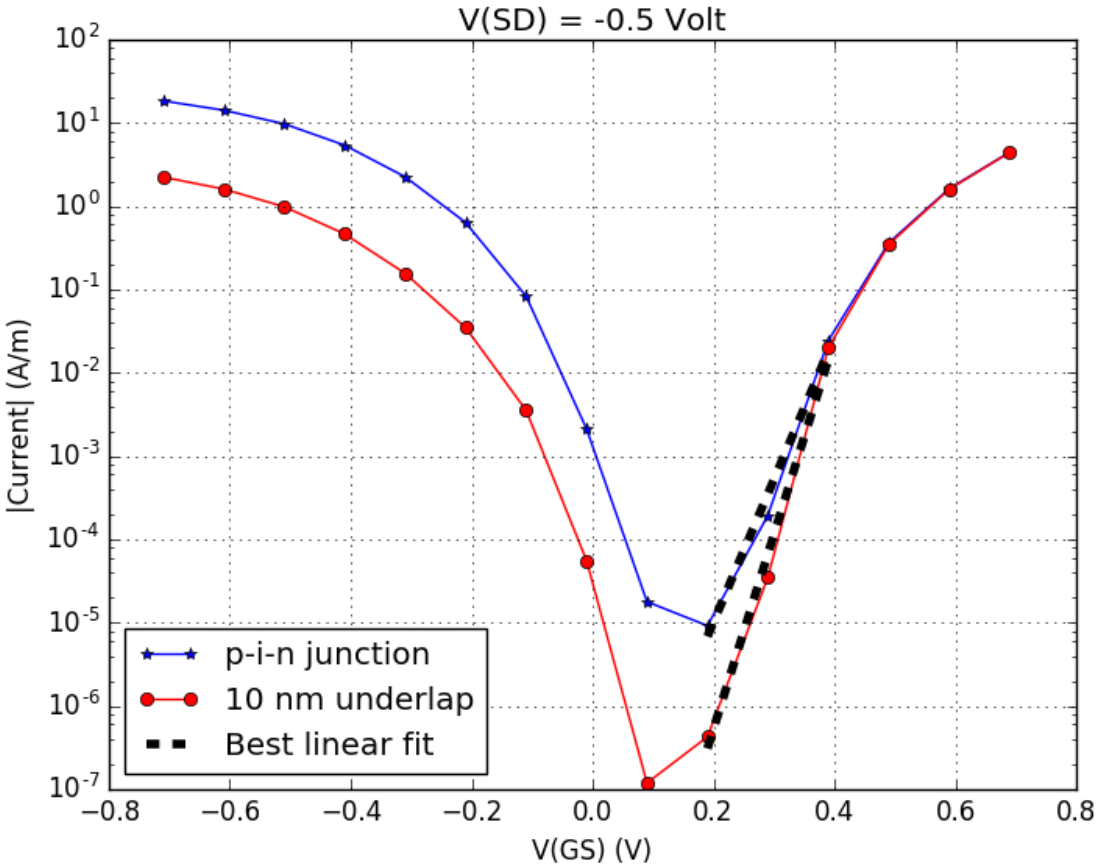

Fig. 3.40: Gate-Source bias, V(GS), dependence of the current for symmetric InAs-2D p-i-n junction. The gate voltage is reported relative to a gold metal gate with a work function equal to 5.28 eV, i.e. V(GS) is shifted by 0.21 V (see the section *Band gap and band edges*.

Finally, you can perform the projected local density of states analysis to any of the configurations saved in `gatescan_conf.nc` or `gatescan_conf_du.nc` as explained in the previous section. In the figure below the PL-DOS of the p-i-n junction and the one with the 10nm drain-underlap region are shown.

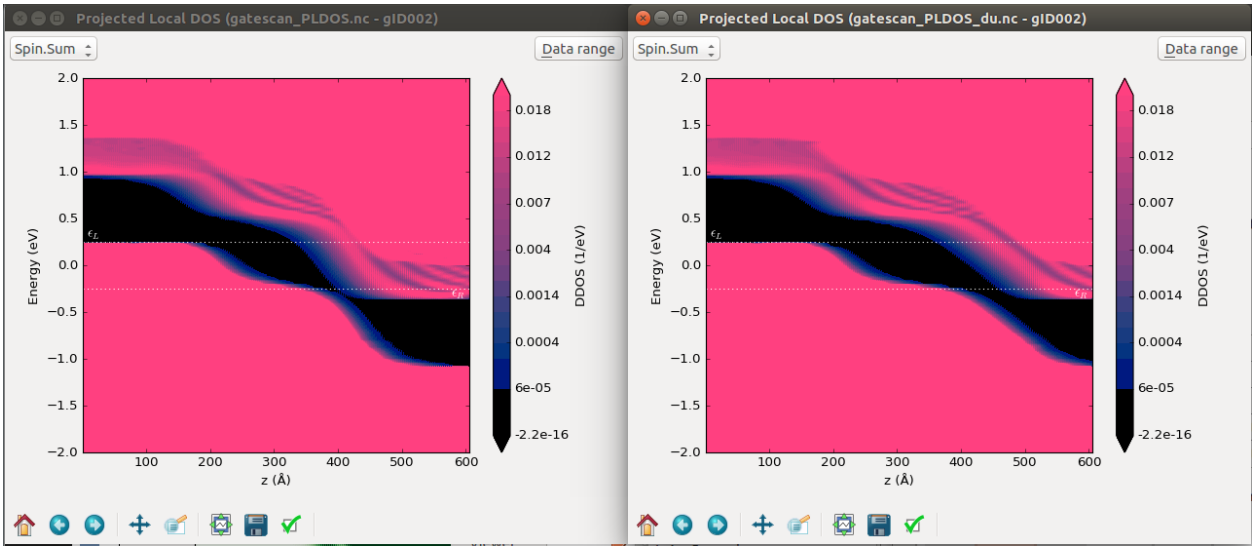

Fig. 3.41: Projected density of states across the 60 nm p-i-n junction device (left) and with 10 nm drain-underlap region (right). A -0.5 V source-drain bias voltage and a 0.4 V gate voltage are applied, respectively. The 0.4 V gate bias corresponds to the points around 0 V(GS) in the previous figure.

References

3.2.11 Inelastic current in a silicon p-n junction

Version: 2017.2

Inelastic scattering effects due to electron-phonon interactions can play a fundamental role in determining the carrier transport through a device. In this tutorial, you will investigate the impact of such effects on the current through a silicon p-n junction in reverse bias. In this system, carrier transport is dominated by band-to-band tunnelling between the valence band of the p region and the conduction band of the n region. This process can be enhanced considerably by inelastic scattering effects.

Specifically, you will use the *InelasticTransmissionSpectrum* module implemented in **ATK** to calculate the transmission spectrum of the device in the presence of electron-phonon interactions. You will also use the **Inelastic Transmission Spectrum Analyzer** plugin in **QuantumATK** to perform a detailed analysis of the current and determine which phonon mode is the main responsible for the current enhancement.

The methodology implemented in QuantumATK is based on the **Lowest Order Expansion (LOE)**[1] and the **eXtended LOE (XLOE)**[2] methods. In this tutorial, you will use the **XLOE** method, which treats the finite energy difference between initial and final states in the transition $\mathbf{k} \rightarrow \mathbf{k} \pm \mathbf{q}$ due to electron-phonon coupling in a more accurate manner. However, the tutorial can be carried out also using the simpler **LOE** method, which will give qualitatively similar results. You can find more details about the theory underlying the two methods in the *Notes* sections of the *InelasticTransmissionSpectrum* module in the **ATK manual**.

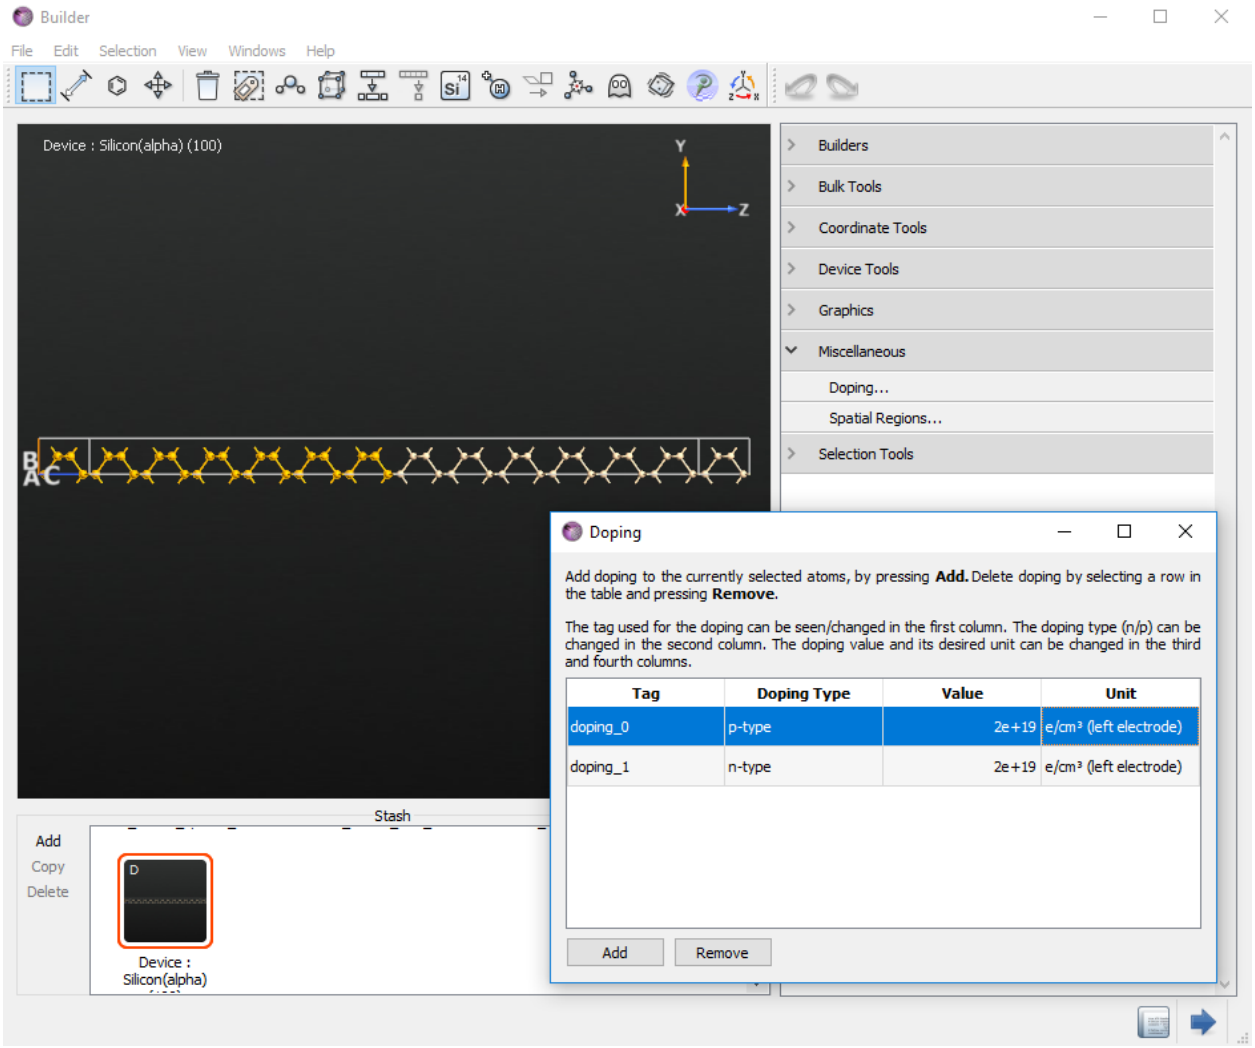
[1] T.ăFrederiksen, M.ăPaulsson, M.ăBrandbyge, and A.-P. Jauho. Inelastic transport theory from first principles: Methodology and application to nanoscale devices. *Phys. Rev. B*, 75:205413, May 2007. doi:10.1103/PhysRevB.75.205413.

[2] J.-T. Lu, R.ăB. Christensen, G.ăFoti, T.ăFrederiksen, T.ăGunst, and M.ăBrandbyge. Efficient calculation of inelastic vibration signals in electron transport: Beyond the wide-band approximation. *Phys. Rev. B*, 89:081405, Feb 2014. doi:10.1103/PhysRevB.89.081405.

Creating the silicon p-n junction

To create the device, you can follow the instruction in the *Create device* section of the *Silicon p-n junction* tutorial. However, in the present tutorial you will create a shorter device to speed up the calculations. In the **Builder**, contruct the device with the following changes:

- When using the **Surface (Cleave)** plugin to create a <100>-oriented structure, set the **thickness** to 24 layers instead of 52 layers;
- When using the **Device from Bulk** plugin, choose 5.4306 Å as the **electrode length**;
- Click the **Doping** plugin in *Miscellaneous* → *Doping* to set the doping of the p and n regions. In this case, select the half of device to set the p doping region and select the remainder part using the `ctrl+i` which will select the inversion part to set the n doping region. In both regions, set a doping of $2 \cdot 10^{19} \mathrm{e/cm^3}$.



You can download the resulting device configuration from here: `Si_pn_junction.py`.

Transmission calculation without electron-phonon interactions

In this section, you will calculate and analyze the electronic structure of the p-n junction at a reverse bias voltage of $V_{\mathrm{bias}} = -0.4$ V, and the associated transmission spectrum without electron-phonon interactions included, using the conventional Landauer formula as implemented in **ATK** in the *TransmissionSpectrum* module.

Setting up the calculation

From the **Builder**, send the structure to the **Script generator** using the button. Add the following blocks and set their parameters as follows:

- *Calculators* → *SemiEmpiricalCalculator*

–In **Main**:

∗Set the **Left electrode voltage** to -0.2 V

∗Set the **Right electrode voltage** to 0.2 V

–In **Hamiltonian**:

∗Untick the *No SCF iteration* option

–In **Numerical Accuracy**, set the **k-point Sampling** to:

∗$\mathrm{k_A} = 7$

∗$\mathrm{k_B} = 7$

∗$\mathrm{k_C} = 101$

–In **Iteration control parameters**, set the **Tolerance** to *4e-05*

- *Analysis* → *ProjectedLocalDensityOfStates*

–Set the **k-point Sampling** to:

∗$\mathrm{k_A} = 21$

∗$\mathrm{k_B} = 21$

- *Analysis* → *TransmissionSpectrum*

–Set the **k-point Sampling** to:

∗$\mathrm{k_A} = 21$

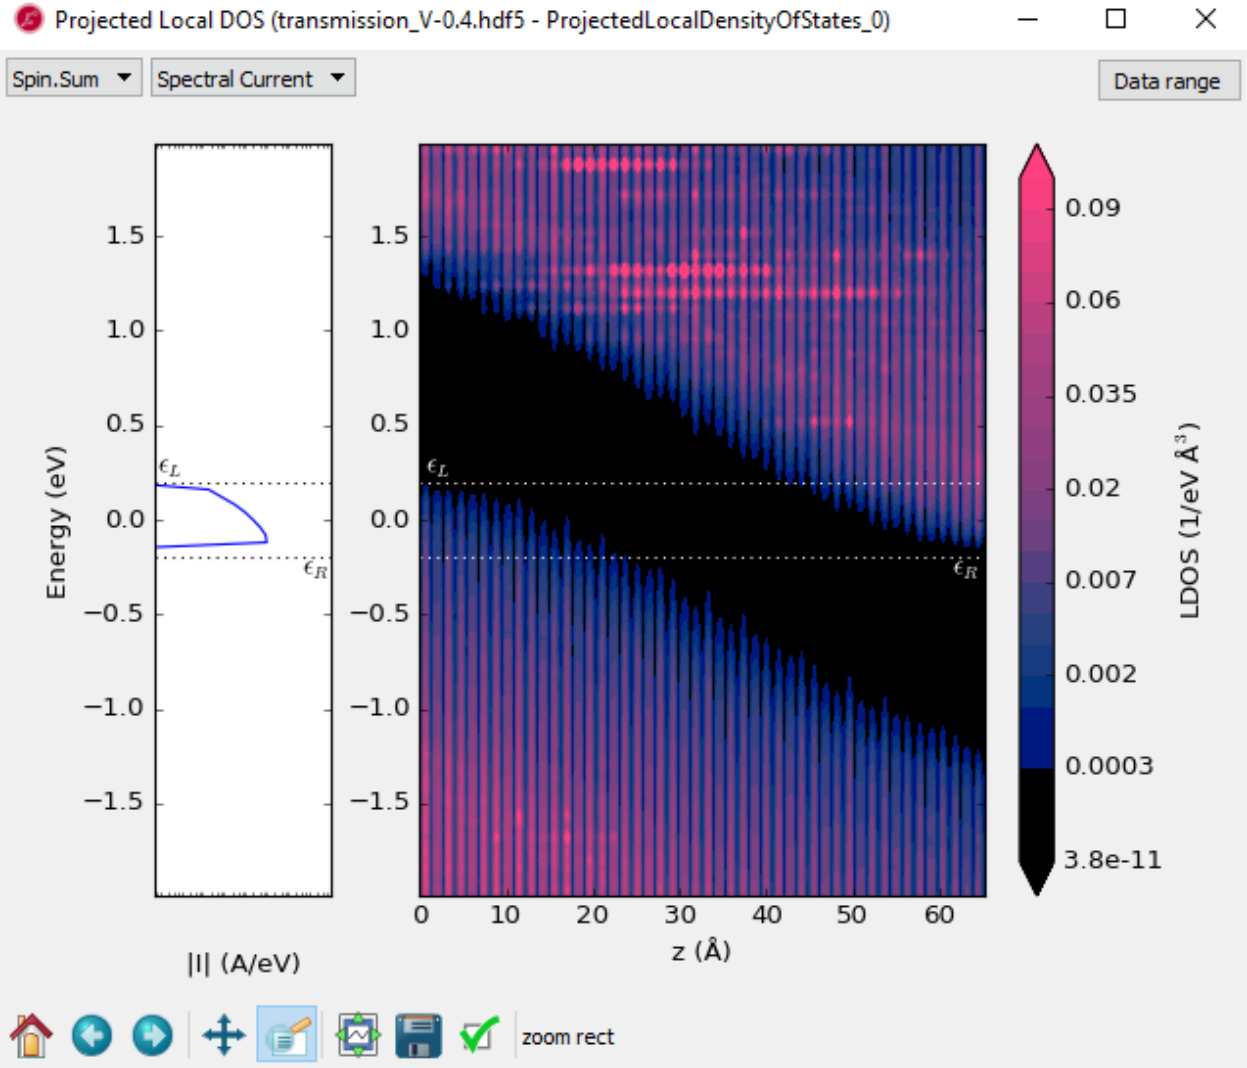
∗$\mathrm{k_B} = 21$

Finally, in the **Global IO** options, change the name of the **Default output file** to `transmission_V-0.4.hdf5`.

Send the script to the **Job manager** using the button, save it as `transmission_V-0.4.py` and press the button to run the calculation. It will take less than 2 minutes on 4 CPUs. You can also download the full script from here: `transmission_V-0.4.py`.

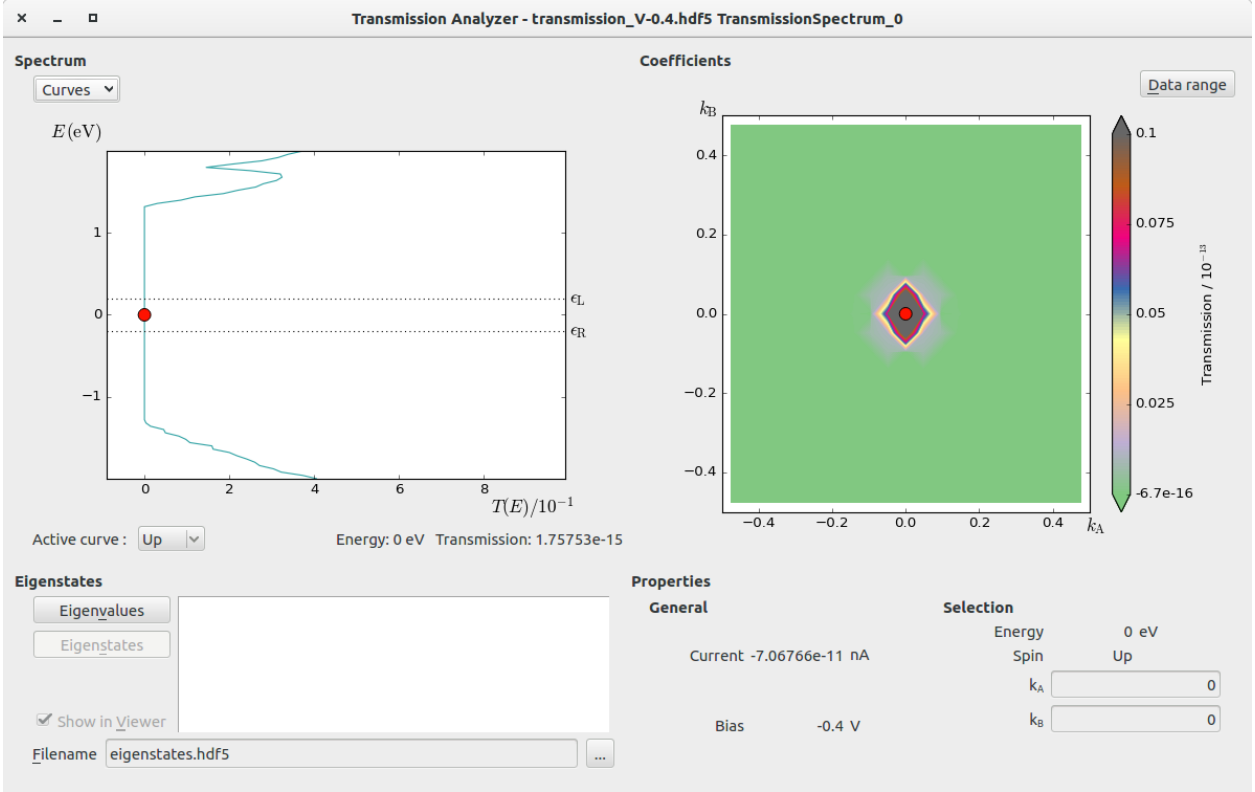
Analysis of the results

In the **LabFloor**, select the $D(\epsilon, z)$ **ProjectedLocalDensityOfStates** object from the file `transmission_V-0.4.hdf5`, and click on the **Projected Local Density of States** plugin. In the plugin window, select *Spectral Current* from the drop-down menu on the top left, and set the maximum value of the **Data range** to 0.1. In the panel on the left-hand side of the screen, use the **Zoom** button to make sure that the minimum value of the current is about $10^{-24}\mathrm{A/eV}$. The features below this value can be associated to numerical noise.



From the left panel of the figure above, it can be seen that the maximum of the spectral current occurs inside the bias window (-0.2 eV $\leq$ Energy ≤ 0.2 eV). Furthermore, from the right panel, which shows the density of states across the device, it can be seen that within the bias window, there are no electronic states in central region ($20 \leq$ z ≤ 45) of the device, so that tunnelling between the left and the right electrodes is the only possible transport mechanism. This indicates that electronic transport in the device in reverse bias is dominated by tunnelling.

To analyze the probability of tunnelling in **k**-space, select the $T(\mathbf{k}, \epsilon)$ **Transmission Spectrum** object from the same file and click on the **Transmission Analyzer** plugin. In the plugin window, set the maximum value of the **Data range** to 0.1.



From the figure above, it can be seen that the tunnelling probability is strongly peaked at the Γ-point of the Brilluoin zone at the Fermi level.

Transmission calculation with electron-phonon interactions

In this section, you will calculate the transmission spectrum of the silicon p-n junction at a reverse bias voltage of $V_{\text{bias}} = -0.4$ V including the effect of the electron-phonon interactions within the **XLOE** approximation[Page 614, 2].

To calculate the *InelasticTransmissionSpectrum*, you first need to calculate the **DynamicalMatrix** and the **HamiltonianDerivatives** of the system.

Setting up the dynamical matrix calculation

In the **LabFloor**, drag and drop the **DeviceConfiguration** object contained in the file `transmission_V-0.4.hdf5` to the **Script generator**. Remove the **DeviceSemiEmpiricalCalculator** and replace it with a **ForceFieldCalculator**

•Select *StillingerWeber_Si_1985* from the list of available classical potentials in the **Parameter set** list.

Add the following blocks and set their parameters as follows:

• *Study Objects → DynamicalMatrix*

–Set **Repetitions** to *Custom*

–Set the **number of repetitions** to:

$*n_A = 3$

$*n_B = 3$

$*n_C = 1$

–Untick the *Acoustic sum rule* option

–Tick the *Constrain electrodes* option

–Untick the *Equivalent bulk* option

• *Analysis → VibrationalMode*

Finally, in the **Global IO** options, change the name of the **Default output file** to `dynmat.hdf5`.

Send the script to the **Job manager** using the button, save it as `dynmat.py` and press the button to run the calculation. You can also download the full script from here: `dynmat.py`.

Note: Alternatively, you can also use the *special thermal displacement - Landauer method* (STD-Landauer) to include part of the electron-phonon coupling effects in the transmission calculation at a much lower computational cost. *The STD-Landauer case study* treats a system which is similar to that discussed in this tutorial.

Setting up the Hamiltonian derivatives calculation

In the **LabFloor**, drag and drop the **DeviceConfiguration** object contained in the file `transmission_V-0.4.hdf5` to the **Script generator**, and modify the **New Calculator** block as follows:

•In **Hamiltonian** tick the *No SCF iteration* option.

Add an *Study Objects → HamiltonianDerivatives* block and set the parameters as follows:

•Set **Repetitions** to *Custom*

•Set the **number of repetitions** to:

–$n_A = 3$

–$n_B = 3$

– $n_C = 1$

- In **Constraints**, click **Add** and constrain the electrode repetitions with *Fixed* constrains. The resulting list of constrained atoms should be: *0,1,2,3,44,45,46,47*.
- Untick the *Equivalent Bulk* option

In the **Global IO** options, change the name of the **Default output file** to `dHdR_V-0.4.hdf5`.

Send the script to the **Job manager** using the button, save it as `dHdR_V-0.4.py` and press the button to run the calculation. The calculation will take around 20 minutes on 8 CPUs. You can also download the full script from here: `dHdR_V-0.4.py`.

Note: Here, the Hamiltonian derivatives are calculated non self-consistently to speed up the calculations.

Calculating the inelastic transmission spectrum

To calculate the inelastic part of the current, click the **Script generator**, and add the following blocks:

- *Analysis from File*
- *Analysis → InelasticTransmissionSpectrum*

Open the *Analysis from File* block, select the `transmission_V-0.4.hdf5` file and load the *DeviceConfiguration* object contained in the file .

You will notice that two additional blocks have also been added:

- *DynamicalMatrix*
- *HamiltonianDerivaties*

In our case, the dynamical matrix and the Hamiltonian derivatives have already been calculated previously and can be re-used. Delete the two blocks, add two more *Analysis from File* blocks and arrange them as shown in the figure below:

Click on the second *Analysis from File* block from the top. Select the file `dynmat.hdf5` and load the *DynamicalMatrix* object. Uncheck the *DeviceConfiguration* object included in the same file. The panel should look like as in the figure below:

Then, click on the third *Analysis from File* block from the top. Select the file `dHdR_V-0.4.hdf5` and load the *HamiltonianDerivatives* object. The panel should look like as in the figure below:

Finally, set the parameters for the *Analysis → InelasticTransmissionSpectrum* block as shown below:

Analysis of the inelastic transmission spectrum

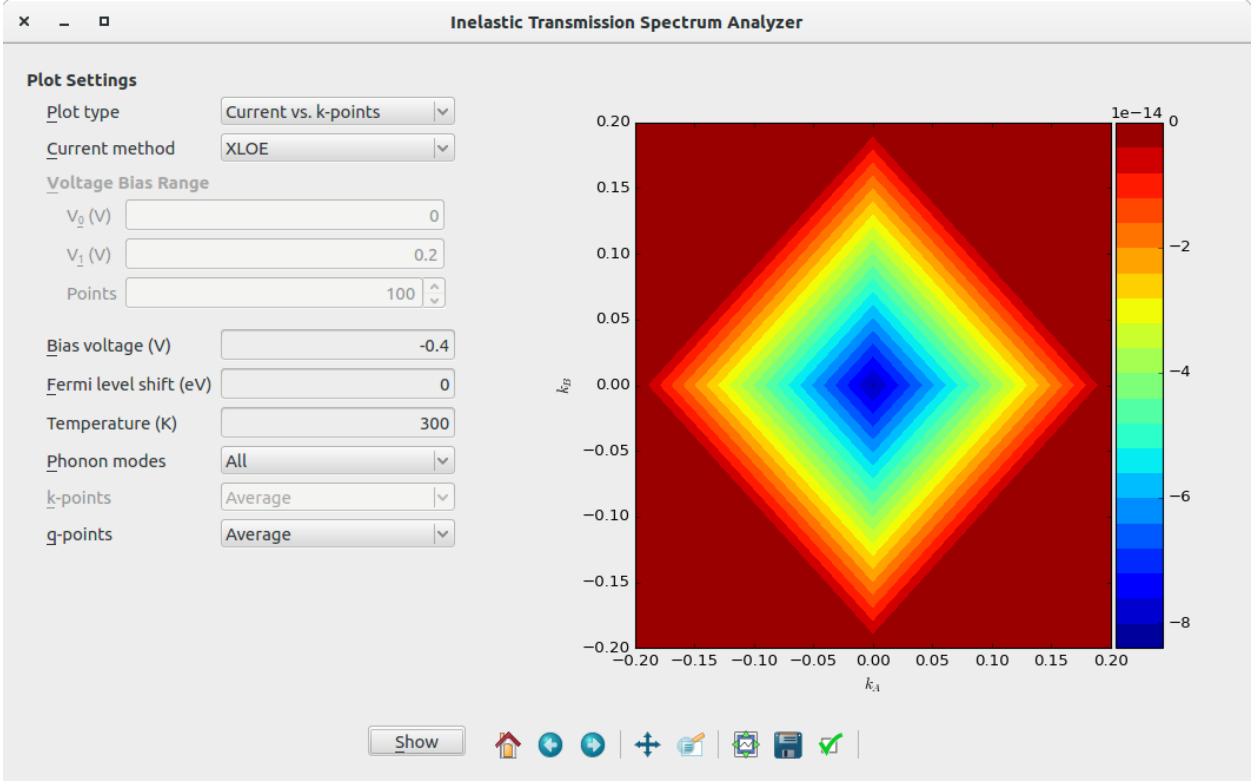
The results of the inelastic transmission spectrum can be analyzed in detail using the **Inelastic Transmission Spectrum Analyzer**.

In the **LabFloor**, select the $T(\mathbf{k},\mathbf{q})$ **InelasticTransmissionSpectrum** object contained in the file `xloe_V-0.4.hdf5`, and click on the **Inelastic Transmission Spectrum Analyzer** plugin in the plugins panel on the right-hand side of the screen.

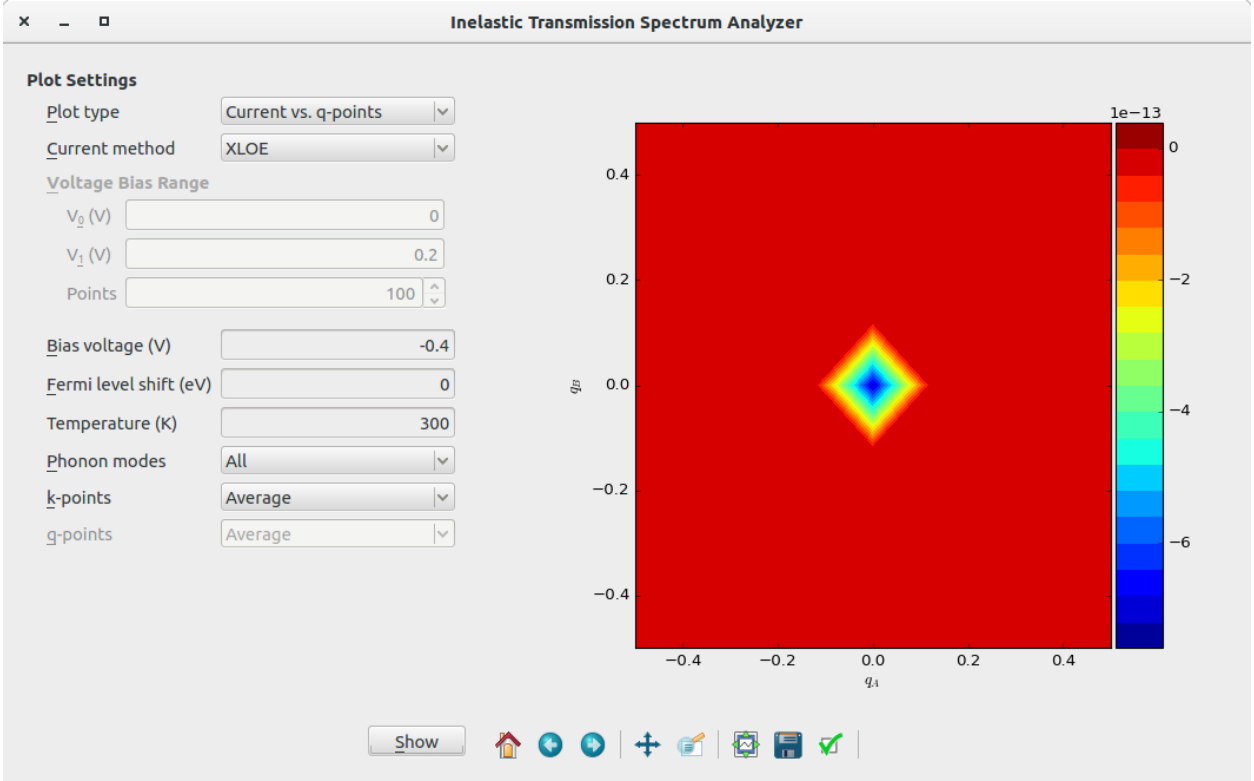
First of all, you will analyze the $\mathbf{k}$- and $\mathbf{q}$-dependency of the current. In the main window of the analyzer, set the following parameters:

- **Plot type** : *Current vs. k-points*
- **Bias voltage** : -0.4 V

You will obtain a figure similar to the one below, showing the $\mathbf{k}$-dependency of the current within the sampled range of k-points. From the figure, it is evident that the main contribution to the current comes from the Γ-point of the two-dimensional Brillouin zone defined by k_A and k_B, with a non-negligible contribution from finite $\mathbf{k}$-vectors.



Next, change the **Plot type** to *Current vs. q-points*. You will obtain a figure similar to the one below, showing the $\mathbf{q}$-dependency of the current. From the figure, it is evident that also in this case the main contribution to the current comes from the Γ-point of the two-dimensional Brillouin zone defined by q_A and q_B, , with a non-negligible contribution from finite $\mathbf{q}$-vectors.



The two figures above indicate that the current is mainly associated with transitions occurring at the Γ-point of the two-dimensional Brillouin zone, both in **k**-space and in **q**-space. To analyze which of the phonon modes at the Γ-point is the one that contributes the most, set the following parameters in the main window of the analyzer:

- **Plot type** : *Current vs. phonon mode*
- **k-points** : *(0.00, 0.00)*
- **q-points** : *(0.00, 0.00)*

From the figure, it can be seen that the phonon that contributes the most to the current is that with index 66, and energy $\hbar\omega = 63.01$ meV.

This phonon mode can be visualized by selecting the **VibrationalMode** object in the file `dynmat.hdf5` calculated in Section *Setting up the dynamical matrix calculation* and using the **Vibration Visualizer** plugin:

Note: In the figures presented above, the values of the current are negative, because the simulations are performed in reverse bias conditions.

Calculation of the current with and without electron-phonon interactions

In order to calculate the current without and with electron-phonon interactions, download the script `current.py` and run it from the terminal as:

`atkpython current.py transmission_V-0.4.hdf5 xloe_V-0.4.hdf5`.

Note: On windows, it is not convenient to run `current.py` script from the terminal. In this script, you can replace filename1 and filename2 to the `transmission_V-0.4.hdf5` and `xloe-V-0.4.hdf5`. In order to run it, drag it on the **Job manager**.

The script will calculate the elastic (I_{el}) and inelastic (I_{inel}) components of the current. The total current without and with electron-phonon interactions will then be calculated as:

$$I(\mathrm{w/o\ interactions}) = I_{\mathrm{el}}$$
$$I(\mathrm{w\ interactions}) = I_{\mathrm{el}} + I_{\mathrm{inel}}$$

The output of the calculation will show the name of the files used as input, as well as the values of the calculated currents (highlighted in yellow):

Total                   :      51.58 s
```

Note: The above calculated currents are different with the *currents* before analysis of the InelasticTransmissionSpectrum because of different k-points samplings. Also in this case, the value of the current is negative, because the simulations are performed in reverse bias conditions.

It can be seen that electron-phonon scattering leads to an increase in the reverse bias current of about three orders of magnitude!

Speeding up the calculations

ATK implements several methods which can be used to speed up the calculations considerably and enable the calculation of the inelastic transmission for devices comprised of thousands of atoms. These methods are:

- *The Phonon energy intervals method*
- The possibility of *using the bulk dynamical matrix and Hamiltonian derivatives*

For a more detailed description of these methods, see the section *Large Device Calculations* of the *InelasticTransmissionSpectrum* module in the **ATK manual**.

The Phonon energy intervals method

This method allows us to group $3N$ phonon modes of a device with N vibrating atoms into M energy intervals to form M new effective phonon modes, with $M << 3N$. The inelastic transmission spectrum will therefore be calculated only for these M effective phonon modes, greatly reducing the computational cost of the calculation.

In the **LabFloor**, drag and drop the **DeviceConfiguration** object contained in the file `transmission_V-0.4.hdf5` to the **Script generator**. Setup the calculation of the inelastic transmission spectrum as in the *Calculating the inelastic transmission spectrum* Section, but in this case set the **Phonon Method** in the **Phonons** part to *Phonon energy intervals*.

Note: The default parameters of the *Phonon energy intervals* are fine for the present calculation, but in general one should ensure that the energy range $[E_0 : E_1]$ spans that of the phonon modes of the calculated dynamical matrix.

In the **Global IO** options, change the name of the **Default output file** to `xloe_pheint_V-0.4.hdf5`.

Send the script to the **Job manager** using the button, save it as `xloe_pheint_V-0.4.py` and press the button to run the calculation. The calculation will take only 20 minutes on 24 CPUs. You can also download the full script from here: `xloe_pheint_V-0.4.py`.

Once the calculation is finished, run the script `current.py` as:

`atkpython current.py transmission_V-0.4.hdf5 xloe_pheint_V-0.4.hdf5`.

If you are a Windows user, see *how to run the script*.

The resulting output will be:

```
+-------------------------------------------------------------------------------+
|                                                                               |

```

One can see that the calculated values for the current are essentially the same as those calculated in the Section *Calculation of the current with and without electron-phonon interactions*, despite the fact that the present calculations are much faster.

Using the bulk dynamical matrix and Hamiltonian derivatives

Another option to speed up the calculations is to use the dynamical matrix and Hamiltonian derivatives of the bulk electrodes, instead of those of the device. However, this is possible only for devices with a structure which is translationally invariant along the C-direction, apart from doping, electrostatic regions and applied bias voltage.

The scripts needed to calculate the dynamical matrix and the Hamiltonian derivatives of the bulk electrodes can be downloaded from here: `dynmat_bulk.py`, `dHdR_bulk.py`. Running the two calculations on 4 CPUs will take less than 2 minutes.

In order to calculate the current inelastic transmission spectrum using the bulk dynamical matrix and Hamiltonian derivatives, repeat the steps followed in Section *Calculating the inelastic transmission spectrum*, with the changes described in the following.

First, click the **Script generator**, add the following blocks, and modify their parameters as follows:

- *Analysis from File*

–Load the *DeviceConfiguration* object from the `tranmission_V-0.4.hdf5` file.

- *Analysis → InelasticTransmissionSpectrum*

–Set parameters as described in the *Inelastic transmission spectrum* section.

Remove the *DynamicalMatrix* and *HamiltonianDerivatives* blocks, add two more *Analysis from File* blocks right after the *Analysis from File* already present, and set their properties as follows:

•Click on the second *Analysis from File* block from the top, select the `dynamic_bulk.hdf5` file and load the *DynamicalMatrix* object contained in the file.

•Click on the second *Analysis from File* block from the top, select the `dHdR_bulk.hdf5` file and load the *HamiltonianDerivatives* object contained in the file.

In the **Global IO** options, set the name of the **Default output file** to `xloe_V-0.4_bulk.hdf5`. In this case, you need to modify the **Inelastic Transmission Spectrum** block in the **Editor** as follows:

```
inelastic_transmission_spectrum = InelasticTransmissionSpectrum(
    configuration=device_configuration,
    bulk_dynamical_matrix=dynamical_matrix,
    bulk_hamiltonian_derivatives=hamiltonian_derivatives,
    energies=numpy.linspace(-0.5, 0.5, 25)*eV,
    kpoints=kpoints,
    qpoints=qpoints,
    self_energy_calculator=RecursionSelfEnergy(),
    energy_zero_parameter=AverageFermiLevel,
    infinitesimal=1e-06*eV,
    phonon_modes=All,
    method=XLOE,
    spectral_representation=True,
    electrode_extensions=[0, 0],
```

Send the script to the **Job manager** using the button, save it as `xloe_V-0.4_bulk.py` and press the button to run the calculation. Also in this case, the calculation will take only 20 minutes on 24 CPUs. You can also download the full script from here: `xloe_V-0.4_bulk.py`.

Once the calculation is finished, run the script `current.py` as:

`atkpython current.py transmission_V-0.4.hdf5 xloe_V-0.4_bulk.hdf5`.

If you use Windows, look at the *how to run the script*.

The resulting output will be:

```
+------------------------------------------------------------------------------+
|                                                                              |
| QuantumATK 2017.2 [Build 997d195]                                  |
|                                                                              |
+------------------------------------------------------------------------------+
------------------------------------------------------------------------------
 TransmissionSpectrum read from file :
 transmission_V-0.4.hdf5
 InelasticTransmissionSpectrum read from file :
 xloe_V-0.4_bulk.hdf5
------------------------------------------------------------------------------
 Current (w/o interactions)    = -3.71e-09 nA
 Current (w interactions)      = -6.42e-06 nA
------------------------------------------------------------------------------

Timing:                          Total     Per Step        %

------------------------------------------------------------------------------

Loading Modules + MPI   :       1.33 s       1.33 s       2.17% |==========|
------------------------------------------------------------------------------
Total                   :      61.15 s (1m01.15s)
```

It can be seen that the calculated values for the current is similar to that calculated using the dynamical matrix and Hamiltonian derivatives of the device configuration, although there are differences due to the fact that in the present case, the loss translational invariance of the Hamiltonian derivatives due to the applied bias is not taken into account.

3.2.12 Elastic scattering, mean free path, mobility: Impurity scattering in a silicon nanowire

Version: 2017.0

Downloads & Links

`sinw_pristine_trans.hdf5` `sinw_P_dopant_trans_1234.hdf5` `T_and_mfp.py` `doped-bandstructures.zip` `mobility.py`

In this tutorial you will study elastic scattering by dopant atoms in a silicon nanowire. Based on calculated transmission spectra you will learn how to estimate the scattering mean free path and mobility, taking into account both the effect of doping and the explicit scattering due to the dopant atoms.

Introduction

In this tutorial you will learn how the transmission spectra can be used to estimate the elastic scattering mean free path and the doping dependent mobility.

The main focus of the tutorial is not on the actual calculations of the transmission spectra, but rather on the subsequent analysis. As some of the calculations are rather time-consuming, data-files with the results are provided as downloads, so you can focus on the analysis.

The methods used in the tutorial are based on Ref.[1], where it was shown that the transmission function of a very long silicon nanowires with several structural defects can be accurately reproduced using a statistical average of the transmissions calculated for relatively small nanowires with a single defect.

Theoretical background

At low temperatures, the conductance of a system can be approximated as $G = G_0 \cdot T(E_F)$, where $G_0 = 2e^2/h$ is the conductance quantum and $T(E_F)$ is the transmission at the Fermi energy. The resistance of the system is $R = 1/G$.

These considerations can be generalized to define an energy dependent and unitless resistance $R(E) = 1/T(E)$, which is just the inverse of the transmission. To get a physical resistance, $R(E)$ should be multiplied with $1/G_0$.

For a one-dimensional system without any defects (pristine), the transmission always takes integer values, $T_0(E) = N(E)$. We shall denote the corresponding resistance $R_c(E) = 1/T_0(E)$ as the contact resistance. If a structural defect (labeled as *1* in the following) is introduced to the system, the transmission will always be lower than the transmission of the pristine system, $T_1(E) < T_0(E)$. We will now write the resistance of the system with the defect as a sum of two contributions:

$$\frac{1}{T_1(E)} = R_1(E) = R_c(E) + R_{1,s}(E),$$

[1] T.ăMarkussen, R.ăRurali, A.-P. Jauho, and M.ăBrandbyge. Scaling Theory Put into Practice: First-Principles Modeling of Transport in Doped Silicon Nanowires. *Phys. Rev. Lett.*, 99:076803, Aug 2007. doi:10.1103/PhysRevLett.99.076803.

which defines the scattering resistance $R_{1,s}(E)$ of defect *1*. If multiple different defects are present – this could be dopant atoms in different positions – we can calculate an average transmission $\langle T(E)\rangle$. Using the same notation as in the equation above, we will define an average scattering resistance, $\langle R_s(E)\rangle$, as:

$$\frac{1}{\langle T(E)\rangle} = \langle R(E)\rangle = R_c(E) + \langle R_s(E)\rangle,$$
$$\langle R_s(E)\rangle = \langle R(E)\rangle - R_c(E) = \frac{1}{\langle T(E)\rangle} - \frac{1}{T_0(E)}$$

It was shown in Ref.[Page 632, 1] that the length- and energy-dependent resistance through a long wire of length L containing many, randomly placed defects with an average defect–defect distance d, can be well approximated as:

$$R(L,E) = R_c(E) + \langle R_s(E)\rangle \frac{L}{d},$$

which may be written as

$$R(L,E) = R_c(E)\left(1 + \frac{L}{L_{\mathrm{mfp}}(E)}\right),$$

which defines the energy-dependent scattering mean free path as

$$L_{\mathrm{mfp}}(E) = d\frac{R_c(E)}{\langle R_s(E)\rangle}.$$

Note: Note that we have now introduced the total length of the wire L, which in this formalism is an arbitrary parameter.

The corresponding transmission through the long wire is $T(L,E) = 1/R(L,E)$. This means that the conductance of a wire with length L can be estimated as

$$G(L,E_F) = \int_{-\infty}^{\infty} T(E,L)\frac{-\partial f(E,E_F)}{\partial E}dE,$$

which generalizes the previous relation $G = G_0T(E_F)$ to finite temperatures. The function $f(E,E_F)$ is the Fermi-Dirac distribution function for electrons in the left and right electrodes with average Fermi level E_F.

The conductivity σ of the system is given by

$$\sigma = G \cdot L,$$

and we can now estimate the mobility μ as

$$\mu = \frac{\sigma}{e \cdot n},$$

where e is the elementary charge and n is the charge density. The Fermi level at a given doping density will be estimated from band structure calculations with compensation charge doping.

Summary of required calculations

In summary, the calculations we need in order to calculate a mean free path are:

- Transmission spectrum, $T_0(E)$, of the pristine (defect free) nanowire.
- A transmission spectrum for each defect – in this case for the same element in four different dopant positions. From these calculations we get the average transmission $\langle T(E)\rangle$.

In order to calculate the mobility at a given doping density, we further need:

- A bandstructure calculation (also using the nanowire unit cell) with compensation charge doping, in order to calculate the Fermi level for the desired doping density.

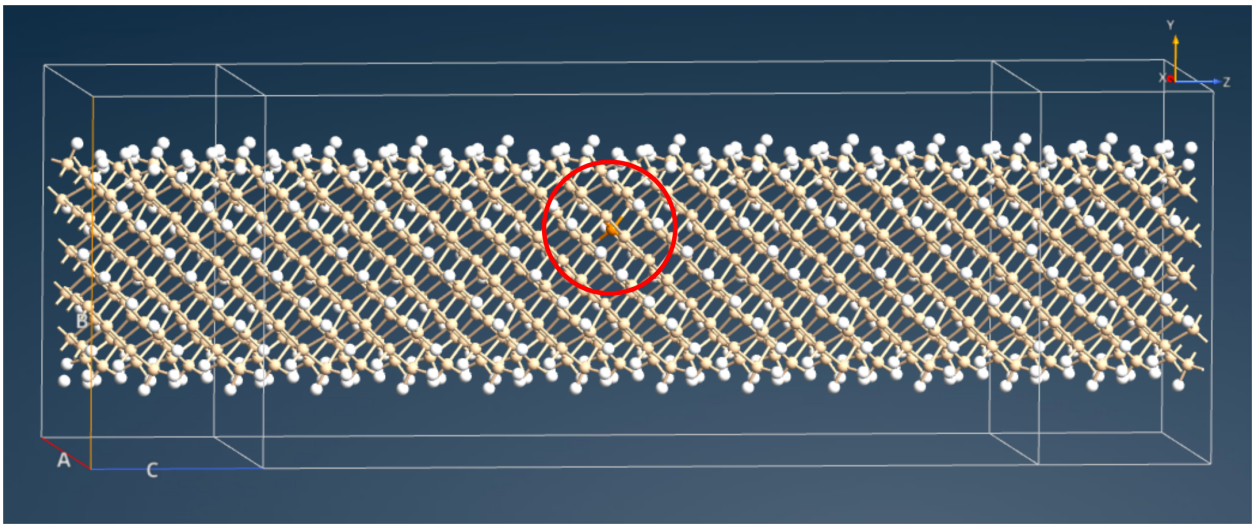
Defected silicon nanowires

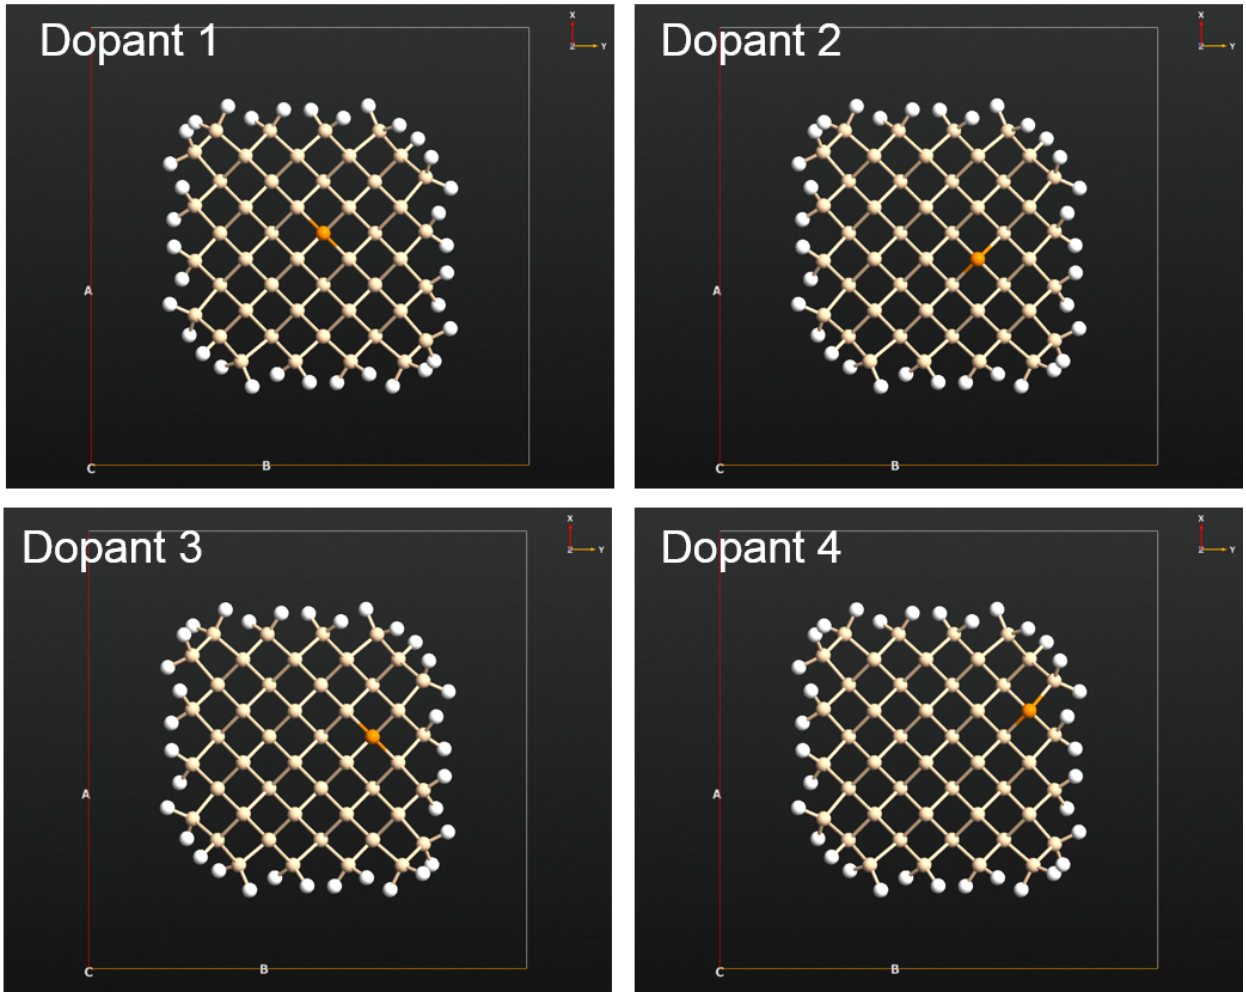
Two different types of nanowires will be considered:

1. The **pristine device** is constructed from pure, defect-free, relaxed silicon, passivated with hydrogen at the surface;
2. The **defected devices** are generated by substituting one Si atom with P (in 4 different positions) and are relaxed as bulk.

More information on how to build the structures can be found at the end of the tutorial, in the *Appendix: Building the nanowires*.

Computational method: The calculations are performed with DFT and NEGF, using a GGA xc-functional and the FHI-SZP basis sets. We use 1x1x51 k-points for the NEGF calculations.





Transmission spectra

The calculated transmission spectra are available via download. They have been calculated using 201 points in an energy range between $E - E_{\mathrm{F}} = 0.5eV$ and $E - E_{\mathrm{F}} = 2.0eV$.

- For the *pristine* nanowire, the transmission is calculated for the infinite bulk. `sinw_pristine_trans.hdf5`
- For the *defected* nanowires, we have used a two-probe device configuration. `sinw_P_dopant_trans_1234.hdf5`

Elastic scattering mean free path

In this section, we will analyze how the presence of an impurity atom impacts the transmission through the nanowire, and we will also estimate the mean free path for the conduction electrons. The script `T_and_mfp.py` calculates and plots the transmission and the mean free path using the theory described in the *theoretical background*.

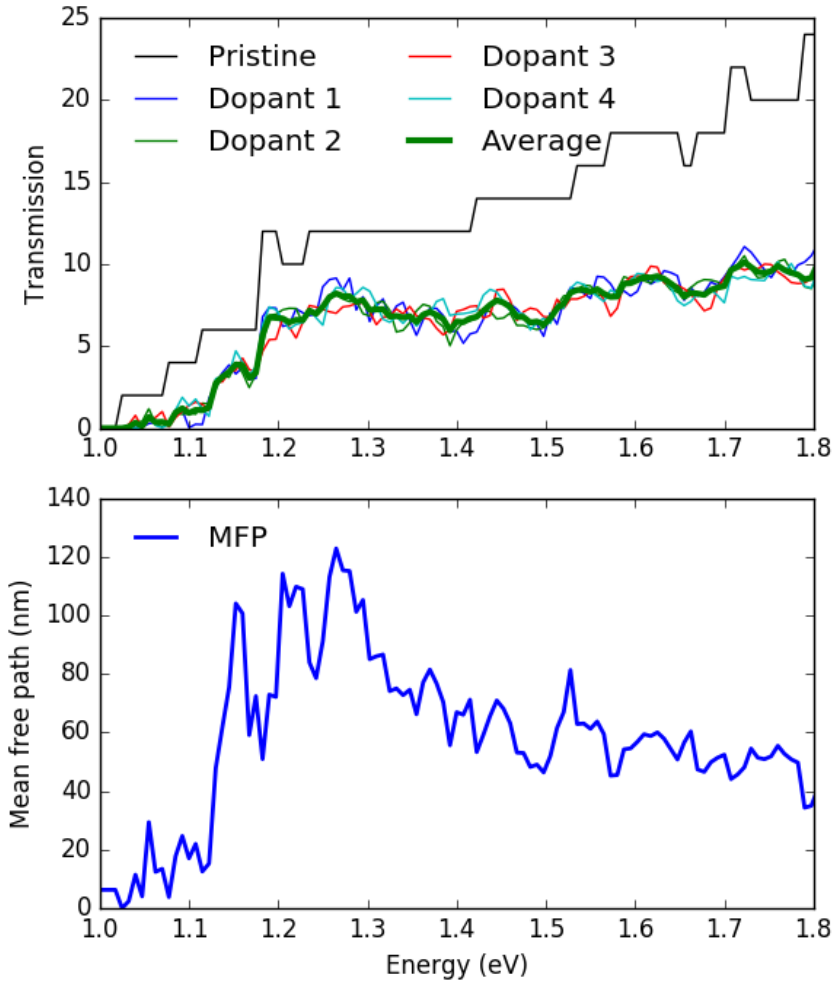
The script does the following:

1. Aligns the conduction band minima, to give the two datasets a common energy reference.
2. Calculates the scattering resistance $R_s(E)$ from the average transmission and the contact resistance $R_c(E)$ from the pristine transmission.
3. Saves the data to a file, for re-use later.

4.Calculates the mean free path from $R_c(E)$ and $R_s(E)$ and the average distance between dopant atoms.

5.Plots of transmissions and mean free path as functions of energy.

Run the script as `atkpython T_and_mfp.py` or with the Job Manager, in the directory where you have saved the files with the transmission spectra, and the following figure should appear:



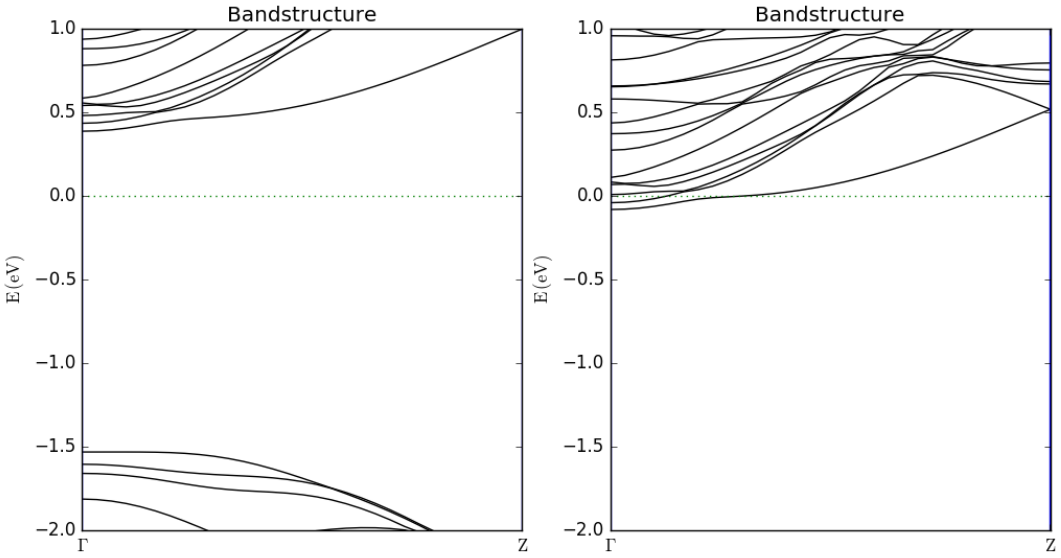
The first plot compares the transmission function for the pristine and the defected nanowires. It can be seen that the transmission of the defected nanowires is similar and always lower than that of the pristine nanowire. The second plot shows the mean free path as a function of energy.

Note how, close to the conduction band edge at energies between 1.0 eV and 1.2 eV, the electrons are strongly scattered by the dopant impurity, and the associated transmission functions are very low. This is reflected in a short mean free path. At higher energies E > 1.2 eV, there is less scattering and both the transmission and mean free path are larger.

Fermi levels in doped nanowires

The next task is to estimate the impurity limited mobility as a function of doping density. In order to do this, you need to know the position of the Fermi level relative to the conduction band edge. This can be achieved by calculating the band structure for silicon nanowires which are uniformly doped. This can be done in QuantumATK using atomic compensation charges. You can learn about doping in QuantumATK in the technical note here: *Doping methods available in QuantumATK* and in the tutorial here: *Silicon p-n junction*. The bandstructure calculations use 1x1x9 k-points and the $\Gamma \rightarrow$ Z route. You can download the data files here: `doped-bandstructures.zip`.

After unzipping the files you can compare the bandstructures in QuantumATK using the **Bandstructure Analyzer**:



Note that in this case, both bandstructures are referenced to the Fermi level, and it is therefore also easiest to align them here. This means that we need to look at the positions of the bands to study the shift in the Fermi level. We see that the conduction band has shifted about 0.5 eV down when going from a doping level of 10^{14} cm^{-3} to 10^{21} cm^{-3}, which is more properly described as the Fermi level shifting up with increasing doping.

Doping dependent mobility

You now have the ingredients needed to estimate the mobility as function of doping concentration. The python script below loads the calculated data and calculate the conductivity as well as mobility for a 1 μm long Silicon nanowire. By calculating the mobility in this way, as also described in the *theoretical background*, the following assumptions are made:

- Each dopant atom is fully ionized and contributes with one electron to the conduction band charge density.
- The transmission of the long wire can be estimated from the single-dopant transmissions.

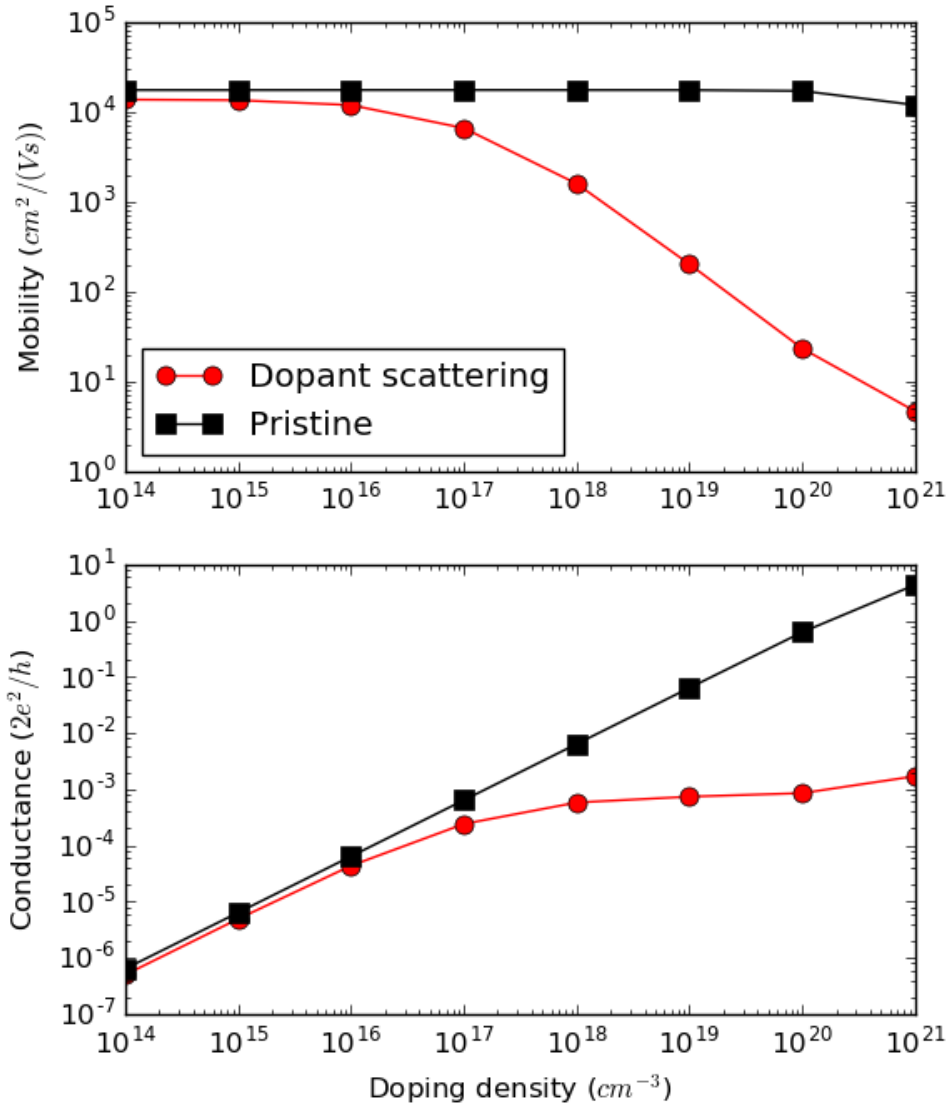
> **Warning:** Note that the mobility defined in this way is very much an estimate of the mobility of electrons for the pristine wire, as we do not include any explicit scattering mechanisms. It is not directly comparable with the, for the pristine wire more appropriate, mobility that is calculated by f.ex. the *Mobility* class.

Notice that although the transmission calculations with the dopant atoms to some extend include the doping effect - i.e. that the P atom becomes partly ionized - this effect is not included in the position of the Fermi level, which is determined

by the electrodes, which are un-doped in this calculation. The bandstructure calculations with the compensation charge doping are thus needed to consider this effect. You can download the script for these calculations here: `mobility.py`. The script does the following:

1. Calculates the conductances and mobilities starting from the transmission;
2. The conductances and mobilities are plotted as a function of doping level, both with and without taking scattering processes due to dopant atoms into account.

Run the script as `atkpython mobility.py`, and the following figure should appear:



Both the mobility and the conductance are calculated and plotted for two cases:

i. Including dopant scattering in the transmission calculation of the long wire (red circles).
ii. For a pristine, but uniformly doped, wire transmission (black squares).

When the dopant scattering is included, two factors affect the conductance:

- As for the pristine wire case, the Fermi level moved closer to the conduction band for increased doping density. This effect increases the conductance.

•Due to the scattering by the dopant impurities, the energy resolved resistance increases linearly with length according to the equations shown in the theory. This effect will decrease the conductance.

From the conductance plot (bottom), one can observe that the two effects approximately cancel out for doping densities $n > 10^{18}$ cm^{-3}, where the conductance is more or less constant. Since the conductance is constant, the mobility will decrease as $\mu \propto 1/n$ for $n > 10^{18}$ cm^{-3}.

For doping levels $n < 10^{18}$ cm^{-3}, the average dopant-dopant distance becomes larger than the wire length of 1 $\mu\mathrm{m}$ and there will on average be no dopants in the wire, which is the reason why the doped wire curves approach the pristine wire curves. If we had chosen a longer wire, this onset would happen at lower doping concentrations, as it is related to the ratio $L/L_{\mathrm{mfp}}(E)$.

Summary and discussion

As mentioned previously, the focus of this tutorial was not so much on how to calculate very accurate and detailed transmission spectra, but rather on how to extract information from them. In the present case of phosphorus dopants in a silicon nanowire we note the following points:

•The actual transmission functions and mobilities will depend on the diameter and orientation of the wire.

•The transmission might also depend on the basis set, and differ from the one presented here, if *e.g.* a larger basis set (like DoubleZetaPolarized) is used.

One should also be aware that the analysis presented in this tutorial is not intended to be very quantitative. It rather provides a relatively straightforward approach to estimate the order of magnitude of the elastic scattering by defects. Recall that the actual system considered would be a 1 $\mu\mathrm{m}$ long nanowire (this would include more than 150,000 atoms) with randomly placed dopants.

Finally, one should notice that the methods presented in this tutorial are applicable to other kinds of structural disorder such as surface defects[2], or surface roughness scattering[3], and can be applied to both electron and phonon transmission spectra[Page 639, 2, 3].

Appendix: Building the nanowires

Detailed instructions for building a Si nanowire can be found in this tutorial: *Silicon nanowire field-effect transistor*. However, you may also use the **Nanowire** plugin in the Builder. In this case, we have used a nanowire bounded by (111) and (100) facets and a radius of 7.0 Å.

3.2.13 Virtual Crystal Approximation for InGaAs random alloy simulations

Version: 2017

Downloads & Links

Effective band structure of random alloy InGaAs VirtualCrystalBasisSet

[2] T.ăMarkussen, A.-P. Jauho, and M.ăBrandbyge. Electron and phonon transport in silicon nanowires: Atomistic approach to thermoelectric properties. *Phys. Rev. B*, 79:035415, Jan 2009. doi:10.1103/PhysRevB.79.035415.

[3] Troels Markussen. Surface Disordered GeSi Core–Shell Nanowires as Efficient Thermoelectric Materials. *Nano Letters*, 12(9):4698–4704, 2012. doi:10.1021/nl302061f.

In this tutorial you will learn how to use the virtual crystal approximation (VCA) in order to simulate properties of random alloys with $In_xGa_{1-x}As$ as the specific system of interest. You will use VCA with the *PBEsol* exchange-correlation (xc) functional for determination of the lattice constant as a function of the In fraction x, and then use VCA with the TB09-MGGA xc-functional to compute the band structures.

Introduction

Random alloys are becoming technologically important materials. SiGe is one of the best known materials for thermoelectric elements and $In_xGa_{1-x}As$ is a prime candidate to substitute or complement silicon in future CMOS devices. Simulations of both thermoelectric elements as well as transistor devices often refers to band structure parameters such as band gaps and effective masses. In a random alloy, one can calculate the so-called *EffectiveBandstructure* (EBS), which includes effects of the random disorder. However, EBS calculations require large unit cells and are rather time consuming. For more details, see the tutorial: *Effective band structure of random alloy InGaAs*.

A different approach to modeling a random alloy is to use the virtual crystal approximation (VCA), which is the topic of the present tutorial. In a VCA simulation of, for instance, $In_xGa_{1-x}As$ one creates a new, virtual atom, which is a mixture of In and Ga with appropriate weights. The actual calculation of e.g. lattice constants or band structures can then be performed on a primitive cell with only two atoms: the normal As atom and the virtual In-Ga atom. See also the manual page: *VirtualCrystalBasisSet*.

Compared with EBS calculations, VCA simulations are much less computationally demanding, since there is no requirement for large super cells. Conversely, VCA simulations do not capture any effects of disorder, as in the EBS approach. However, as it is shown in the EBS tutorial, the random disorder has a small effect on the band structure around the Γ-point, which is also the most important region for InGaAs. For this reason it makes good sense to study the band structure with VCA.

Setting up the VCA calculations for $In_xGa_{1-x}As$

In the first part of the tutorial, you will calculate the lattice constant of $In_xGa_{1-x}As$ vs. In fraction x. You will be using the the GGA-type PBEsol exchange-correlation functional.

- Open the **Builder** and add an InAs bulk configuration:

  – *Add* → *From Database* → *InAs*

  – Send the InAs structure to the **Script Generator**.

In the **Script Generator** go through the following points:

- Add a **New Calculator**, open it and apply the settings:

  – Calculators: *ATK-DFT:LCAO* (default)

  – k-point sampling: 9x9x9.

  – Exchange correlation: *PBES*

  – Basis set: Change *Arsenic* to *High*.

- Add an **OptimizeGeometry** object and open it.

  – Un-check *Constrain Lattice Vectors* to also optimize the lattice parameter.

Note: Note that we use Medium basis sets for all elements. It was changed to High in the Script Generator to make sure the basis set was printed in the script, allowing us to easily modify it.

- Add a **Bandstructure** object and open it.
  - Set *Points pr. segment* to 100
  - Change the *Brillouin zone route* to **L, G, X** to just include a region around the Γ-point.
- Note the filename - you will need it later.

Note: The particular choice of filename is not important, as we will change it later. In this way it is easy to do an automatic search and replace without changing other things by accident.

In order to use the VCA basis set, you need to modify the python script. Send the script to the **Editor** and find the lines:

```
basis_set = [
    BasisGGASG15.Arsenic_High,
    BasisGGASG15.Indium_Medium,
    ]
```

and replace them with the following lines:

```
VirtualCrystalBasis = VirtualCrystalBasisSet([BasisGGASG15.Indium_Medium,BasisGGASG15.
↪Gallium_Medium], x=x)
basis_set = [
    VirtualCrystalBasis,
    BasisGGASG15.Arsenic_Medium,
    ]
```

In the first line the VirtualCrystalBasis is defined, based on regular basis sets of the SG15-Medium type. The VirtualCrystalBasis is constructed with:

- A list of two basis sets.
- A number $0x1$, defining the fraction of the first basis set.

The VirtualCrystalBasis will be associated with atoms in the configuration corresponding to the first element in the list - in this case Indium. So we now have a configuration containing regular Arsenic, and an atom which is a tunable mix of In and Ga, represented by the In atom in the actual BulkConfiguration.

You can now calculate the lattice constant and band structure for $In_xGa_{1-x}As$ with an arbitrary value of x. However, an advantage of VCA is the very short calculation time, so we would rather do calculations for many values of x to show the detailed dependence on x. We therefore need to modify the script to loop over x. Add the following lines at the top of the script:

```
# -*- coding: utf-8 -*-

x_range = numpy.linspace(0, 1.0, 11)
print('x_range', x_range)
for x in x_range:
    filename = 'ingaas-x%i.hdf5' % (x*100)
```

This will make a loop over x in intervals of 0.1, and create a separate file for each. Now go through the script (manually or with automatic replacement) and replace all instances of the filename (default is `'InAs.hdf5'`) with simply

`filename` and indent all the lines as required by Python in a loop. Finally, we need to add the TB09-MGGA calculator, to get the band gap calculated with TB09-MGGA instead of PBES. Insert these lines between the OptimizeGeometry and Bandstructure parts, and make sure they have the correct indentation

```
exchange_correlation = MGGA.TB09LDA

calculator = LCAOCalculator(
    exchange_correlation=exchange_correlation,
    basis_set=basis_set,
    numerical_accuracy_parameters=numerical_accuracy_parameters,
    )

bulk_configuration.setCalculator(calculator)
bulk_configuration.update()
nlsave(filename, bulk_configuration)
```

Read the script and make sure you understand what is being done and then run the calculation. It should take a couple of hours depending on hardware. Your script should look like this: `vca-ingaas-full.py`.

Note: For scientific use you should always carefully investigate if your numerical settings are converged. This includes in particular:

•k-point sampling

•Density mesh cutoff.

•Choice of basis sets/pseudopotentials - and their influence on the required mesh cutoff.

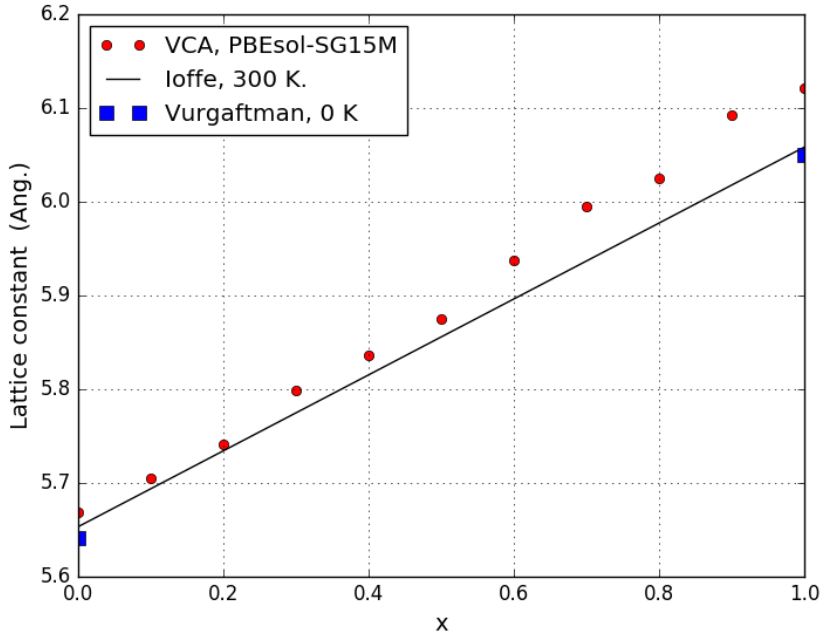
Analyzing the results for VCA with $In_xGa_{1-x}As$

Lattice constants

When the calculations are done, the results can be visualized with the `plot-lattice-constant.py` script. The lattice constant is plotted vs. the In fraction x. The solid line is an analytical expression which is based on experimental room temperature lattice constants[1], while the computed results correspond to zero temperature. Experimental low temperature lattice constants for GaAs ($x = 0$) and InAs ($x = 1$) lie slightly below the solid line[2].

[1] New Semiconductor Materials - Characteristics and Properties. GaInAs. http://www.ioffe.ru/SVA/NSM/Semicond/GaInAs/basic.html. Accessed: 2017-06-21.

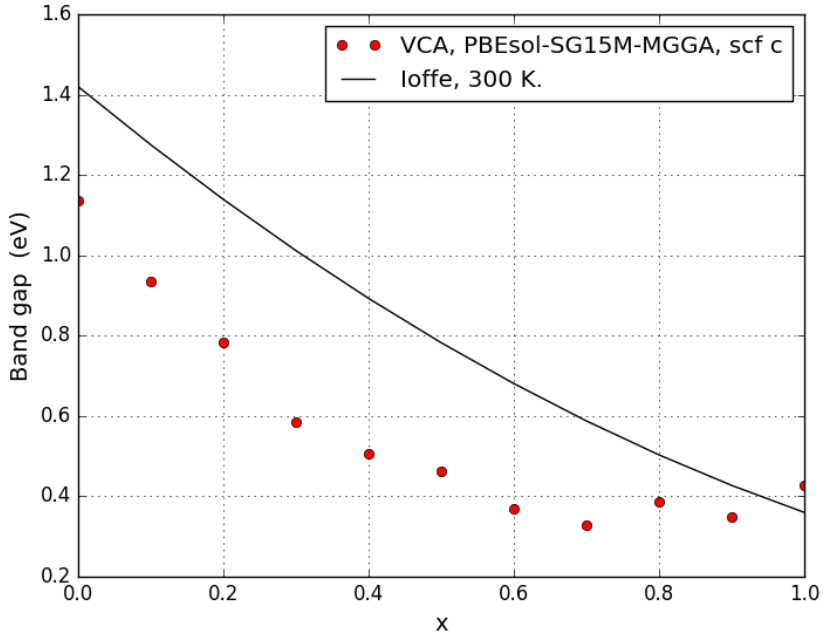
[2] I.ăVurgaftman, J.ăR. Meyer, and L.ăR. Ram-Mohan. Band parameters for III-V compound semiconductors and their alloys. *J. Appl. Phys.*, 89(11):5815–5875, jun 2001. arXiv:1206.0723, doi:10.1063/1.1368156.



We see that the experimental lattice constants are well reproduced in the Ga-rich region on the left of the figure, while the deviation is higher, about 1 %, in the In-rich region on the right. This is in line with general expectations, as PBEsol is designed to give accurate lattice constants, while GGA-type functionals generally overestimate them.

Band gaps - self-consistent TB09-MGGA

We also calculated bandstructures, from which we can extract the band gaps with the following script: `plot-band-gaps.py`. This will produce this plot:



We see that the band gaps show a qualitatively correct trend, but with rather large deviations in the Ga-rich region on the left and a bit of an oscillation on the right. Fortunately, it is possible to fit the c-parameter of TB09-MGGA to reproduce the correct band gaps of the end-points, which should also improve the band gaps in the intermediate region.

Band gaps - TB09-MGGA with fitted c-parameter

In order to fit the c-parameter, we need to re-visit the calculations for $x = 0$ and $x = 1$. The procedure for doing the fitting is rather straightforward and described in this tutorial: *Meta-GGA and 2D confined InAs*.

For our combination of computational parameters, we find that a c-parameter of 1.1331 optimizes the band gap of InAs and a c-parameter of 1.2680 optimizes the band gap of GaAs. We cannot know beforehand which parameter values optimize the band gap for the various compositions in between, so the most straightforward choice, is to simply make a linear interpolation between the two values.

We make a modified version of the previous script, which reads in the finished calculations, re-calculates with TB09-MGGA with a linear interpolation between the fitted c-parameter values and computes and saves a bandstructure:

```
# -*- coding: utf-8 -*-
x_range = numpy.linspace(0, 1.0, 11)
print('x_range', x_range)
for x in x_range:
    filename = 'ingaas-x%i.hdf5' % (x*100)

    bulk_configuration=nlread(filename,BulkConfiguration)[-1]
    old_calculator=bulk_configuration.calculator()

    # Interpolated fitted c
    c = 1.2679609982 - 0.13488609 * x
    exchange_correlation = MGGA.TB09LDA(c=c)

    calculator = old_calculator(
```

(continues on next page)

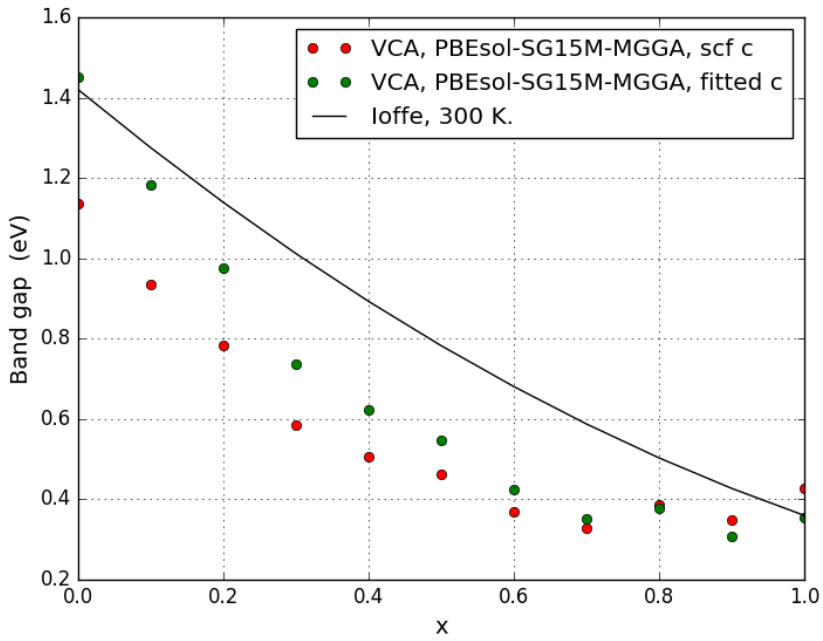
(continued from previous page)

```
        exchange_correlation=exchange_correlation,
        )

    bulk_configuration.setCalculator(calculator)
    bulk_configuration.update()

    bandstructure = Bandstructure(
        configuration=bulk_configuration,
        route=['L', 'G', 'X'],
        points_per_segment=200,
        bands_above_fermi_level=All
        )
    nlsave(filename, bandstructure)
```

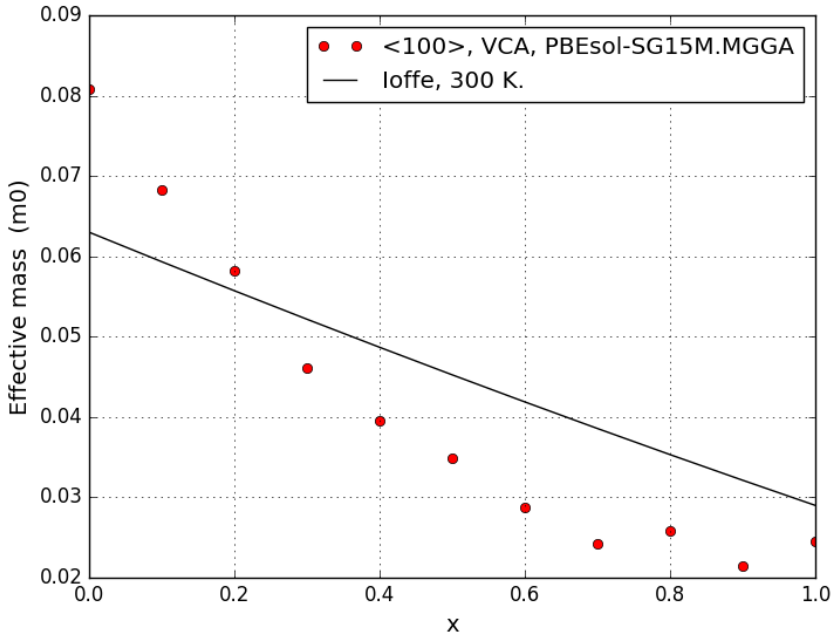
Run the script in the same folder, to re-do the TB09-MGGA calculations with a fitted c-parameter and get the corresponding bandstructures. We also modify the plotting script to include both datasets (`plot-both-band-gaps.py`), giving us this plot:



We see that this has improved the band gaps quite a bit in the Ga-rich part on the left, while the improvement is smaller in the In-rich part on the right.

Calculating effective masses

It is also possible to calculate the effective mass of the electrons as a function of x. See this tutorial: *Effective mass of electrons in silicon*, for general information on calculation of effective masses. The script is equivalent to the one used for the new TB09-MGGA calculations, and also plots the data, and can be found here: `effective-masses.py`. It will give this plot:



We see that the effective mass of GaAs is overestimated, leading to an overall distortion of the shape of the curve. However, it does capture the overall downwards trend in the effective mass from GaAs to InAs.

Summary and discussion

You have now learned how to use the VCA in order to calculate structural properties (lattice constants) and band structure properties (band gaps and effective masses) of $In_xGa_{1-x}As$. The lattice constants were well-reproduced, and while the fundamental band gap at the Γ point came out satisfyingly with the fitted TB09-MGGA c-parameter, the effective masses were not as accurate.

When using the VCA you must be aware that you are ignoring all effects of the random disorder. You are implicitly assuming that Blochs theorem applies and that the band structure is a well-defined quantity (or, alternatively that k is a good quantum number). This might, however, not always be the case, as shown in the calculations in the tutorial *Effective band structure of random alloy InGaAs*, which includes the random disorder. However, the effective band structure calculations also indicate that close to the Γ point, the band structure is indeed well-defined in $In_xGa_{1-x}As$. In that case it makes good sense to study the band structure details (effective mass, band gap, strain dependence, etc.) with the VCA, which is computationally much easier than the effective band structure calculation, which requires large supercells.

3.2.14 DFT-1/2 and DFT-PPS density functional methods for electronic structure calculations

Version: R-2020.09

Downloads & Links

DFTHalfParameters *PseudoPotentialProjectorShift*

QuantumATK offers two novel density functional corrections for computing the electronic structure of semiconductors and insulators: the DFT-1/2 and pseudopotential projector shift (DFT-PPS) methods. This tutorial gives an introduction to these methods.

DFT-1/2 is often also denoted LDA-1/2 or GGA-1/2, and is a semi-empirical approach to correcting the self-interaction error in local and semi-local exchange-correlation density functionals for extended systems, similar in spirit to the *DFT+U* method. As such, it can be viewed as an alternative to the TB09-*Meta-GGA* method with broadly the same aims; to improve the description of conduction-band energy levels and band gaps. Just like with TB09-MGGA, the DFT-1/2 method is **not** suitable for calculations that rely on total energy and forces, e.g., geometry optimization or molecular dynamics.

PPS is an abbreviation for pseudopotential projector shift. This method introduces empirical shifts of the nonlocal projectors in the SG15 pseudopotentials, in spirit of the empirical pseudopotentials proposed by Zunger and co-workers in[1]. The projector shifts have been adjusted to reproduce technologically important properties of semiconductors such as the fundamental band gap and lattice constant. The PPS method currently works out-of-the-box for the elements silicon and germanium, but may be used for other elements also by manually specifying the appropriate projector shifts (these must somehow first be determined). Importantly, the PPS method **does work** for geometry optimization of semiconductor material structures.

DFT-1/2 methods

The DFT-1/2 method attempts to correct the DFT self-interaction error by defining an atomic self-energy potential that cancels the electron-hole self-interaction energy. This potential is calculated for atomic sites in the system, and is defined as the difference between the potential of the neutral atom and that of a charged ion resulting from the removal of a fraction of its charge, between 0 and 1 electrons. The total self-energy potential is the sum of these atomic potentials. The addition of the DFT-1/2 self-energy potential to the DFT Hamiltonian has been found to greatly improve band gaps for a wide range of semiconducting and insulating systems[2]. For more information, see the QuantumATK Manual entry on the *DFT-1/2 method*.

Important: The method is not entirely free of empirical parameters. For eaxmple, a cutoff radius is employed. Following Refs.[3] and[Page 647, 2] it is chosen such as to maximize the band gap.

[1] L.-W. Wang and A.ăZunger. Local-density-derived semiempirical pseudopotentials. *Phys. Rev. B*, 51:17398–17416, 1995. doi:10.1103/PhysRevB.51.17398.

[2] LuizăG. Ferreira, Marcelo Marques, and LaraăK. Teles. Slater half-occupation technique revisited: The LDA-1/2 and GGA-1/2 approaches for atomic ionization energies and band gaps in semiconductors. *AIP Adv.*, 1(3):032119, 2011. doi:10.1063/1.3624562.

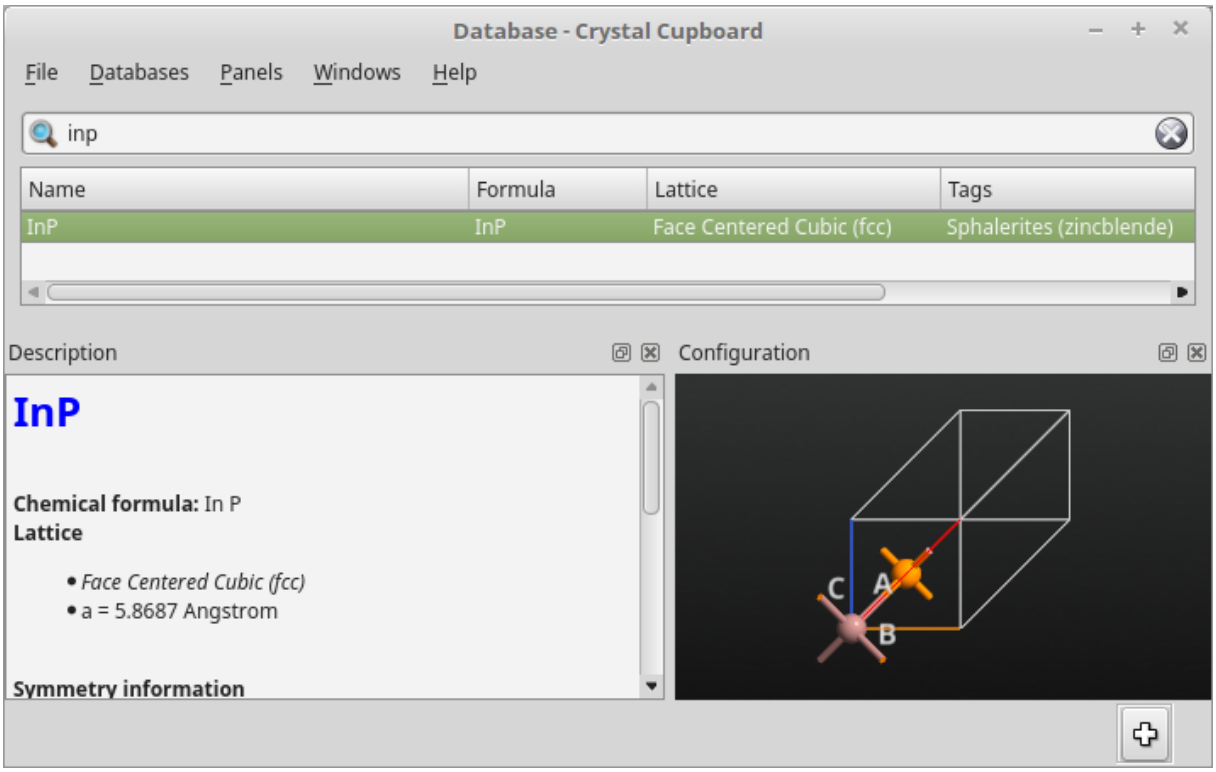
[3] LuizăG. Ferreira, Marcelo Marques, and LaraăK. Teles. Approximation to density functional theory for the calculation of band gaps of semiconductors. *Phys. Rev. B*, 78:125116, Sep 2008. doi:10.1103/PhysRevB.78.125116.

Note also that not all elements in the system necessarily require the DFT-1/2 correction; it is generally advisable only to add this to the anionic species, and leave the cationic species as normal.

Default DFT-1/2 parameters are available in QuantumATK; these have been optimized against a wide range of materials, and should improve upon the standard LDA or GGA band gap in most cases.

InP bandstructure using PBE-1/2

Create a new QuantumATK project (preferably in a new folder), and open the **Builder**. Then click *Add* → *From Database* and locate the InP crystal in the **Database**.

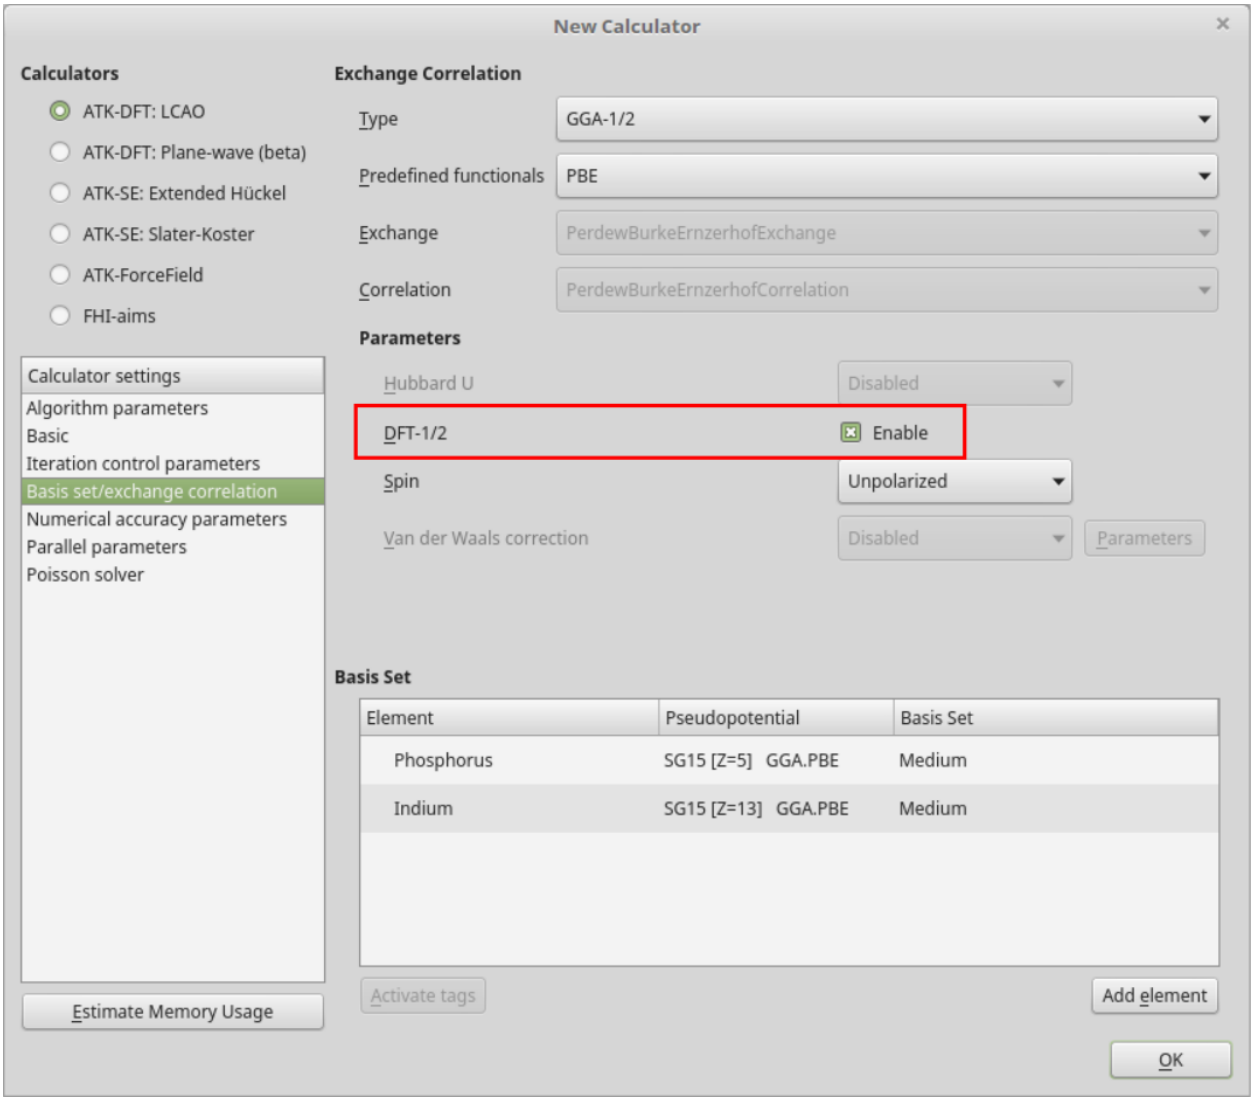


Add the InP cystal to the Builder **Stash**, and send the configuration to the **Script Generator**. Then add the following script blocks:

- **New Calculator**
- **Bandstructure**

and open the calculator widget to adjust the calculator parameters.

Select a 9x9x9 k-point grid, and navigate to the *Basis set/exchange correlation* tab. Note that the default exchange-correlation method is GGA (PBE). Enable the DFT-1/2 correction by ticking the checkbox indicated below.

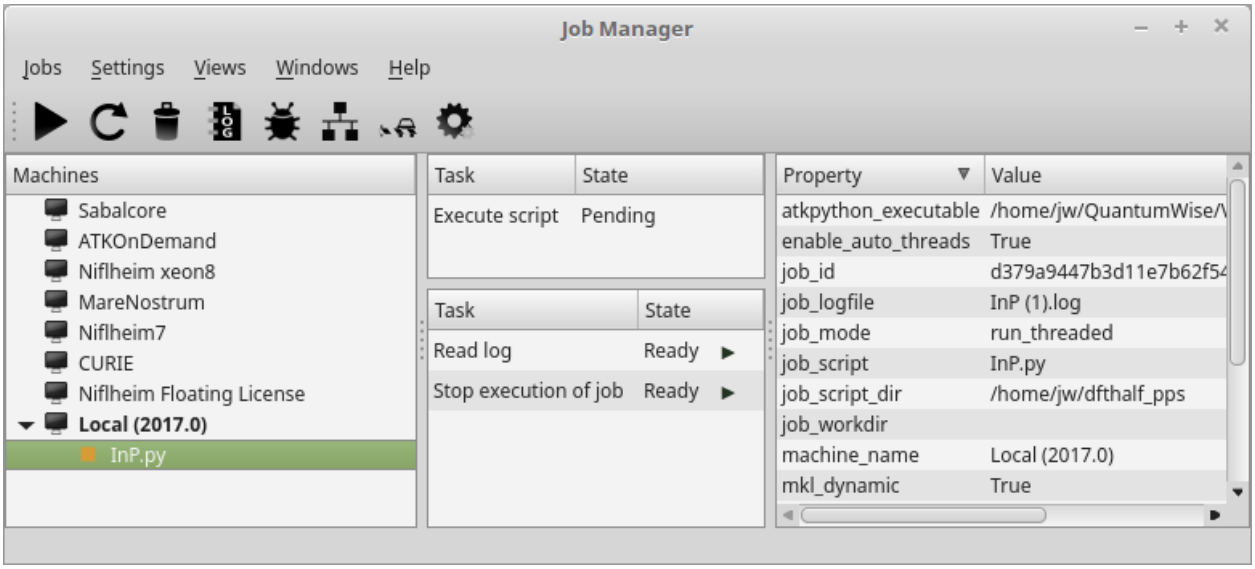


Close the calculator widget and save the script as `InP.py`. If you open the script using the **Editor**, you will see that the exchange-correlation method is `GAHalf.PBE`:

```
#------------------------------------------
# Exchange-Correlation
#------------------------------------------
exchange_correlation = GGAHalf.PBE
```

that is, GGA-1/2 using the PBE functional, which might also be denoted PBE-1/2. You may download the script here if needed: `InP.py`

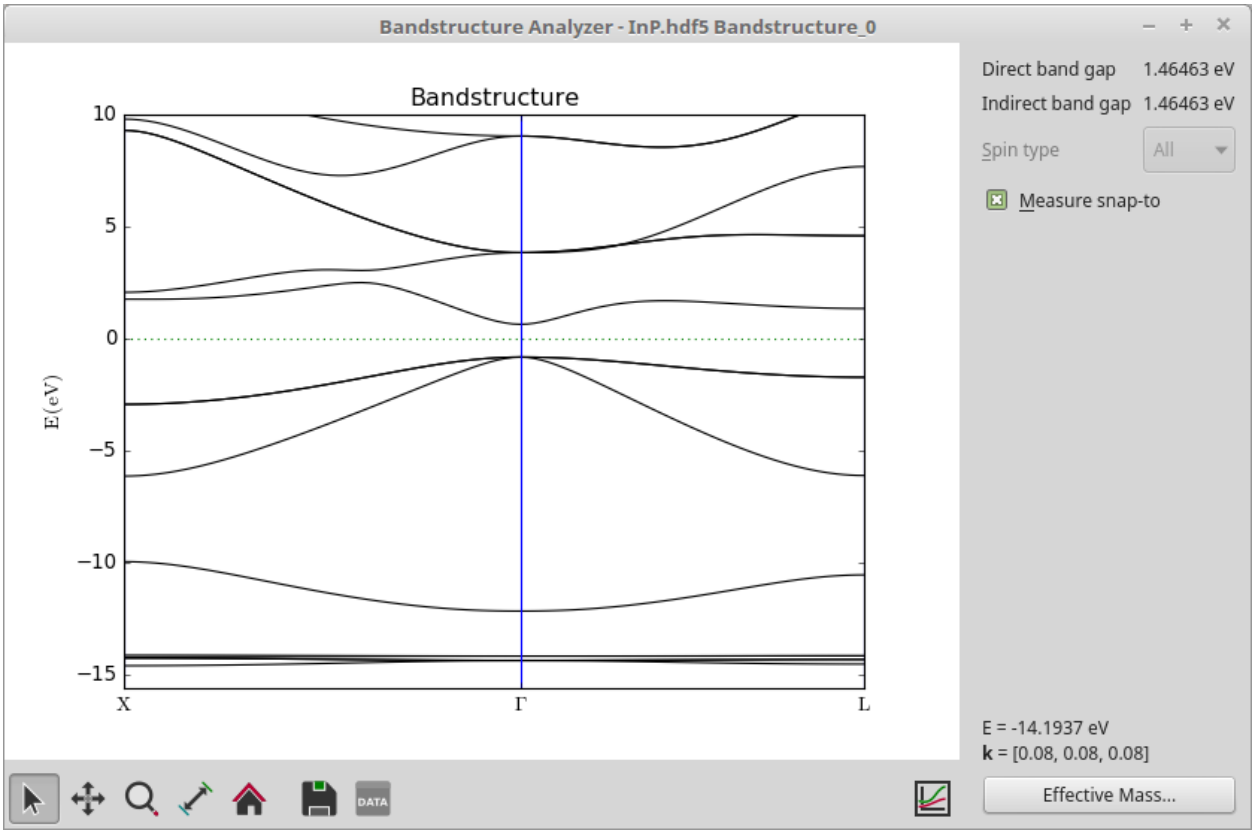
Run the script using either the **Job Manager**:



or from a terminal:

```
$ atkpython InP.py > InP.log
```

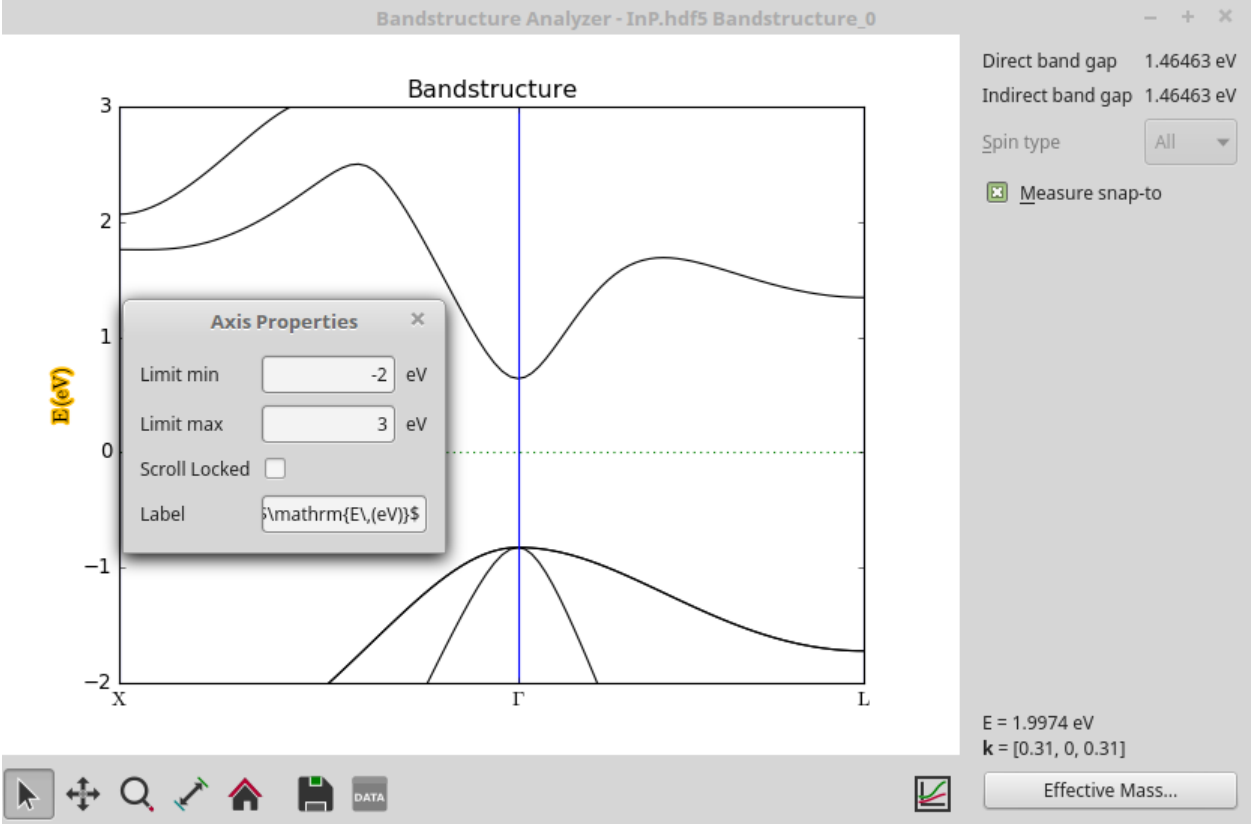
The calculation will be very fast. Once done, use the **Bandstructure Analyzer** to plot the resulting band structure. You will correctly find that InP is a direct-gap semiconductor with a band band gap of 1.46 eV, which is close to the experimental gap of 1.34 eV from Ref.[4].



[4] M.ăLevinshtein, S.ăRumyantsev, and M.ăShur, editors. *Handbook Series on Semiconductor Parameters*. Volumeă1. World Scientific Publishing Cp. Pte. Ltd., Singapore, 1996. ISBN 978-981-02-2934-4.

Tip: You may want to **zoom in** on the bands around the Fermi level for a better view. There are two ways to do this:

1. use the Zoom Tool (third icon from the left);
2. or click the y-axis label to select it, then right-click and select *Edit item* in order to open the *Axis Properties* widget, where you can adjust the limits of the y-axis.



III-V type semiconductor band gaps

The plots below show how the DFT-1/2 methods (LDA-1/2 and GGA-1/2) compare to LDA, GGA, and TB09-MGGA standard band gap calculations using default pseudopotentials and basis sets. A 9x9x9 k-point grid was used in all calculations, and experimental band gaps were adapted from Ref.[Page 650, 4].

It is quite clear that the DFT-1/2 correction improves on standard LDA and GGA band gaps, which are usually too small or non-existing (no bar). TB09-MGGA calculations with self-consistently determined c-parameter also improves band gaps in general.

The red bars for Ge using LDA-1/2 and GGA-1/2 indicate that a *direct* band gap is wrongly predicted (Γ–Γ instead of Γ–L as in experiments). The orange bar for GaP using GGA-1/2 indicates that the gap is correctly predicted to be *indirect*, but that the band energy in the L-valley is wrongly predicted to be a little lower than in the X-valley.

Manually specifying DFT-1/2 parameters

It is of course possible to manually specify the DFT-1/2 parameters instead of using the default ones. This is done by creating an instance of the *DFTHalfParameters* class, which is then given as an argument to the basis set.

For example, lets consider the case of GaAs. The following script manually sets up the As DFT-1/2 parameters identical to the default ones, and leaves the DFT-1/2 correction disabled for Ga, which is also default behavior. Note the `dft_half_parameters` argument to the basis set:

```
#----------------------------------------
# Basis Set
#----------------------------------------
# LDA-1/2 parameters for As
dft_half_parameters = DFTHalfParameters(
    element=Arsenic,
    fractional_charge=[0.3, 0.0],
    cutoff_radius=4.0*Bohr,
    )
# No LDA-1/2 parameters are needed for Ga (Disabled)
basis_set = [
    LDABasis.Arsenic_DoubleZetaPolarized(
        dft_half_parameters=dft_half_parameters),
    LDABasis.Gallium_DoubleZetaPolarized(
        dft_half_parameters=Disabled),
    ]
```

For more information, see the sections *Input format for DFT-1/2* and *DFT-1/2 default parameters* in the QuantumATK Manual.

Warning: Choosing the appropriate DFT-1/2 parameters may be a very delicate matter, and great care has been taken in determining the default parameters. If you choose to use non-default DFT-1/2 parameters, the quality of those parameters is entirely your own responsibility as a user!

QuantumATK does not offer support for determining custom DFT-1/2 parameters; we recommend in general that users stick to the default ones.

DFT-PPS method

As already mentioned, the DFT-PPS method applies shifts to the nonlocal projectors in the SG15 pseudopotentials. The nonlocal part of the pseudopotential, $\hat{V}_{\mathrm{nl}}$, is modified according to

$$\hat{V}_{\mathrm{nl}} \rightarrow \hat{V}_{\mathrm{nl}} + \sum_{l} |p_l\rangle \alpha_l \langle p_l|,$$

where the sum is over all projectors p_l, and α_l is an empirical parameter that depends on the orbital angular momentum quantum number l. Note that this approach does not increase the computational cost of DFT calculations!

The required projector shift parameters have been optimized for silicon and germanium and for use with the PBE density functional and SG15 pseudopotentials only. These are implemented as separate basis sets:

```
BasisGGASG15.Silicon_LowProjectorShift
BasisGGASG15.Silicon_MediumProjectorShift
BasisGGASG15.Silicon_HighProjectorShift
```

(continues on next page)

(continued from previous page)

```
BasisGGASG15.Silicon_UltraProjectorShift

BasisGGASG15.Germanium_MediumProjectorShift
BasisGGASG15.Germanium_HighProjectorShift
BasisGGASG15.Germanium_UltraProjectorShift
```

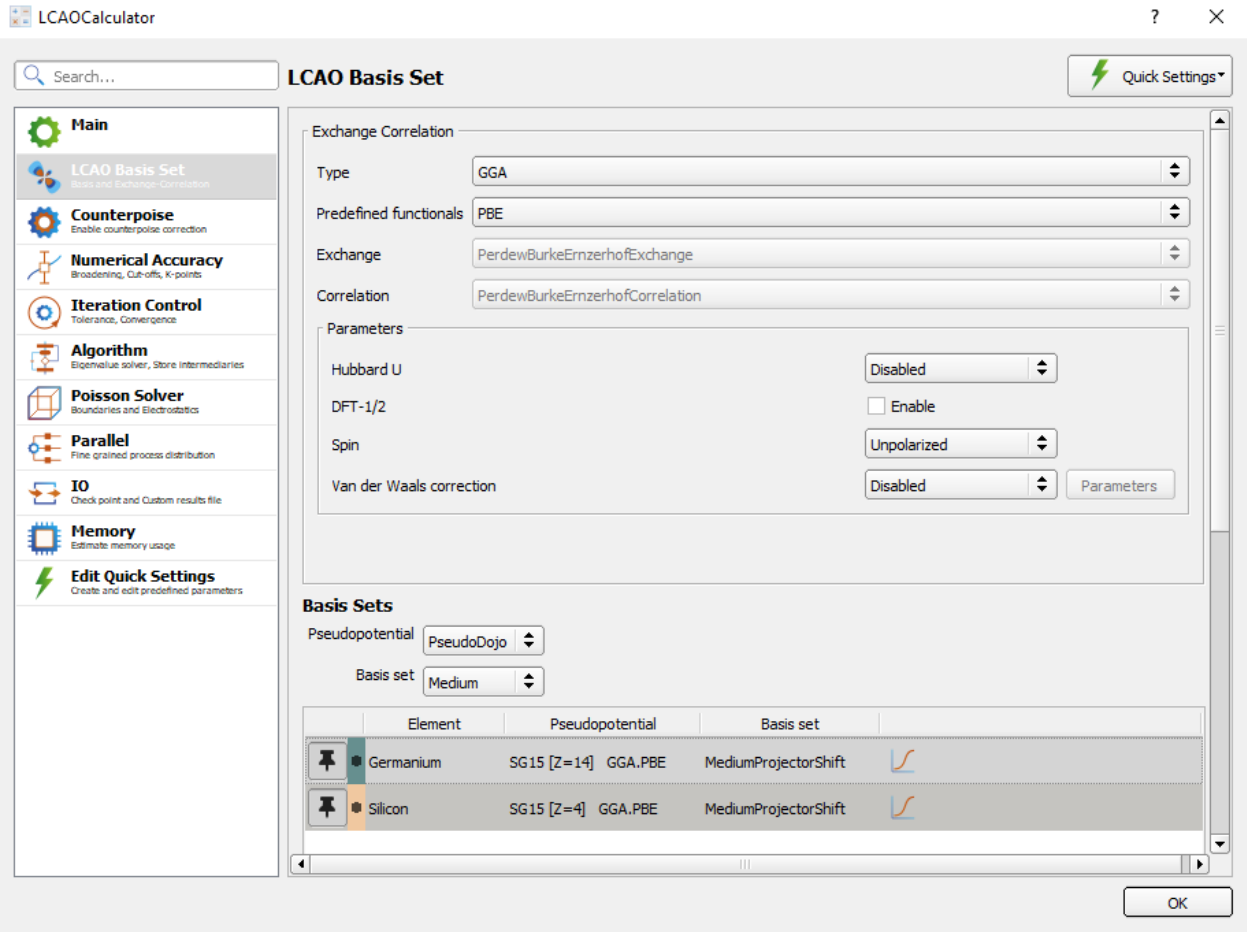
For each element, the same set of optimized projector shifts are applied in all SG15 basis sets. The script `projector_shifts.py` prints the built-in DFT-PPS parameters for Si and Ge:

```
Si
s-shift: +21.33 eV
p-shift: -1.43 eV
d-shift: +0.00 eV
Ge
s-shift: +14.55 eV
p-shift: +0.20 eV
d-shift: -2.17 eV
```

Note that the `d-shift` for Si is 0.0 eV since silicon has no d-electrons.

Si, SiGe, and Ge band gaps and lattice constants

The DFT-PPS method is enabled in the **Script Generator** by selecting one of the `ProjectorShift` basis sets for Si or Ge, as indicated below. No other calculator settings need to be changed in order to switch from ordinary PBE to DFT-PPS.



One very convenient aspect of the DFT-PPS method is that it allows for geometry optimization (forces and stress minimization) just like ordinary GGA calculations do – in fact, the DFT-PPS parameters may often be chosen such as to give highly accurate semiconductor lattice constants while also producing accurate band gaps.

In the following, you will consider bulk Si and Ge, and a simple 50/50 SiGe alloy. These 3 bulk configurations are defined in the script `bulks.py`. The script `pbe.py` runs geometry optimization and band structure analysis for all 3 configurations, while the script `pps.py` does the same using the DFT-PPS method.

The latter script looks like shown below. Note the lines from 2 to 31 in that particular script, where the bulk configurations are imported from the external script, and a Python loop over these configurations and basis sets is set up. Also, the DFT-PPS shifts are here manually specified.

```
1  # -*- coding: utf-8 -*-
2  from bulks import si, ge, sige
3  setVerbosity(MinimalLog)
4
5  configurations = [si,ge,sige]
6  labels         = ['Si','Ge','SiGe']
7
8  # Basis set for Silicon
9  SiliconBasis_projector_shift = PseudoPotentialProjectorShift(
10     s_orbital_shift=21.33*eV,
11     p_orbital_shift=-1.43*eV,
12     d_orbital_shift=0.0*eV,
```

(continues on next page)

(continued from previous page)

```
    f_orbital_shift=0.0*eV,
    g_orbital_shift=0.0*eV
    )
SiliconBasis = BasisGGASG15.Silicon_Medium(projector_shift=SiliconBasis_projector_shift)

# Basis set for Germanium
GermaniumBasis_projector_shift = PseudoPotentialProjectorShift(
    s_orbital_shift=14.55*eV,
    p_orbital_shift=0.20*eV,
    d_orbital_shift=-2.17*eV,
    f_orbital_shift=0.0*eV,
    g_orbital_shift=0.0*eV
    )
GermaniumBasis = BasisGGASG15.Germanium_Medium(projector_shift=GermaniumBasis_projector_
↪shift)

# Combined basis sets
basis_sets = [[SiliconBasis], [GermaniumBasis], [SiliconBasis, GermaniumBasis]]

for bulk_configuration,label,basis_set in zip(configurations,labels,basis_sets):
    outfile = "%s_PPS.hdf5" % label

    # ------------------------------------------------------------
    # Calculator
    # ------------------------------------------------------------
    k_point_sampling = MonkhorstPackGrid(
        na=9,
        nb=9,
        nc=9,
        )
    numerical_accuracy_parameters = NumericalAccuracyParameters(
        k_point_sampling=k_point_sampling,
        density_mesh_cutoff=90.0*Hartree,
        )

    calculator = LCAOCalculator(
        basis_set=basis_set,
        numerical_accuracy_parameters=numerical_accuracy_parameters,
        )

    bulk_configuration.setCalculator(calculator)
    nlprint(bulk_configuration)
    bulk_configuration.update()
    nlsave(outfile, bulk_configuration)

    # ------------------------------------------------------------
    # Optimize Geometry
    # ------------------------------------------------------------
    fix_atom_indices_0 = [0, 1]
    constraints = [FixAtomConstraints(fix_atom_indices_0)]

    bulk_configuration = OptimizeGeometry(
```

(continues on next page)

(continued from previous page)

```
        bulk_configuration,
        max_forces=0.05*eV/Ang,
        max_stress=0.1*GPa,
        max_steps=200,
        max_step_length=0.2*Ang,
        constraints=constraints,
        trajectory_filename=None,
        optimizer_method=LBFGS(),
        constrain_bravais_lattice=True,
    )
    nlsave(outfile, bulk_configuration)
    nlprint(bulk_configuration)

    # ------------------------------------------------------------
    # Bandstructure
    # ------------------------------------------------------------
    bandstructure = Bandstructure(
        configuration=bulk_configuration,
        route=['L', 'G', 'X'],
        points_per_segment=50
        )
    nlsave(outfile, bandstructure)
```

Download all 3 scripts (`bulks.py`, `pbe.py`, `pps.py`) and run the latter two using either the **Job Manager** or from a terminal:

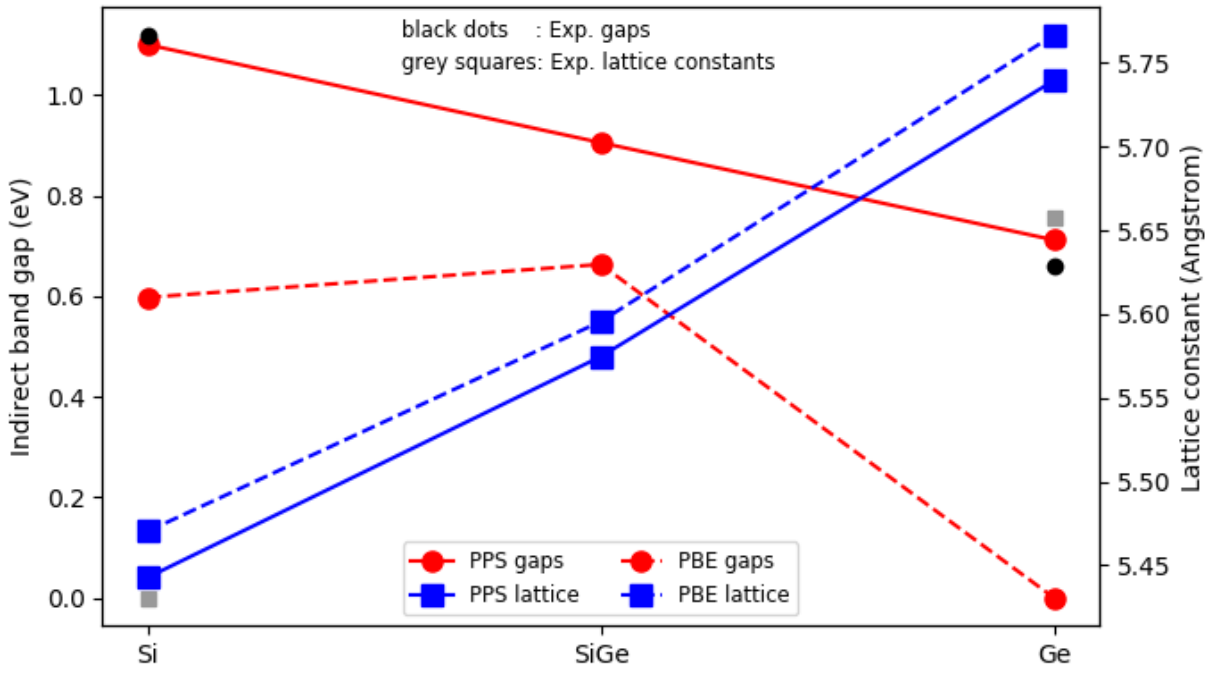
```
$ atkpython pps.py > pps.log
$ atkpython pbe.py > pbe.log
```

The jobs should take around 5 minutes each.

Use then the script `plot_pps.py` to plot the results. Running that script should produce the figure shown below, where the calculated indirect band gaps are shown in red circles, and the calculated lattice constants are shown in blue squares, both for PBE (dashed lines) and DFT-PPS (solid lines).

The DFT-PPS band gaps of Si and Ge compare very well to experiments (block dots; from Ref.[Page 650, 4]), and varies roughly linearly with germanium content. On the contrary, the ordinary PBE method predicts zero Ge band gap.

The DFT-PPS lattice constants of pure Si and Ge are also closer to experiments (grey squares) than found with non-corrected PBE.



Manually specifying DFT-PPS parameters

It can be very convenient to manually specify the DFT-PPS projector shift parameters. This may be especially useful in DFT-PPS calculations for elements where there are no default DFT-PPS parameters (only Si and Ge currently have defaults).

The projector shifts are supplied using an instance of the *PseudoPotentialProjectorShift* class, which is then given as an argument to the SG15 basis set. The following script manually sets the Si and Ge DFT-PPS parameters identical to the default ones:

```
#-----------------------------------------
# Basis Set
#-----------------------------------------
# Basis set for Silicon
SiliconBasis_projector_shift = PseudoPotentialProjectorShift(
    s_orbital_shift=21.33*eV,
    p_orbital_shift=-1.43*eV,
    d_orbital_shift=0.0*eV,
    f_orbital_shift=0.0*eV,
    g_orbital_shift=0.0*eV
    )
SiliconBasis = BasisGGASG15.Silicon_Medium(projector_shift=SiliconBasis_projector_shift)

# Basis set for Germanium
GermaniumBasis_projector_shift = PseudoPotentialProjectorShift(
    s_orbital_shift=14.55*eV,
    p_orbital_shift=0.20*eV,
    d_orbital_shift=-2.17*eV,
    f_orbital_shift=0.0*eV,
```

(continues on next page)

(continued from previous page)

```
    g_orbital_shift=0.0*eV
    )
GermaniumBasis = BasisGGASG15.Germanium_Medium(projector_shift=GermaniumBasis_projector_
↪shift)

# Total basis set
basis_set = [
    SiliconBasis,
    GermaniumBasis,
    ]
```

Warning: Choosing the appropriate DFT-PPS parameters may be a very delicate matter, and often requires a numerical optimization procedure. The SciPy software offers numerous such routines, but if you choose to use non-default DFT-PPS parameters, the quality of those parameters is entirely your own responsibility as a user!

QuantumATK does not offer support for optimizing DFT-PPS parameters; we recommend in general that users stick to the default parameters, if they exist.

3.2.15 Electrical characteristics of devices using the IVCharacteristics study object

Version: U-2022.12

Downloads & Links

IVCharacteristics Study objects `soi_device_configuration.py` `Workflow 1` `Workflow 2` `Workflow 3` `soi_device_ivc_through_scripting.py`

This tutorial introduces the *IVCharacteristics* **study object** used within the framework of the **Workflow Builder**. The *IVCharacteristics* study object enables the calculation and analysis of the most relevant electrical characteristics of field-effect transistor (FET) device models, including the on/off ratio (I_{on}/I_{off}), the subthreshold slope (SS), the transconductance (g_m) and the drain-induced barrier lowering (DIBL)[1].

In the present tutorial, you will learn how to use *IVCharacteristics* study object in the **Workflow Builder** to setup, calculate and analyze some of the electrical characteristics of a model silicon-on-insulator (SOI) device. These workflows will be demonstrated for a preconstructed SOI FET device modeled with the *DeviceSemiEmpiricalCalculator* adopted for the *IVCharacteristics* study object to calculate the SS, and DIBL parameter values and then benchmark them against the available experimental data.

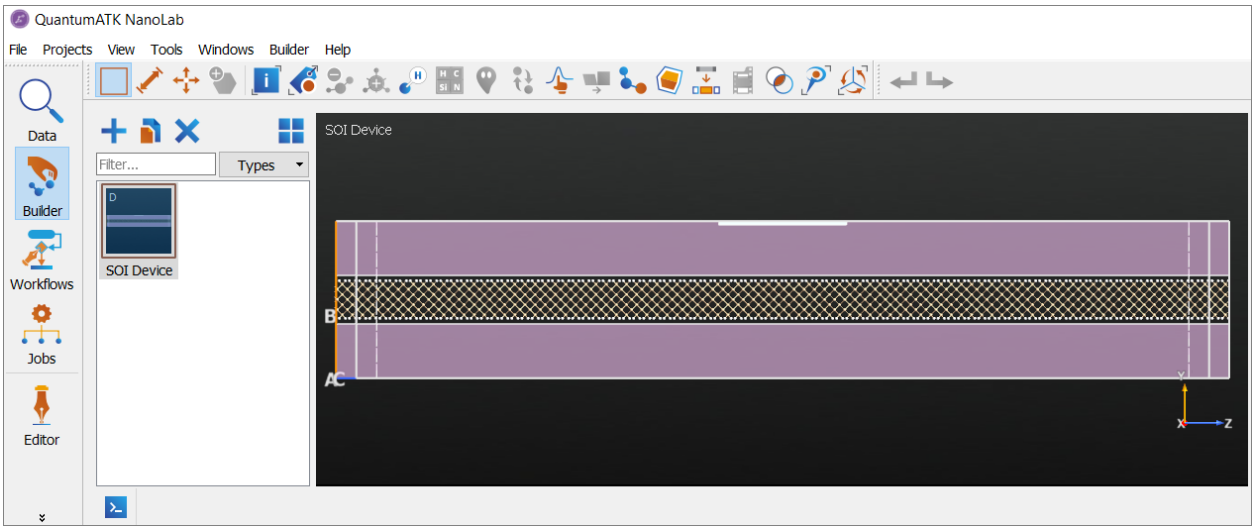
[1] S.ăM. Sze and K.ăN. Kwok. *Physics of Semiconductor Devices*. Wiley, 3rd edition, 2006.

Prerequisites

A general knowledge of the charge carrier transport in microelectronics devices and related IV characteristics is expected, e.g., IV curve, on/off ratio, subthreshold slope, transconductance, and drain-induced barrier lowering. If you are not familiar with these concepts you can still learn from this tutorial, but will not get the full benefit. If you wish to learn about them, we recommend reading this paper:[Page 659, 1].

Calculation and analysis of the $\mathrm{I_{ds}} - \mathrm{V_{gs}}$ curve for the FET on-state

The SOI FET device model structure considered in the tutorial is shown in the figure below. It consists of a hydrogen-passivated **2D** silicon slab, which includes a Si channel region connected with an ideal contact to source and drain leads made of highly-doped Si; two continuum dielectric regions acting as the SiO_2 dielectric substrate or spacer (with $\epsilon = 3.9\epsilon_0$) between a continuum metal gate and atomistic Si channel region.



For the sake of computational efficiency, the electronic structure of the device model will be calculated using a semi-empirical tight-binding model[2].

Setting up a Workflow

To create a workflow for *IVCharacteristics* calculations in the **Workflow Builder**, follow the step-by-step protocol described below. For a general introduction to the **Workflow Builder**, please see the dedicated guide: *Introduction to the Workflow Builder*.

- To add the SOI FET device configuration (shown in the previous figure) to the NanoLab Builder, download the script `soi_device_configuration.py`, and drag-and-drop it on to the NanoLab Builder icon from the **Data View**. Or use the Add button in the NanoLab Builder to import the device structure from the script `soi_device_configuration.py`.

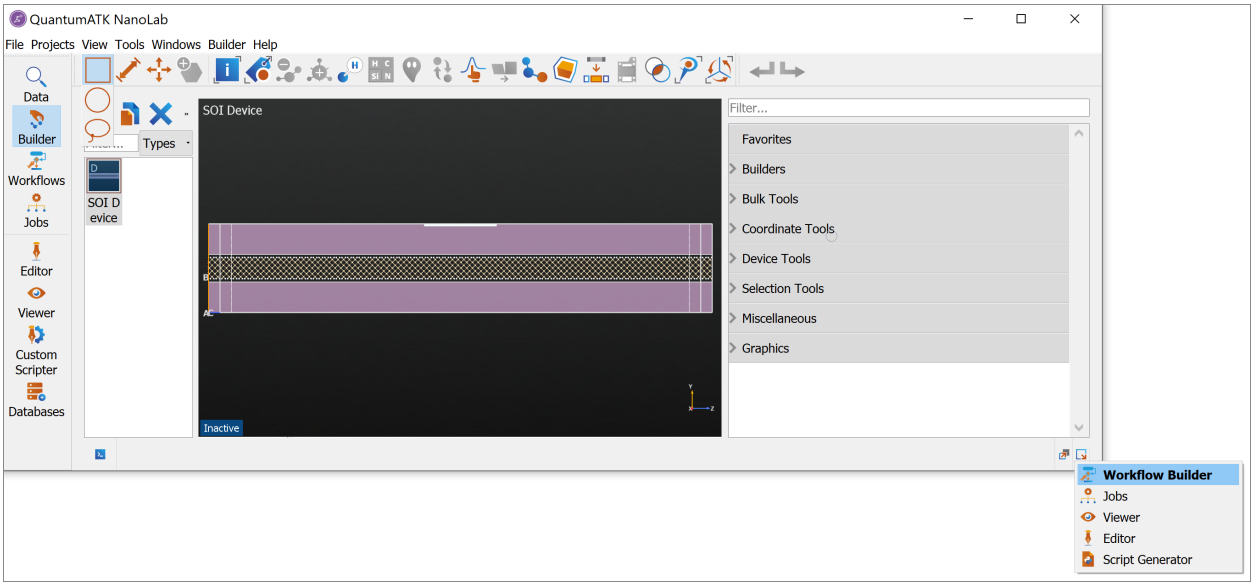
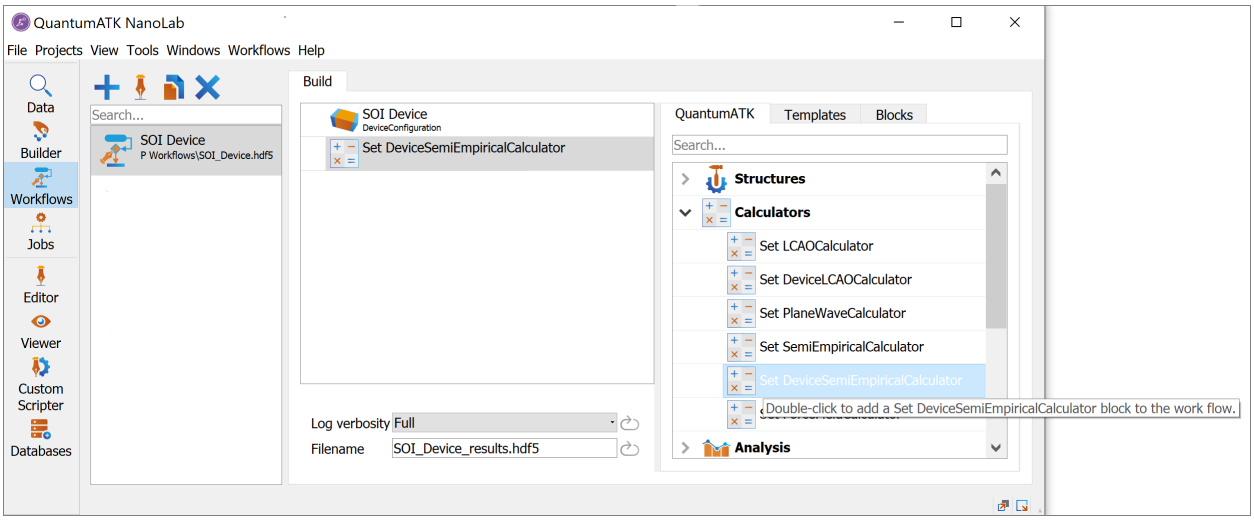
•In the NanoLab Builder, send the SOI `DeviceConfiguration` to the **Workflow Builder**.



•In the **Workflow Builder** window, add a *Set SemiEmpiricalCalculator* to the *SOI Device* workflow.



•In the QuantumATK Search bar, type *ivcharacteristics* to find the corresponding *IVCharacteristics* study $I(V_g, V)$ object and then add it to the workflow by double-clicking.

•In the Main section of the *Set SemiEmpiricalCalculator* block, change the *Parameter set* to *Boykin.SiH*, uncheck the *No SCF iteration* box, change *k-points* from *Density* to *Monkhorst-Pack k-grid*, and set the *k-point sampling* to 3x1x174.

•Change the **Poisson Solver** settings of the *Set SemiEmpiricalCalculator* block by switching to the [*Parallel*] *Conjugate gradient* Poisson solver, and set the top and bottom boundary conditions (in the B-direction) to Neumann,

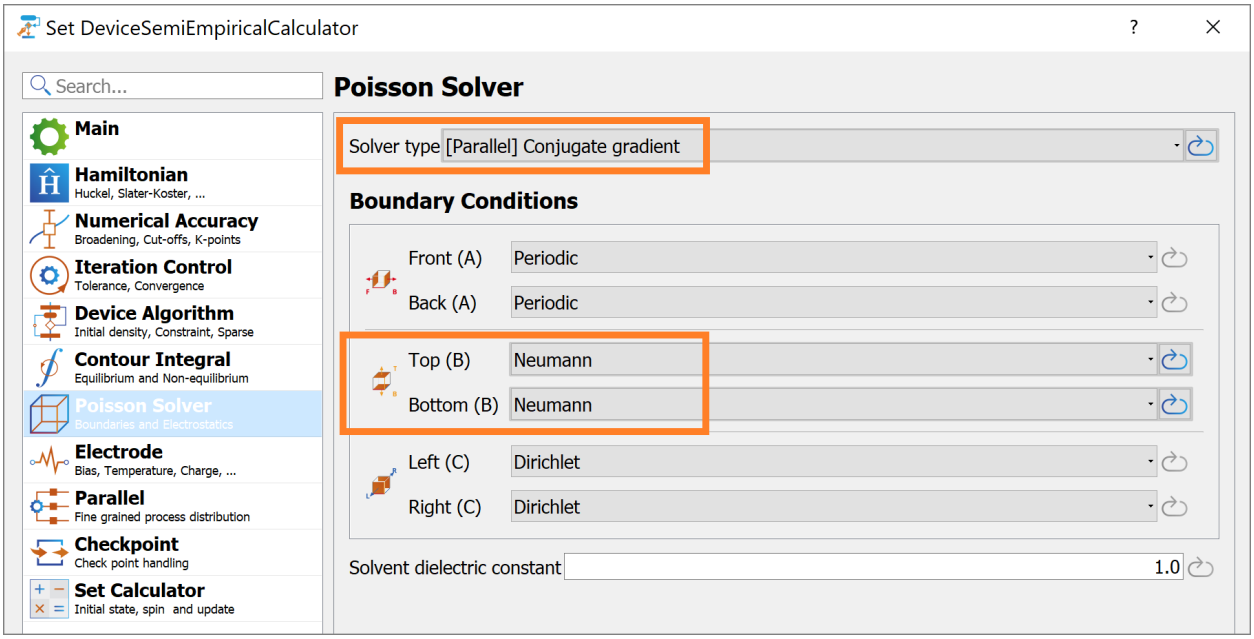
because there exists no periodicity in the direction perpendicular to the Si slab surfaces.



•Edit the *IVCharacteristics* settings in the workflow to set a range of gate voltage values for calculating the $I(V_g, V)$ $\mathrm{I_{ds}} - \mathrm{V_{gs}}$ curve.

Note: Given these settings, the `IVCharacteristics` study object will do a scan over the gate-source voltage values from $\mathrm{V_{gs0}} = -0.3\mathrm{V}$ to $\mathrm{V_{gs1}} = 0.0\mathrm{V}$, at regular intervals of $\Delta\mathrm{V_{gs}} = 0.05\mathrm{V}$ and at a small drain-source bias voltage applied, $\mathrm{V_{ds}} = 0.05\mathrm{V}$.

Using a predefined Workflow

To verify if the *SOI Device* workflow in the previous section is created correctly, one can compare it to a predefined workflow, which can be downloaded at `Workflow 1`. To use the predefined workflow, one should place the corresponding workflow (hdf5) file in your project folder in the *Workflows* subfolder (create it, if missing), and it will then appear in the **Workflow Builder** window of the **QuantumATK NanoLab GUI** as follows.

The *SOI Device* workflow created in the previous section and predefined *SOI Device IVC Workflow: Simulation 1* are supposed to be identical. Rename the *SOI Device* workflow to *SOI Device IVC Workflow: Simulation 1* in the **Workflow Builder** window.

Running Workflows

To run the *SOI Device IVC Workflow: Simulation 1*, send it to the **Job manager** using the button, saving it, e.g., with a default filename *soi_device_results.py*. When submitting it to a *Local Machine*, then you might also need pressing the button in the **Job manager** to actually start running the calculation. This device calculation will take about 5 minutes using 40 MPI processes.

Once the device calculation is done (or started), go to the **Data View** (or to the working directory on a remote machine) and click on the log file `soi_device_results.log` in the *Data View* window (or use a text editor on the remote machine) to view the log information in the **Editor**. A list of all the planned tasks that are to be done by the *IVCharacteristics* study object can then be seen in the log, see the following figure with the first 3 (out of 14) workflow tasks highlighted in yellow.

```
+-------------------------------------------------------------------------------+
| IV Characteristics Study                                                      |
+-------------------------------------------------------------------------------+
| 14 task(s) will be executed.                                                  |
|                                                                               |
| * Update configuration                                                        |
|   Gate voltage: -0.3 V                                                        |
|   Left electrode voltage: 0.0 V                                               |
|   Right electrode voltage: 0.05 V                                             |
| * Update configuration                                                        |
|   Gate voltage: -0.25 V                                                       |
|   Left electrode voltage: 0.0 V                                               |
|   Right electrode voltage: 0.05 V                                             |
| * Update configuration                                                        |
|   Gate voltage: -0.2 V                                                        |
```

During the workflow execution, an additional information box will be printed out to the main log file for each started task of the workflow. In the following example of the main log file, there are 14 tasks to be executed, *task 1* is finished and *task 2* is in progress.

```
+-------------------------------------------------------------------------------+
| Executing task 1 / 14:                                                        |
|   Update configuration                                                        |
|   Gate voltage: 0.0 V                                                         |
|   Left electrode voltage: 0.0 V                                               |

+-------------------------------------------------------------------------------+
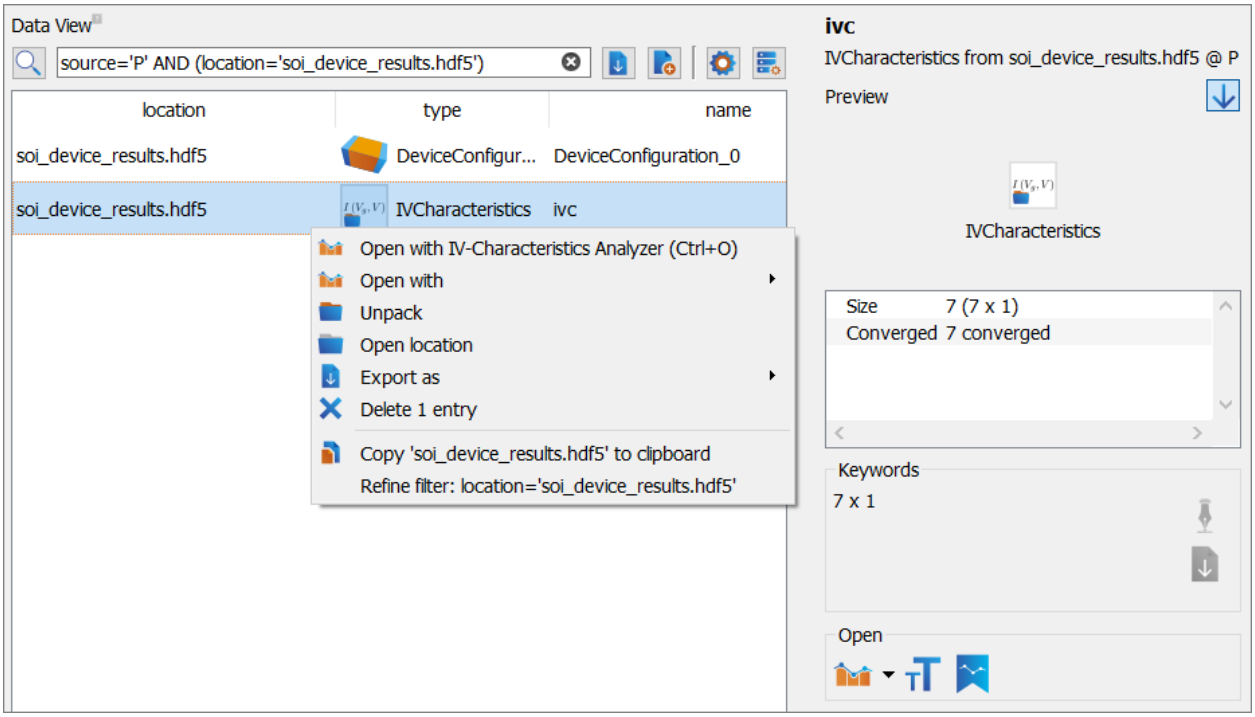
```

Note: For each gate voltage point, the study object will create an additional log file with the usual NEGF-SCF convergence information, as well as information on related analysis object calculations, e.g., on the *Transmission Spectrum* calculation. We will not discuss that in more detail here.

Analyzing the Workflow results

Close the **Editor** and go back to the **Data View** of the **QuantumATK NanoLab GUI**. In the *Data Sources*, select the file `soi_device_results.hdf5` and then click on (or right-click to Open with) the $I\left(V_g, V\right)$ *IVCharacteristics* object in the *Data View* window to open the object, e.g., to view it with the *IV-Characteristics Analyzer*.

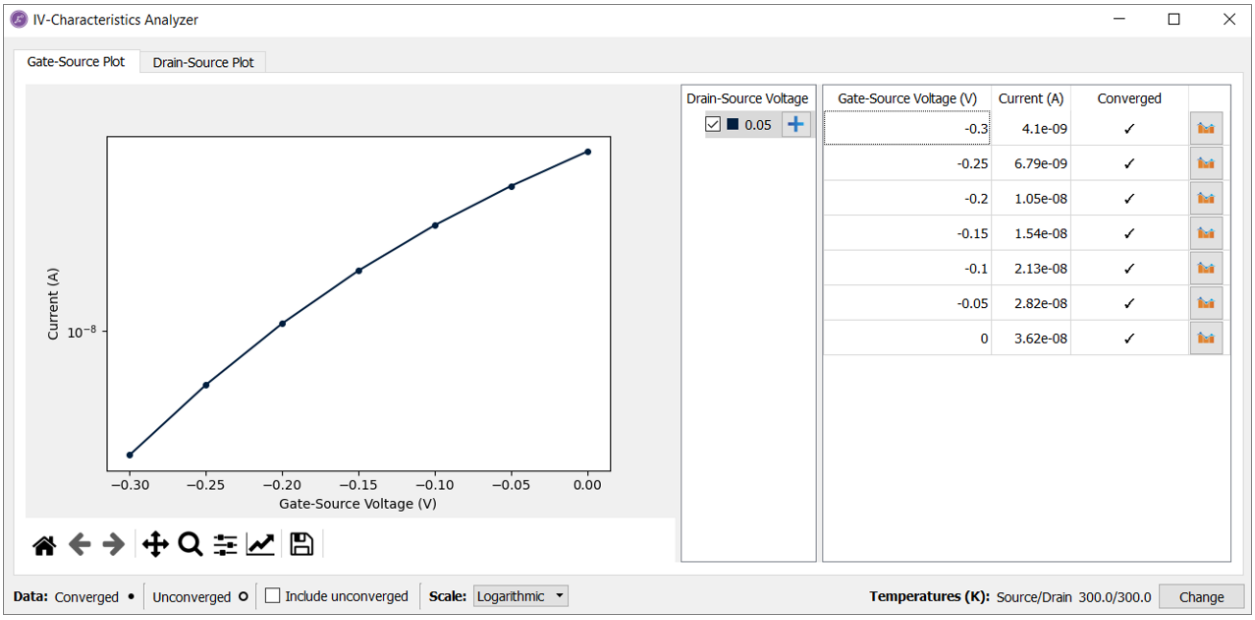


The *IV-Characteristics Analyzer* widget will then appear as follows.

The bottom part of the *IV-Characteristics Analyzer* widget contains the following supplemental information:

- **Data**: the convergence information for individual self-consistent device calculations at different voltages. In this case all bias points are converged.

Note: An unconverged point in the $\mathrm{I_{ds}}$ *vs.* $\mathrm{V_{gs}}$ data set means that the NEGF-SCF calculation did not reach the target convergence parameter value (which is set in the *Device Calculator*) for the corresponding gate voltage value and are thus unreliable. For tips on how to reach the convergence target, see the guidelines in the *NEGF Convergence Guide*.



•**Scale**: the plotting scale used on the Y-axis for the drain-source current $\mathrm{I_{ds}}$, which can be viewed as either *Linear* or *Logarithmic*.

•**Temperatures**: the electron temperature in the electrodes adopted to calculate the drain-source current $\mathrm{I_{ds}}$, using the `TransmissionSpectrum` calculated by the `IVCharacteristics` study object. Note that the temperature for each electrode can be modified by the user, and the current is then re-calculated accordingly.

The top part of the *IV-Characteristics Analyzer* shows the actual plots of the `IVCharacteristics` data, allowing one to switch between two different types of visualization:

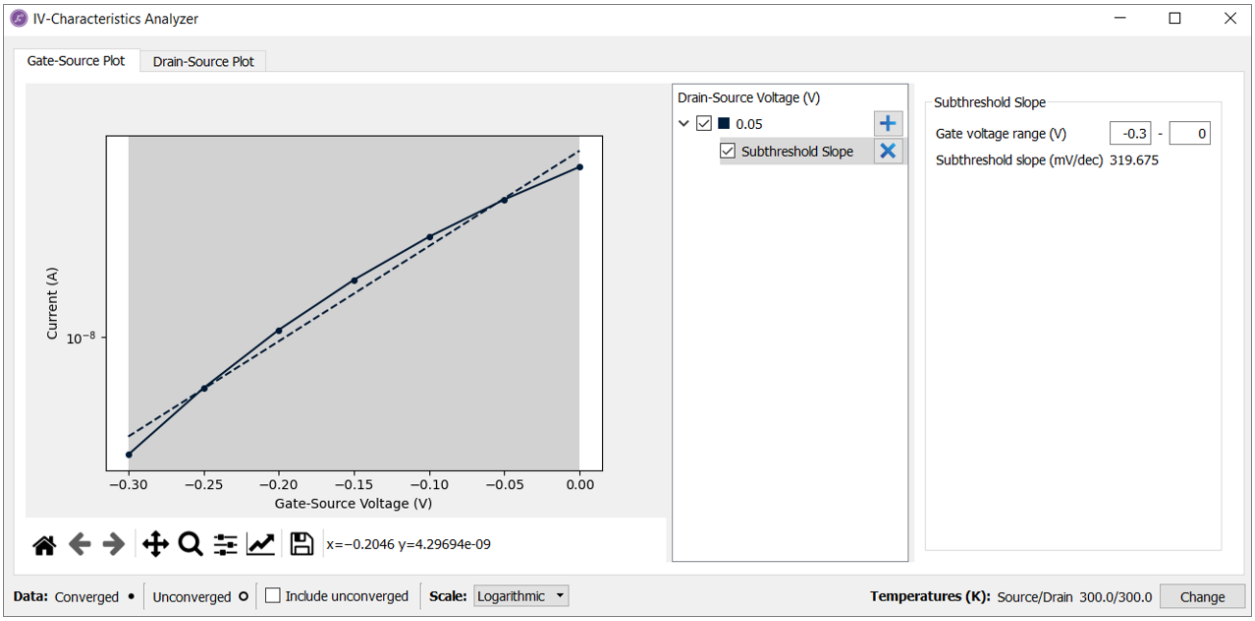
•*Gate-Source Plot* of the drain-source current vs. the gate-source voltage ($\mathrm{I_{ds}}$ $vs.$ $\mathrm{V_{gs}}$ curve),

•*Drain-Source Plot* of the drain-source current vs. the drain-source voltage ($\mathrm{I_{ds}}$ $vs.$ $\mathrm{V_{ds}}$ curve).

Given that a single bias voltage $\mathrm{V_{ds}}$ has been considered in this *Workflow 1*, only the $\mathrm{I_{ds}}$ $vs.$ $\mathrm{V_{gs}}$ characteristics will be analyzed at this time.

To calculate relevant characteristics of the FET device, e.g., the subthreshold slope SS, click on the + button in the *Drain-Source Voltage* section at the center of the panel and select the *Subthreshold Slope* option from the drop-down menu. The *Gate voltage range* over which the SS is calculated will be highlighted in gray in the $\mathrm{I_{ds}}$ $vs.$ $\mathrm{V_{gs}}$ plot. You can adjust this range to calculate the SS in the *Subthreshold Slope* panel on the right-hand side of the screen.

Note: For the obtained $\mathrm{I_{ds}} - \mathrm{V_{ds}}$ curve, the value of SS is highly overestimated. The SS value is also very sensitive to the actual choice of the *Gate voltage range*. This is because the curve section, which is used to compute the SS parameter here, lies outside the subthreshold region / FET off-state. In the latter, the current $\mathrm{I_{ds}}$ is supposed to vary linearly (on a logarithmic scale) with $\mathrm{V_{gs}}$. For a reliable calculation of the SS, the range of $\mathrm{V_{gs}}$ voltage values must therefore be extended to the subthreshold region, or, in other words, to the FET off-state, as done in the following section.



Extending the range of the $\mathrm{I_{ds}} - \mathrm{V_{gs}}$ curve to the FET off-state

To sample the subthreshold region for the SOI FET device considered, the range of $\mathrm{V_{gs}}$ has to be extended to $-0.9\mathrm{V} \leq \mathrm{V_{gs}} \leq 0.0\mathrm{V}$. This can be achieved in two ways:

- *2A. Extending the gate-source voltage range through the QuantumATK NanoLab GUI in the Workflow Builder*
- *2B. Use scripting to add data points to the IVCharacteristics study object*

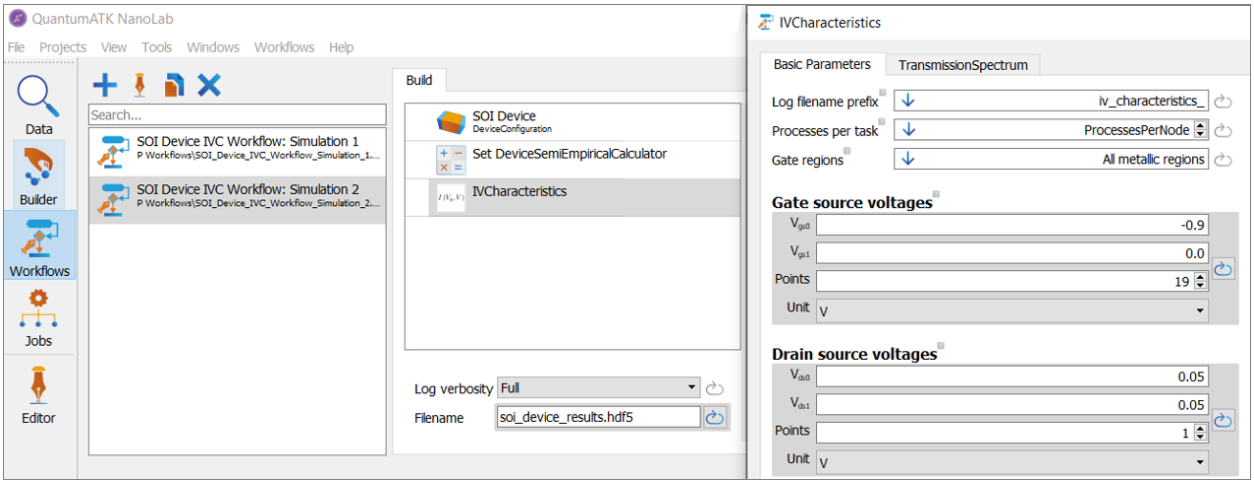
2A. Extending the gate-source voltage range through the QuantumATK NanoLab GUI in the Workflow Builder

To extend the gate-source voltage range in the *Workflow*, one can select the *SOI Device IVC Workflow: Simulation 1* (described in *Section 1*) and copy it with the *Duplicate* button, rename it to the *SOI Device IVC Workflow: Simulation 2* in the **Workflow Builder** window to then modify the **Gate source voltage range** settings in the `IVCharacteristics` study object as follows:

- Set the lower limit to $\mathrm{V_{gs0}} = -0.9\mathrm{V}$,
- Set the number of voltage points to 19 to also include the original gate voltage range (for the on-state), $-0.3\mathrm{V} \leq \mathrm{V_{gs}} \leq 0.0\mathrm{V}$, see also a note in the following.

Note: For the sake of comparison, the predefined *SOI Device IVC Workflow: Simulation 2* is enclosed to this tutorial and can be downloaded at `Workflow 2`.

To do the *Workflow 2* for the extended gate voltage range, send *SOI Device IVC Workflow: Simulation 2* to the **Job manager** using the button, save it as `soi_device_results.py` and press the button to run the corresponding job, if needed. The calculation will take about 5 minutes using 40 MPI processes.



Inspecting the log file of the follow-up *Workflow 2* calculation, one can notice that only the V_{gs} voltage points added to the original gate voltage range of *Section 1* have been calculated. It means that the `IVCharacteristics` study object automatically performs a check of which values of V_{gs} have been already considered, and run calculations only for the remaining values of V_{gs}.

It is important that:

- The output / results (hdf5) file obtained in *Section 1* is located in the same folder as the `soi_device_results.py` file,
- And the new output / results (hdf5) file for the *Workflow 2* calculation has the same filename as that used for the *Workflow 1* calculation in *Section 1*. In the present example, keep the *Results file* filename as *soi_device_results.hdf5*.

Note: The range of the gate-source voltage values and number of voltage points have been chosen such that the gate-source voltage values in the range of $-0.3\text{V} \leq V_{gs} \leq 0.0\text{V}$ are the same as those used in the section *Section 1*. This ensures that the study object will not repeat any calculation in that gate-source voltage range.

2B. Use scripting to add data points to the *IVCharacteristics* study object

There exists another option to instruct the `IVCharacteristics` study object to do calculations for additional values of V_{gs}. That can be done through Python scripting by adding the required voltage values by directly modifying the script, e.g., if the original workflow is missing or one cannot run the **QuantumATK NanoLab GUI** for some reason.

Note: An extensive list of all the commands available to interact with the IVCharacteristics study object is available in the `IVCharacteristics` entry of the reference manual.

To do this, click on (or right-click to open with) the script `soi_device_results.py` in the **Data View** window (or just open this script in some text editor) to open it the **Editor**. Add the line highlighted in yellow in the *IVCharacteristics* block.

```
iv_characteristics = IVCharacteristics(
    configuration=soi_device,
    filename='soi_device_results.hdf5',
```

(continues on next page)

(continued from previous page)

```
    object_id='ivc',
    gate_regions=None,
    gate_source_voltages=numpy.linspace(-0.3, 0.0, 7)*Volt,
    drain_source_voltages=numpy.linspace(0.05, 0.05, 1)*Volt,
    gate_potential_alignment=gate_potential_alignment,
    energies=None,
    kpoints=kpoints,
    kpoints_weights=None,
    self_energy_calculator=self_energy_calculator,
    energy_zero_parameter=AverageFermiLevel,
    infinitesimal=1e-06*eV,
    log_filename_prefix='iv_characteristics_',
    number_of_processes_per_task=ProcessesPerNode,
    device_transmission_method=device_transmission_method,
    enforce_zero_transmission_in_band_gap=True,
    source_electrode=Left,
    max_initial_state_configurations=3
)
iv_characteristics.addVoltages(gate_source_voltages=numpy.linspace(-0.9, -0.35, 12)*Volt)
iv_characteristics.update()
```

To run the device calculation, send the script to the **Job manager** using the button, save it as `soi_device_ivc_through_scripting.py`, and press the button in the **Job manager**, if needed. The calculation will take about 5 minutes on 40 MPI processes. You can also download the full script at `soi_device_ivc_through_scripting.py`.

Note: In general, we recommend to save *Workflows* and use them in the **Workflow Builder**, as described in *Introduction to the Workflow Builder*. This allows for a higher flexibility in adjusting simulation settings and the simulation workflow itself, e.g., by adding new or removing old workflow steps through the **QuantumATK NanoLab GUI** in a simpler manner than in a script.

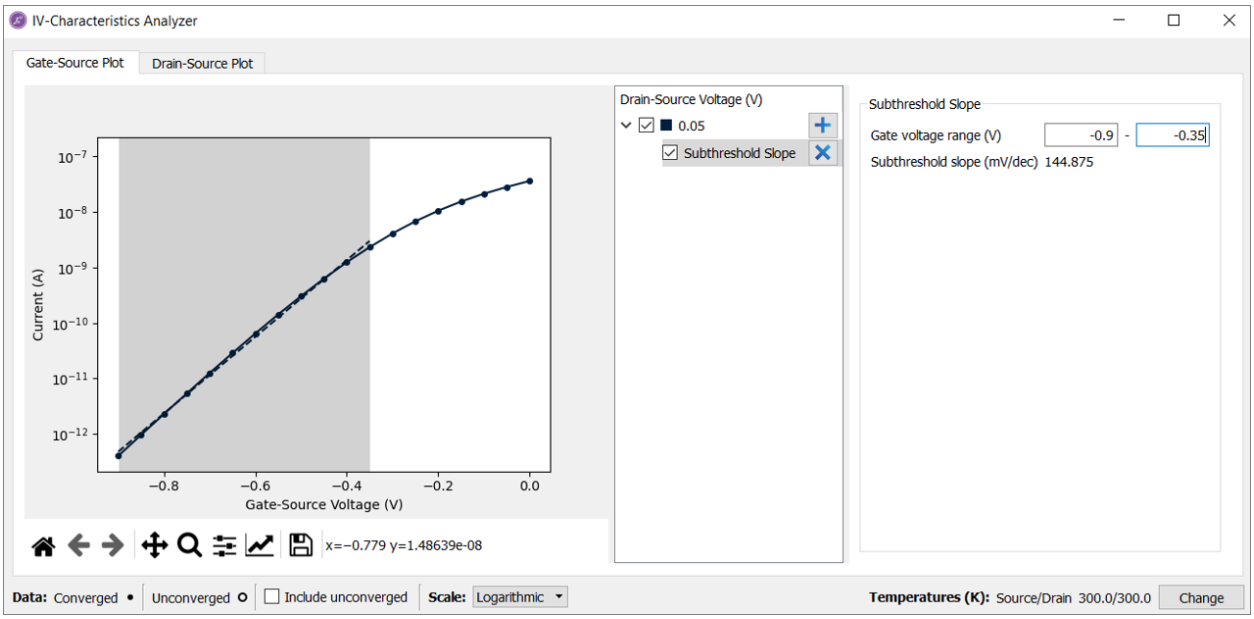
Analysis of the $\mathrm{I_{ds}} - \mathrm{V_{gs}}$ curve in the subthreshold region

Once the device calculations are done, you are ready to analyze the characteristics of the device and extract the subthreshold slope SS, using the appropriate set of data, which includes the subthreshold region / FET off-state.

Similarly to the discussion in *Section 1*, click on (or right-click to open with) the *IVCharacteristics* object $I\left(V_g, V\right)$ contained in the file `soi_device_results.hdf5` present in the **Data view** window to open the *IV-Characteristics Analyzer* widget.

This time, the *IV-Characteristics Analyzer* will show an $\mathrm{I_{ds}} - \mathrm{V_{gs}}$ curve exhibiting a virtually linear behavior with respect to $\mathrm{V_{gs}}$ in the gate voltage range of $-0.9\mathrm{V} \leq \mathrm{V_{gs}} \leq -0.35\mathrm{V}$. This indicates that this range of $\mathrm{V_{gs}}$ corresponds to the subthreshold region / FET off-state. Approximating the $\mathrm{I_{ds}} - \mathrm{V_{gs}}$ curve with a linear fit allows for extracting the subthreshold slope SS.

Click on the + button in the **Drain-Source Voltage** section at the center of the panel and select the *Subthreshold Slope* option from the available options in the drop-down menu. Adjust the *Gate voltage range* in the *Subthreshold Slope* panel to include only the subthreshold region by setting it from $-0.9\mathrm{V}$ to $-0.35\mathrm{V}$, as shown in the following figure.



The calculated value of the subthreshold slope is now $\mathrm{SS} = 145\ \mathrm{meV/dec}$, being of the same order of magnitude as a measured value of $\mathrm{SS}^{\mathrm{exp}} = 95\ \mathrm{meV/dec}$[3]. The discrepancy is related to a simplified model for the SOI FET device adopted in this tutorial for the sake of basic workflow demonstration.

Calculating the drain-induced barrier lowering

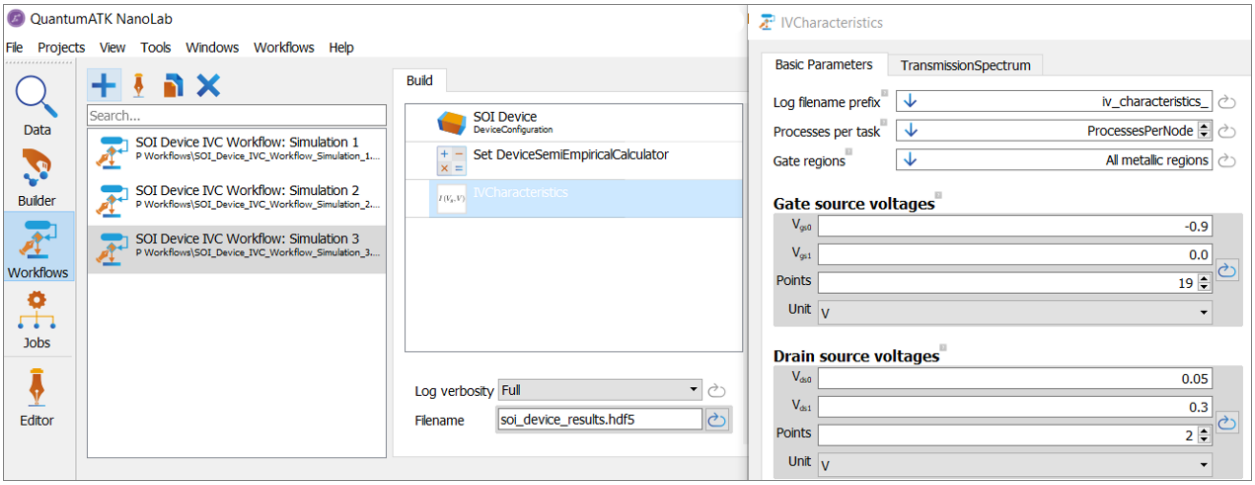
To calculate the drain-induced barrier lowering (DIBL), one needs to obtain a second $\mathrm{I_{ds}}\ vs.\mathrm{V_{gs}}$ curve at a somewhat higher value of the source-drain bias voltage, $\mathrm{V_{ds}} = 0.3\mathrm{V}$, for example.

To extend the range of the source-drain voltage values in the study object, one can select the *SOI Device IVC Workflow: Simulation 2* (described in *Section 2A*) and copy it with the *Duplicate* button, and rename it to the *SOI Device IVC Workflow: Simulation 3* in the **Workflow Builder** window to then modify the **Drain-source voltage range** settings in the `IVCharacteristics` study object as follows:

- Set the upper limit of the drain-source voltage range to $\mathrm{V_{ds1}} = 0.3\mathrm{V}$,
- Set the number of points to 2.

Note: For the sake of comparison, the predefined *SOI Device IVC Workflow: Simulation 3* is enclosed to this tutorial and can be downloaded at `Workflow 3`.

[3] Shinji Migita, Yukinori Morita, Meishoku Masahara, and Hiroyuki Ota. Electrical performances of junctionless-FETs at the scaling limit (LCH=3nm). *Proceedings of the Electron Device Meeting (IEDM) 2012*, 2012. URL: http://ieeexplore.ieee.org/document/6479006, doi:10.1109/IEDM.2012.6479006.



To do the *Workflow 3* for the extended gate voltage range, send *SOI Device IVC Workflow: Simulation 3* to the **Job manager** using the button, save it as `soi_device_results.py` and press the button to run the corresponding job, if needed. The calculation will take about 10 minutes using 40 MPI processes.

It is important that:

- The output / results (hdf5) file obtained in *Section 2A* is located in the same folder as the `soi_device_results.py` file,
- And the new output / results (hdf5) file for the *Workflow 2* calculation has the same filename as that used for the *Workflow 1* calculation in *Section 2A*. In the present example, keep the *Results file* filename as *soi_device_results.hdf5*.

Note: By inspecting the log file, you will notice how, thanks to the smart handling of pre-existing calculations, the **IV Characteristics** object has calculated only the curve at $\mathrm{V_{ds}} = 0.3\mathrm{V}$, using the points calculated at $\mathrm{V_{ds}} = 0.05\mathrm{V}$ as initial states until there are $\mathrm{V_{ds}} = 0.3\mathrm{V}$ points available.

When the calculation is done, select the $I\left(V_g, V\right)$ *IVCharacteristics* object contained in the file `soi_device_results.hdf5` in the **Workflow Builder** window, and click on the *IV-Characteristics Analyzer* plugin in the right-hand side of the **Quantum ATK NanoLab GUI window**. The *IV-Characteristics Analyzer* plugin will now show also the two additional curves calculated at $\mathrm{V_{ds}} = 0.3\mathrm{V}$, in addition to that previously calculated at a lower bias voltage of $\mathrm{V_{ds}} = 0.05\mathrm{V}$, as shown in the following figure.

To calculate the DIBL parameter, click on the button next to the *Additional Analysis* option in the *Drain-Source Voltage* section at the center of the panel, and select *Drain Induced Barrier Lowering* from the drop-down menu. The calculated value of DIBL will be shown in the **Drain Induced Barrier Lowering** section, as shown in the figure below.

Note: Notice that the DIBL value of 0.589 is given as unitless quantity, which corresponds to $589\ \mathrm{mV/V}$ as often reported in literature.

There are a number of parameters that can be tuned in the **Drain Induced Barrier Lowering** panel to tune the calculation of the DIBL. In particular, it is worth mentioning that:

- The *Threshold current*, which is the value of the current corresponding to a value of V_{gs} equal to the threshold voltage, is set by default at the mid-point between the maximum and the minimum values of the current I_{ds}, but can be modified by the user.
- The *Subthreshold factor* determines the current range used to fit the subthreshold characteristics of the device to accurately determine the threshold voltage. A range containing at least 3 points is then requested. If not enough points are included, the DIBL will not be calculated and an error message will be shown instead.
- The *Gate voltage range* can be modified to include only that part of the curve for which the DIBL should be calculated. This can be important for device models showing bipolar characteristics, where one has two subthreshold regions.

Warning: The value of the DIBL calculated for the FET device considered in the present tutorial is significantly larger than that measured experimentally. This can be ascribed to the high sensitivity of the DIBL parameter value to the doping profile and the geometrical characteristics of the device. For a FET device with an ultra-short metal gate length, one can expect the DIBL parameter value between 0.1 and 1, as obtained in the present example.

3.2.16 Formation energies and transition levels of charged defects

Version: O-2018.06

Downloads & Links

`bulk-diamond.py` `bulk-boron.py` `boron_in_diamond.py` *`ChargedPointDefect`*

In this tutorial you will learn how to calculate the formation energies of neutral and charged point defects, and the transition levels between stable charge states for a given defect centre. Specifically, we will work with the substitution of boron in diamond. We will use the **ChargedPointDefect** study object, to set up and analyze the calculations.

If you are unfamiliar with this topic, you might also want to consult the introductory tutorial on formation energies, which focuses on bulk systems and neutral defects: *Calculation of Formation Energies*.

Note: The **ChargedPointDefect** study object was introduced in the O-2018.06 release, and is the recommended way of studying charged point defects in QuantumATK. Users of previous versions can still do the calculations and analysis in a more complex, and manual, workflow, as described here: *Formation energies of charged defects - manual workflow*

Procedure for calculating the formation energy

The formation energy E^f of a defect X is defined as the energy difference between the investigated system and the components in their reference states. This is analogous to the formation energy of a bulk material, but for charged defects it is less clear how to choose the reference states. Here we follow the procedure outlined in the review by C. Freysoldt *et al.*[1], originally formualted by Zhang and Nrthrup[2]:

$$E^f[X^q] = E_{tot}[X^q] - E_{tot}[bulk] - \sum_i n_i\mu_i + q\left(E_{VBM} + \mu_e\right) + E_{corr}.$$

$E_{tot}[X^q]$ is the total energy of the host crystal with the defect with charge q, which is given in units of the elementary charge ($e > 0$), $E_{tot}[bulk]$ is the total energy of the same cell of crystal without the defect, and $n_i\mu_i$ is the reference energy of n_i added, or substracted with a change of sign, atoms of element i at chemical potential μ_i. The term in parenthesis accounts for the chemical potential of the electron(s) involved in charging the defect. E_{VBM} is the valence band maximum as given by the QuantumATK band structure calculation for the bulk material of the study (diamond in this tutorial), and μ_e is the electron chemical potential defined here with respect to the top of the corresponding valence band. The μ_e parameter can then be treated as a free parameter, allowing to account for a shift of the Fermi level, e.g., due to doping. Note that $\mu_e = E_{gap}/2$ corresponds to the undoped semiconductor case, where E_{gap} is the intrinsic semiconductor band gap. Finally, E_{corr} is a sum of relevant correction terms. In our case, it corrects for electrostatic interactions between periodic images of the charged defects and the shift in the electronic bands from the introduction of the defect, using the scheme of Freysoldt et al.[3]. Due to the long-ranged nature of the Coulomb interaction, it can be quite difficult to work with systems that are large enough not to need this correction. The **ChargedPointDefect** study object allows you to scale the system in an easy way, and see how the formation energy converges with system size. More details of the correction scheme can be found in the *Appendix*.

In order to calculate the formation energy, we need to compute each of the terms outlined above. The total workflow is listed below:

•Select the compound and defect to be investigated, and the computational model to be used (exchange-correlation, pseudopotentials, etc.).

•Relax the pristine bulk system using the chosen computational model.

•Determine the chemical potential of the elements in the defect. In this case we use the total energy of the bulk for the element added substitutionally.

•Setup the undefected supercell to calculate $E_{tot}[bulk]$ and E_{VBM}.

•Introduce the (charged) defect and relax the system to obtain $E_{tot}[X^q]$.

•Calculate the correction terms in E_{corr} and finally the formation energy.

The latter three, and most complicated items, will be handled by the study object. These three items must also be repeated for each supercell size, and the latter two also for each charge state. In comparison, the first three items must only be done once.

[3] Christoph Freysoldt, Jörg Neugebauer, and ChrisăG. Van De Walle. Fully Ab Initio finite-size corrections for charged-defect supercell calculations. *Phys. Rev. Lett.*, 102:016402, 2009. doi:10.1103/PhysRevLett.102.016402.

Setting up the calculation

Initial calculations - optimized bulk diamond, dielectric constant and boron chemical potential

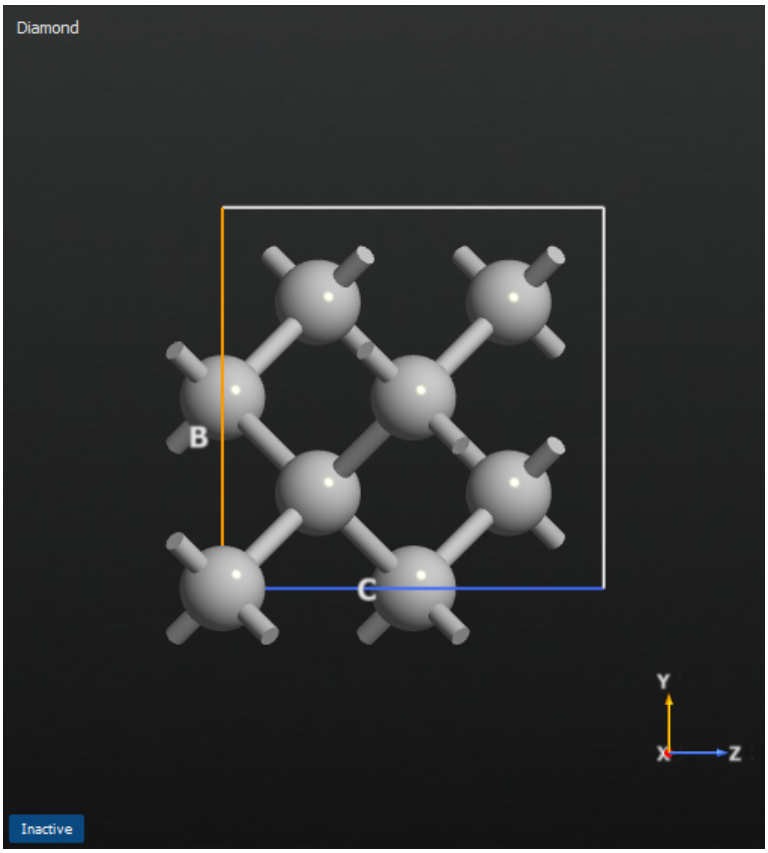
We first need to do some small initial calculations, to generate the input structure and the parameters required for the calculation of the formation energies, including corrections:

•Optimized structure of diamond

•Dielectric constant of diamond

•Chemical potential of boron atoms, from bulk boron

In order to make the interpetration easier when analyzing the results, we will use the cubic/conventional form of the unit cell of diamond. It can be generated from the primitive cell by using the function: *Bulk Tools* → *Supercell* tool in the Builder.



We will do the first two calculations in the same script. Set up a script to optimize the geometry of diamond and then calculate the optical spectrum. Use the following changes from default in the script for diamond:

•**New calculator**: k-point density of 4 Å.

•**Optimize geometry**: Untick *Constrain lattice vectors* and fix fractional coordinates.

•**Optical Spectrum**: k-point density of 12 Å and 100 bands above and below the Fermi level.

For boron, set up a script to optimize the geometry and calculate the total energy. Make the following changes from default values:

•**New Calculator**: k-point density of 4 Å and a density mesh cutoff of 55 Ha.

•**Optimize geometry**: Untick *Constrain lattice vectors* and fix fractional coordinates.

As the focus of this tutorial is on the **ChargedPointDefect** study object, you can save time and download the scripts for the preliminary calculations here: `bulk-diamond.py` and `bulk-boron.py`. However, if you are unsure of how to do these basic calculations, please see the appropriate tutorials to familiarise yourself with the concepts.

Tip: If you need more guidance on how to set up these calculations, please see these tutorials:

- *Geometry optimization: CO/Pd(100)*
- *Optical Properties of Silicon*
- *Molecular builder*

Extracting initial parameters

We get the dielectric constant from the OpticalSpectrum analysis object. Open the **OpticalSpectrum** object $\epsilon_{i,j}(\hbar\omega)$ on the LabFloor in Text Representation, and copy the dielectric function value for the xx-component at zero energy. It should be approximately 6.3.

In this tutorial, we will use bulk boron as the energetic reference for the substitutional boron atom. This means that the chemical potential for boron is the total energy per atom of bulk boron. Open the **TotalEnergy** object E_{Total} on the LabFloor in *Text Representation*, copy the energy value and divide it by 12. The result should be approximately -80.0 eV.

The ChargedPointDefect study object

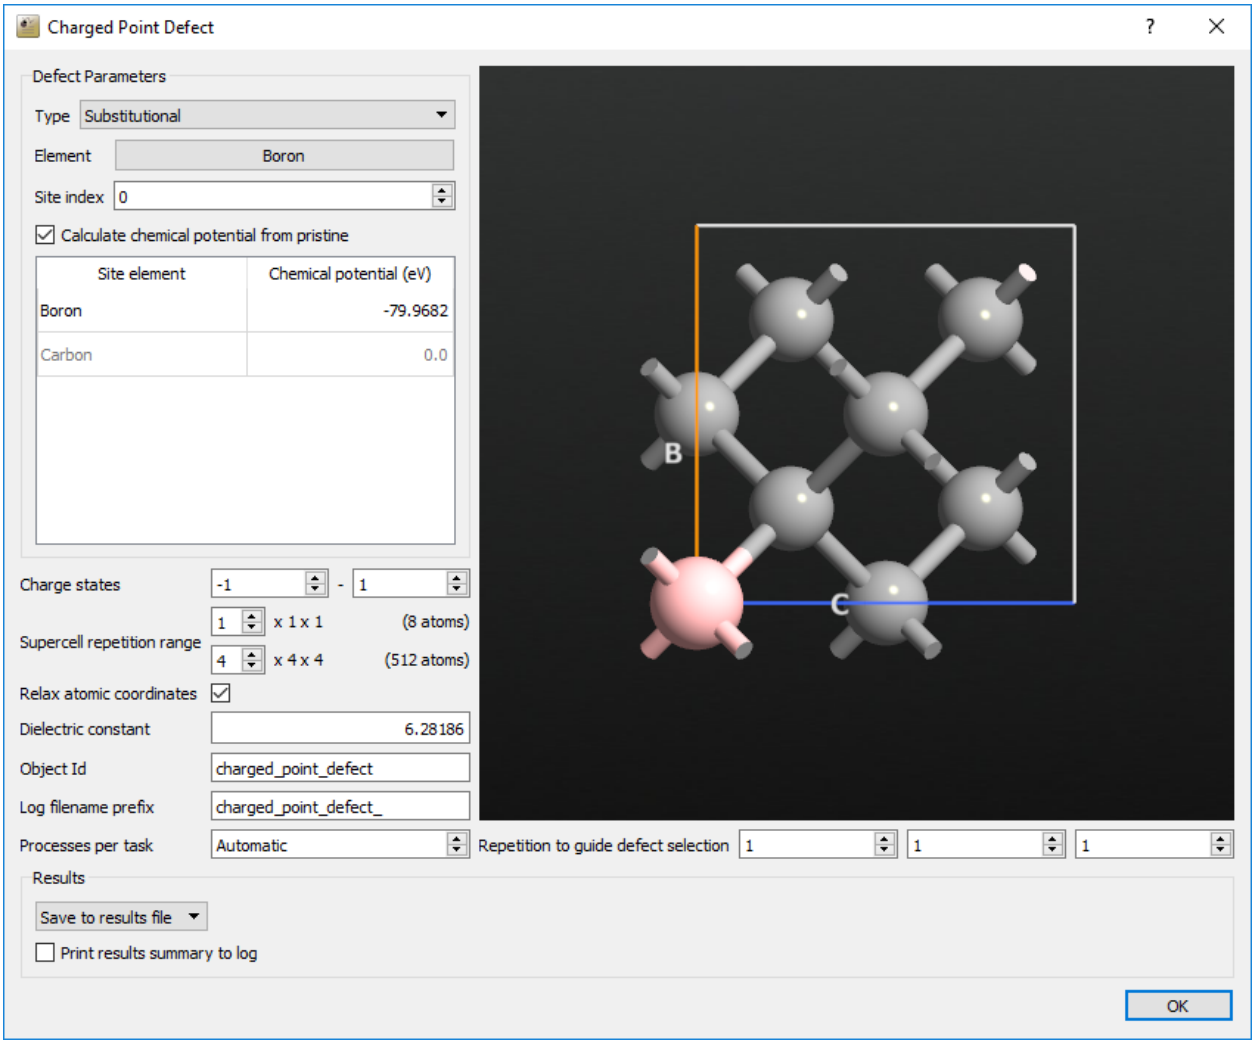
We will now set up the full calculation of the `ChargedPointDefect` study object. Drag the optimized structure onto the **Builder** and send it on to the **Script Generator**. Add a **New Calculator** and a **ChargedPointDefect** study object.

The calculator should be set up with the same parameters as used for the geometry optimization of bulk diamond in the previous section. We are now ready to set up the study object:

- Change **Type** from *Vacancy* to *Substitutional*.
- Change **Element** from *Indium* to *Boron*.
- Type in the desired value of the **chemical potential** for boron, which is *-79.96822167 eV* in this case.
- Change **Charge states** to *-1* as the lower bound and *+1* as the higher bound.
- Change the upper limit of **Supercell repetition range** to *4x4x4*.
- Change the **Dielectric constant** to *6.28186*.

Warning: For substitutional defects, the **ChargedPointDefect** study object automatically assigns the default pseudopotential and basis set to the substitutional element. In this tutorial, this is what we wish to use, and therefore no additional steps are needed. However, if you wish to use a non-default basis set, you should manually add it to the calculator, either in the Script Generator or in the script.

The window should now look like this:



Save the script and run it on your desired cluster. In our case, it took about 13 hours to run on a total of 32 cores. If you encounter any problems, you can compare your script against the one we have provided here: `boron_in_diamond.py`

Warning: From the P-2019.03 release the **ChargedPointDefect** study object was moved to the SMW package. In order to run `boron_in_diamond.py` with this version it is therefore necessary to add

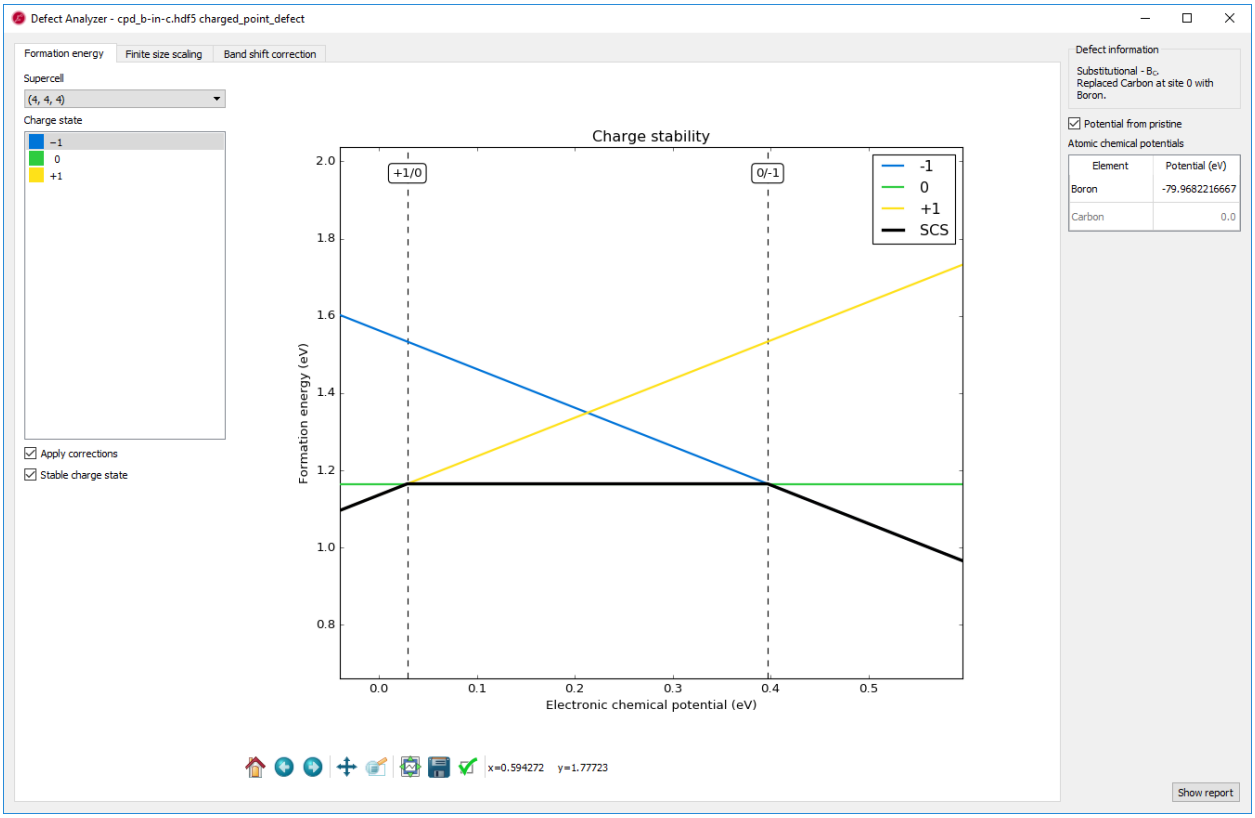
```
from SMW import *
```

at the top of the script.

Tip: The study objects contain automatic restart functionality. If the script does not complete for some reason, simply run it again. It will automatically read the status from the `.hdf5`-file, and set about completing the remaining tasks.

Analyzing the results

We are now ready to analyze the results of our calculations. Select the **ChargedPointDefect** object on the $E_f^q(\Delta\mu_e)$ LabFloor. In the right-hand list, open the **Defect Analyzer**. You should now see a window looking like this:

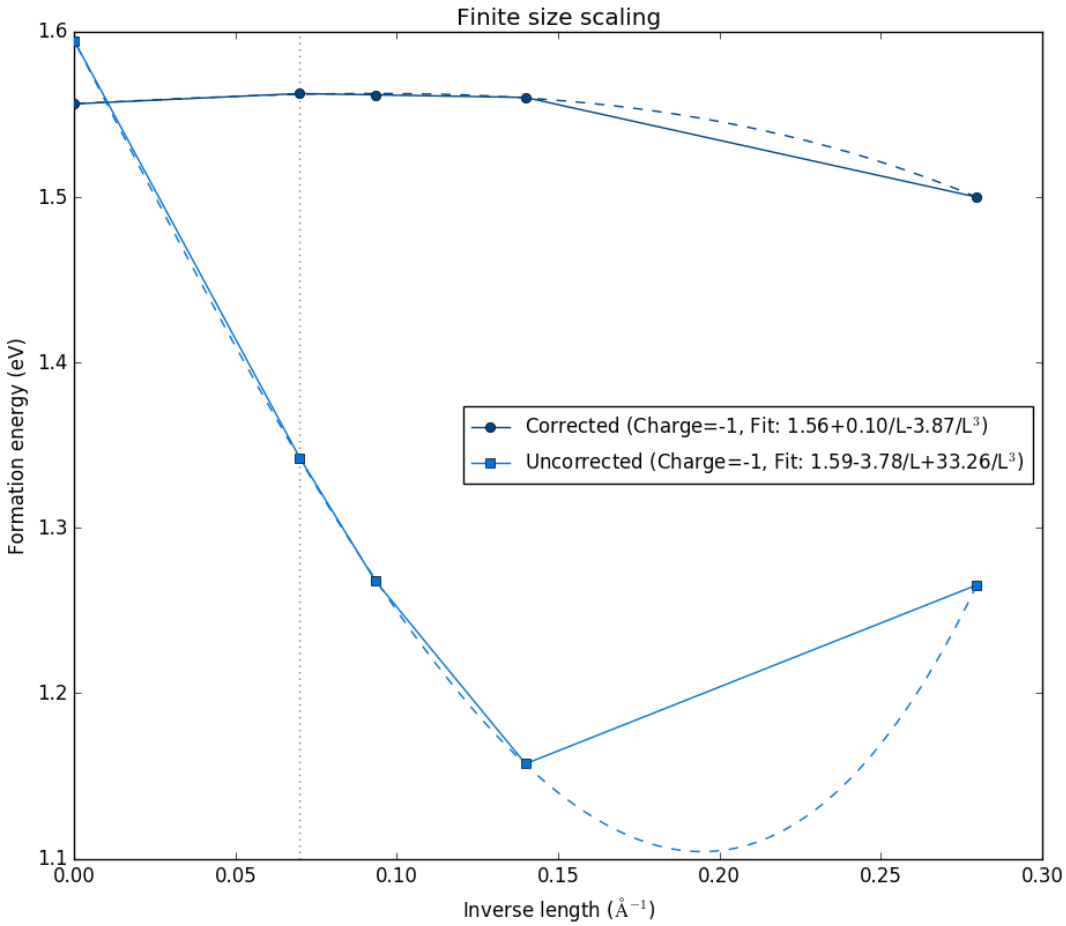


This is the formation energy for each charge state of the defect, as a function of the chemical potential of the electrons, relative to the valence band maximum. The colored lines each represent a charge state, the solid black line shows the most stable charge state at a given electronic chemical potential, and the dotted lines show the transitions between different charge states. In this case, the +1 state is stable only for very low values of the electron chemical potential, while the neutral state is most stable up to about 0.4 eV. If the electronic chemical potential is higher than that, the -1 charge state is most stable.

On the left, you can choose which supercell to base the plot on, including the extrapolation to infinity, and which charge state to highlight. You can also choose whether or not to include the corrections and whether the black line should be shown or not. On the right, you can change the chemical potentials of the elements.

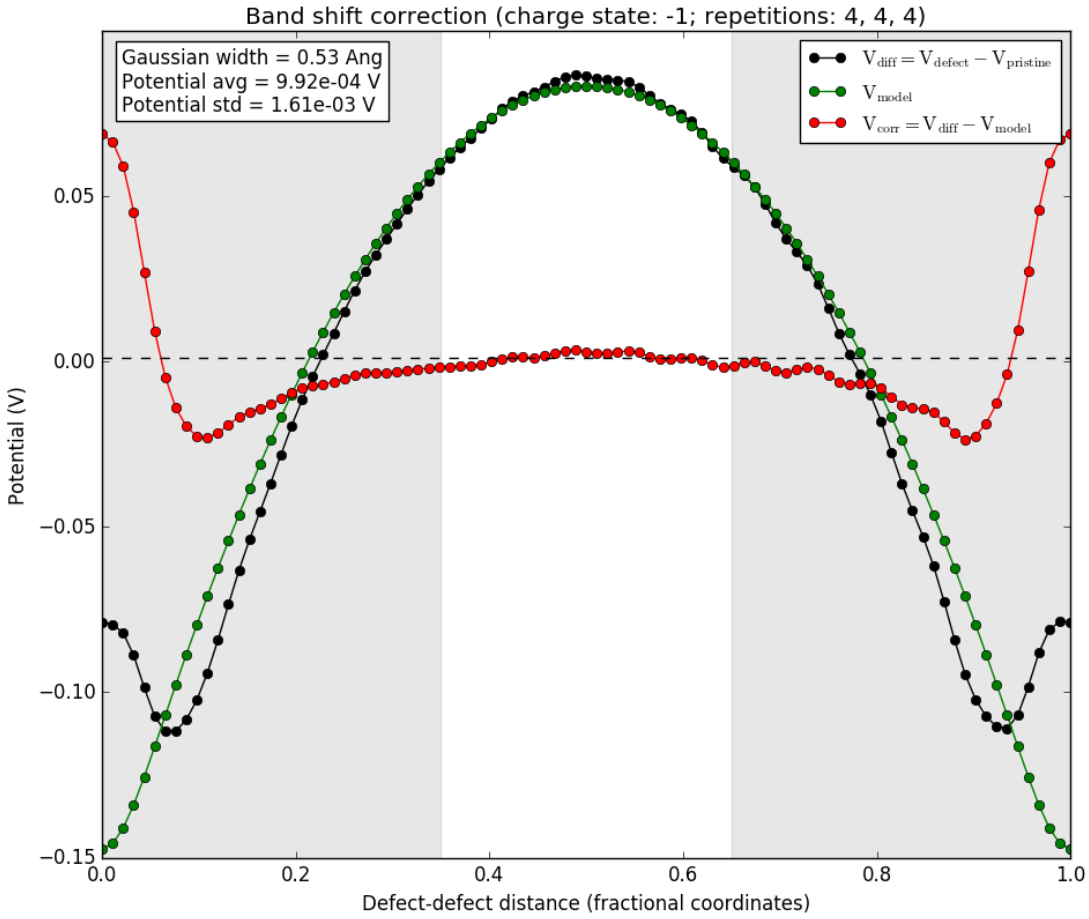
Charge state -1

We will now look more closely at each of the charge states, starting with the -1 state. Click on the tab titled **Finite size scaling**. The main panel in the window should now look like this:



The figure shows the formation energy as a function of the inverse length of the supercell, defined as the the cubic root of the volume. It shows both with the correction terms (dark blue), and without corrections (light blue). In both cases, they are extrapolated to infinite supercell size, with the fits shown as dashed lines. Notice how they both converge to approximately the same formation energy value, and how the formation energy values with the corrections included are already converged to the extrapolated value for the second-smallest 2x2x2 supercell. This shows that this charge state is well-localized within the 2x2x2 supercell, and the correction scheme, which mitigates finite-size effects on the charged defect formation energy, is valid for this particular charged defect state.

Next, click on the tab titled **Band shift correction**. The window should now look like this:



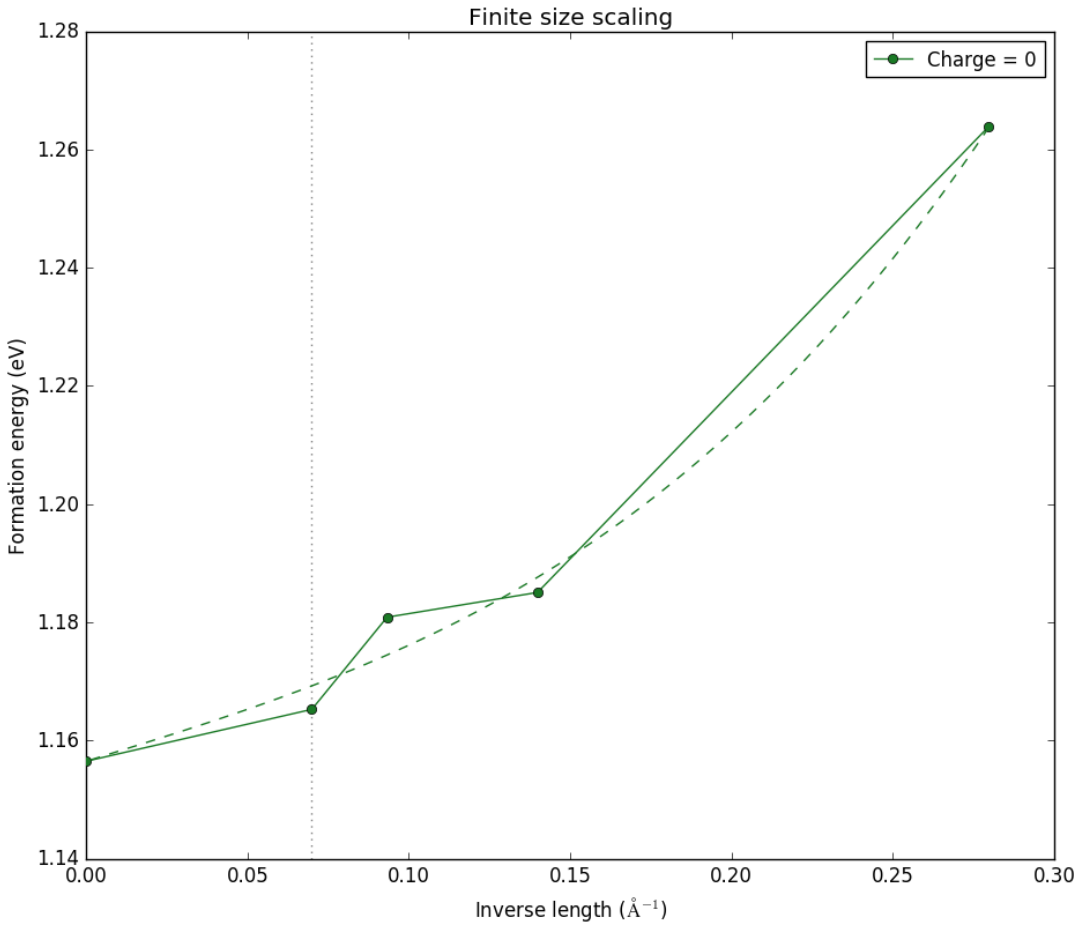
The black line is the difference between the potentials of the supercell with the defect and the pristine supercell without the defect. The green line is the potential from a Gaussian model charge placed at the defect position (the origin of the plot), and the red line is the difference between the two. The light area in the middle is the region where the red line is averaged to produce the value of the band shift term of the correction. The red line should be flat in this region for the correction term to be appropriately calculated. If this is not the case, the assumptions of the correction scheme are violated and it does not apply. In this case, however, the defect charge is well-localized and the red line is flat in the region where the bandshift is evaluated.

You may also select the other supercell sizes, and see how the defect charge is well-behaved, even for the 2x2x2 supercell. However, it is not well-localized for the very smallest 1x1x1 supercell, as expected. This supercell is much too small to give sensible results, even with the correction sceheme, and is included here only for comparison.

This behavior is not surprising, as the boron atom has one less (valence) electron than carbon atoms. Therefore, the -1 charge state leads to the boron atom being electronically equivalent to a carbon atom, stabilizing it as a substitutional defect.

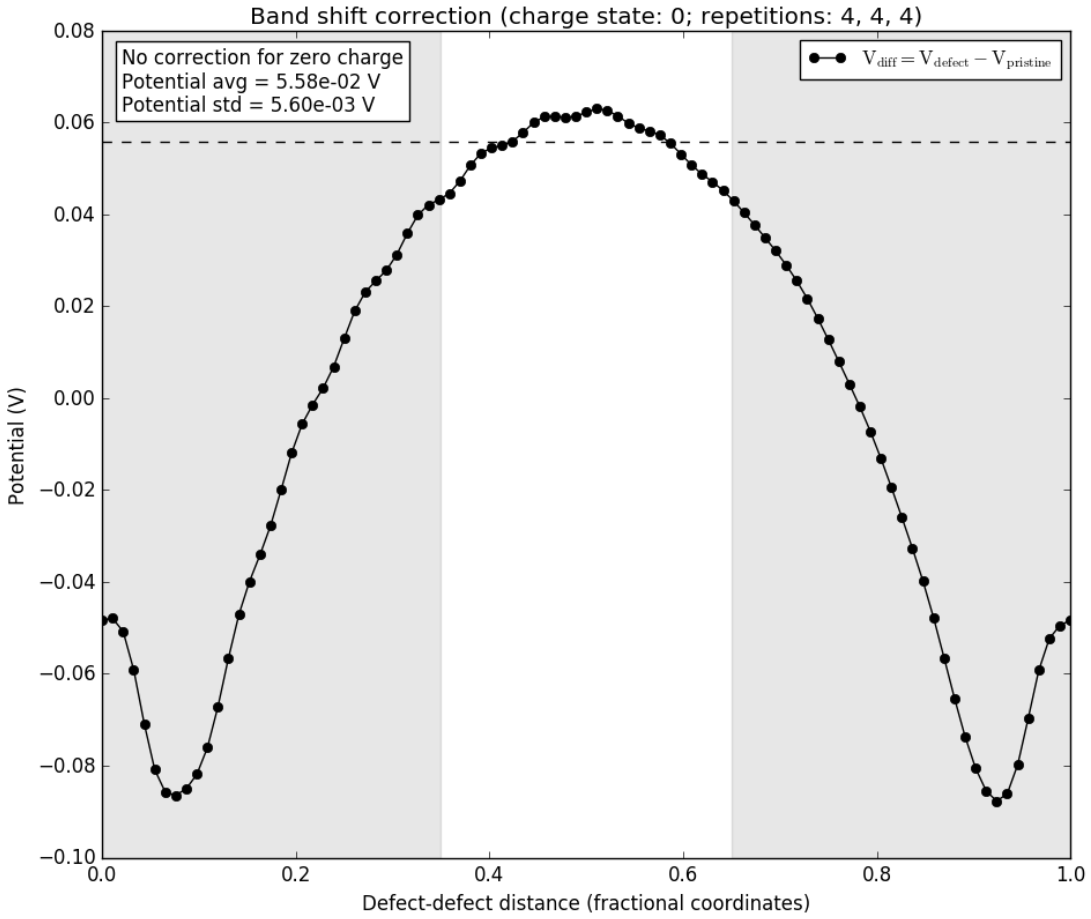
Charge state 0

We now move on to the neutral defect. Go again to the **Finite size scaling** tab, and change the charge state to *0*. Select also the *4x4x4* supercell if you have changed away from that. The window should now look like this:



Note that there is now only one data-set, as the corrections only apply if the system is charged. We see also that the variation in formation energy with size is significantly smaller than before. Here, the total range is about 0.1 eV, compared with 0.4 eV before. This is expected, as the neutral defect has no explicit charge that can suffer from finite-size effects. However, there can still be, e.g., elastic interactions between the defects, and it is therefore expected to see some size dependence, as we do here.

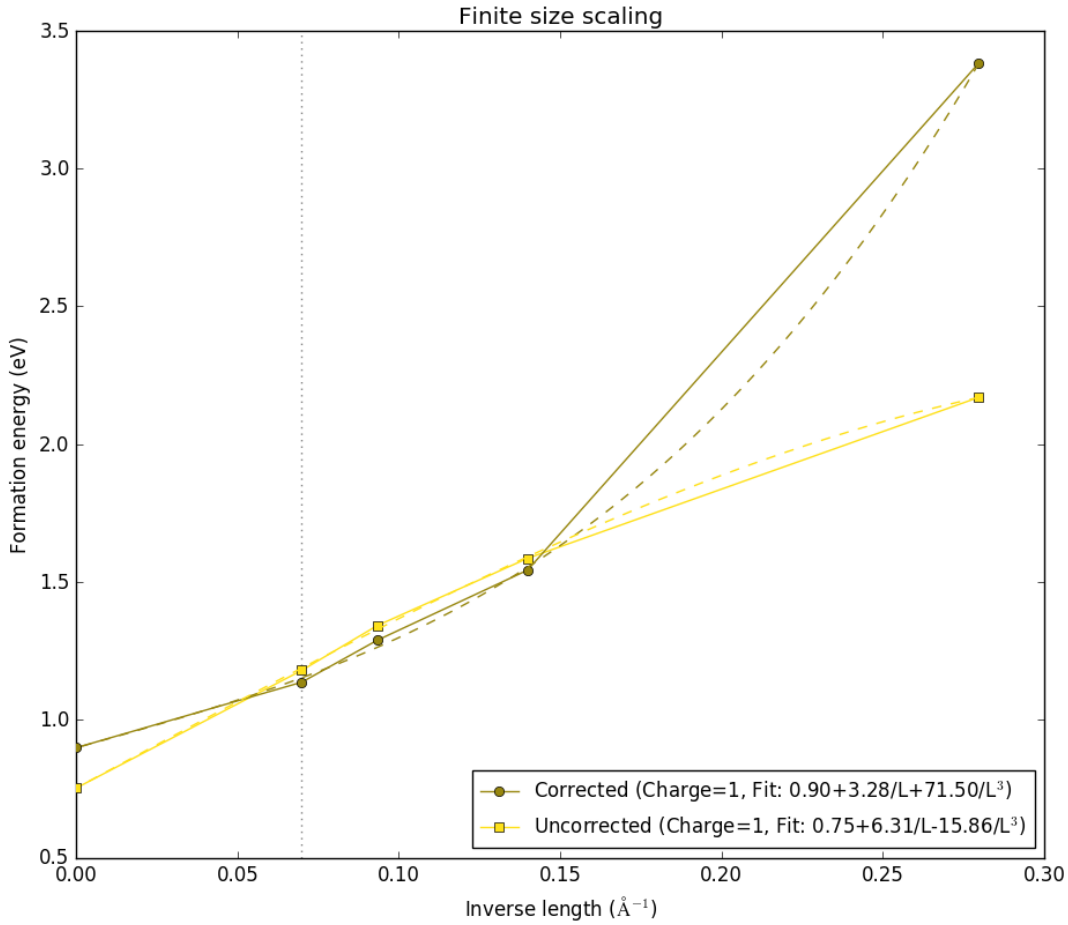
For completeness, we will take a short look at the **Band shift correction** tab. Click it, and the window should now look like this:



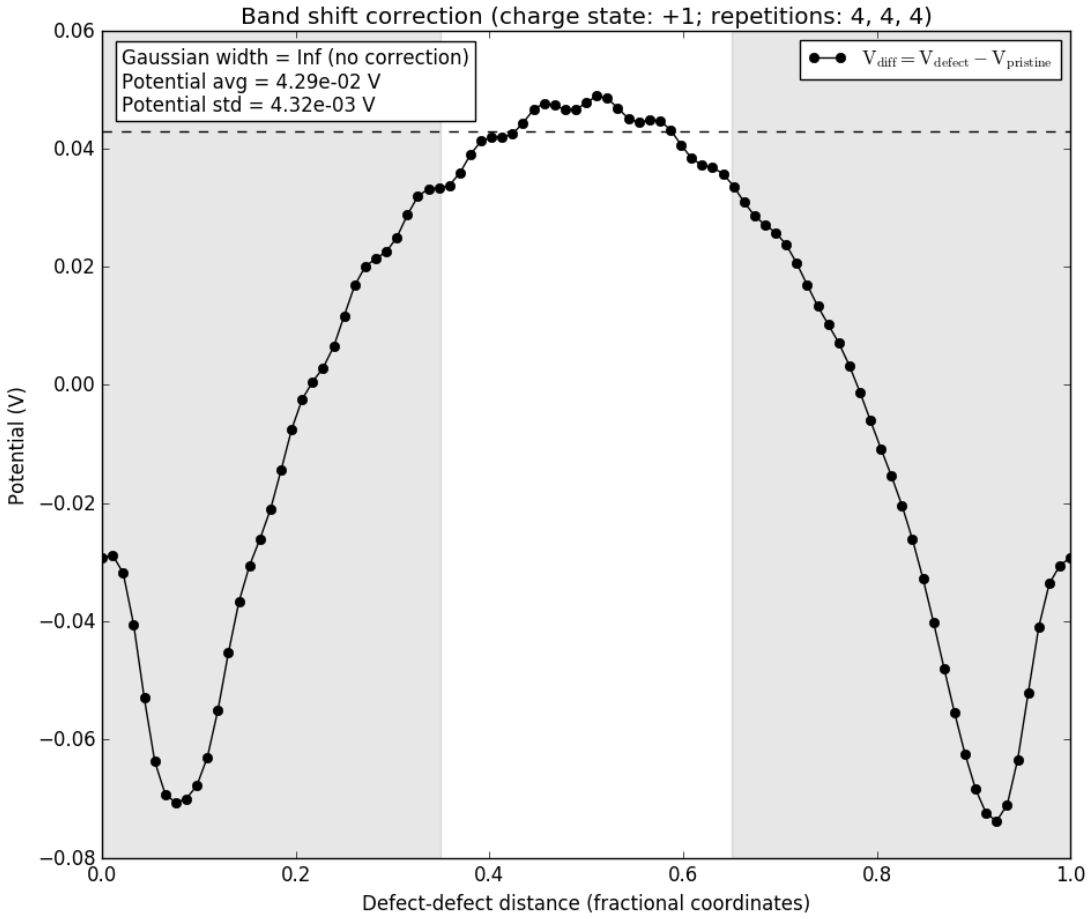
Only the black line is present as there is no charge to model, and hence no difference to investigate. Note also the box in the upper left, which informs that there is no correction for the neutral defect.

Charge state +1

Finally, we turn our attention to the +1 charge state. Select again the **Finite size scaling** tab, and change the charge state to *+1*. Select also the *4x4x4* supercell if you have changed away from that. The window should now look like this:



In this case it is very hard to see at first glance which data-set is the raw data and which includes the corrections, in contrast to what we saw for the -1 charge state. They still seem to converge to approximately the same value, but the corrections do not really add any useful information in this case. This indicates either a defect that cannot be modelled using the correction scheme, or a defect that is simply unphysical. In both cases, it will often be a delocalized charge. In order to look further at this charge state, select the tab **Band shift correction** again. The window should now look like this:



Note the box in the upper left again. We see that the Gaussian width is described as infinite, and no corrections are therefore applied, as they require a finite width of the charge distribution.

In this case, the best approach is to use as large a supercell as possible, removing the need for corrections and the accompanying approximations and assumptions.

Discussion and summary

Boron is a p-type dopant in group-IV semiconductors such as diamond. As mentioned above, this is because boron has one less valence electron than carbon, and so its effect as a substitutional defect in the diamond lattice is to add an effective positive charge (i.e., a hole) to the crystal. This also makes boron an acceptor dopant, as it will attract an electron from the crystal to completely fill its covalent bonds with its neighbours in the lattice.

When the neutral boron dopant captures an electron it becomes ionized. The ionization energy is readily measured experimentally, and corresponds to the stable-charge transition level between the 0 and -1 charge states shown in the main plot of the Defect Analyzer. The experimental value is 0.37 eV[4], in good agreement with our calculated value of 0.4 eV.

The +1 charge state, instead, is not experimentally relevant; this is again confirmed by our results, which show it to be

[4] Klaus Thonke. The boron acceptor in diamond. *Semiconductor Science and Technology*, 18(3):S20, 2003. URL: http://stacks.iop.org/0268-1242/18/i=3/a=303.

almost completely absent as a stable charge state within the band gap, as the transition level between +1 and 0 is close to the valence band maximum.

In this tutorial, we have used the **ChargedPointDefect** study object to set up and analyze a calculation of the formation energies for various charge states of boron substitution in diamond. QuantumATK includes a correction scheme that can mitigate the errors due to periodic interaction between the defects in finite supercells, if the defect is well-localized. In general, and especially if the defect charge is not well-localized, charged defects are best studied with larger supercells, and we have seen how the convergence with respect to size can be studied.

Appendix

The periodic correction scheme

As already mentioned, we use the correction scheme proposed by Freysoldt *et al.*[Page 675, 3] to correct for the electrostatic interaction between the periodic images of the charges and the band shift caused by introduction of the defect. This correction contains two terms:

$$E_{corr} = E_{lat} - q\Delta V_{q/b},$$

where E_{lat} corrects for the interaction between the periodic images of the charge and $q\Delta V_{q/b}$ corrects for the band shift. E_{lat} is calculated by considering the electrostatics of a model charge distribution, which is fitted to the actual calculation by the study object, and comparing the potential in the periodic cell with the potential where the boundary conditions are not periodic:

$$E_{lat} = \int_{\Omega} \left[\frac{1}{2} q(\tilde{V}_q^{lr} - V_q^{lr}) \right] d^3r.$$

V_q^{lr} is the long-range potential of the model charge distribution and $\tilde{V}_q^{lr}$ is the corresponding quantity in the periodic cell and shown in green. $\Delta V_{q/b}$ is calculated from the shift in the electrostatic potential due to introduction of the defect:

$$\Delta V_{q/b} = \tilde{V}_{q/b} - \tilde{V}_q^{lr},$$

where $\tilde{V}_{q/b}$ is the difference between the electrostatic potential in the pristine bulk configuration and with the defect added and shown in black. $\Delta V_{q/b}$ is shown in red, and should be evaluated far from the defect, where it is constant, in order to get the correct offset in the zero-point reference energy . This is shown by the lightly colored region in the plots above.

Note that the obtained difference is defined between two *screened* potentials, see the reference[Page 675, 3]. The dielectric screening is described by the static dielectric constant computed in the preliminary calculations.

3.2.17 Introduction

The papers investigate the accuracy of a range of different *DFT: LCAO* electronic-structure methods in calculations for bulk semiconductors. In particular, we apply GGA and MGGA exchange-correlation functionals, as well as the *Pseudopotential Projector-Shift* method. Some comparisons to *HSE* results are also included.

Both structural and electronic quantities are computed and the different methods are benchmarked against each other. Computational settings such as *k*-point sampling and density mesh cutoff energy are also considered.

Note: Thepapers are continously expanded with more data and more semiconductors.

All calculations are done using the newest updates (August 2016) to the *SG15/PseudoDojo* pseudopotentials and basis sets. The applied exchange-correlation functionals usually include PBE, PBEsol, TB09-MGGA, and PBE augmented with the PPS method. Each combination of pseudopotential, basis set, and exchange-correlation functional constitutes a **computational method**.

The following **structural and electronic quantities** are considered:

•Lattice constant(s)

•Elastic constants

•Band structure

•Band gaps

•Effective masses

•Dielectric constant(s)

Extensive **convergence studies** are conducted for the different computational methods. In particular, the convergence of the lattice constant, bulk total energy and band gap is thoroughly studied with respect to k-point sampling and density mesh cutoff energy.

3.2.18 Methods

The *SG15/PseudoDojo* normconserving pseudopotentials were recently implemented in the *DFT: LCAO* calculator engine. This suite of pseudopotentials was generated using the Optimized Norm-Conserving Vanderbilt (ONCV) method, as described in[1] and[2]. More information is available on the SG15-ONCV website.

As explained in the document *Pseudopotentials and basis sets available in QuantumATK*, three different QuantumATK basis sets are available for each element when using the SG15 pseudopotentials, with increasing accuracy; **Medium**, **High**, and **Ultra**. All three derive from the numerical atom-centered basis sets of the FHI-aims package, but have been significantly modified and optimized with respect to computational speed with the ATK-DFT calculator.

The Medium basis set is default for the SG15 pseudopotentials, and should be sufficient for most applications. However, if extreme accuracy is needed, the High and Ultra basis sets add more basis functions at the expense of increased computational load. The Ultra basis set is exceptionally large, and will usually add only little extra accuracy as compared to the High basis set, but at a fairly high extra computational cost. The Medium and High basis sets will in most cases constitute a better trade-off between computational accuracy and speed, so these are the two SG15 basis sets used in the papers.

HSE

The HSE06 screened hybrid density functional[3] is implemented in the FHI-aims package. The Tier 1 basis set is used with both Light and Tight accuracy settings, here denoted l1 and t1, respectively.

Nomenclature

Each computational method is specified by a combination of exchange-correlation functional, pseudopotential, and basis set. Since this study uses only the SG15 pseudopotentials, this is omitted from the naming of a method. For example, a PBE calculation with the Medium basis set is simply denoted PBE-m. If a calulation with some method was not done at the lattice constant computed with that method, it is indicated in a paranthesis, e.g. PBEsol(PBE)-h for PBEsol-h at the PBE-h lattice constant.

Note: The ATK-DFT density mesh cutoff and *k*-point sampling used in a calculation are not contained in the naming scheme described above. One single choice of mesh cutoff and *k*-point sampling is determined in a convergence study.

Pseudopotential Projector-Shift

The Pseudopotential Projector-Shift (PPS) method for ATK-DFT was introduced with QuantumATK 2017. The method introduces shifts to the angular momentum projector channels used for constructing the pseudopotential, which affects the theoretical predictions obtained with standard exchange-correlation functionals, e.g. band gaps and equilibrium lattice constants. The projector shifts are essentially free parameters, which can be fitted against relevant data and used in ATK-DFT calculations, e.g. to obtain better band gaps with otherwise ordinary PBE.

The projector-shifted pseudopotential, $V_{\mathrm{ps}}(\mathbf{r})$, is written

$$V_{\mathrm{ps}}(\mathbf{r}) = V_{\mathrm{ps}}^{\mathrm{loc}}(\mathbf{r}) + \sum_{\alpha\beta} |\alpha\rangle [V_{\alpha\beta} + U_{\alpha\beta}] \langle\beta|,$$

where $V_{\mathrm{ps}}^{\mathrm{loc}}$ is the local part of the pseudopotential, $V_{\alpha\beta}$ the pseudopotential coupling matrix, and $U_{\alpha\beta}$ the pseudopotential projector-shift matrix. The sum runs over projectors α and β.

All entries in the matrix $U_{\alpha\beta}$ are zero when performing a standard GGA calculation, while the PPS method adds projector shifts along the matrix diagonal. These entries correspond to different angular momentum channels; *s*, *p*, *d*, *f*, etc. Only the *s* and *p* channels are relevant for silicon, which has no *d*-electrons, while both *s*, *p* and *d* are relevant for other elements, e.g. germanium. Choosing the projector shifts to use for a particular exchange-correlation functional is then a matter of fitting the shifts, or manually tuning them.

3.2.19 Silicon

Here we investigate computational methods for ATK-DFT calculations for bulk silicon in the diamond crystal structure. We apply the SG15 pseudopotentials and a number of exchange-correlation functionals; PBE, PBEsol, TB09-MGGA, and PBE. A limited number of HSE calculatios have been done for comparison.

The following **quantities** have been calculated for each computational method, both at the experimental silicon lattice constant and at the theoretically predicted ones:

•Elastic constants: Bulk modulus, Poisson ratio, and Youngs modulus.

•Band structure along the X—L Brillouin zone path.

•Direct and indirect band gaps.

•Effective masses in the valence band maximum and conduction band minimum.

•Static dielectric constant.

Convergence studies indicate that a 9x9x9 k-point grid and a 100 Hartree density mesh cutoff yields a well-converged silicon lattice constant, and these settings were used for computing the silicon ground state electronic structure used in all the ATK-DFT analyses listed above.

The projector shifts used for the **pps-PBE** method are 11.23 eV for *s*-orbitals and -1.09 eV for *p*-orbitals. This yields a single computational method with fairly high accuracy for predicting the fundamental band gap and lattice constant for silicon. Note that these PPS parameters should only be used with SG15 pseudopotentials.

This document is organized as follows. The section *Summary* gives a short summary of the main results from this study, while the section *Convergence* briefly presents the convergence studies mentioned above, and the section *Timing* compares CPU timings and scalability of different SG15 basis sets for silicon. Next, the section *Results* contains figures illustrating the performance of the different computational methods in predicting the materials properties listed above. Finally, the *Appendix* gives a template QuantumATK Python script for setting up ATK-DFT calculations for silicon similar to the ones presented here, and also elaborates on how to calculate hole effective masses using ATK-DFT.

Summary

The following list summarizes the main conclusions from this study.

- The PBEsol and pps-PBE methods both yield very accurate silicon **lattice constants**, but it is hard to say which method is most appropriate for computing elastic constants.
- All tested methods yield a qualitatively correct silicon **band structure**, although the position of the conduction band minimum depends a little on the method used.
- The TB09-MGGA, pps-PBE, and HSE methods accurately reproduce the fundamental (indirect) **band gap** of silicon.
- Electron **effective masses** in the silicon comduction band minimum are quite well captured by all tested methods. However, for hole effective masses in the valence band maximum, including spin-orbit interactions in the DFT calculations is crucial.
- As for the silicon static **dielectric constant**, the TB09-MGGA(PBE) and pps-PBE methods appear very accurate.

Convergence

An optimum combination of Monkhorst–Pack *k*-point grid and density mesh cutoff energy must be chosen such as to maximize computational accuracy while minimizing the computational effort. The two figures below illustrate how the calculated silicon lattice constant depends on these two parameters.

We see from Fig. 3.42 that a 9x9x9 *k*-point grid is in general sufficient to get a well-converged silicon lattice constant: The convergence curves are similar across different combinations of exchange-correlation functionals and SG15 basis sets, and with a 9x9x9 grid and denser, the lattice constant is converged to within roughly 10^{-3} % of the most dense k-point grid tested (19x19x19).

Similarly, Fig. 3.43 shows that a density mesh cutoff energy of 100 Hartree is in general sufficient: The calculated silicon lattice constant is converged to within roughly 10^{-3} % of the most dense density mesh tested (200 Ha cutoff energy).

Note: All remaining ATK-DFT calculations in this study of pure silicon therefore use a 100 Hartree mesh cutoff energy and a 9x9x9 Monkhorst–Pack *k*-point grid.

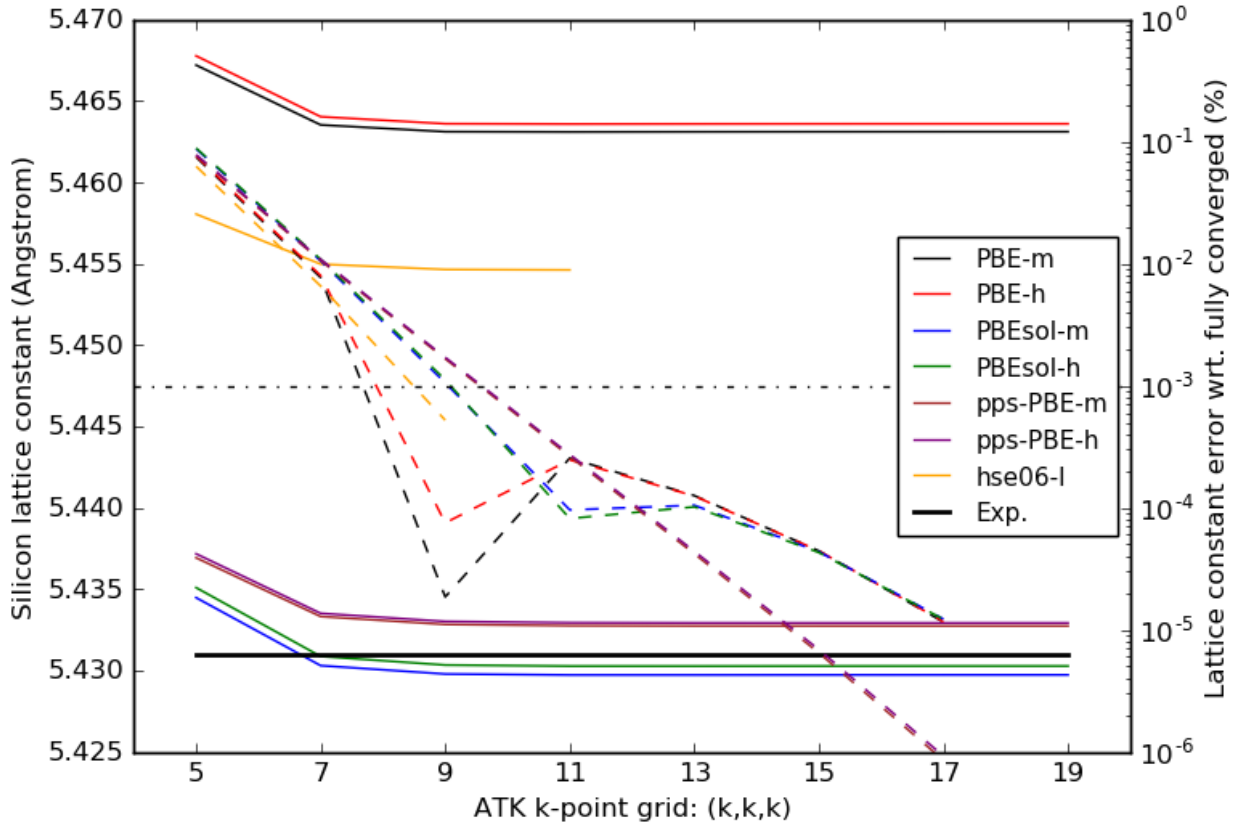

Fig. 3.42: Convergence of the silicon lattice constant with respect to k-point sampling (using Monkhorst-Pack grids). For the QuantumATK calculations the PBE and PBEsol exchange-correlation functionals, and PBE with the pseudopotential projector-shift (pps-PBE) have been used. Both the medium (m) and high (h) SG15 basis sets with 200 Hartree mesh cutoff energy have been used. HSE calculations have been performed using FHI-AIMS and the light basis set. The dashed lines indicate the (absolute) relative difference to the fully converged lattice constant (right-hand y-axis, in percent).

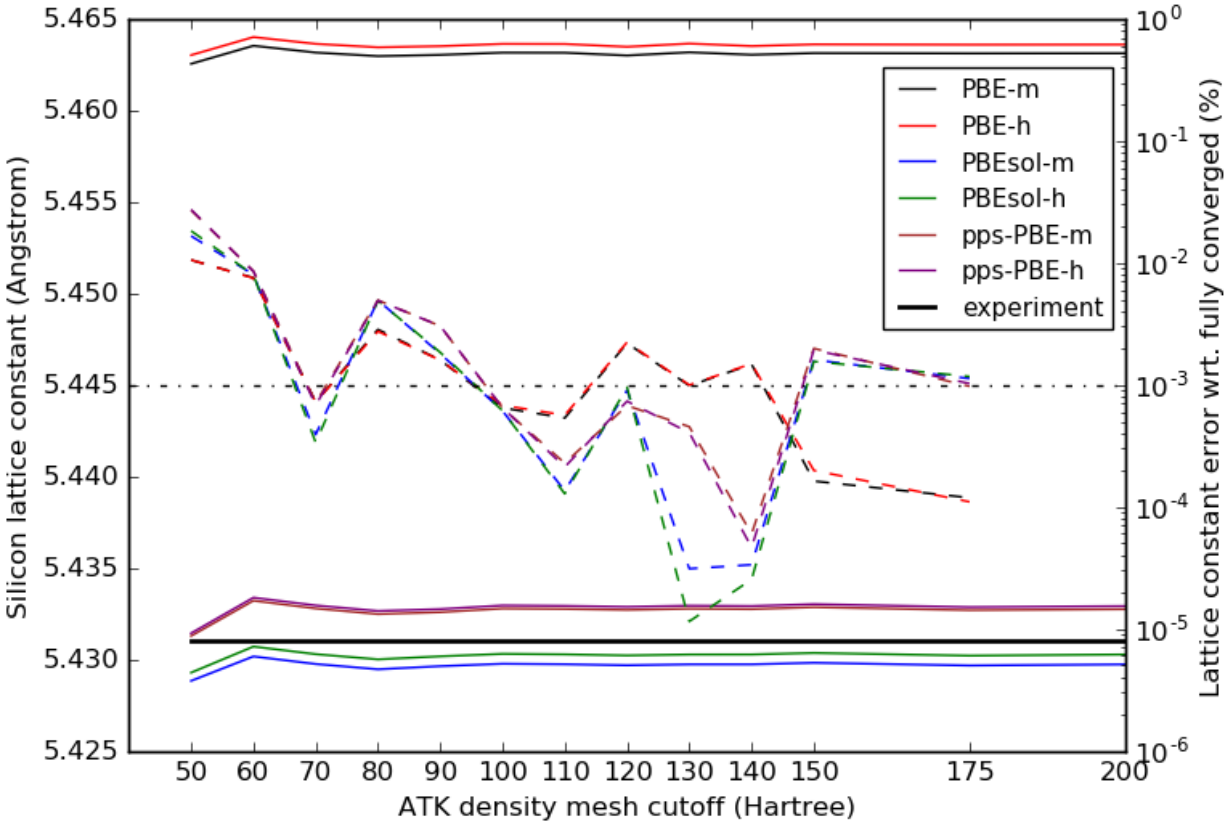

Fig. 3.43: Convergence of the silicon lattice constant with respect to the QuantumATK mesh cutoff energy using the PBE and PBEsol exchange-correlation functionals, and PBE with the pseudopotential projector-shift (pps-PBE), all for both the medium (m) and high (h) SG15 basis sets with a 15x15x15 k-point grid. The dashed lines indicate the (absolute) relative difference to the fully converged lattice constant (right-hand y-axis, in percent).

Timing

The computational cost of a calculation may depend critically on the choice of basis set, particularly for calculations on large systems with many atoms. Fig. 3.44 shown below illustrates this for the present case of silicon and the Medium, High, and Ultra SG15 basis sets.

The silicon primitive cell (containing 2 atoms) was systematically repeated in steps of one along all three lattice vectors, resulting in rapidly increasing systems sizes. PBE calculations were then performed for each system, using -point sampling only, to avoid any influence of k-point sampling on the recorded CPU times.

It is quite clear from the figure that the computational loads of the SG15 Medium and High basis sets for silicon are not much different for relatively small system sizes, but the High basis set becomes significantly more demanding for larger system sizes. For the 432-atom silicon unit cell, the CPU time difference is roughly a factor of 2. Moreover, the Ultra basis set appears in comparison extremely demanding, and will not be used in the remaining calculations in this study.

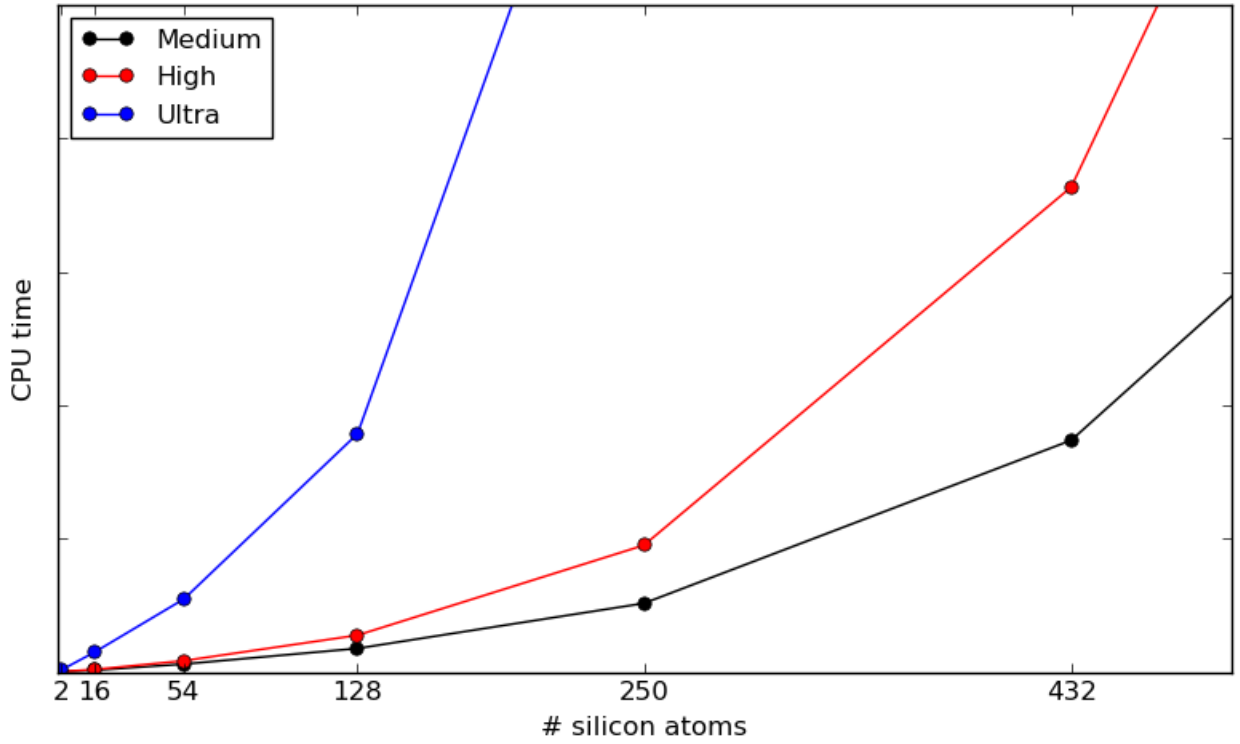

Fig. 3.44: Total CPU time for the first 5 SCF iterations by the ATK-DFT calculator for the Medium (black), High (red), and Ultra (blue) SG15 basis sets, against the number of silicon atoms in the increasingly larger (repeated) silicon unit cell. Only the point is sampled (1x1x1 k-point grid) and the calculations were executed on a single CPU. Note that both figure axes are linear.

Results

This section presents results obtained with the PBE, PBEsol, pps-PBE, and TB09-MGGA methods using Medium and High basis sets with the SG15 pseudopotential for silicon. The list below gives direct links to all subsections:

•*Lattice constant*

•*Elastic constants*

•*Band structure*

•*Band gaps*

•*Effective masses*

•*Dielectric constant*

Lattice constant

The PBEsol lattice constant for silicon is very close to the experimental value, 5.431 Å, but the pps-PBE method is also very accurate. The bare PBE functional (without any pseudopotential projector shifts) is known to overestimate lattice constants in general, but for silicon only by 0.6%.

Elastic constants

Almost all methods tested appear to underestimate the silicon bulk modulus and Youngs modulus, but overestimate the Poisson ratio. The PBE-m method is a curious exception to this rule, but the pps-PBE method appears in general better.

Band structure

All tested methods correctly predict a valence band maximum (VBM) at the Brillouin zone point, and a conduction band minimum (CBM) close to the X point, along the –X path. However, the position of the CBM depends slightly on the method applied, and the band energy in the CBM significantly so (see also section *Band gaps*). On the other hand, the Medium and High basis sets appear to give very similar silicon band structures.

Band gaps

The silicon fundamental band gap is well reproduced by the TB09-MGGA, pps-PBE, and HSE methods, both at experimental and DFT optimized lattice constants, the pps-PBE yielding a particularly accurate band gap. Note, however, that the TB09-MGGA c-parameter was calculated self-consistently from the silicon electronic structure (no fitting), while the pps-PBE projector shifts were essentially fitted to the silicon band gap and lattice constant. On the other hand, the TB09-MGGA functional cannot be used for geometry optimization, which the pps-PBE method is well suited for. Also note that the HSE direct gap, E_{Γ_1}, is very accurate.

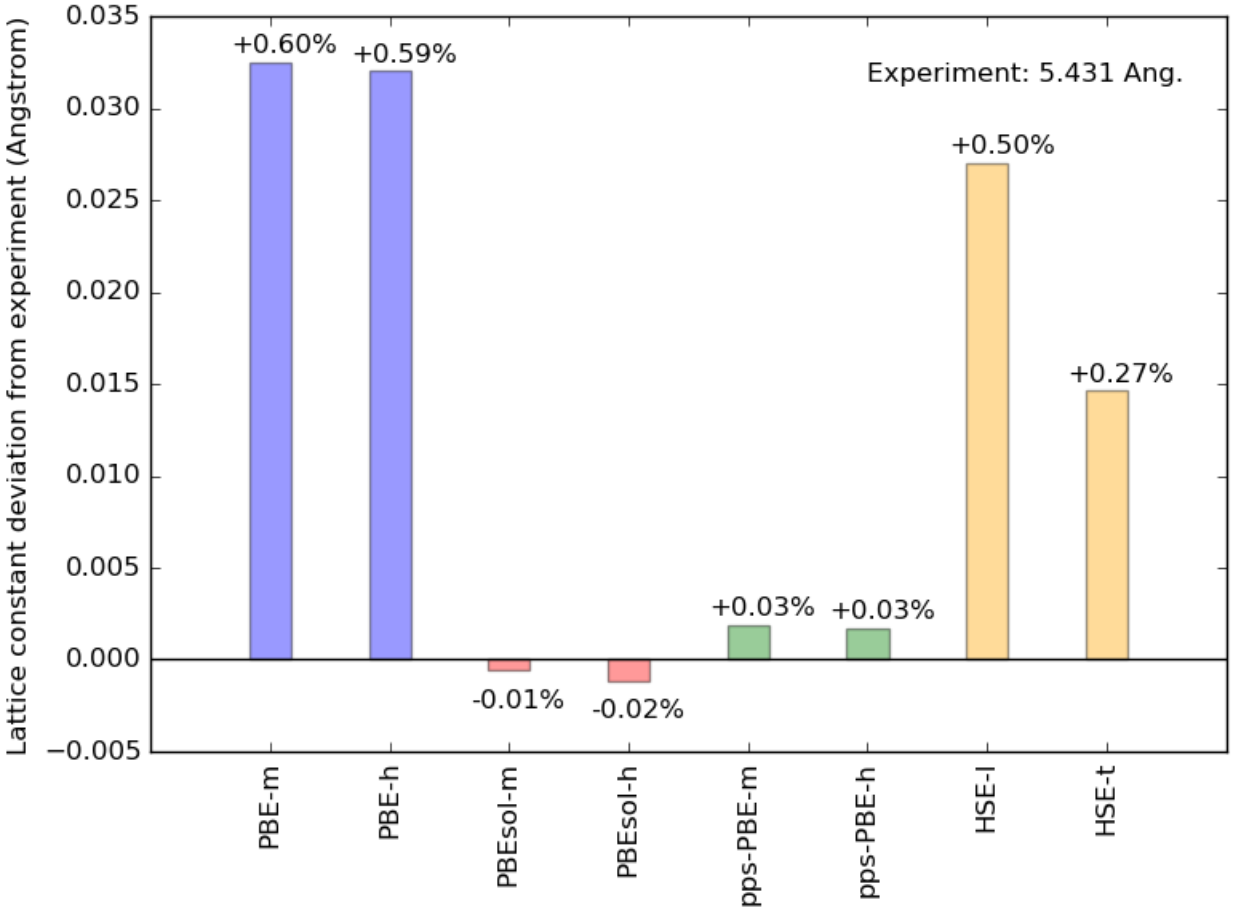

Fig. 3.45: Silicon lattice constant calculated using QuantumATK and the PBE (blue), PBEsol (red) exchange-correlation functionals and the pps-PBE method (green), plotted as deviation from the experimental value. Both medium (m) and high (h) SG15 basis sets are used. HSE calculations have been performed using FHI-AIMS with light (l) and tight (t) basis sets.

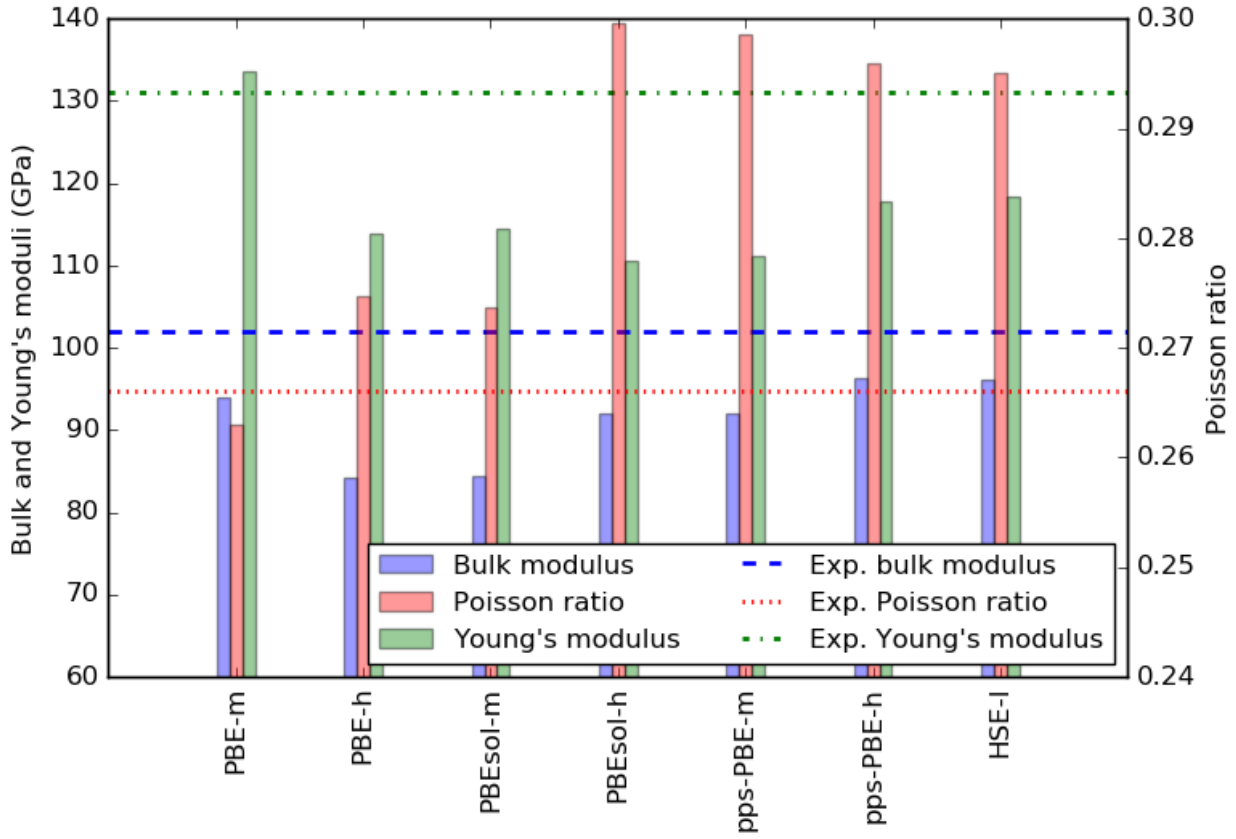

Fig. 3.46: Silicon bulk modulus (blue), Poisson ratio (red), and Youngs modulus (green) calculated using the PBE, PBEsol, pps-PBE, and HSE methods. The horizontal lines indicate experimental values, all from www.crystran.co.uk.

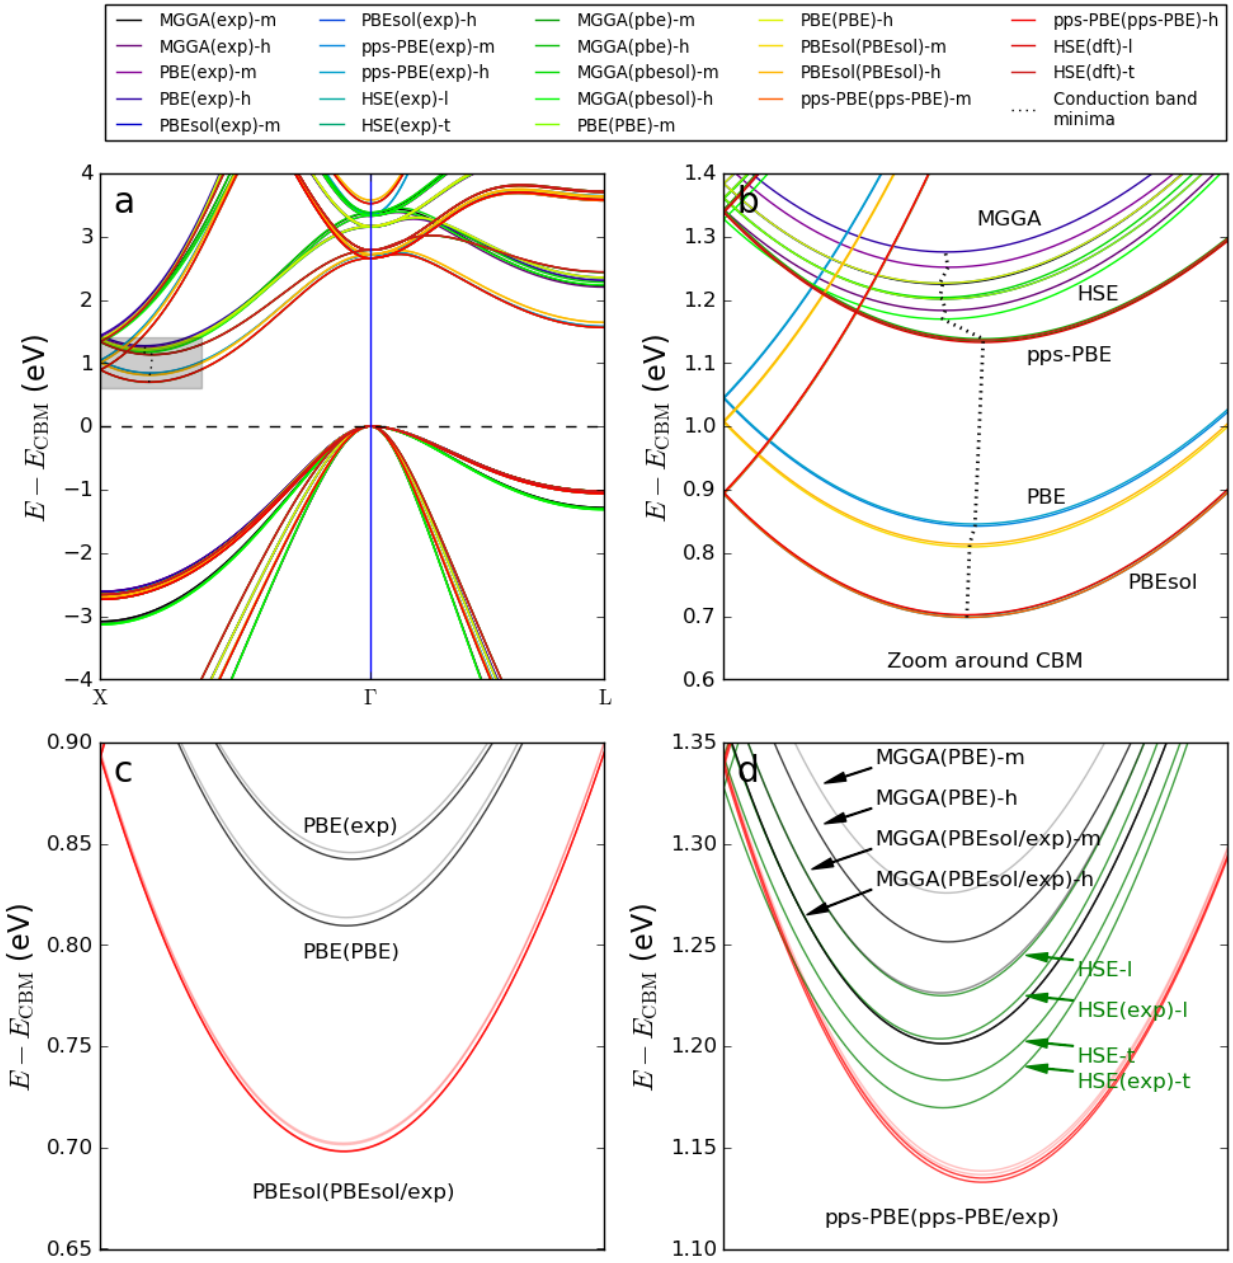

Fig. 3.47: (**a**) Bandstructure of silicon calculated using QuantumATK with the PBE, pbesol and TB09-MGGA exchange-correlation functionals and with the pps-PBE method. The bandstructure has also been calculated using FHI-AIMS and the HSE functional. All the plotted band structures are aligned at the valence band maximum (VBM). Both medium (m) and high (h) SG15 basis sets are used in the QuantumATK calculations. In the FHI-AIMS calcualtions, light (l) and tight (t) basis sets have been used. The name in parenthesis in the labels refers to the lattice constant: exp means lattice constant fixed at the experimental value, 5.431 Angstrom, while PBE, PBEsol, and pps-PBE indicate that the lattice constant was optimized using DFT. The shaded black area indicates the region around the conduction band minimum (CBM) shown in panel **b**. (**b**) Zoom around the CBM of the data shown in panel **a**. The dashed black line marks the position of the calculated CBMs.

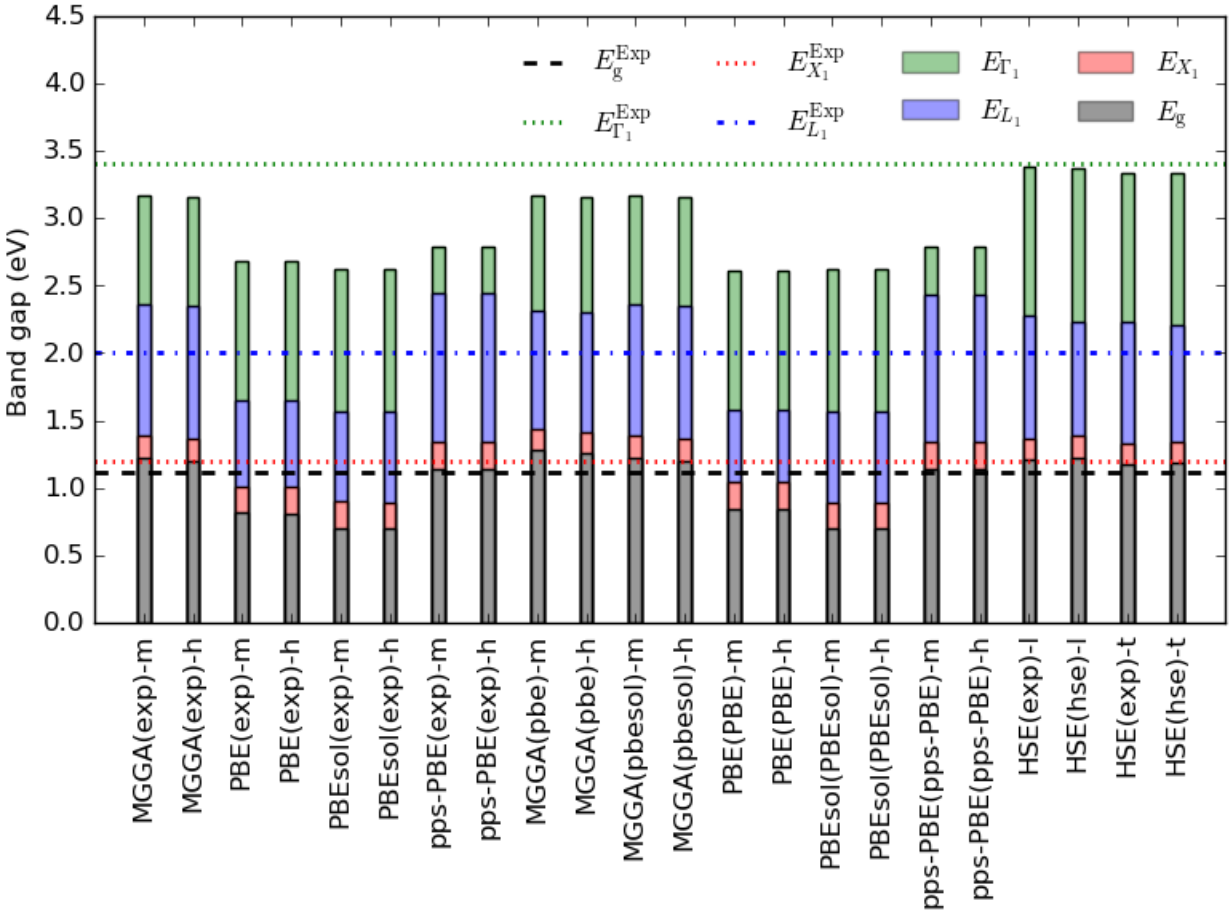

Fig. 3.48: Silicon band gaps; E_g (fundamental gap, black) and energy gaps from the Γ-point valence band maximum to the conduction band minima at X (red), L (blue), and Γ (green), calculated using the PBE, PBEsol, and TB09-MGGA, HSE (using FHI-AIMS) exchange-correlation functionals and with the pps-PBE method. Both medium (m) and high (h) SG15 basis sets are used, while for the HSE calculations the FHI-AIMS light and tight are used. The name in parenthesis in the labels on the x-axis refers to the lattice constant: exp means lattice constant fixed at the experimental value, 5.431 Angstrom, while pbe, pbesol, pps-pbe and hse indicate that the lattice constant was optimized using DFT and the corresponding functional. The reference values E_g^{Exp} (black, dashed), $E_{X_1}^{Exp}$ (red, dotted), $E_{L_1}^{Exp}$ (blue, dash-dotted), and $E_{\Gamma_1}^{Exp}$ (green, dotted) are from http://www.ioffe.ru/SVA/NSM/Semicond/Si/Figs/121.gif.

Effective masses

The silicon effective masses that are calculated with spin-orbit interaction included are in fair agreement with experiment for all the density functionals, basis sets, and pseudopotentials adopted in this study, see the two figures and table in this section. There exists a certain trend that the hole effective mass values tend to be somewhat underestimated as compared to experimental values for the LDA and GGA-PBE density functionls, which underestimate the silicon band gap, whereas the hole effective masses for the TB09-MGGA and pps-PBE density functionals, which give accurate band gap for bulk Si, tend to be overestimated. The electron longitudinal and transversal masses calculated at the X-valley minimum are relatively insensitive to the choice of density functional. Having the spin-orbit interaction included into the effective mass calculation is crucial for reproducing the experimental effective mass values.

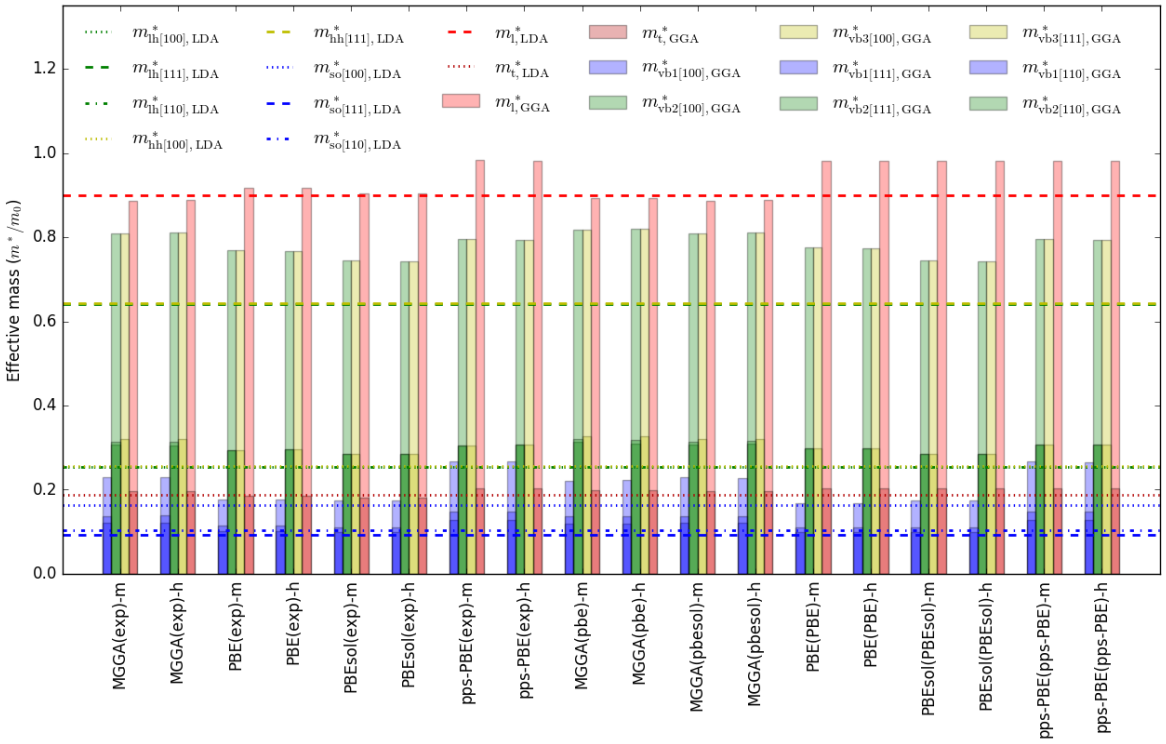

Fig. 3.49: Silicon effective masses calculated with different methods, basis sets, and lattice parameters, without including spin-orbit interaction. The LDA effective masses calculated with the FHI pseudopotential and DoubleZetaPolarized basis set are given with red dashed and red dotted lines for the longitudinal and transversal electron masses, respectively. The yellow, green, and blue lines stand for the heavy, light, and split-off hole effective masses for different crystollagraphic directions: the (100) direction (dotted line), (111) direction (dashed line), and (110) direction (dot-dashed line). The LDA results are taken as a reference for the case of no spin-orbit coupling, since the LDA derived effective masses of Si calculated with spin-orbit coupling are in good agreement with experiment. Note that the same color scheme is chosen for the ATK-DFT calculated effective mass data that are given with color bars.

Fig. 3.51: Table of silicon effective masses calculated with different computational methods, all including spin-orbit interaction. The literature LDA+SO data were calculated using the ABINIT plane-wave code[1], while the experimental data for the heavy and light hole effective masses are fromPage 698, 2 and from http://www.ioffe.ru/SVA/NSM/Semicond/Si/bandstr.html for split-off masses. For the sake of comparison, effective masses calculated without including spin-orbit interaction are provided in parenthesis.

Dielectric constant

The static ($\omega = 0$) dielectric constant of the silicon bulk is most reliably reproduced by the TB09-MGGA functional at the PBE lattice constant and by the pps-PBE method at the corresponding theoretical lattice constant. The lattice constant used seems in general to significantly affect the calculated dielectric constant; note for example how the PBE dielectric constant changes from 11 to 14 depending on the lattice constant used, but independently of the basis set.

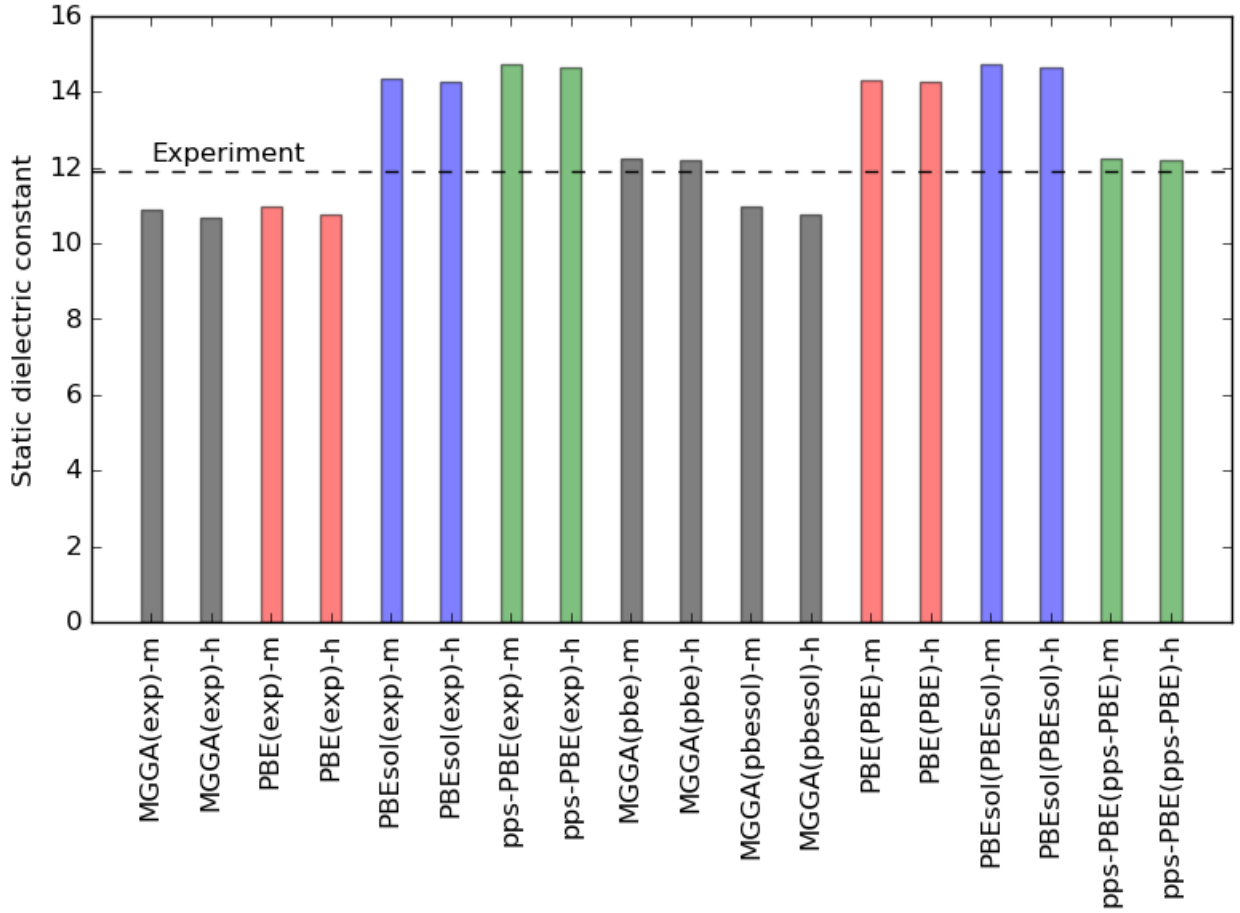

Fig. 3.52: Static dielectric constant calculated using the TB09-MGGA (black), PBE (red) and PBEsol (blue) exchange-correlation functionals and the pps-PBE method (green). Both medium (m) and high (h) SG15 basis sets are used, and the number of included electronic bands were 10 below the Fermi level and 20 above it. The name in parenthesis in the labels on the x-axis refers to the lattice constant: exp means lattice constant fixed at the experimental value, 5.431 Angstrom, while PBE, PBEsol, and pps-PBE indicate that the lattice constant was optimized using DFT. The dashed line indicates the exprimental value, 11.9.

Appendix

The QuantumATK Python script shown below may be used as a template for ATK-DFT calculations for silicon with the SG15 pseudopotential. The script defines the silicon bulk configuration and then sets up the ATK-DFT calculator with PBE exchange-correlation. The script blocked named `Basis Set` shows various options for the SG15 basis set; ordinary PBE and PBE with pseudopotential projector shifts, both with Medium and High basis sets.

The script is available for direct download: `silicon.py`.

Calculation of effective masses

The following is a list of important points abouth calculations of masses using ATK-DFT. See also section *Effective masses*.

1. As seen from Fig. 3.49, the SG15_medium basis set is rather accurate for calculating the electron and hole effective masses of Si, as suggested by comparison of effective masses obtained with the SG15 Medium and SG15 High basis sets.
2. The calculated effective masses are not sensitive to the choice of either DFT-derived or experimental lattice parameter value for DFT calculations, see Fig. 3.49 and Fig. 3.50, i.e., the electron and hole effective masses of Si depend weakly on the lattice constant near its experimental value.
3. The ATK-DFT-LCAO calculations of effective masses are in consistency with the corresponding plane-wave pseudopotential calculations done with the ABINIT code, see Janssen *et al.* [Phys. Rev. B 93, 205147 (2016)], which provides a reference for the quality of the LCAO basis set. The agreement does not depend on whether the calculations are done with or without spin-orbit interaction included.
4. In general, the spin-orbit interaction has to be taken into account for hole effective mass calculations to achieve a good agreement with experiment. Otherwise, the effective masses are unphysically anisotropic and are heavily overestimated as seen in the first figure and the table. Unlike the hole effective masses, the longitudinal and transversal electron effective masses are both virtually unaffected by the spin-orbit interaction.
5. The electron, light, and split-off hole effective masses calculated using the LDA and GGA-PBE functionals with the SG15 basis set are closer to the corresponding experimental values, compared to the masses obtained with the OMX basis set. The heavy hole masses seem to be in a better agreement with experiment if obtained with the OMX basis set. Note that the LDA and GGA functional underestimate the indirect band gap of Si by roughly a factor of 2, as compared to experiment.
6. Using the TB09 meta-GGA and pps-GGA-PBE functionals corrects for the band gap value mentioned in #5. At the same time, it results in hole effective mass values that are larger than the LDA and GGA-PBE derived masses, and

are somewhat overestimated compared to the corresponding experimental values. That might be explained by the fact that the TB09 meta-GGA and pps-GGA-PBE calculated band gap increases as compared to the LDA and GGA-PBE functionals, so that it drives the system into more insulating state. That is consistent with the increase of the hole effective masses. We also notice that using the pps-GGA-PBE functional, which has adjustable parameters, allows correcting the lattice constant value of Si (in addition to correcting the band gap) that is otherwise highly overestimated compared to the experimental value if a standard GGA-PBE functional is adopted for volume optimization of the Si unit cell.

8. There exists a subtle issue in hole effective mass calculation for degenerate bands at the G point. The accurate extraction of effective masses with a finite-difference method requires calculating the effective mass for a given crystallographic direction as a function of the k-mesh density by varying delta parameter (which is a k-mesh descretization step) in the EffectiveMass analyzer. The actual effective mass value is then to be taken in a parabolic band region where the corresponding mass values should show virtually no delta dependence, i.e., the effective mass as a function of delta (k-mesh density) reaches a plateau. Note that the default value of 0.001 $Å^{-1}$ for delta is good enough for calculating electron and split-off masses, but it may need to be increased to ~0.01 $Å^{-1}$ for light and heavy hole masses. The TB09-MGGA derived light and heavy hole effective masses were calculated at even higher value of delta ~0.03 $Å^{-1}$.

References

3.2.20 Germanium

Here we investigate computational methods for ATK-DFT calculations for bulk germanium in the diamond crystal structure. We apply the SG15 pseudopotentials and a number of exchange-correlation functionals; PBE, PBEsol, TB09-MGGA, and PBE.

The following **quantities** have been calculated for each computational method, both at the experimental germanium lattice constant and at the theoretically predicted ones:

- Elastic constants: Bulk modulus, Poisson ratio, and Youngs modulus.
- Band structure along the X—L Brillouin zone path.
- Band gaps: –L (fundamental gap), – (direct gap), and the –X and –Δ indirect gaps.
- Electron effective masses in the L point; transverse and longitudinal.
- Static dielectric constant.

Convergence studies indicate that a 100 Hartree mesh cutoff in conjunction with a 8x8x8 *k*-point grid for calculation of elastic properties (e.g. lattice constant) and a 9x9x9 *k*-point grid for electronic properties (e.g. band gap) are suitable for well-converged and computationally efficient ATK-DFT calculations for bulk germanium. These settings were used for computing the quantities listed above.

The projector shifts used for the **pps-PBE** method are 15.0 eV for *s*-orbitals, 0.2 eV for *p*-orbitals, and -2.0 eV for *d*-orbitals. This yields a single computational method with fairly high accuracy for predicting the fundamental band gap and lattice constant for germanium. Note that these PPS parameters should only be used with SG15 pseudopotentials.

This document is organized as follows. The section *Summary* gives a short summary of the main results from this study, while the section *Convergence* briefly presents the convergence studies mentioned above, and the section *Timing* compares CPU timings and scalability of different SG15 basis sets for germanium. Next, the section *Results* contains figures illustrating the performance of the different computational methods in predicting the materials properties listed above. Finally, the *Appendix* gives a template QuantumATK Python script for setting up ATK-DFT calculations for germanium similar to the ones presented here.

Summary

The following list summarizes the main conclusions from this study.

•The PBEsol, pps-PBE, and HSE methods all yield fairly accurate germanium **lattice constants**, but pps-PBE and HSE appear somewhat more accurate than PBEsol for computing elastic properties of germanium.

•GGA methods, such as PBE and PBEsol, tend to yield a qualitatively wrong (semi-metallic) germanium **band structure**. The TB09-MGGA, pps-PBE, and HSE methods do much better, though the lowest TB09-MGGA valence bands are in general shifted upwards as compared to those found with pps-PBE and HSE. Note, however, that the TB09-MGGA c-parameter was computed self-consistently. Manually tuning the c-parameter could probably bring the TB09-MGGA valence bands down in energy.

•The PBE and PBEsol density functionals should not be used for computing germanium **band gaps**. Conversely, the pps-PBE and HSE methods can yield fairly accurate numbers for the fundamental band gap. Tuning the TB09-MGGA c-parameter may possibly bring better TB09-MGGA band gaps, but this was not tested.

•The predicted band gaps appear to depend somewhat on the germanium lattice constant used for the calculation. In general, the **fundamental band gap** increases as the unit cell volume decreases.

•Even though PBE and PBEsol do not predict the correct **band gap ordering** in germanium, they are actually significantly better for computing **effective electron masses** in the germanium L point (the experimental conduction band minimum), than the TB09-MGGA and pps-PBE methods. However, all tested methods overestimate the electron effective masses, especially the fairly small transverse effective mass.

•The PBE and PBEsol functionals should not be used for computing **optical properties** of germanium, such as the static dielectric constant. The vanishing -point direct band gap with GGA methods is most likely the reason for this. The ppsPBE method appears significantly better in this respect.

Convergence

The type of Monkhorst–Pack k-point grid and the density mesh cutoff energy are essential ATK-DFT parameters that affect the computational efficiency and precision: A dense k-point grid and high cutoff energy usually give high precision, but may also be computationally intense. It is therefore important to investigate the trade-off between computational precision and cost. Fig. 3.53 illustrates how the germanium total energy, fundamental band gap, and lattice constant depend on the mesh cutoff and k-point grid.

Note that a standard Monkhorst–Pack k-point grid is -centered for odd numbers of points (e.g. 3x3x3), but does not include the point for even number of points (e.g. 4x4x4). The blue lines in Fig. 3.53 are for k-point grids where even grids are shifted to (such that both 3x3x3 and 4x4x4 grids **do** include), while the red lines are for calculations where odd grids are shifted away from (such that both 3x3x3 and 4x4x4 grids **do not** include).

For the SG15 pseudopotential with both Medium and High basis sets, a 100 Hartree mesh cutoff gives band gaps and lattice constants that are converged to within 10^{-4} eV and roughly 10^{-4} Å, respectively.

It is also clear that an off- k-point grid (non-centered, red) gives faster convergence of the total energy and lattice constant than the k-point grid that includes the point (centered, blue). We see that the non-centered 8x8x8 Monkhorst–Pack grid yields higly converged lattice constants.

On the other hand, the computed band gap converges fastest with the -centered k-point grid (blue). This may be because the valence band maximum is located at the point. The 9x9x9 Monkhorst–Pack grid is -centered by default, and yields highly converged band gaps.

Note: All remaining ATK-DFT calculations in this study therefore use a 100 Hartree mesh cutoff energy and a standard (non-centered) 8x8x8 Monkhorst–Pack k-point grid for elastic properties and the standard 9x9x9 grid for computing electronic properties.

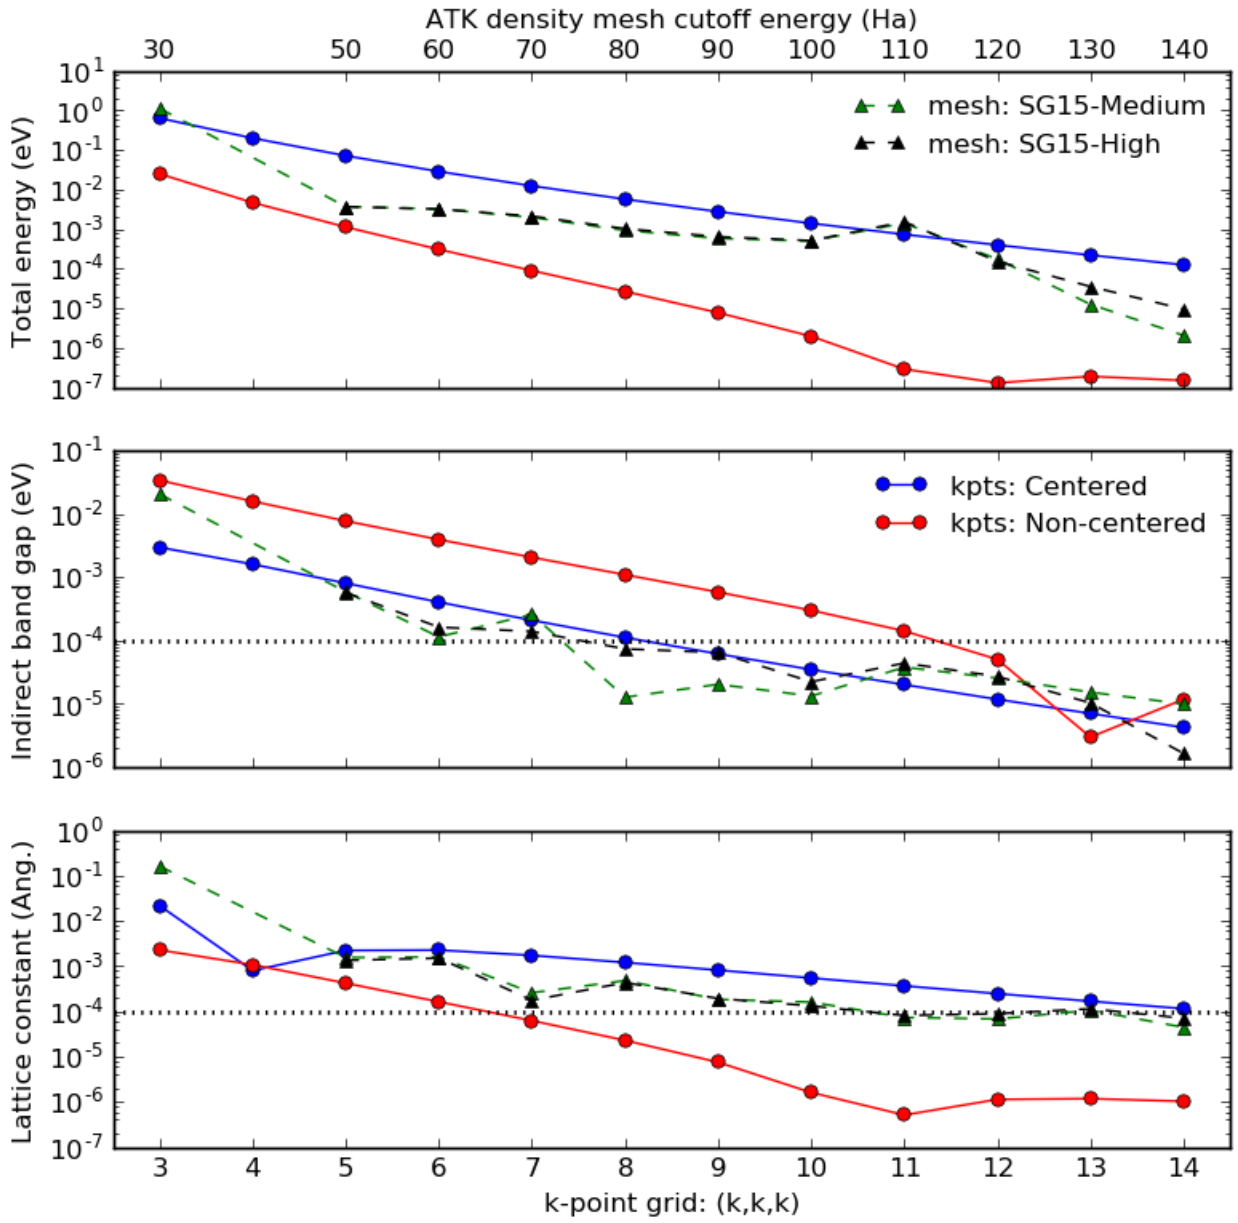

Fig. 3.53: Convergence of the germanium total energy, fundamental (indirect) band gap, and lattice constant with respect to the ATK-DFT density mesh cutoff (top x-axis in all three panels; green and black dashed lines) and k-point grid (bottom x-axis in all three panels; blue and red lines). The centered k-point grids are shifted to the Γ point (only affects even grids, e.g. 4x4x4), while the non-centered k-point grids are shifted by (0.5,0.5,0.5) and therefore do not sample the Γ point (only affects odd grids, e.g. 3x3x3). The horizontal dotted lines indicate tight convergence criteria.

Timing

The computational cost of a calculation may depend critically on the choice of basis set, particularly for calculations on large systems with many atoms. Fig. 3.54 shown below illustrates this for the present case of germanium and the Medium, High, and Ultra SG15 basis sets.

The germanium primitive cell (containing 2 atoms) was systematically repeated in steps of one along all three lattice vectors, resulting in rapidly increasing systems sizes. PBE calculations were then performed for each system, using -point sampling only, to avoid any influence of k-point sampling on the recorded CPU times.

It is quite clear from the figure that the computational loads of the SG15 Medium and High basis sets for germanium are not much different for relatively small system sizes, but the High basis set becomes more demanding for larger system sizes. Moreover, the Ultra basis set appears in comparison extremely demanding, and will not be used in the remaining calculations in this study.

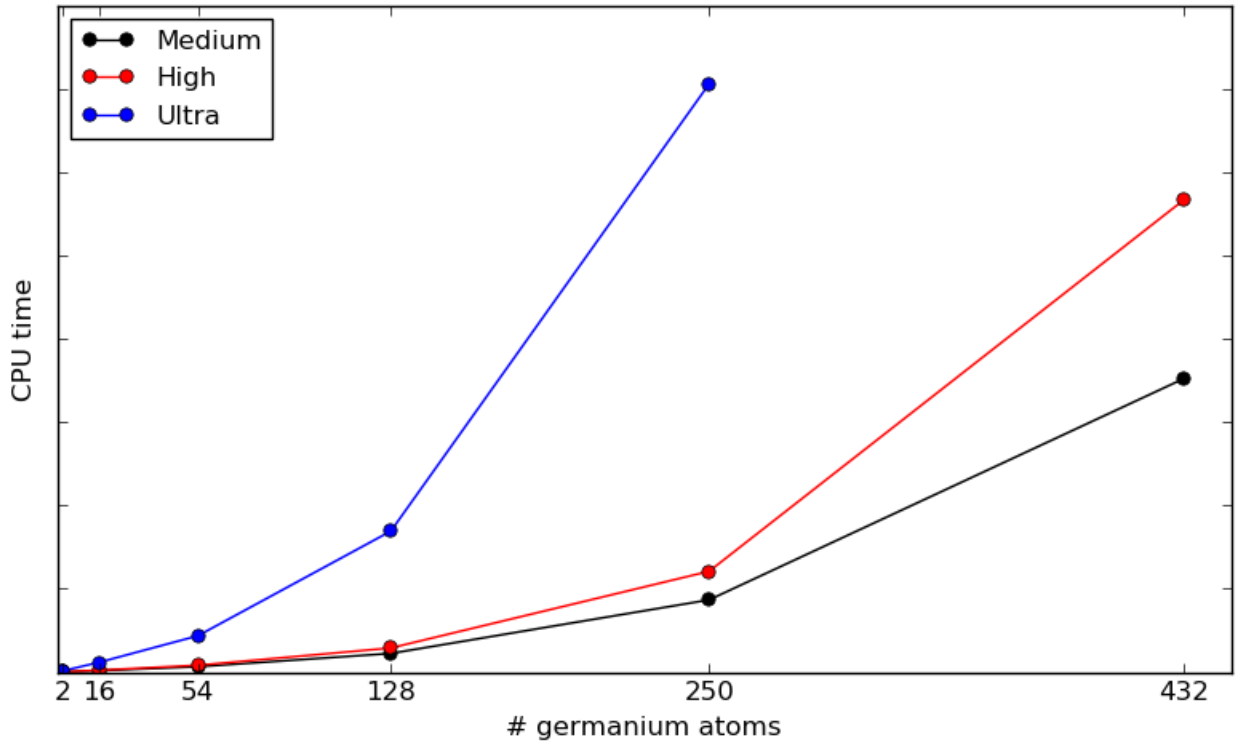

Fig. 3.54: Total CPU time for the first 5 SCF iterations by the ATK-DFT calculator for the Medium (black), High (red), and Ultra (blue) SG15 basis sets, against the number of germanium atoms in the increasingly larger (repeated) bulk unit cell. Only the point is sampled (1x1x1 k-point grid) and the calculations were executed on a single CPU core. Note that both figure axes are linear. For reference, the 432-atom SG15-Medium calculation reach full convergence in 11 SCF steps, which take less than 30 minutes if running in parallel on 16 modern CPU cores.

Results

This section presents ATK-DFT results obtained with the PBE, PBEsol, pps-PBE, and TB09-MGGA methods using Medium and High basis sets with the SG15 pseudopotential for germanium, as well as HSE results obtained with the FHI-aims calculator. The list below gives direct links to all subsections:

•*Lattice constant*

•*Elastic constants*

•*Band structure*

•*Band gaps*

•*Electron effective masses*

•*Dielectric constant*

Lattice constant

The PBEsol lattice constant for germanium is very close to the experimental 300 K value, 5.6574 Å, but the pps-PBE and HSE methods are also quite accurate. The bare PBE functional (without any pseudopotential projector shifts) is known to overestimate lattice constants in general, and for germanium by almost 3%.

Elastic constants

The experimental bulk modulus, Poisson ratio, and Youngs modulus of germanium are well reproduced by the pps-PBE method, but HSE also does well in this respect. PBEsol is in general a bit more off, and pure PBE underestimates all three elastic quantities.

Band structure

The germanium fundamental band gap is fairly small (0.66 eV at 300 K), and occurs between the and L high-symmetry points in the Brillouin zone. The remaining conduction band minima are quite close in energy (see also *Band gaps*). This band structure is hard to correctly reproduce within GGA-DFT. As seen in the figure below, PBE and PBEsol tend to close the direct gap at , and yield a rather small –L band gap. On the other hand, the TB09-MGGA, pps-PBE, and HSE methods correctly yield a significant direct band gap at , and also appear to preserve the correct band gap ordering. The SG15 High basis set (dash-dotted lines) gives in general slightly lower band energies than the Medium basis set does (full lines). A similar trend is observed for the tight and light accuracy settings for the FHI-aims HSE calculations.

Band gaps

As noted just above, the PBE and PBEsol exchange-correlation functionals predict a qualitatively wrong band gap ordering for germanium; the -point direct gap vanishes, and the lowest conduction band at the L point may even cross the Fermi level. No PBE or PBEsol band gaps are therefore included in the figure below.

The germanium band gaps are quite well reproduced by the pps-PBE and HSE methods. Especially the pps-PBE calculation at the pps-PBE lattice constant with the SG15 High basis set appears very accurate. The TB09-MGGA method correctly predicts that the fundamental germanium band gap is the –L gap, but overestimates the band gaps in general. Note, however, that the TB09-MGGA c-parameter was calculated self-consistently from the germanium electronic structure (no fitting), while the pps-PBE projector shifts were essentially fitted to the germanium fundamental

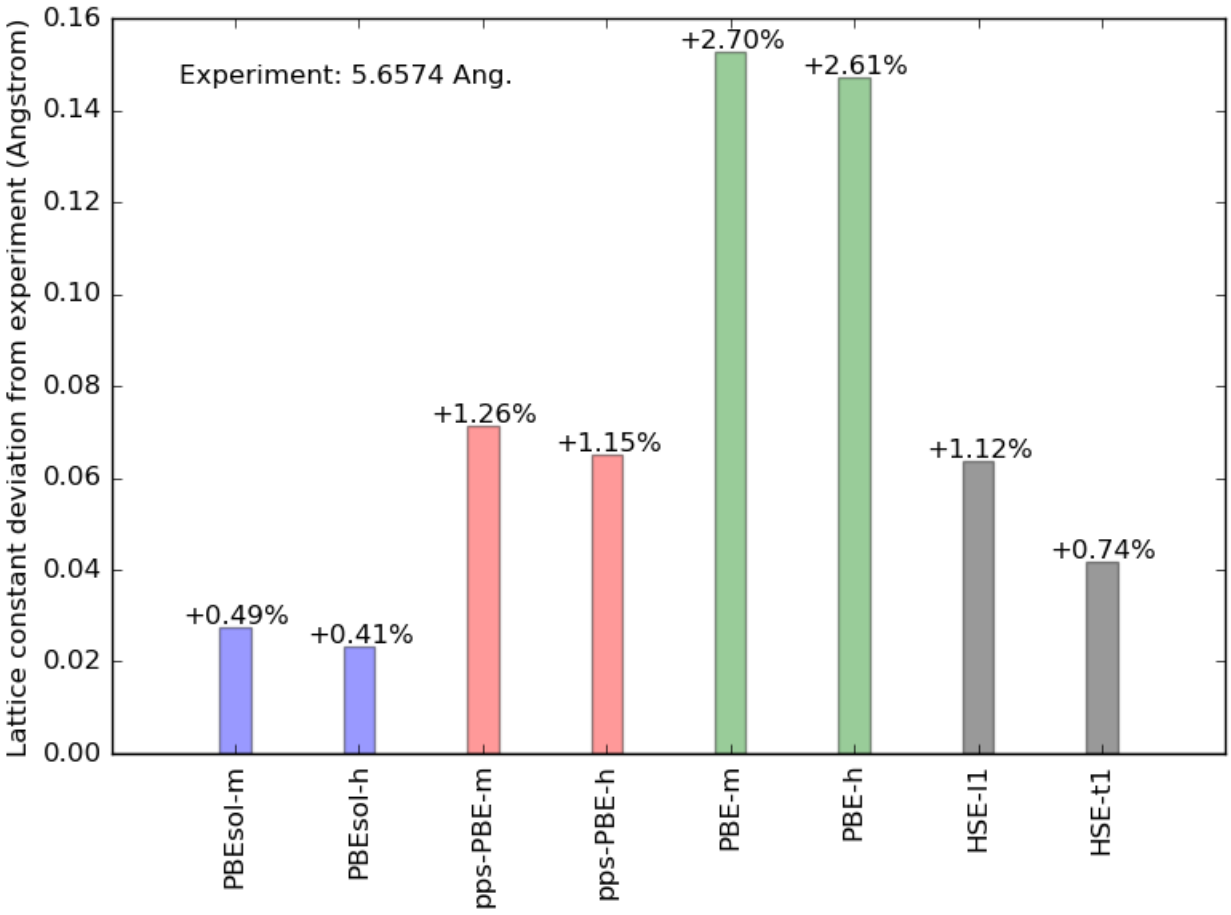

Fig. 3.55: Germanium lattice constant calculated using the PBEsol (blue), pps-PBE (red), PBE (green), and HSE (black) methods, plotted as deviation from the experimental value.

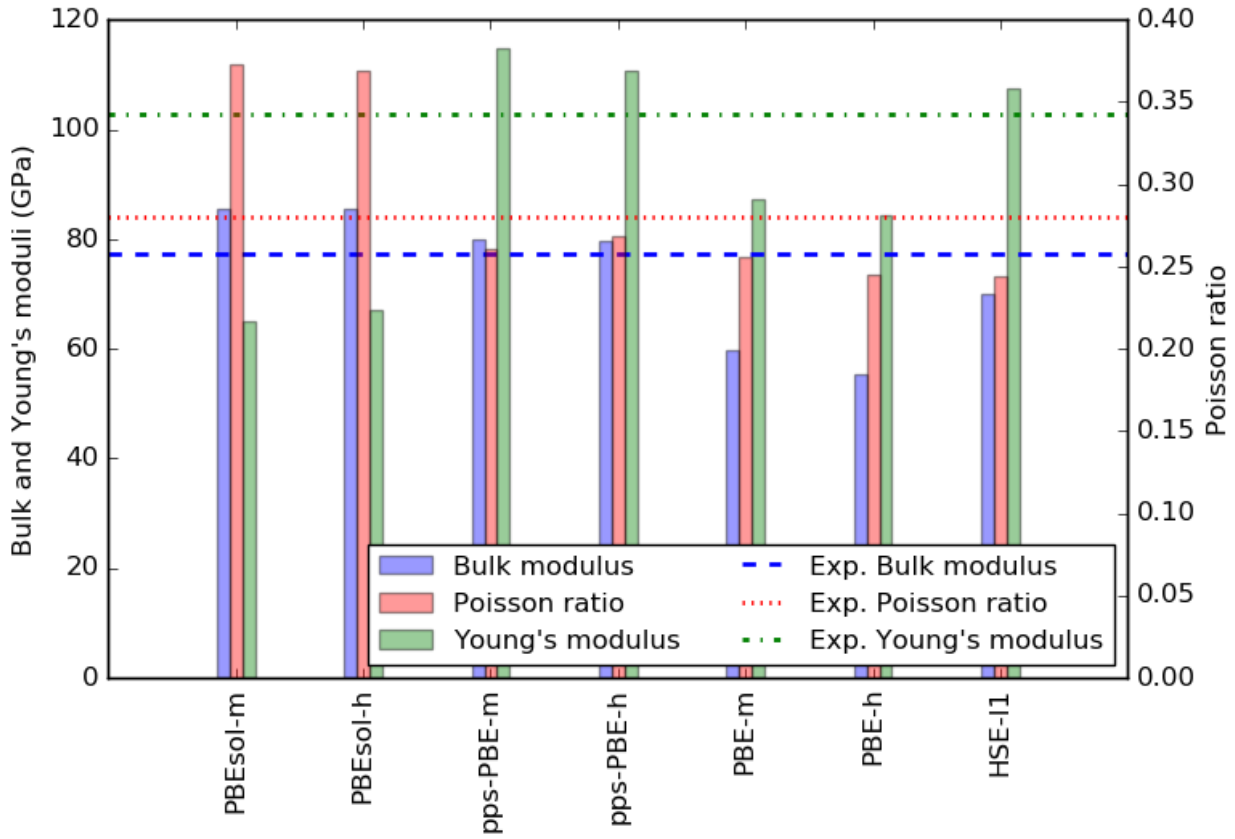

Fig. 3.56: Germanium bulk modulus (blue), Poisson ratio (red), and Youngs modulus (green) calculated using the PBEsol, pps-PBE, PBE, and HSE methods. The blue dashed, red dotted, and green dash-dotted lines indicate the experimental values, all from www.crystran.co.uk.

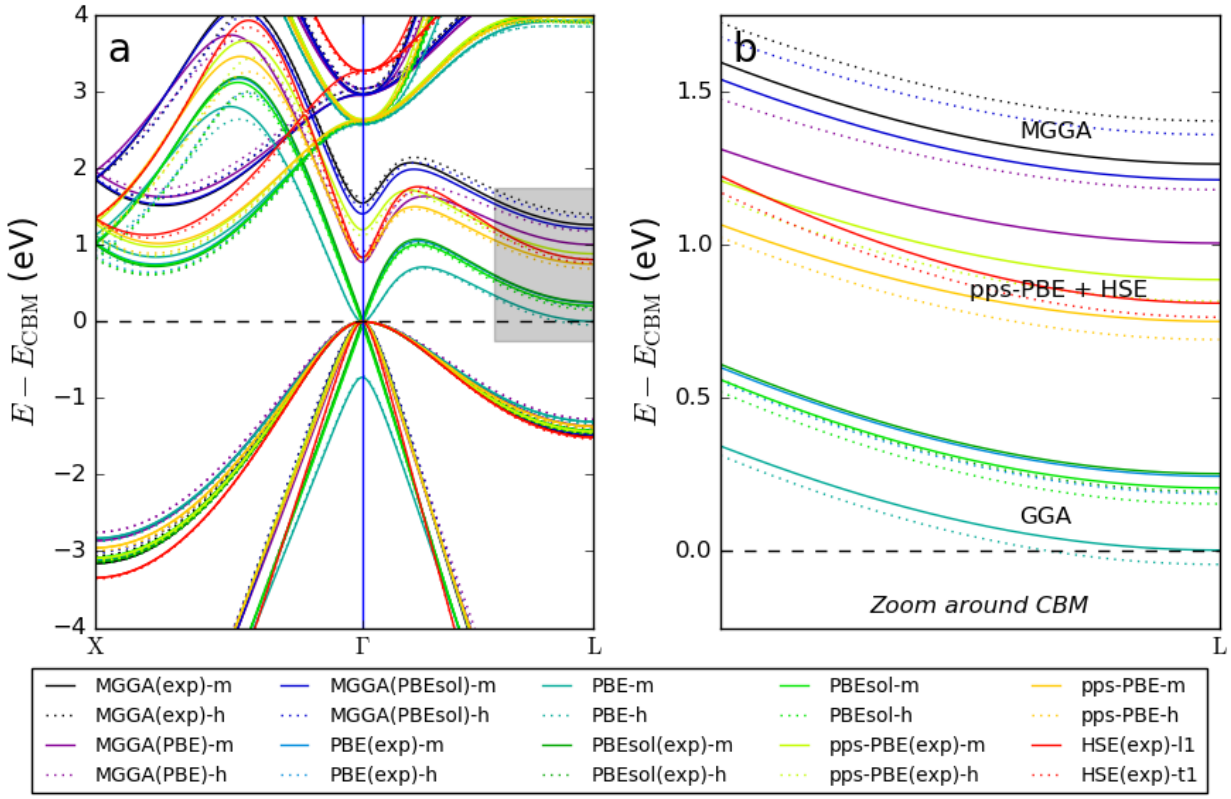

Fig. 3.57: Germanium band structure calculated with the TB09-MGGA, PBE, PBEsol, pps-PBE, and HSE methods. All band structures are aligned at the Γ-point valence band maximum. The shaded area in panel **a** indicates the region around the conduction band minimum (CBM) shown in panel **b**.

gap and lattice constant. On the other hand, the TB09-MGGA functional cannot be used for geometry optimization, which the pps-PBE method is well suited for.

We also observe that the band gaps may depend somewhat on the applied germanium lattice constant. For example, the pps-PBE E_{Γ_1} gap is significantly larger at the experimental lattice constant than at the pps-PBE lattice constant.

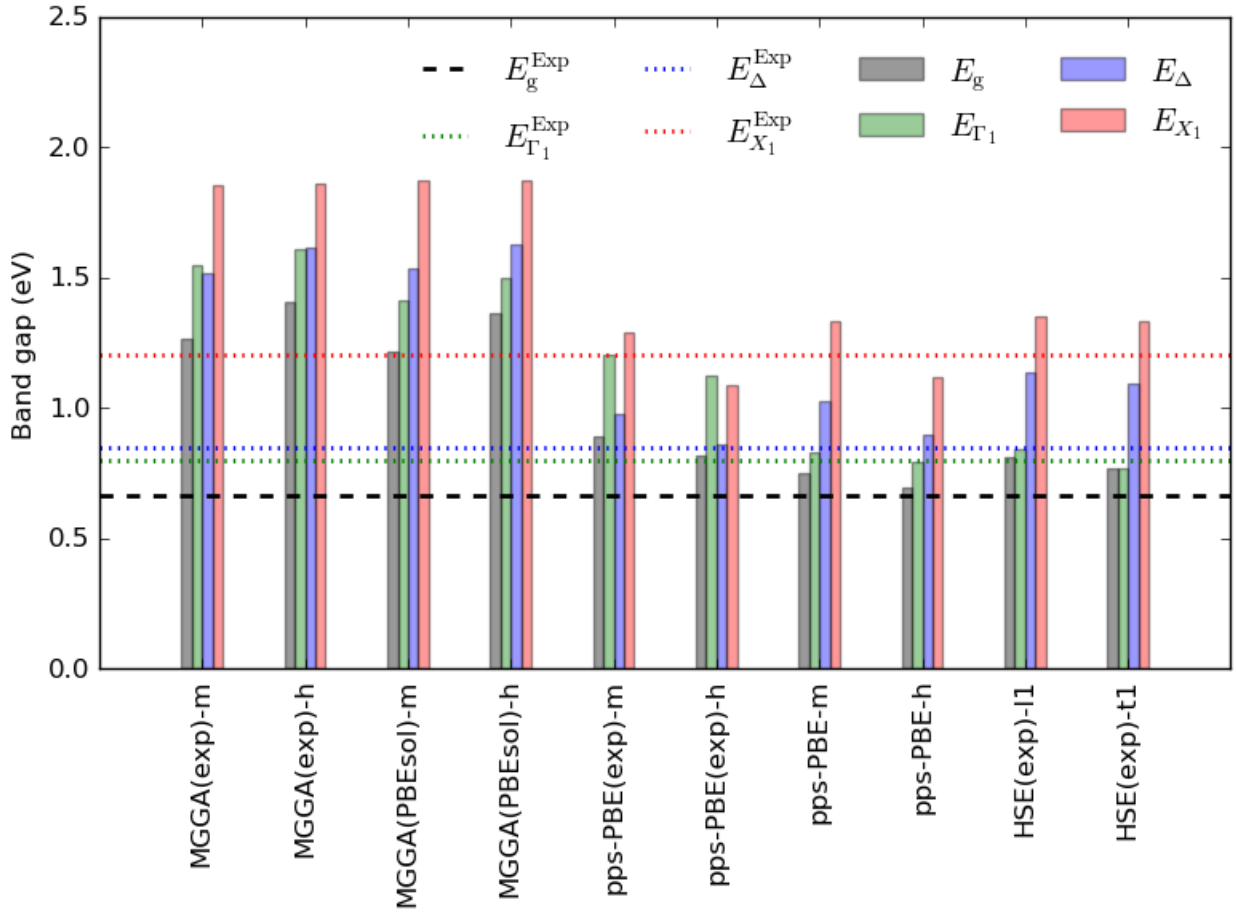

Fig. 3.58: Germanium band gaps; E_g (fundamental gap, black) and energy gaps from the Γ-point valence band maximum to the conduction band minima at X (red), Δ (X-point valley, blue), and Γ (green), calculated using the TB09-MGGA, pps-PBE, and HSE methods. Note that PBE and PBEsol calculations predict a qualitatively wrong band-gap ordering (often semi-metallic at Γ), so results from those methods are not included. TB09-MGGA at the PBE lattice constant yields a direct fundamental band gap, so TB09-MGGA(PBE) results are also not included. Experimental (300 K) values E_g^{Exp} (black, dashed), $E_{X_1}^{Exp}$ (red, dotted), E_Δ^{Exp} (blue, dotted), and $E_{\Gamma_1}^{Exp}$ (green, dotted) from http://www.ioffe.ru/SVA/NSM/Semicond/Ge/Figs/221.gif.

Electron effective masses

The figure below shows the computed transverse (blue; left y-axis) and longitudinal (red; right y-axis) effective masses for electrons in the germanium conduction band minimum at the L point. PBE and PBEsol data are included, even though those methods do not capture that the conduction band minimum is at the L point. Both electron effective masses are in general overestimated by the TB09-MGGA and pps-PBE methods, while PBEsol and PBE do better, especially for the transverse effective masses.

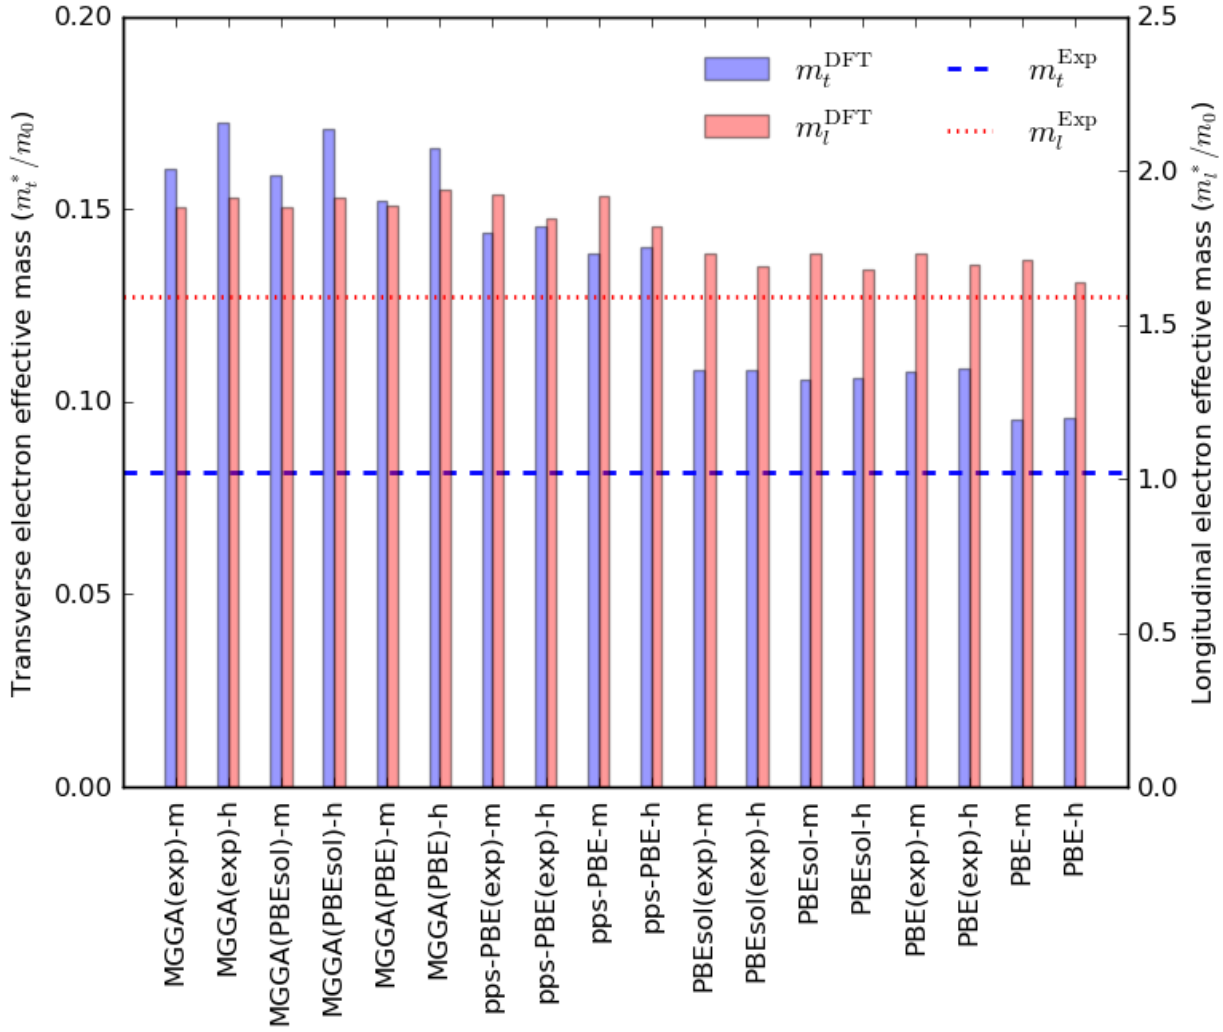

Fig. 3.59: Germanium transverse (blue; left y-axis) and longitudinal (red; right y-axis) electron effective masses calculated in the L point (the experimental conduction band minimum), using the TB09-MGGA, pps-PBE, PBEsol, and PBE methods. The blue dashed and red dotted lines mark the experimental values, adapted from http://www.ioffe.ru/SVA/NSM/Semicond/Ge/bandstr.html.

Dielectric constant

The static ($\omega = 0$) dielectric constant of the germanium bulk is most reliably reproduced by the pps-PBE method: The pps-PBE values in the figure below are in general closer to experiment than the TB09-MGGA values, while the PBEsol and PBE values are far too large. The latter is most likely due to the completely wrong PBEsol and PBE germanium band structure in the region around the Fermi level.

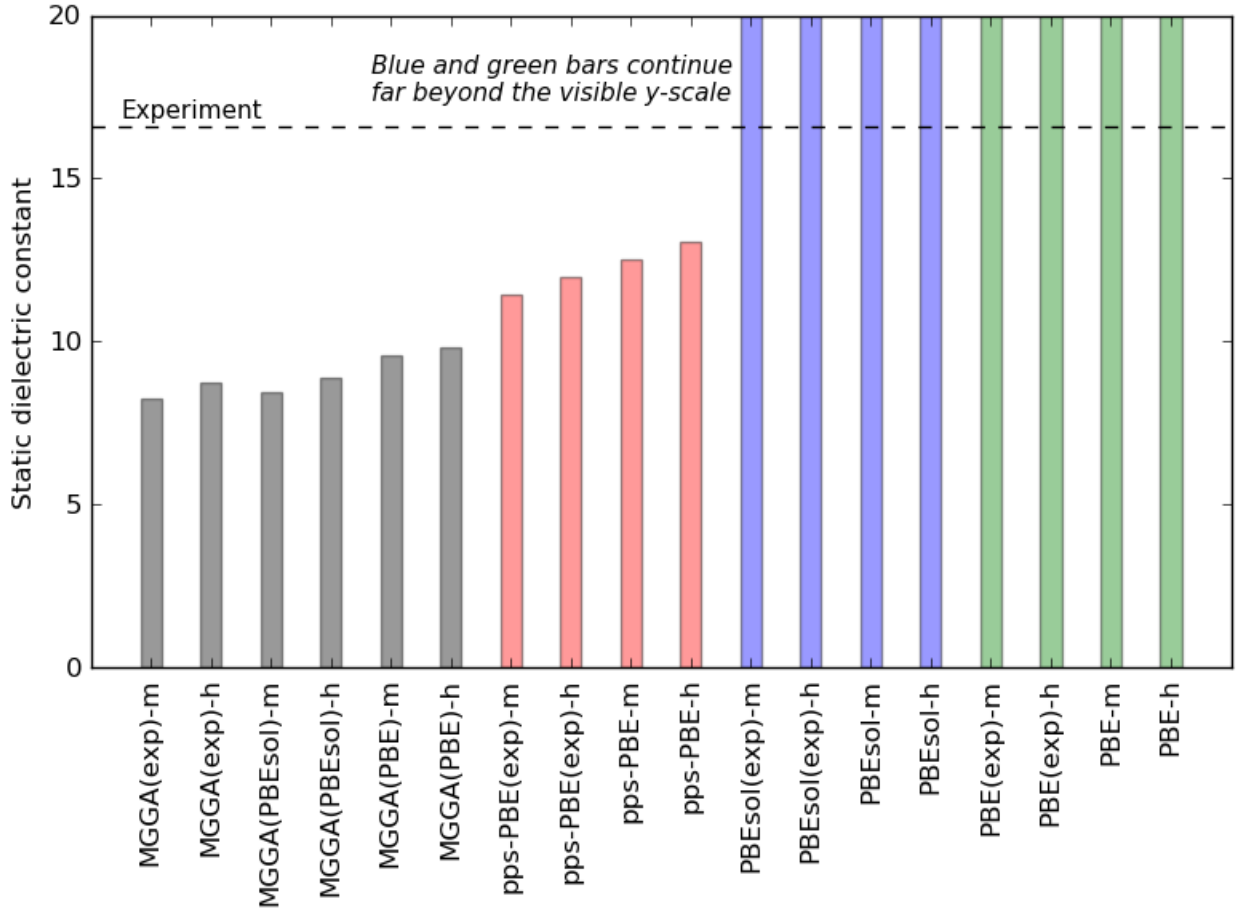

Fig. 3.60: Static dielectric constant of germanium calculated using the TB09-MGGA (black), pps-PBE (red), PBEsol (blue), and PBE (green) methods. The number of electronic bands included in the OpticalSpectrum analysis were 10 below the Fermi level and 20 above it. The dashed line indicates the experimental value, 16.6, from www.crystran.co.uk.

Appendix

The QuantumATK Python script shown below may be used as a template for ATK-DFT calculations for germanium with the SG15 pseudopotential. The script defines the germanium bulk configuration and then sets up the ATK-DFT calculator with PBE exchange-correlation. The script block named `Basis Set` shows various options for the SG15 basis set; ordinary PBE and PBE with pseudopotential projector shifts, both with Medium and High basis sets.

The script is available for direct download: `germanium.py`.

3.2.21 $Si_{0.5}Ge_{0.5}$

Here we investigate computational methods for ATK-DFT calculations for a simple $Si_{0.5}Ge_{0.5}$ alloy in the diamond crystal structure, i.e., with an atom of each element in the basis (in this document also denoted SiGe for brevity). We apply the SG15 pseudopotentials and a number of exchange-correlation functionals; PBE, PBEsol, TB09-MGGA, and PBE with the *Pseudopotential Projector-Shift* method. A limited number of HSE calculatios have been done for comparison. See the section *Introduction* for more information.

The following **quantities** have been calculated for each computational method, both at the experimental $Si_{0.5}Ge_{0.5}$ lattice constant and at the theoretically predicted ones:

•Elastic constants: Bulk modulus, Poisson ratio, and Youngs modulus.

•Band structure along the X—L Brillouin zone path.

•Direct and indirect band gaps.

•Effective masses in the conduction band minimum.

•Static dielectric constant.

Convergence studies indicate that a 8x8x8 k-point grid and a 100 Hartree density mesh cutoff yields well-converged values for the $Si_{0.5}Ge_{0.5}$ lattice constant, total energy and indirect band gap. These settings were used for computing the ground state electronic structure used in all the ATK-DFT analyses listed above.

The projector shifts used for the **pps-PBE** method are 11.23 eV for Si s-orbitals and -1.09 eV for Si p-orbitals, while shifts of 15.0 eV are used for Ge s-orbitals, 0.2 eV for Ge p-orbitals, and -2.0 eV for Ge d-orbitals. Note that these PPS parameters should only be used with SG15 pseudopotentials.

This document is organized as follows. The section *Convergence* briefly presents the convergence studies mentioned above, and the section *Timing* compares CPU timings and scalability of different SG15 basis sets for $Si_{0.5}Ge_{0.5}$. Next, the section *Results* contains figures illustrating the performance of the different computational methods in predicting the materials properties listed above. Finally, the *Appendix* gives a template QuantumATK Python script for setting up ATK-DFT calculations for $Si_{0.5}Ge_{0.5}$ similar to the ones presented here.

Summary

The following list summarizes the main conclusions from this study.

- The PBEsol, and to a lesser degree pps-PBE, methods both yield very accurate $Si_{0.5}Ge_{0.5}$ **lattice constants**, and also give the best results for elastic constants.
- All tested methods yield a qualitatively correct $Si_{0.5}Ge_{0.5}$ **band structure**, but with significant differences between the different methods. The method which is closest to the HSE reference is pps-PBE.
- The pps-PBE method accurately reproduces the fundamental (indirect) **band gap**. There is a large spread in the results for the direct gaps, so care is needed to describe these accurately.
- **Electron effective masses** in the Δ-point CBM are quite well captured by all tested methods.
- Even though PBE and PBEsol do not describe the band gaps as accurately as pps-PBE, they are actually significantly better for the **static dielectric constant**. It is underestimated by the other methods.

Convergence

The type of Monkhorst–Pack k-point grid and the density mesh cutoff energy are essential ATK-DFT parameters that affect the computational efficiency and precision: A dense k-point grid and high cutoff energy usually give high precision, but may also be computationally intense. It is therefore important to investigate the trade-off between computational precision and cost. Fig. 3.61 illustrates how the bulk total energy, fundamental band gap, and lattice constant depend on the mesh cutoff and k-point grid.

Note that a standard Monkhorst–Pack k-point grid is -centered for odd numbers of points (e.g. 3x3x3), but does not include the point for even numbers of points (e.g. 4x4x4). The blue lines in Fig. 3.61 are for k-point grids where even grids are shifted to (such that both 3x3x3 and 4x4x4 grids **do** include), while the red lines are for calculations where odd grids are shifted away from (such that both 3x3x3 and 4x4x4 grids **do not** include).

For the SG15 pseudopotential with both Medium and High basis sets, a 100 Hartree mesh cutoff gives band gaps and lattice constants that are converged to within 10^{-4} eV and roughly 10^{-4} Å, respectively.

It is also clear that an off- k-point grid (non-centered, red) gives faster convergence of the total energy and lattice constant than the k-point grid that includes the point (centered, blue). We see that the non-centered 8x8x8 Monkhorst–Pack grid yields highly converged lattice constants.

Note: All remaining ATK-DFT calculations in this study therefore use a 100 Hartree mesh cutoff energy and a standard (non-centered) 8x8x8 Monkhorst–Pack k-point grid for both elastic properties and electronic properties.

Timing

The computational cost of a calculation may depend critically on the choice of basis set, particularly for calculations on large systems with many atoms. Fig. 3.62 shown below illustrates this for the present case of $Si_{0.5}Ge_{0.5}$ with the Medium, High, and Ultra SG15 basis sets.

The SiGe primitive cell (containing 2 atoms) was systematically repeated in steps of one along all three lattice vectors, resulting in rapidly increasing systems sizes. PBE calculations were then performed for each system, using -point sampling only, to avoid any influence of k-point sampling on the recorded CPU times.

It is quite clear from the figure that the computational loads of the SG15 Medium and High basis sets are not much different for relatively small system sizes, but the High basis set becomes significantly more demanding for larger system sizes. For the 432-atom unit cell, the CPU time difference is roughly a factor of 2. Moreover, the Ultra basis set appears in comparison extremely demanding, and will not be used in the remaining calculations in this study.

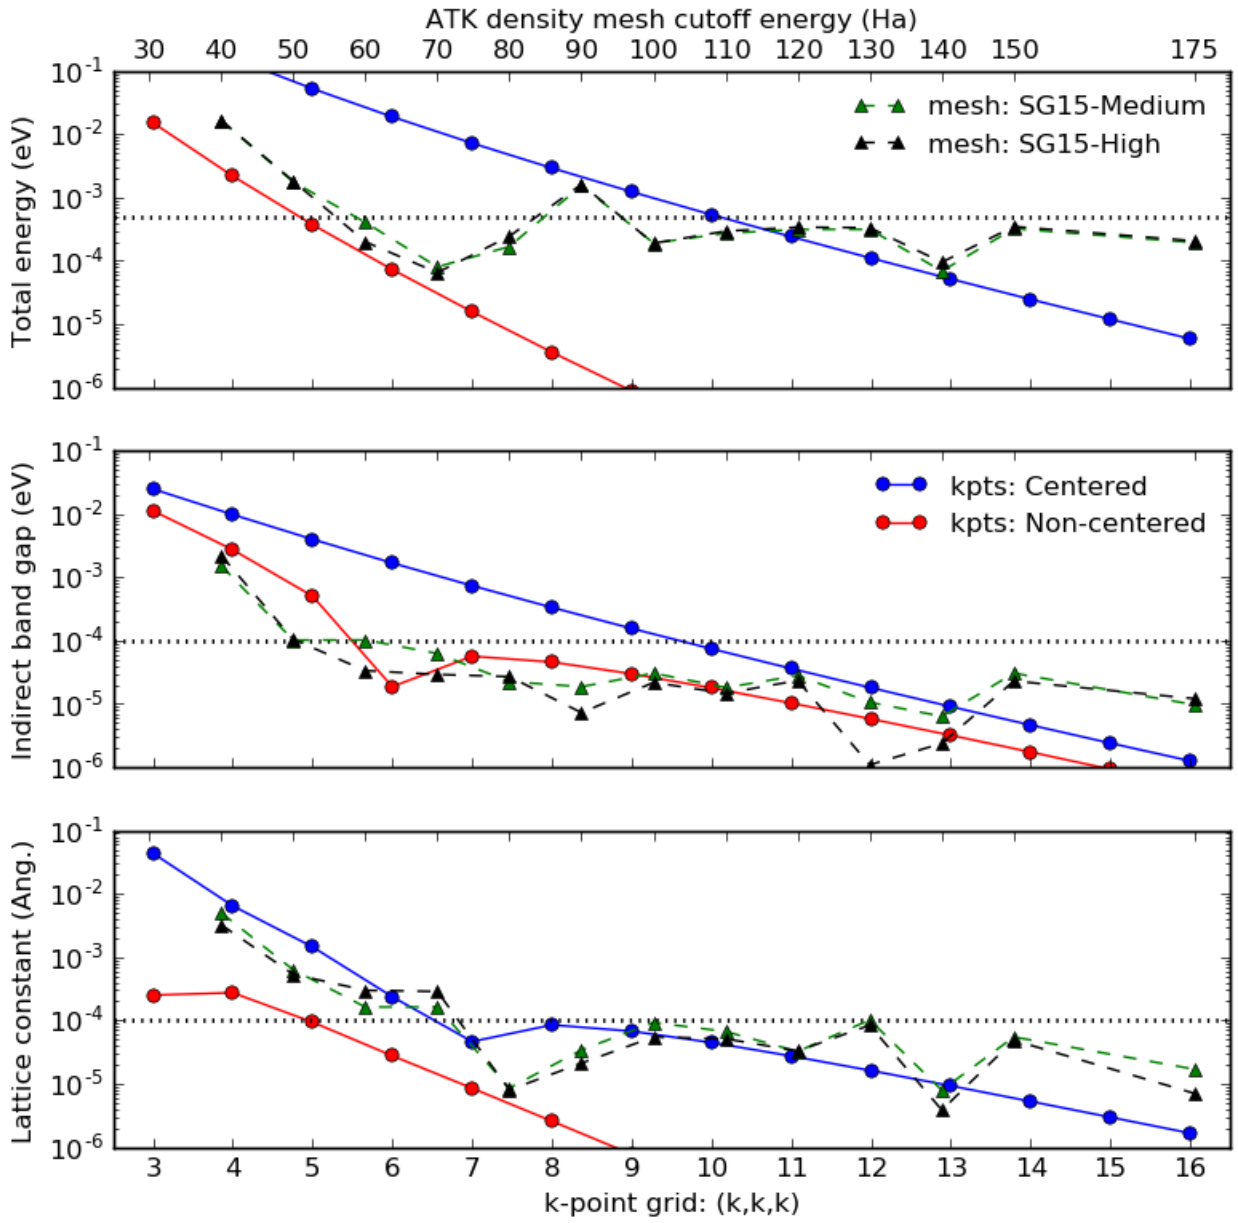

Fig. 3.61: Convergence of the SiGe total energy, fundamental (indirect) band gap, and lattice constant with respect to the ATK-DFT density mesh cutoff (top x-axis in all three panels; green and black dashed lines) and k-point grid (bottom x-axis in all three panels; blue and red lines). The centered k-point grids are shifted to the Γ point (only affects even grids, e.g. 4x4x4), while the non-centered k-point grids are shifted by (0.5,0.5,0.5) and therefore do not sample the Γ point (only affects odd grids, e.g. 3x3x3). The horizontal dotted lines indicate tight convergence criteria.

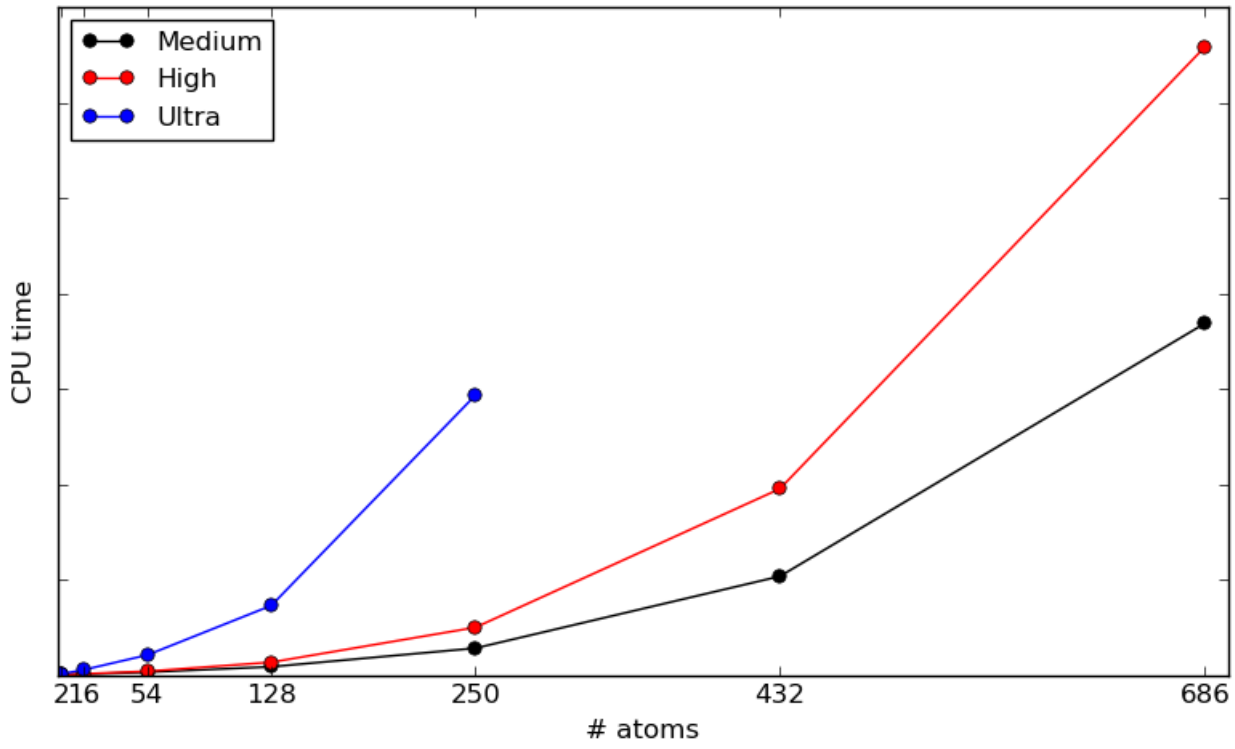

Fig. 3.62: Total CPU time for the first 5 SCF iterations by the ATK-DFT calculator for the Medium (black), High (red), and Ultra (blue) SG15 basis sets, against the number of atoms in the increasingly larger (repeated) SiGe bulk unit cell. Only the point is sampled (1x1x1 k-point grid) and the calculations were executed on a single CPU core. Note that both figure axes are linear.

Results

This section presents results obtained with the PBE, PBEsol, pps-PBE, and TB09-MGGA methods using Medium and High basis sets with the SG15 pseudopotentials for $Si_{0.5}Ge_{0.5}$.

The cited experimental reference values are in general for a 50/50 mix of Si and Ge, but with no local order in the distribution of Si and Ge on the lattice. There may therefore be a slight difference between the experimentally investigated system and the very small model system used here.

The list below gives direct links to all subsections:

•*Lattice constant*

•*Elastic constants*

•*Band structure*

•*Band gaps*

•*Effective masses*

•*Dielectric constant*

Lattice constant

The PBEsol lattice constant for $Si_{0.5}Ge_{0.5}$ is very close to the experimental value, 5.538 Å, but the pps-PBE method is also quite accurate. The bare PBE functional (without any pseudopotential projector shifts) is known to overestimate lattice constants in general, and in this case it overestimates by more than 1%. This is in contrast to pure silicon where PBE only overestimates the lattice constant by 0.6%. HSE performs better than PBE, but slightly worse than pps-PBE. However, HSE is expected to perform much better for the details of the electronic structure.

In all cases, except for PBEsol, we see a significantly smaller error for the better basis set (High or Tight).

Elastic constants

Both PBESol and pps-PBE hit close to the experimental bulk modulus, while regular PBE underestimates it. The same trend is observed for Youngs modulus, but without a reference value for comparison. The Poisson ratio is approximately the same for all methods.

Band structure

All tested methods correctly predict a valence band maximum (VBM) at the Brillouin zone point, and most also predict a conduction band minimum (CBM) close to the X point, along the –X path. However, the position of the CBM depends slightly on the method applied, and the band energy in the CBM significantly so (see also section *Band gaps*). In fact, for PBE the CBM may shift to the L point depending on basis set.

There is also a qualitative difference between HSE and pps-PBE at the X point. HSE has a gap of about 0.3 eV between the two lowest conduction bands, while they (almost) touch for pps-PBE.

Changing the basis set from Medium to High gives a shift of about 0.1 eV at the X point, and quickly decreasing towards . In all cases, the shift brings the result closer to the HSE values. For HSE, there is almost no difference between Light and Tight basis sets.

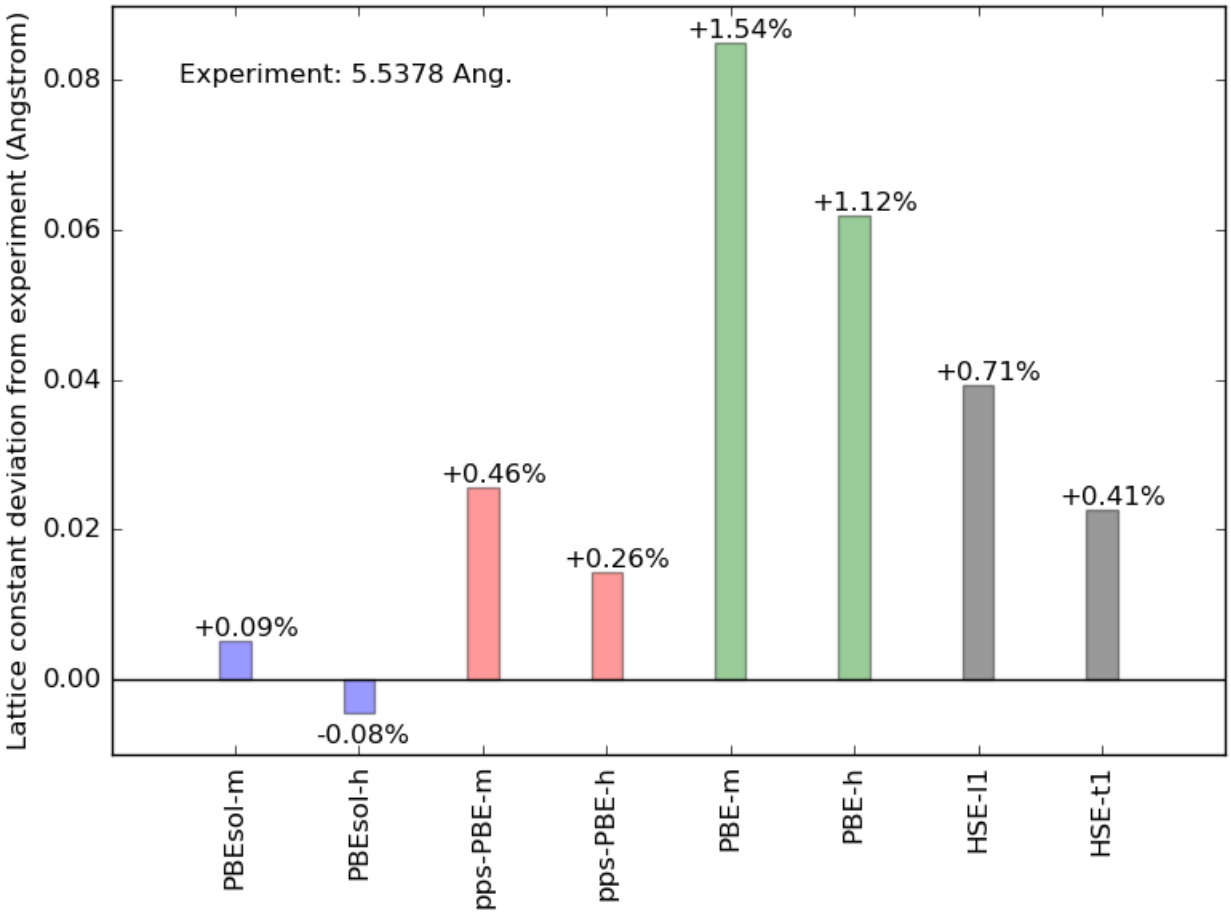

Fig. 3.63: SiGe lattice constant calculated using the PBEsol (blue), pps-PBE (red), PBE (green), and HSE (black) methods, and two different qualities of basis sets, plotted as deviation from the experimental value from the Ioffe website.

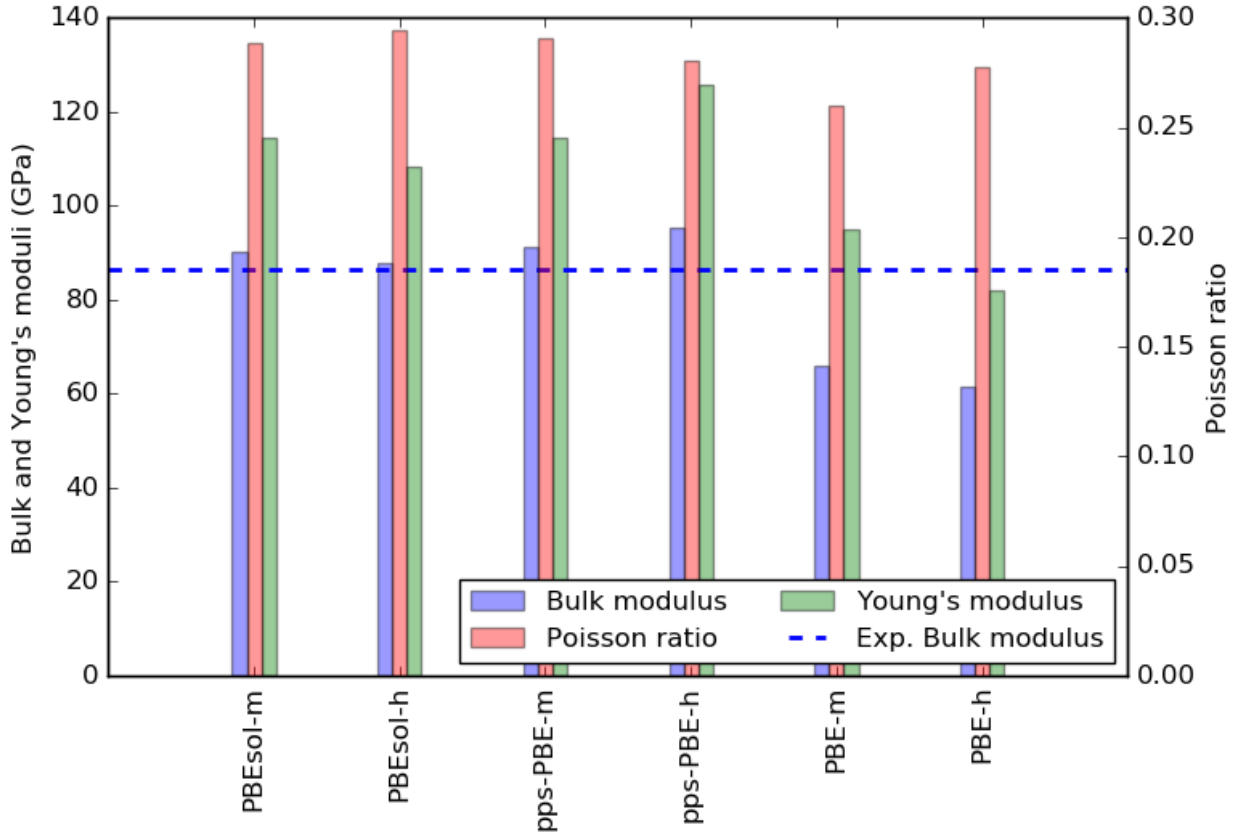

Fig. 3.64: SiGe bulk modulus (blue), Poisson ratio (red), and Youngs modulus (green) calculated using the PBEsol, pps-PBE, and PBE methods, and two different qualities of basis sets. The blue dashed line indicates the experimental bulk modulus, 86.5 GPa, adapted from the Ioffe website.

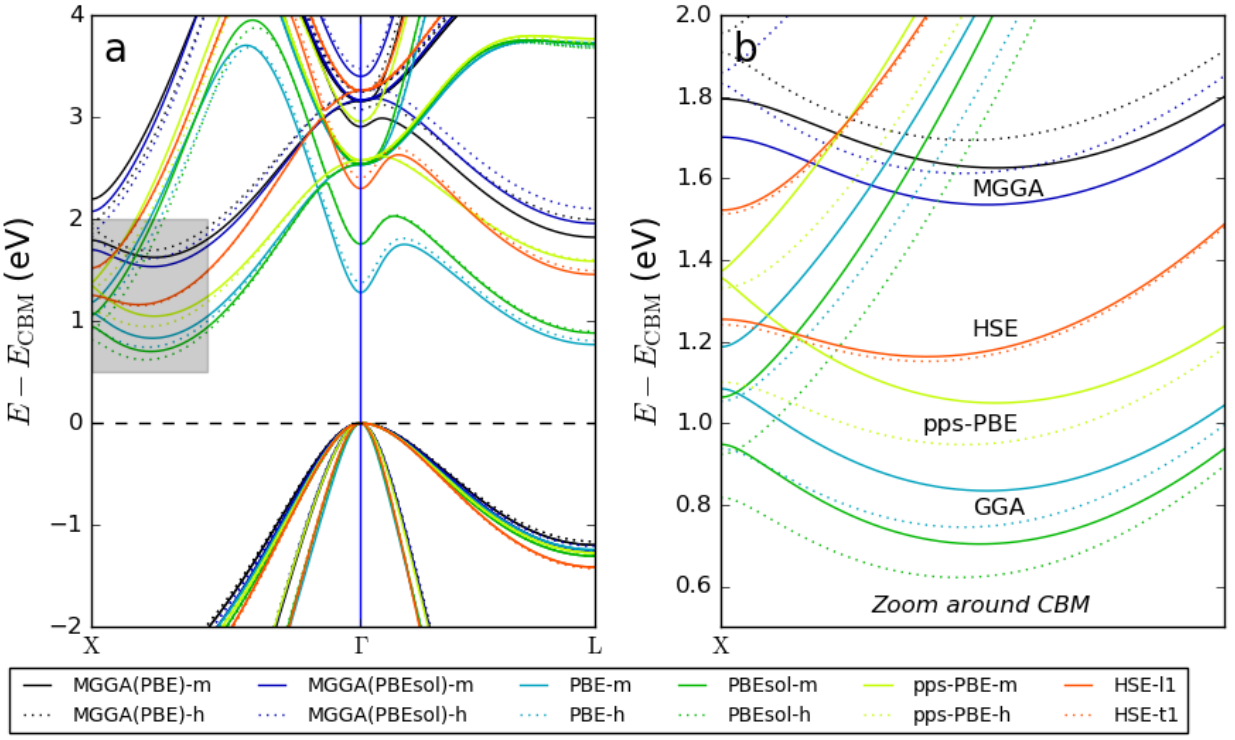

Fig. 3.65: SiGe band structure calculated with the PBE, pps-PBE, PBEsol, TB09-MGGA and HSE exchange-correlation functionals with two different qualities of basis sets. All bandstructures are calculated with the equilibrium structure for that computational model, except for TB09-MGGA, which has been calculated with both the PBE and PBEsol lattice constants.

Band gaps

The SiGe fundamental band gap (E_Δ) is especially well reproduced by the pps-PBE method, but also HSE, regular PBE and PBESol give reasonable agreement with experiment. Note, however, that the TB09-MGGA c-parameter was calculated self-consistently from the electronic structure (no fitting), while the pps-PBE projector shifts were essentially fitted to the silicon and germanium band gaps and lattice constants. On the other hand, the TB09-MGGA functional cannot be used for geometry optimization, which the pps-PBE method is well suited for.

There is much less agreement between the methods when it comes to the direct gaps, with TB09-MGGA consistently giving larger values, PBE and PBESol giving smaller values, and pps-PBE and HSE in between.

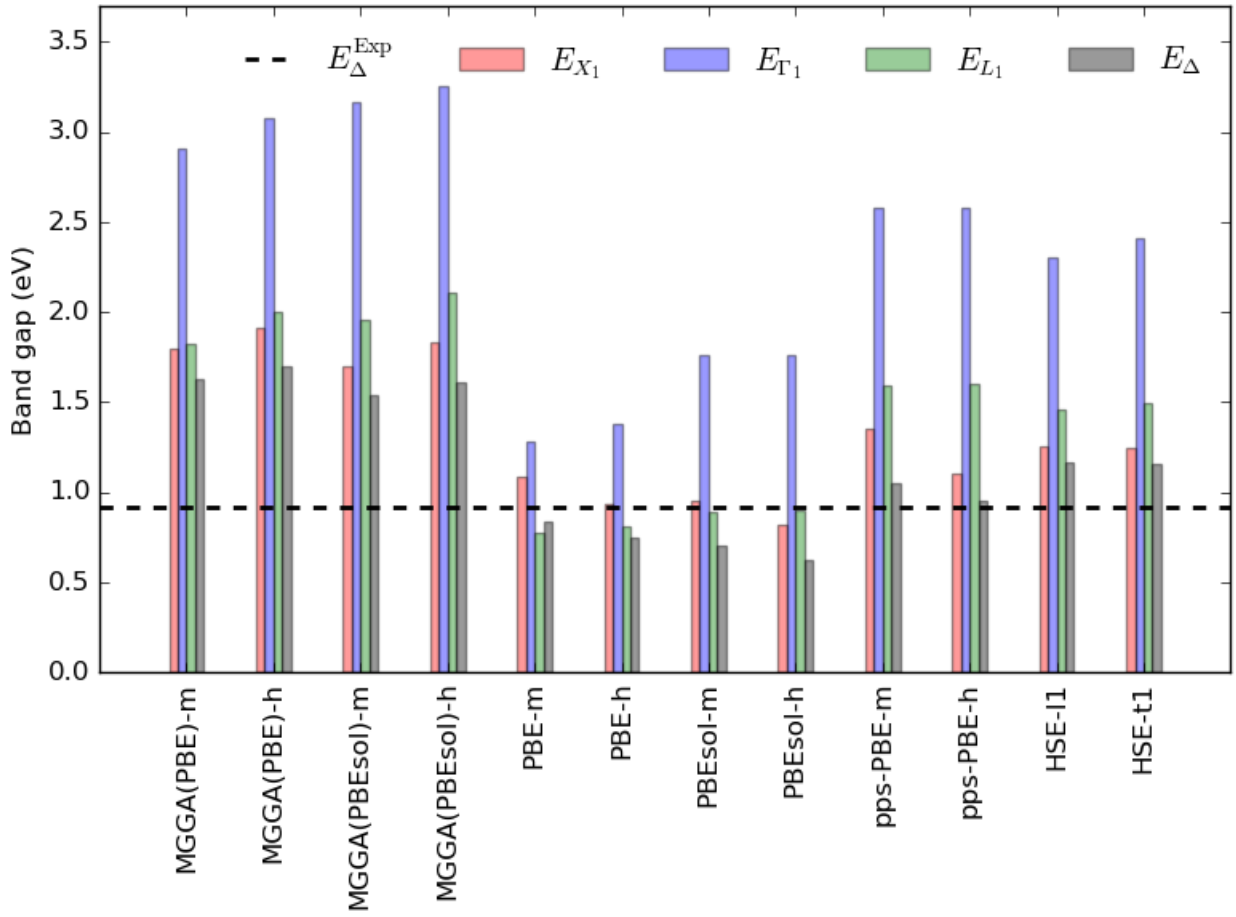

Fig. 3.66: SiGe band gaps, including both the fundamental gap (E_Δ, indirect), and the direct gaps to the X, Γ, and L points. The experimental E_Δ of 0.917 eV is from the Ioffe website, and is indicated by a black dashed line.

We also evaluate the effect of using HSE for band gap calculations. The figure below shows GGA and HSE band gaps of SiGe computed at the GGA lattice constants. The HSE indirect (fundamental) gaps are all roughly the same, while the direct gap at the Γ point does vary with lattice constant. The latter is probably due to strain effects. The PBE and PBEsol gaps are all significantly smaller than the corresponding HSE ones, as expected. On the other hand, the pps-PBE gaps are quite similar to the corresponding HSE gaps.

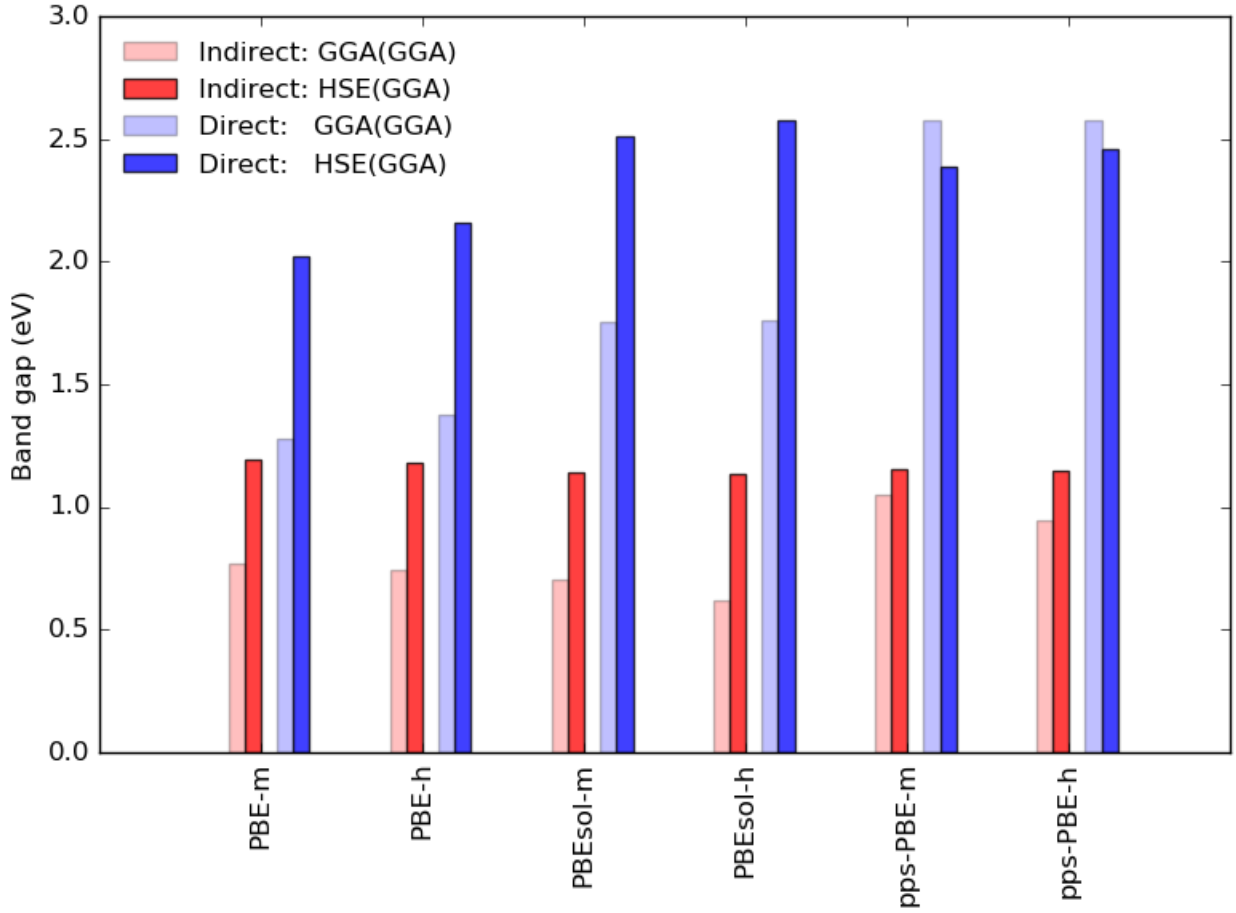

Fig. 3.67: Comparison of GGA and HSE indirect (E_{Δ}) and direct (E_{Γ_1}) band gaps at GGA lattice constants.

Effective masses

The SiGe electron effective masses in the Δ-point CBM are fairly close to experimental values for all applied methods.

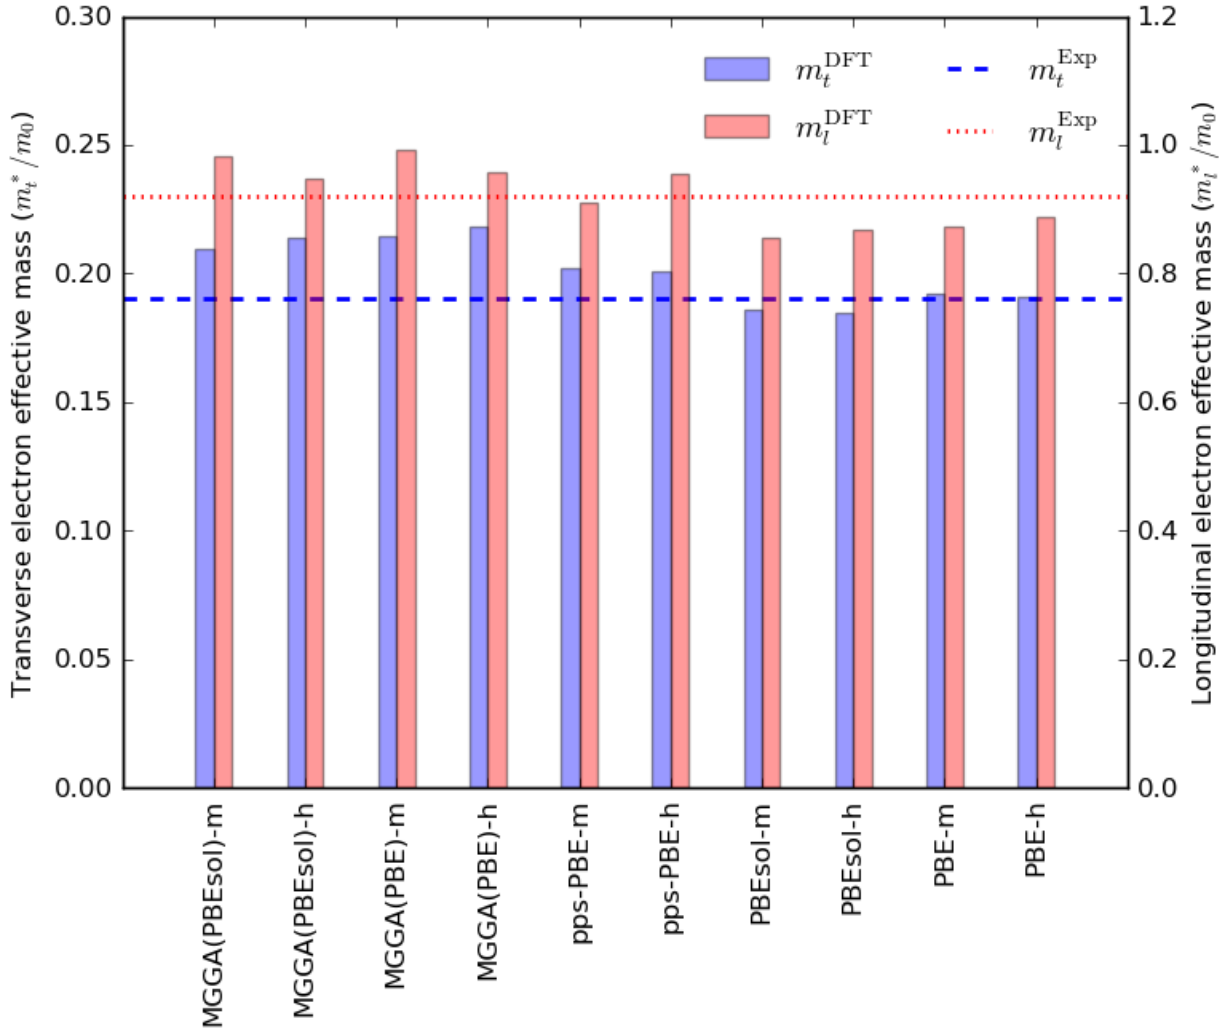

Fig. 3.68: SiGe transverse (blue; left y-axis) and longitudinal (red; right y-axis) electron effective masses calculated in the Δ-point conduction band minimum. Experimental effective masses are from the Ioffe website.

Dielectric constant

The static ($\omega = 0$) dielectric constant of the SiG lattice is most reliably reproduced by the PBE and PBEsol functionals, with the pps-PBE method a bit off, and TB09-MGGA more than 30% off. The latter is probably related to the fact that TB09-MGGA severely overestimates the direct band gap, while PBE and PBEsol are closer to the experimental direct gap. However, the fact pps-PBE gives a very good direct gap, but is somewhat off for the static dielectric constant, may indicate that the overall bandstructure is not as accurately described as the direct gap itself. We see almost no dependence of the dielectric constant on the basis set quality.

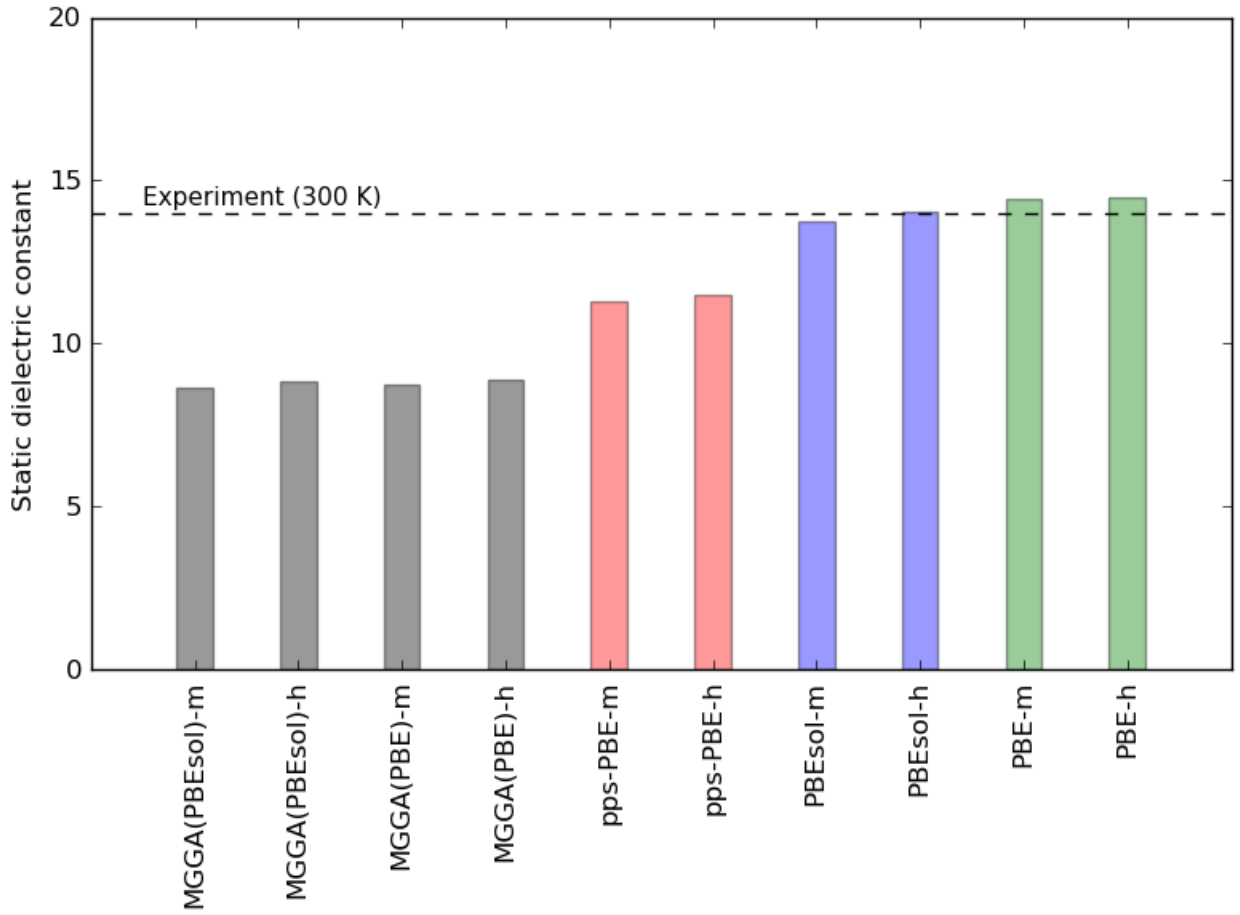

Fig. 3.69: Static dielectric constant of SiGe calculated with PBE, PBEsol, TB09-MGGA and pps-PBE methods, and two qualitites of basis sets. The experimental static dielectric constant of 14.0 is from the Ioffe website.

Appendix

The QuantumATK Python script shown below may be used as a template for ATK-DFT calculations for $Si_{0.5}Ge_{0.5}$ with the SG15 pseudopotential. The script defines the SiGe bulk configuration and then sets up the ATK-DFT calculator with PBE exchange-correlation. The script blocked named `Basis Set` shows various options for the SG15 basis set; ordinary PBE and PBE with pseudopotential projector shifts, both with Medium and High basis sets.

The script is available for direct download: `si50ge50.py`.

3.3 Batteries & Energy Storage

3.3.1 Li-air battery interface

Version: 2015.1

Li-ion batteries are, at the moment, the most widely used in most most electric vehicles and hybrid electric vehicles. However, there are some disadvantages such as high price, slow charging, and low energy/power density. Li-air batteries are attracting attention due to the higher energy storing capacity and are being seen as possible alternative for Li-ion batteries. Nevertheless, still a lot of research has to be done in order to make Li-air battery competitive. In particular, various complex chemical and electrochemical side-reactions occurs at the interfaces. Li_2O_2/Li_2CO_3 is indeed a very important interface since Li_2CO_3 is formed at the cathode with Li_2O_2 when carbonate-based electrolytes are used. In this tutorial you will use **QuantumATK** to create the Li_2O_2/Li_2CO_3 and use **ATK** study its electronic properties. You will compare the results with Ref.[1].

You will:

[1] YedilfanaăS. Mekonnen, JuanăM. Garcia-Lastra, JensăS. Hummelshøj, Chengjun Jin, and Tejs Vegge. Role of Li2O2-Li2CO3 Interfaces on Charge Transport in Nonaqueous Li-Air Batteries. *The Journal of Physical Chemistry C*, 119(32):18066–18073, 2015. doi:10.1021/acs.jpcc.5b04432.

•Import/create Li_2O_2 and Li_2CO_3 bulk structures.

•Cleave surfaces.

•Create Li_2O_2/Li_2CO_3 interface.

•Create device and optimize geometry.

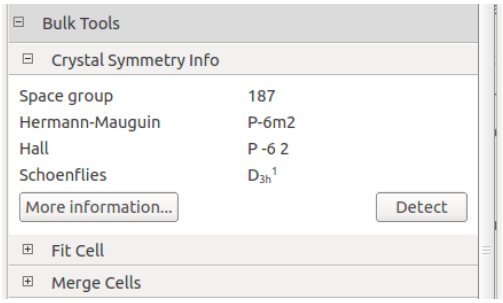
•Calculate electronic properties of the Li_2O_2/Li_2CO_3.

Li_2O_2 bulk and surface structures

Bulk structure

•Open the **Builder** and use *Add* → *From Database* to add the Li_2O_2 structure to the **Stash**.

Tip: You can use the *Bulk Tools* → *Crystal Symmetry Info* plugin to get the corresponding space group, for example



•Optimize the lattice parameters by running the `Li2O2_opt.py` script or use the experimental ones if you wish. In this tutorial you will use the GGA-RBE exchange-correlation potential by following the computational details as in Ref.[Page 729, 1].

Cleave surface

•Use the *Builders* → *Surface(Cleave)* tool to cleave the Li_2O_2 (0001) surface from the optimized Li_2O_2 structure as illustrated in the next figures.

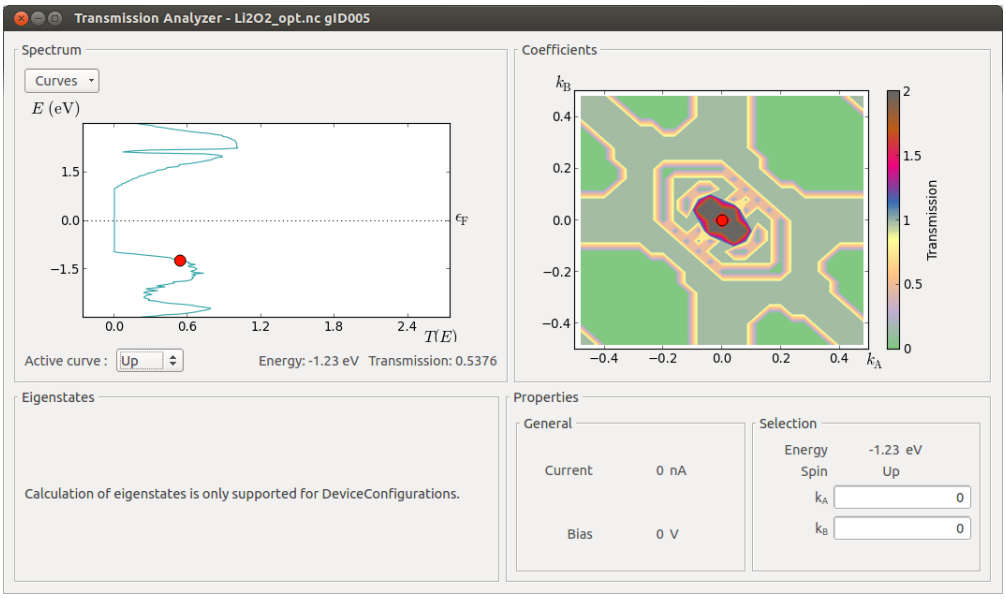
Electronic structure at zero bias

In the `Li2O2_opt.py` script a few analysis have been added such as the *TransmissionSpectrum* analysis which $T(\mathbf{k}, \epsilon)$ you can find loaded in the **LabFloor** once your simulation is done.



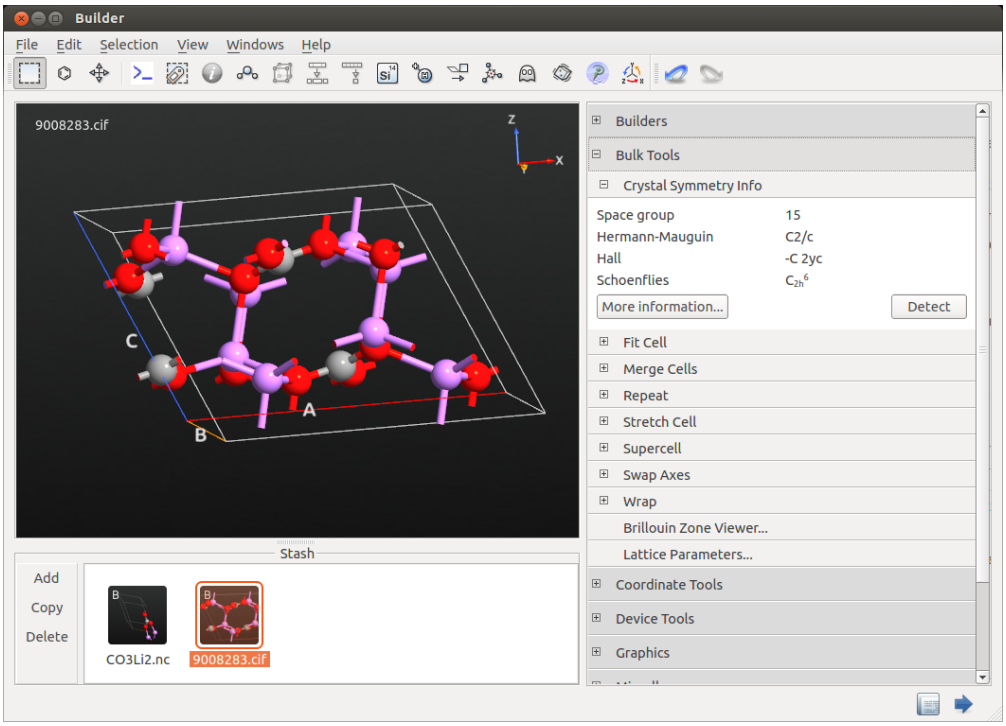
From the figure above, you can see that Li_2O_2 shows a wide band gap and no electronic conduction is expected at low bias voltages. Moreover, as demonstrated in[Page 729, 1], when introducing Li vacancies the electronic conduction decreases even more.

Note: You can follow the transmission_spectrum_perfect_sheets_graphene_mos tutorial for more details and how to set up a transmission spectrum analysis for a perfect periodic bulk system.

Li_2CO_3 bulk and surface structures

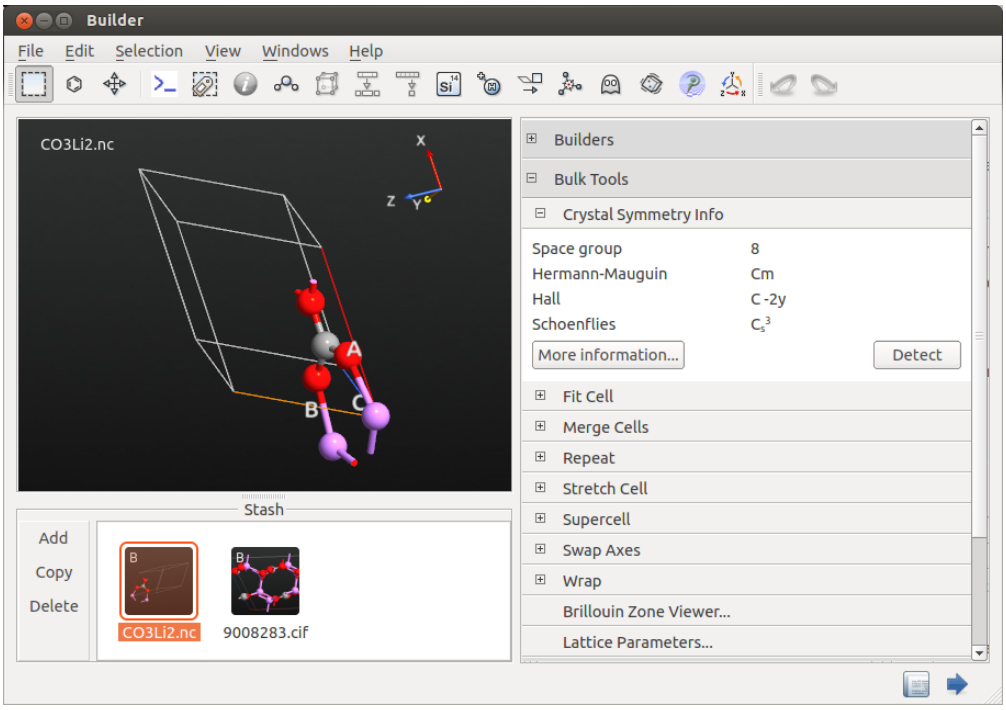
Bulk structure

The Li_2CO_3 bulk structure is not present in the internal database of **QuantumATK**. You need to get the structure file, usually a CIF file, from an external database, e.g. you can use the . Search, download and copy the `9008283.cif` file to your project folder. It will be automatically loaded in the **LabFloor**. For more options see *Import XYZ, CIF, CAR, VASP Files in QuantumATK tutorial*.



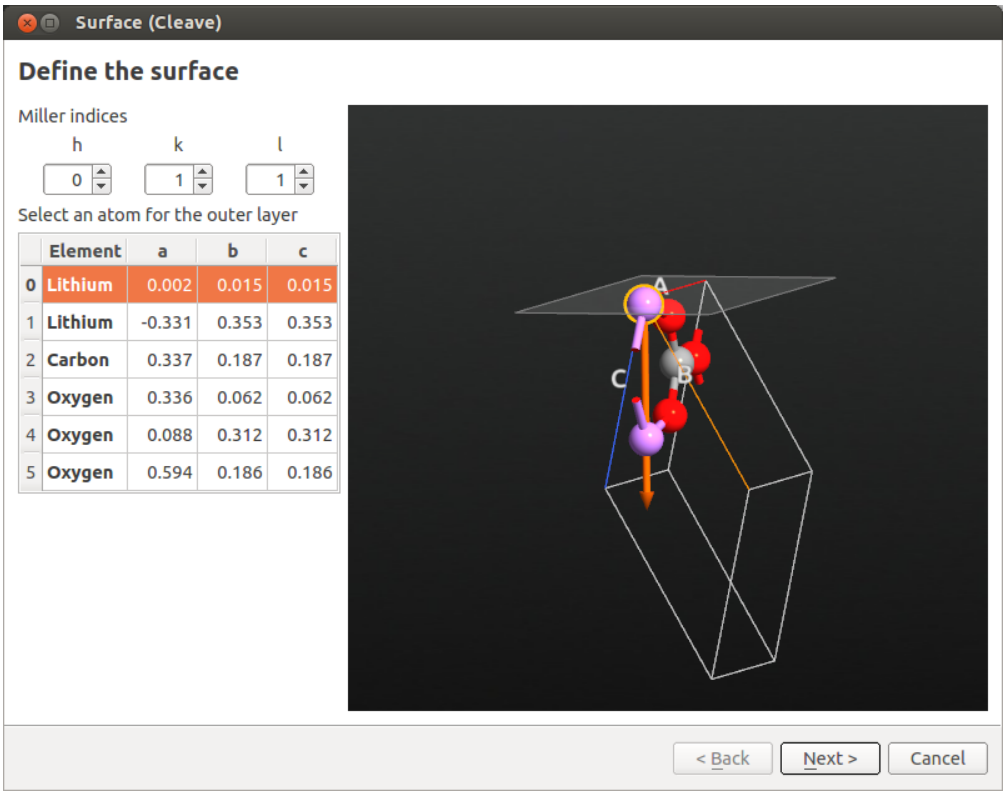
When interfacing the Li_2CO_3 surface with the Li_2O_2 you will need to use a large cell to get a small lattice mismatch. This is because the CO_3 planes in the *C2/c* space group are slightly misaligned from the cell axes. In this tutorial you will use a modified Li_2CO_3 structure with space group *Cm* where the CO_3 planes are perpendicular to the (011) plane. Also, this is the structure used in cite:*Yedilfana2015*.

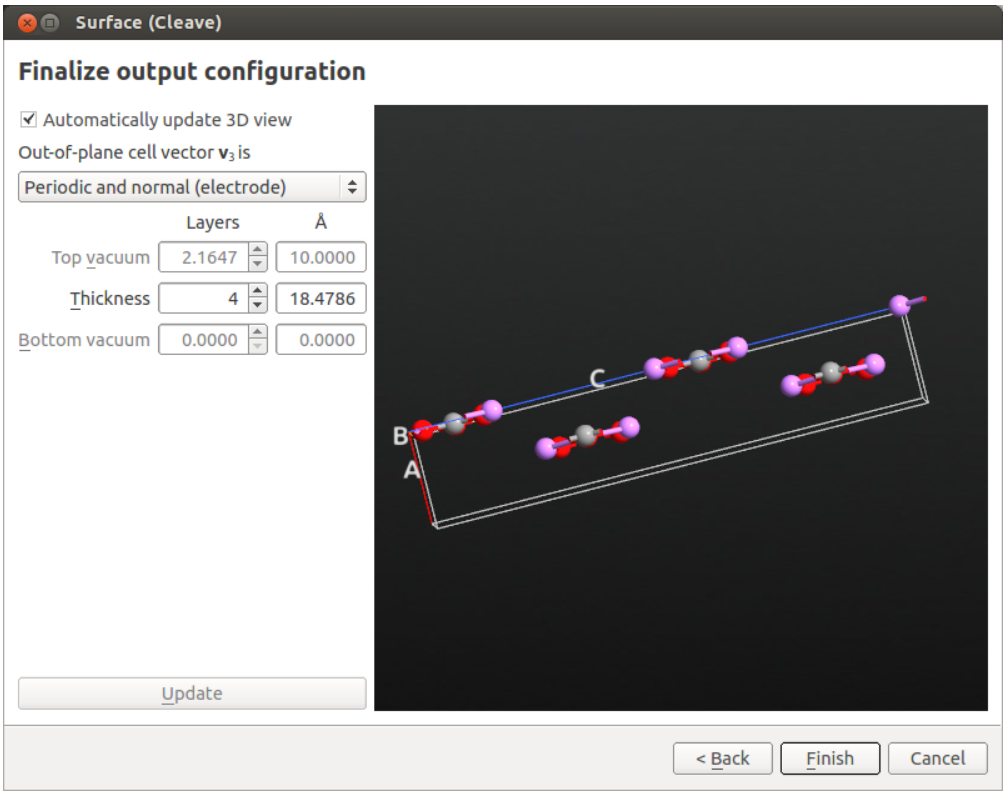
Download the `Li2CO3.py` script and import the structure to the **Builder** to analyze it.



Cleave surface

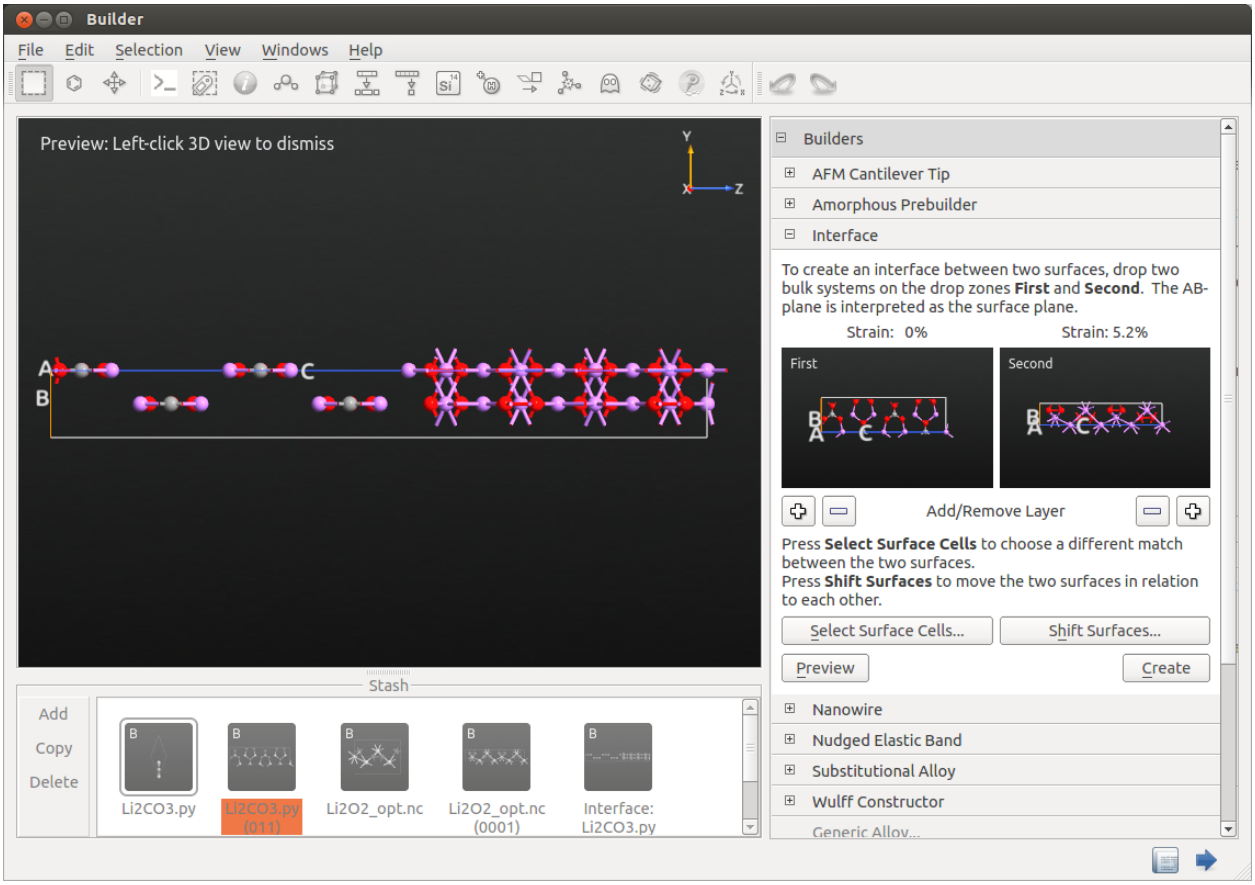
Use the *Builders* → *Surface(Cleave)* tool to cleave the (011) surface as indicated in the figures below.



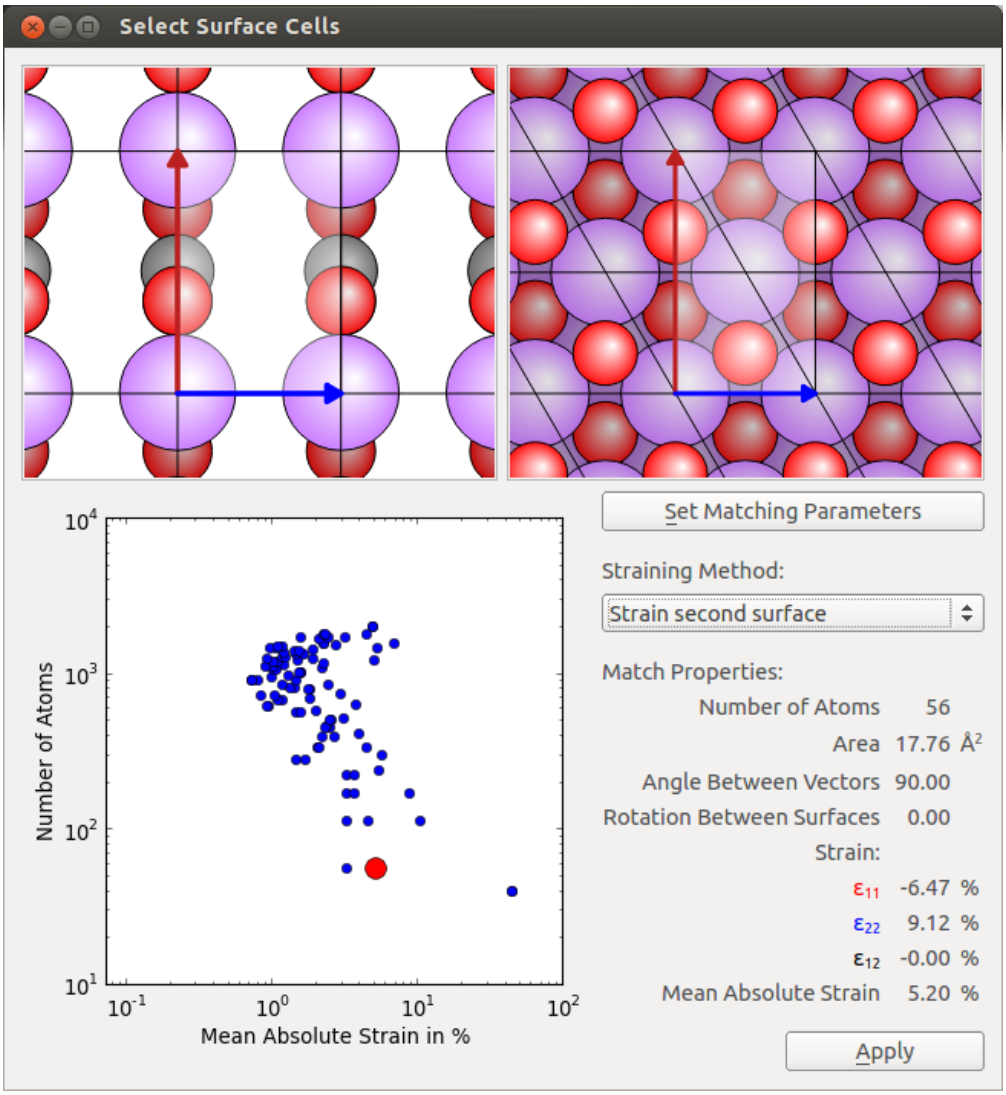


The Li_2O_2/Li_2CO_3 interface

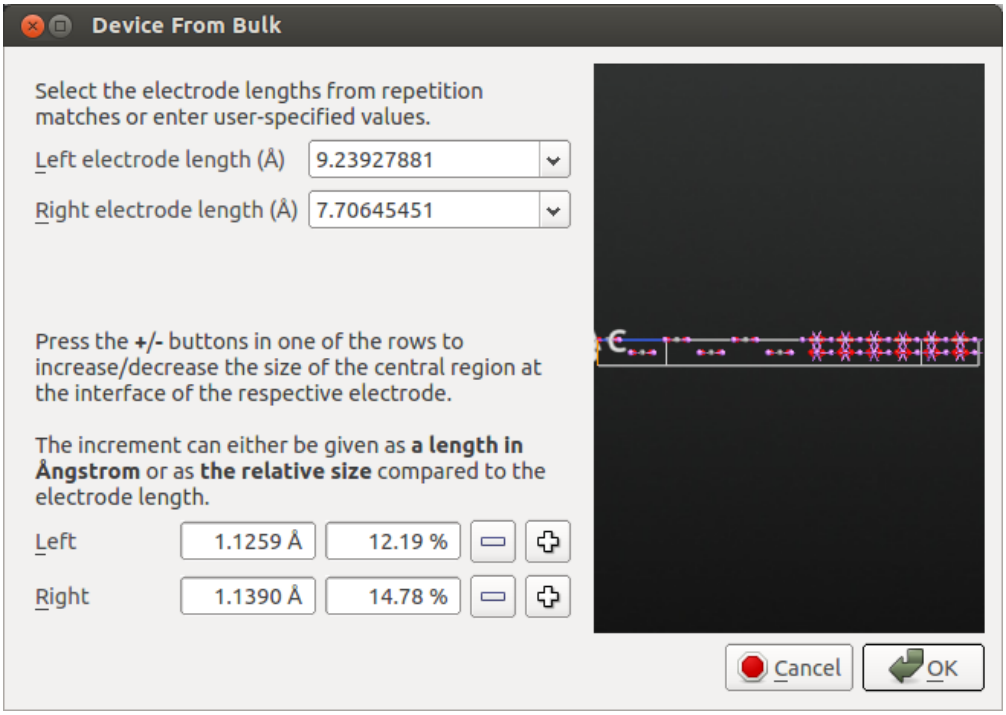
Open the *Builders* → *Interface* tool and drag and drop the Li_2CO_3 surface and the optimized Li_2O_2 surface to the first and second drop zones.



The default results are correct. However, if you want to choose another interface you can click on *Select Surface Cells* button and choose the desired matching parameters.



You can now create the device configuration with the *Device Tools* → *Device From Bulk* plugin. The default electrode lengths are fine.



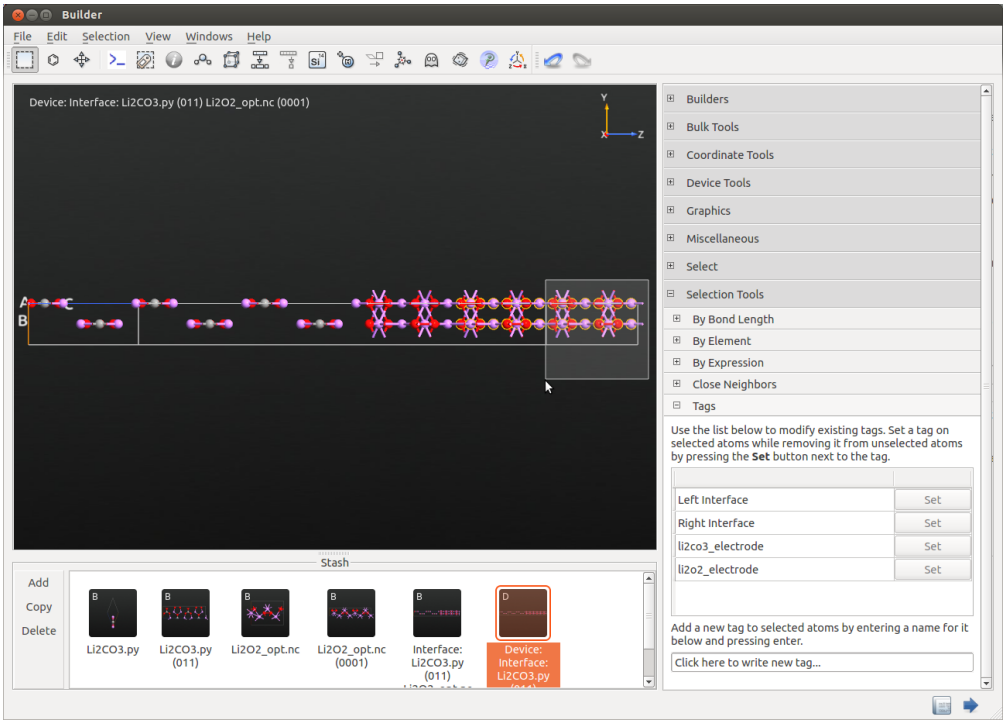
You can download this structure here: `device_configuration_initial.py`. Note that in this final structure the Li_2CO_3 side has been slightly shifted towards the Li_2O_2 side to allow for a proper relaxation

Tip: You can learn more about the Interface Builder in the Technical Notes on *Interface Builder*.

Optimizing the interface

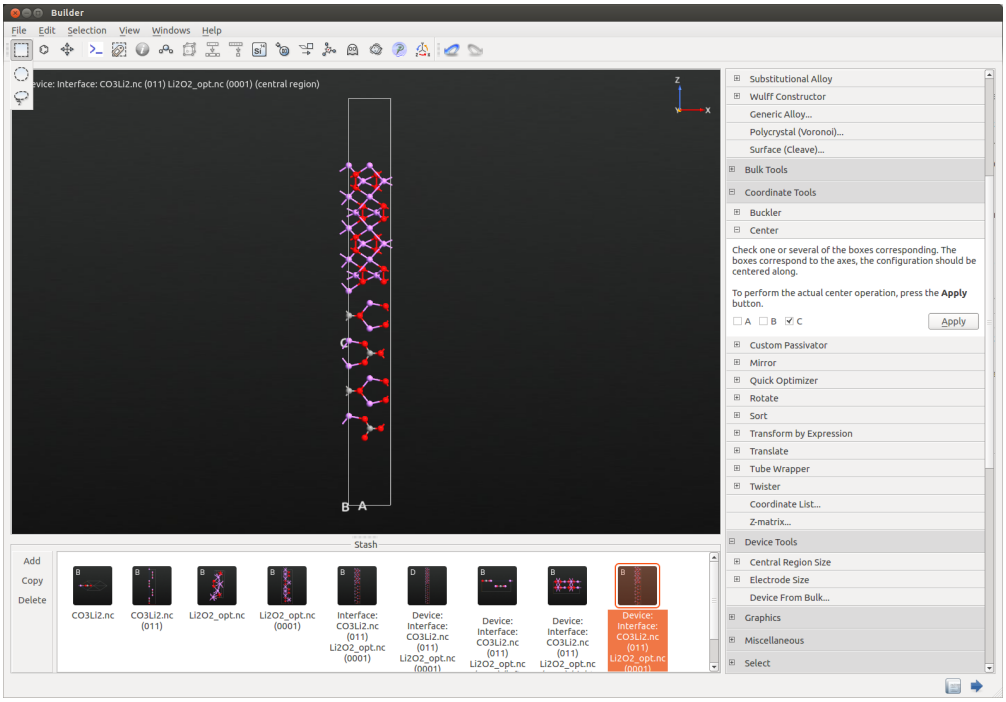
A step-by-step procedure on how to optimize the geometry of a device configuration is described in the *Advanced device relaxation - manual workflow*. The main steps are the following:

- Tag the electrode extension regions by using the *Selection Tools* → *Tags* plugin. You can do that by selecting the atoms in the electrodes, the electrode extension region will be automatically selected.



Hint: Tag also the first layer outside the electrode extension regions which is already part of the central region.By doing so, the *Device From Bulk* plugin will be able to recognize the proper periodicity and recreate the device structure (see below).

•Extract the central region as *BulkConfiguration* by using the split device plugin, increase the C vector and center the configuration.



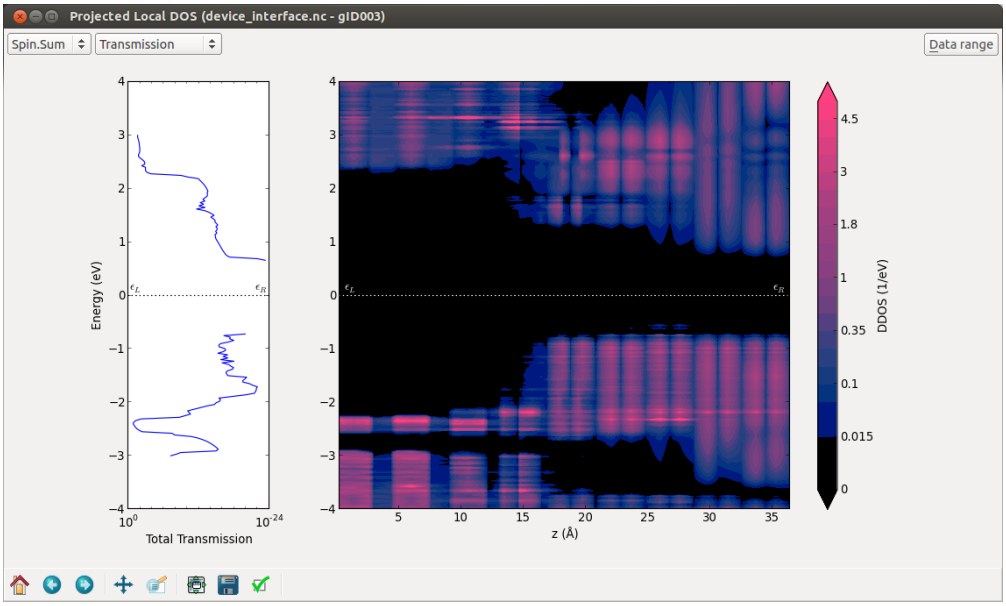
•Set up a geometry optimization calculation with rigid body constrain for the Li_2O_2 tagged region and fixed constrain for the Li_2CO_3 one. You can also download the corresponding `interface_bulk_opt.py`.

•Finally, when the optimization of the interface in a bulk configuration is done, import in the **Builder** the optimized structure and recreate the device as described in the previous section.

Electronic structure

Send the device configuration from the **Stash** to the **Scripter** and set up a new device calculator with the GGA-RPBE exchange-correlation potential and a 7x15x200 k-point sampling. You can leave all other parameters as defaults. Here, you can download the whole script: `device_interface.py`.

You can add various analysis to investigate in more detail the electronic structure and the transport properties. Below, for example, the projected device density of state analysis is shown in the picture. Here you can see that Li_2CO_3, on the left side, has a much higher band gap than Li_2O_2. Electronic conduction is thus expected to be very low, as it is indeed shown in[Page 729, 1].



Hint: You can further investigate the Li diffusion processes in Li_2O_2 and Li_2CO_3 crystals by following the *Li-ion diffusion in LiFePO4 for battery applications*.

References

3.3.2 Li-ion diffusion in $LiFePO_4$ for battery applications

Version: 2016.3

$LiFePO_4$ is among the typical rechargeable Li-ion battery cathode materials with high energy density and low cost, while also being environmentally friendly[1,2]. In this tutorial you will use ATK-DFT to estimate the Li-ion diffusion rates along different crystallographic directions in $LiFePO_4$.

[1] M.ăSaiful Islam and Craig A.ăJ. Fisher. Lithium and sodium battery cathode materials: computational insights into voltage, diffusion and nanostructural properties. *Chem. Soc. Rev.*, 43(1):185, 2014. doi:10.1039/C3CS60199D.

[2] William DavidsonăRichards YanăWang. Design principles for solid-state lithium superionic conductors. *Nature Materials*, 14(10):1026, 2015. doi:10.1038/nmat4369.

In particular, you will:

•Import the $LiFePO_4$ bulk structure.

•Optimize the $LiFePO_4$ lattice parameters.

•Create the $Li_{1-x}FePO_4$ structures.

•Optimize the initial and final configurations.

•Create initial NEB trajectories (IDPP interpolation).

•Optimize the Li diffusion path.

•Calculate the reaction rates using harmonic transition state theory (HTST).

Import $LiFePO_4$ bulk structure

The $LiFePO_4$ structure can be imported from the **Crystallography Open Database** plugin in QuantumATK.

1.Click the **Builder**.

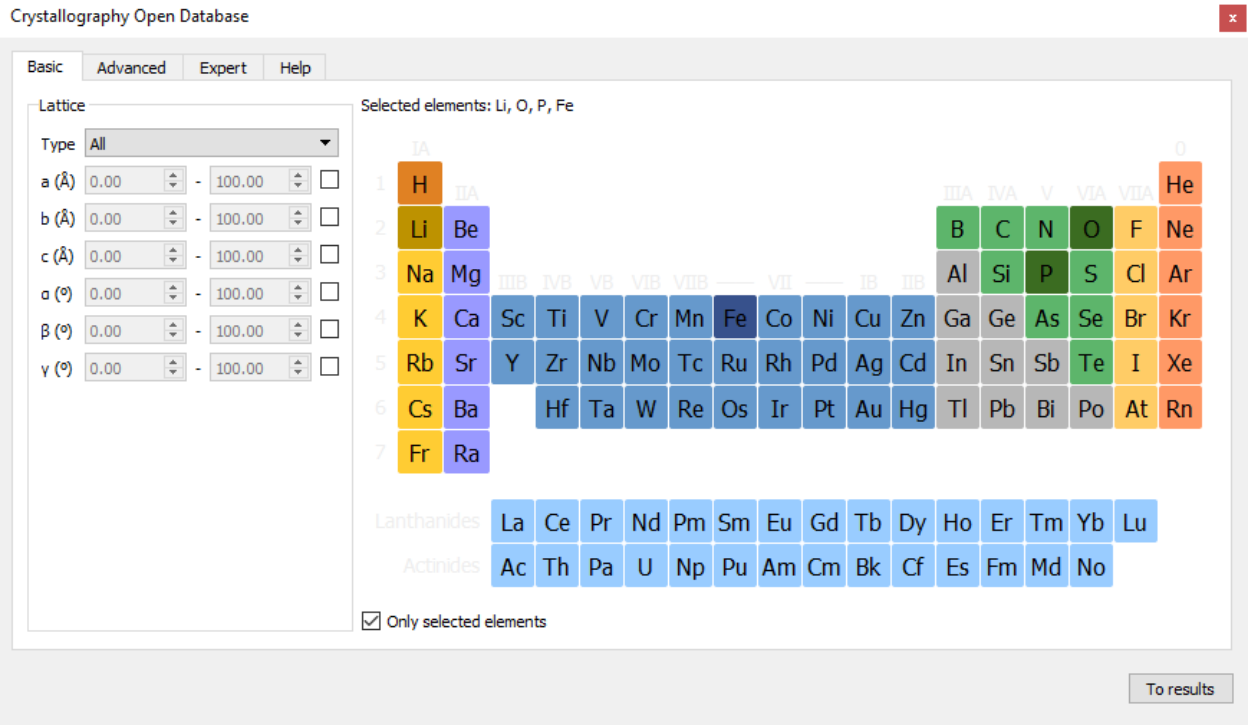
2.Open the *From Plugin* → *Crystallography Open Database*.

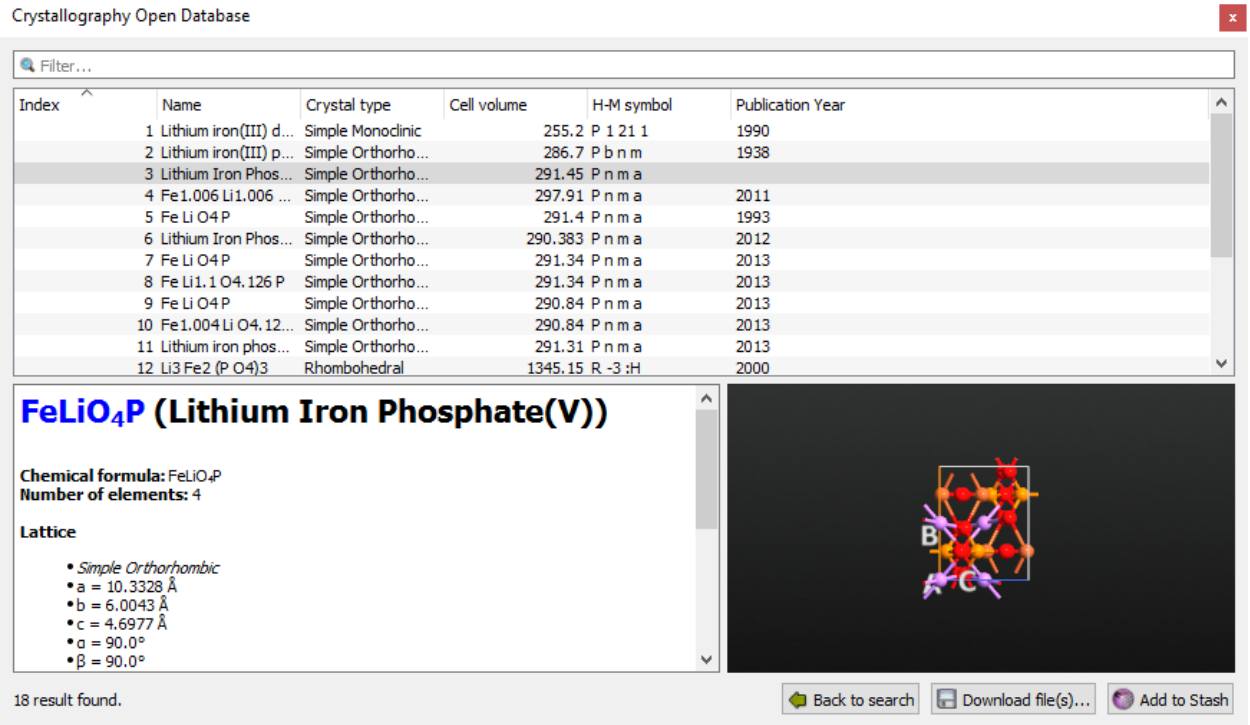
3.Select *Li, Fe, P, O* as elements and click the **To results** button.

4.Choose *Lithium Iron Phosphate(V), Simple Orthorhombic(Pnma)*.

5.Click **Add to stash** button.

It will be automatically loaded in the **Builder** stash.

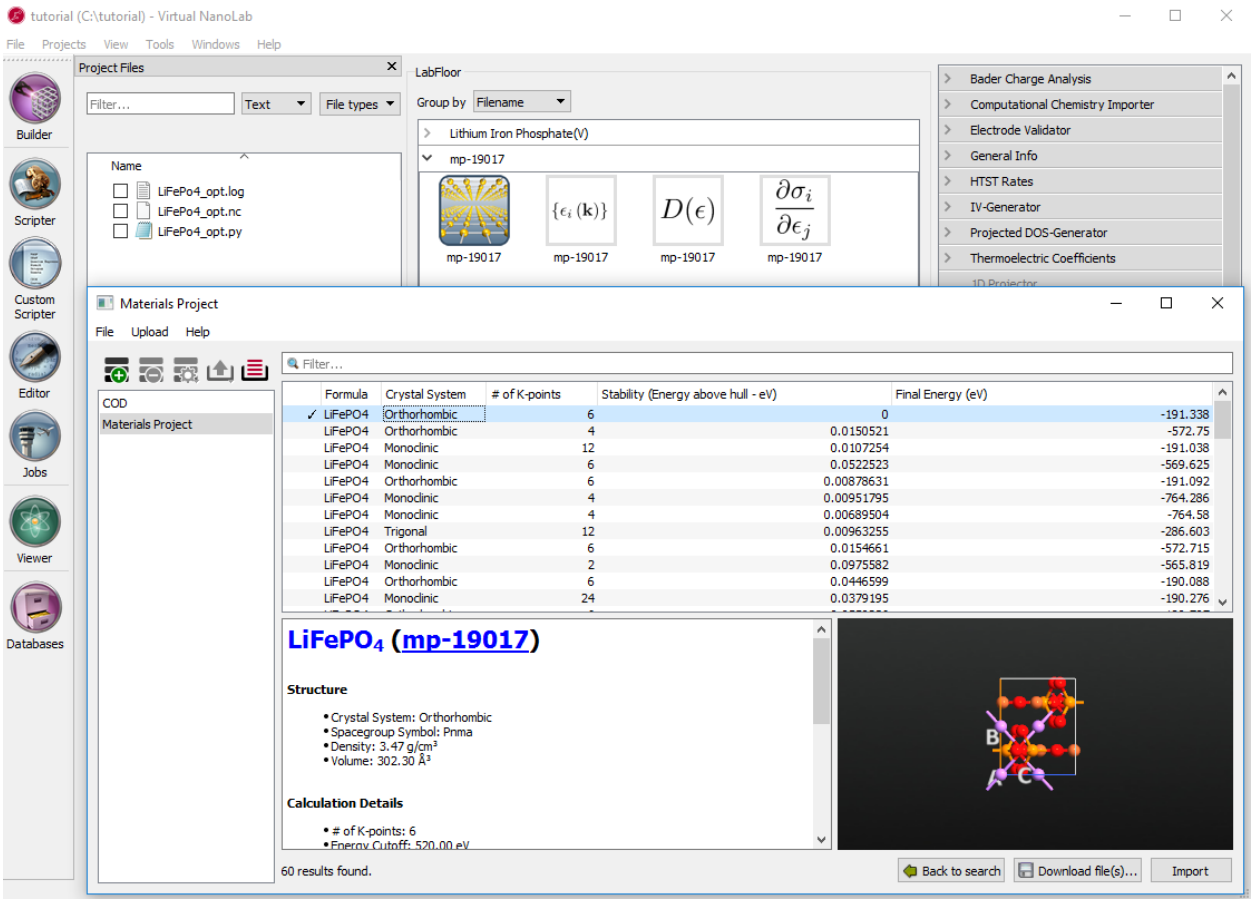




New functionality in QuantumATK 2017:

From the **QuantumATK 2017** version, crystal structures such as $LiFePO_4$ can be imported by the QuantumATK **Databases** tool as follows: Click the **DataBases**. See **COD** (Crystallography Open Database) and **Materials Project**. Both are possible to get the $LiFePO_4$ structure. In the COD case, select *Li, Fe, P, O* as elements and click the **Search** button.

You can also use the **Materials Project** database. Choose the Materials Project. Select elements or type LiFePO4. Select one and click the **import** button, it will be automatically loaded in the **LabFloor** in the same way as the COD. In this case, you can get more calculation information including the structure from the Material Project database.



For more options, see also *Import XYZ, CIF, CAR, VASP files in QuantumATK tutorial*.

Optimize $LiFePO_4$ lattice parameters

You can import the $LiFePO_4$ structure to the **Builder** to have a deeper look into the structure.

Note: In order to better compare with the results of reference[3] you can use the *Bulk Tools* → *Swap Axes* tool to swap **C<->A** and **Z<->X**. However, by doing so, the configuration will lose the information about the symmetry type, in this case *Simple orthorhombic*. Use the *Bulk Tools* → *Lattice Parameters* tool to set the *Lattice type* to *Simple orthorhombic*.

In order to optimize the lattice parameters, send the $LiFePO_4$ structure from the **Stash** to the **Scripter** to set up a new DFT calculation as follows:

1. Add the **New Calculator** block and modify the following parameters:

- SGGA-PBE exchange correlation potential
- 7x5x3 k-point sampling

(We will use the the default FHI pseudopotentials and DZP basis set).

2. Add an **OptimizeGeometry** block and modify:

[3] DhamodaranăSanthanagopalan YuriăJanssen. Reciprocal Salt Flux Growth of LiFePO 4 Single Crystals with Controlled Defect Concentrations. *Chemistry of Materials*, 25(22):4574, 2013. doi:10.1021/cm4027682.

- Max forces 0.02 eV/Å
- Max stress 0.1 GPa
- Remove check from **Constrain cell** to allow for cell optimization
- Check **Save trajectory** and specify the file `LiFePo4_opt.nc`

3. Change default output file name to `LiFePo4_opt.nc`
4. Finally, send the script to the **JobManager** and run the calculation.

It takes about 30 minutes on 8 cores. After finishing the job, open the optimized *BulkConfiguration* with object ID `glD002` with the **Builder**. Check the new optimized lattice parameters which agree to within 0.1 percent with the experimental data.

Create the $Li_{1-x}FePO_4$ structures

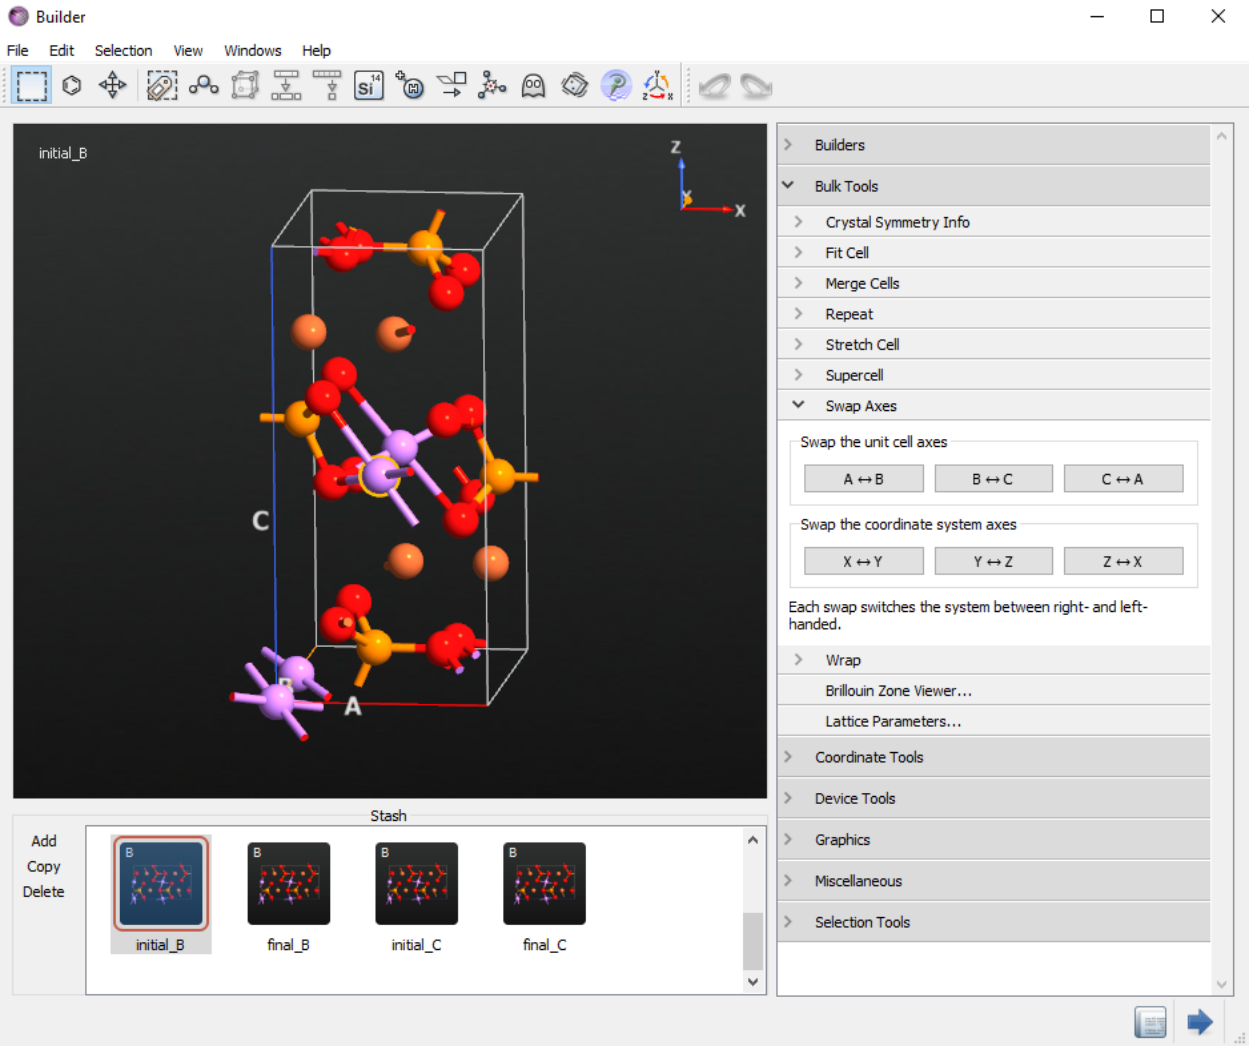
In this tutorial you will study the diffusion of one Li atom for a Li-deficient structure such as $Li_{1-x}FePO_4$. In particular, you will remove one of the four Li atoms from the bulk configuration. Note that the diffusion energy barriers depend on the Li concentration[4].

In the next section you will set up the calculation for the diffusion of a Li atom along two different directions. You thus need to create initial configurations and final configurations for the same Li atom diffusing along the B and C directions.

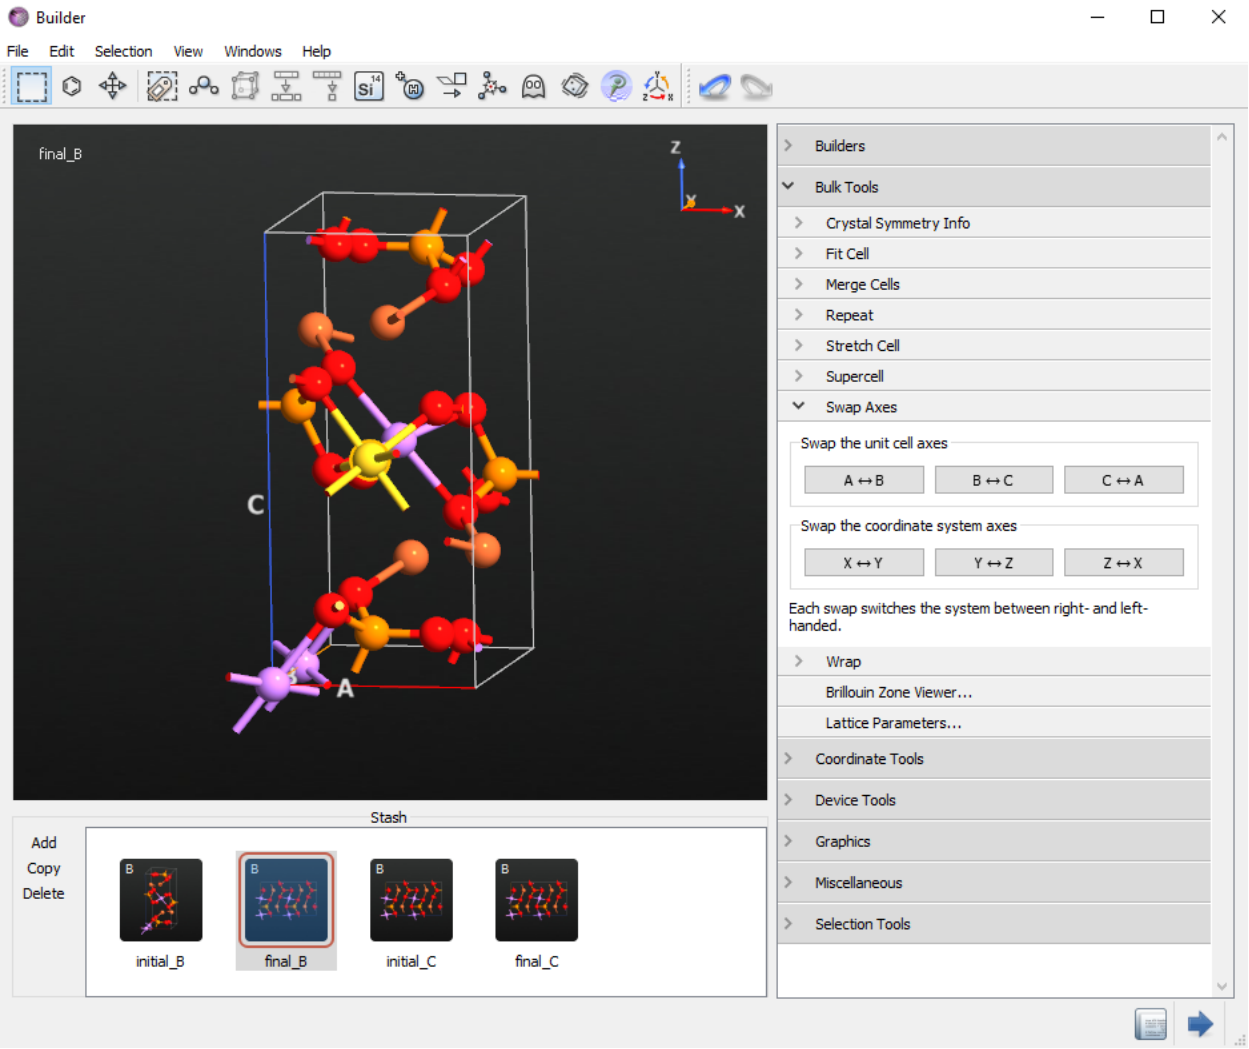
Create initial and final structures for diffusion along B direction

1. Right-click on the configuration on the **Stash** and make three copies such that you have 4 identical configurations. We will make initial and final structures for the B and C directions.
2. From the first configuration, delete one Li atom as in the figure below. This will be your initial structure for the B direction NEB calculations and you can rename it *initial_B*.

[4] Chuying Ouyang, Siqi Shi, Zhaoxiang Wang, Xuejie Huang, and Liquan Chen. First-principles study of Li ion diffusion in LiFePO4. *Physical Review B*, 2004. doi:10.1103/PhysRevB.69.104303.

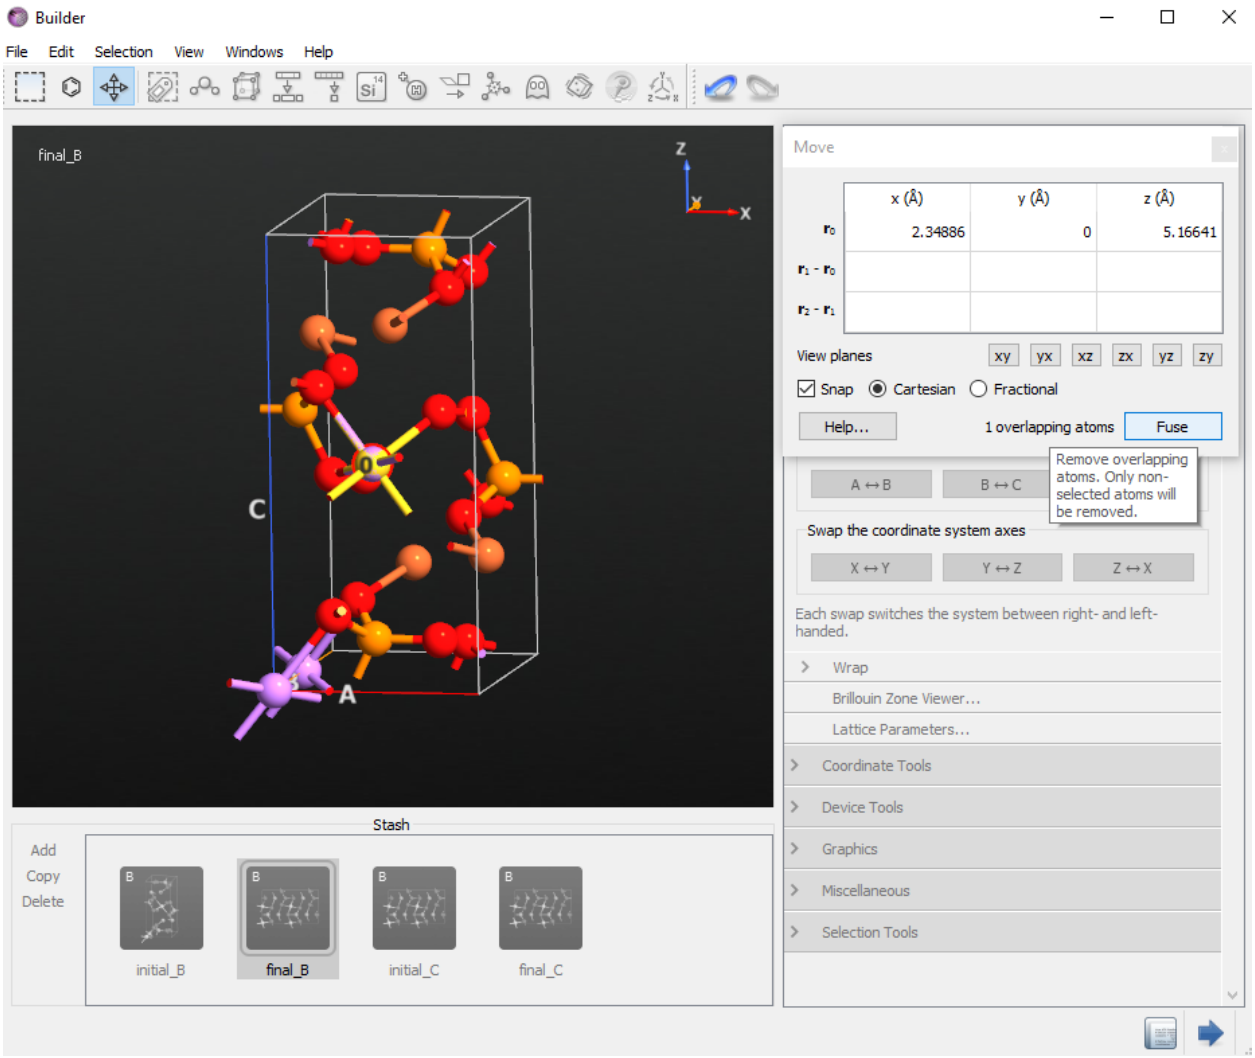


3. Double click the second configuration to make it active. Next rename it *final_B*. Select the same Li atom you just deleted from the initial configuration and open the **Periodic Table** tool. Click on **Gold** (Au) element to change the Li atom to Gold.



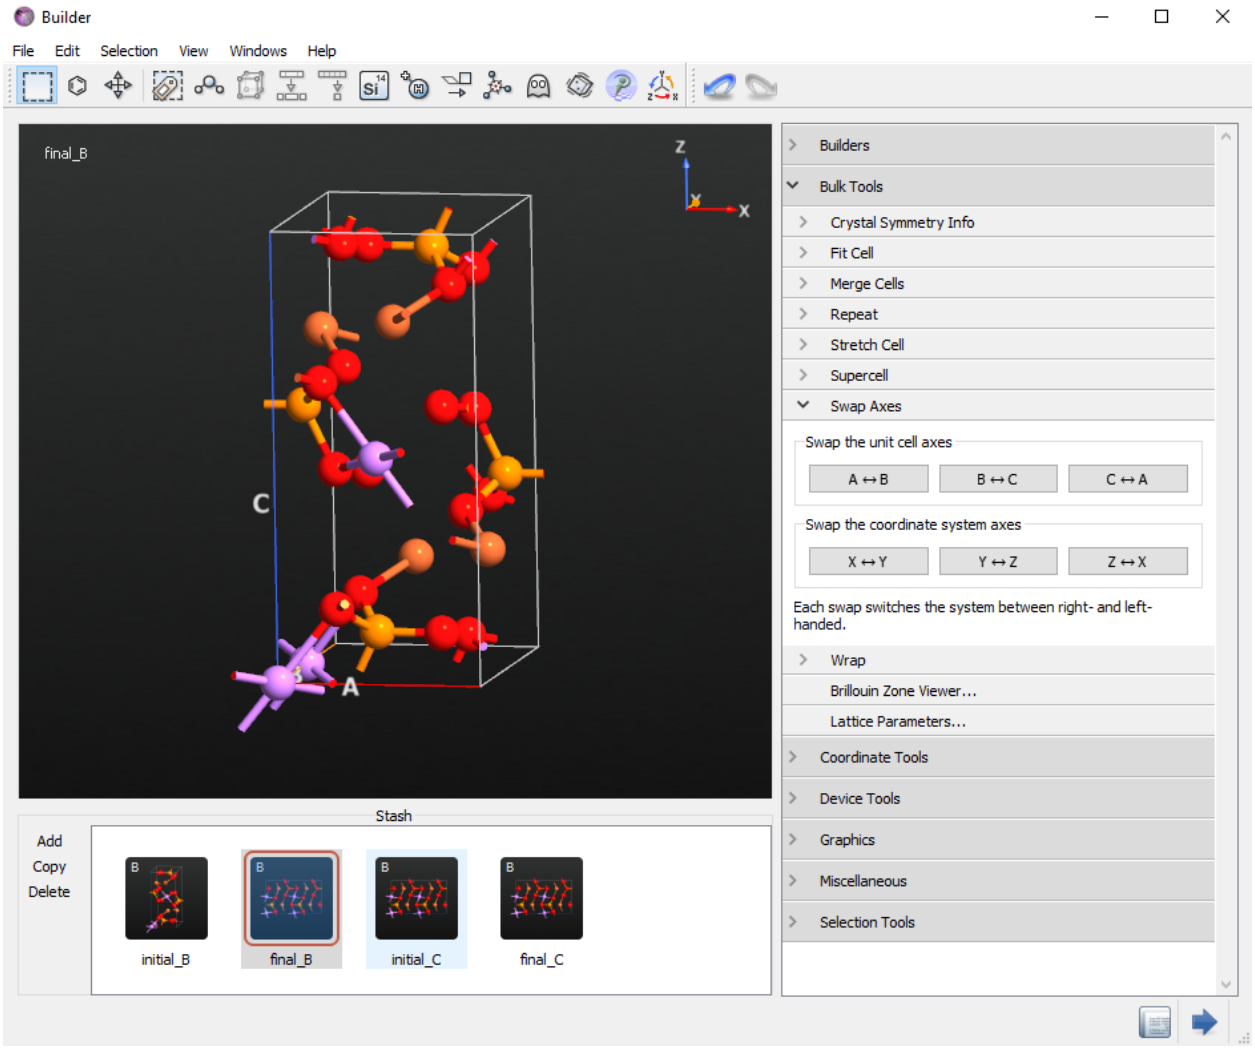
Tip: You are applying this trick to be able to move the Li atom into a specific position. In this case, the position of the Li vacancy defined by the Gold atom. There are indeed several other workarounds to build this final configuration, e.g. by copying the coordinates of the original Li atom you removed. You are welcome to use here the procedure that you find more relevant and intuitive for you.

4. Select Li atom number 7 (the one next to the Gold atom along the B direction) and use the **Move** tool to move it on top of the Gold atom. Be sure that the *Snap* option is enabled.



5. Use the *Fuse* option to remove the Gold atom and your final structure is now ready.

6. Finally, check the Li atom number 6 in the *initial_B* and *final_B* configurations. Li atom number 6 should be moved in the B direction.



Create initial and final structures for diffusion along C direction

Follow the same procedure as above to create the configuration along the C direction. The initial structure for the C direction is the same as the *intial_B* structure. Rename it *initial_C*. In this case, the final structure moves Li atom number 4 to the removed Li position (substituted Gold) in the *inital_C* structure. Rename the final structure, *final_C*.

Optimize initial and final configurations

Send each structure, *initial_B*, *final_B*, *initial_C* and *final_C*, to the **Scripter** and set up a geometry optimization calculation with the same parameters as for the $LiFePO_4$ structure. However, in this case you will not optimize the lattice parameters. Check the *Constrain cell* option as indicated below.

Moreover, in this case you can use the unpolarized GGA.PBE functional. This will allow you to run your calculation much faster. Here you can download the four input scripts: `initial_B.py`, `final_B.py`, `initial_C.py` and `final_C.py`.

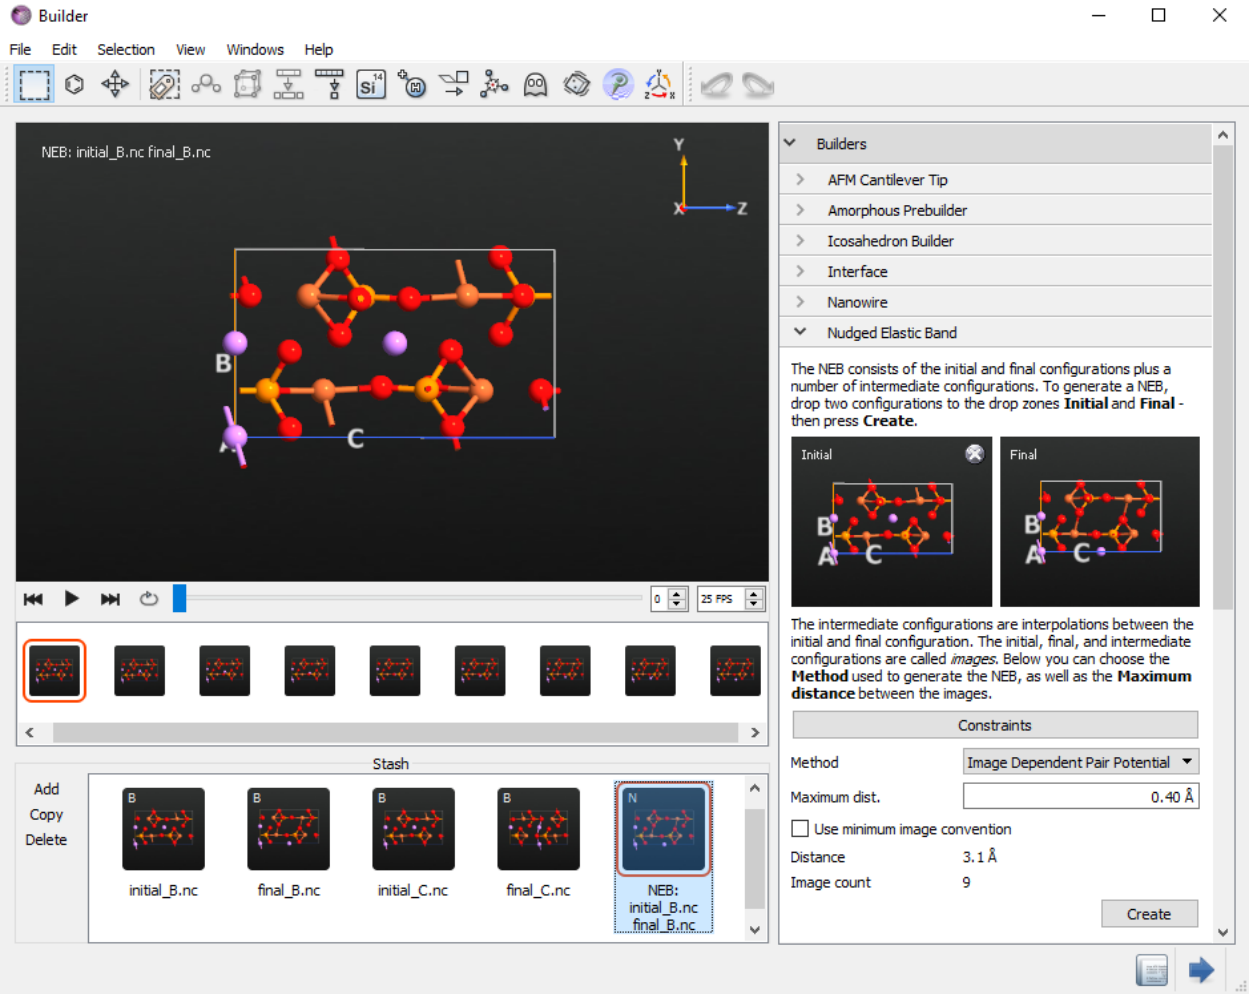
Create initial NEB trajectories

The tutorial *Pt diffusion on Pt surfaces using NEB calculations* will teach you how to set up the NEB object. Here we will highlight only the main steps.

1. When the optimization of the end points are done you will find the optimized configurations loaded in the **LabFloor** with object ID equal to *glD002*. Drag and drop these *BulkConfiguration* objects directly into the **Builder**.

2. In the **Builder** open the *Builders* → *Nudged Elastic Band* plugin and drag and drop from the **Stash** the initial and final configurations corresponding to the diffusion of a Li atom along the B direction, `initial_B.nc` and `final_B.nc` configurations.



3. Select the *Image Dependent Pair Potential* interpolation method and use 9 images including the end points.

4. Create the initial Li diffusion path along C direction with the `initial_C.nc` and `final_C.nc` configurations. Use 9 images with 0.8 Å maximum distance including the end points .

Optimize Li diffusion path

You are now ready to set up and optimize the Li diffusion path in $LiFePO_4$.

1. Send the two NEB objects from the **Stash** to the **Scripter**.
2. Add and set up a **New Calculator** with the same settings as for the calculators of the end points.
3. Add a **OptimizeGeometry** block and be sure to select the *Climbing Image Method*.
4. Finally, run the two NEB calculations `neb_B.py` and `neb_C.py`.

Note that as described in the *Pt diffusion on Pt surfaces using NEB calculations*, you can run this calculation in parallel over many MPI processes. In particular, a NEB run is parallelized over the internal images. **ATK** will try to detect the best parallelization strategy and it will write a small report at the beginning of your log file.

In this example, you will immediately see that a load balance problem has been detected. However, 2 out 16 cores will be idle, so it is a rather small loss of efficiency, not greatly reduced as it says in the log file below. It takes about 2 hours in 16 processes. You can also change the number of MPI processes you are using to achieve the best performance.

```
+-------------------------------------------------------------------------------+
| NEB image level parallelism enabled.                                          |

|          reduce parallel performance. Either modify the parameter             |
|          "processes_per_image" or the number of MPI processes.                |
|                                                                               |
|          With 2 processes_per_image ideal performance will be obtained       |
|          by using 14 MPI processes.
```

Tip: You can speed up the optimization by first running a simple NEB calculation with a high force tolerance, e.g. 0.08 eV/Å, and without using the *Climbing Image Method*. This will in general be a faster calculation giving you a rough estimate of the energy barrier and the diffusion path. After this step, you can set up a more precise NEB run and also use the climbing method to finalize your results.

Analyze the results

Once the calculation is properly converged you will find the optimized *NudgedElasticBand* object loaded in the **LabFloor**

Tip: Always remember to check the log file at the end of your simulation. In particular, check that convergence is achieved:

```

```

In the two figures below, the optimized Li diffusion process for the Li atom moving along the B and C directions are illustrated by using the **Movie Tool** plugin.

While the Li atom can more easily move along the B direction with 0.39 eV energy barrier, you found a high energy barrier, 2.3 eV for the Li atom moving along the C direction. The results are in agreement with reference[Page 743, 4].

Calculate the reaction rates using harmonic transition state theory

For detailed information about how reaction rates are calculated and the theory behind the harmonic transition state theory please refer to the *Calculating reaction rates using harmonic transition state theory*.

To set up the analysis:

1. Open the **Scripter**.
2. Double click on **Analysis from file** and select the `neb_B.nc` configuration with object ID *glD001*.
3. Add the **HTSTEvent** analysis and set the prefactor to 1e+13 1/s.

4.Run the analysis which will only take a minute. Here is the input script. `HTST_analysis.py`

Note: The time required for an HTSTEvent analysis strongly depends on whether or not the prefactor is assumed or calculated. If you need to calculate the prefactor, it can take a long time, depending on the method and system. Therefore, it is usually a very good approximation to assume the prefactor for solid state reactions like bulk diffusion.

In order to visualize the results from the **HTSTEvents** analysis, select the corresponding object from the **LabFloor** and select the *HTST Rates* plugin on the right hand side.

Here, you can calculate the forward and reverse reaction rates for your diffusion mechanism. In this case you will find these two values to be very close to each other because the initial and final states are essentially equivalent.

Here, you can also set the options for an Arrhenius plot:

The table below summarized the results found in this tutorial.

3.3.3 Open-circuit voltage profile of a Li-S battery: ReaxFF molecular dynamics

Version: 2017.1

Sulfur is a promising cathode material for rechargeable energy storage devices. During battery discharge, lithium ions migrate from the Li-rich anode to the sulfur cathode, and react with the sulfur (lithiation of the cathode):

$$x\mathrm{Li} + \mathrm{S} \rightarrow \mathrm{Li}_x\mathrm{S}$$

The **open-circuit voltage (OCV)** is the electrochemical driving force for this lithiation process.

In this tutorial we apply molecular dynamics (MD) simulations to calculate the OCV profile during cell discharge. We use the **ATK-ForceField** calculator and employ the **ReaxFF** force field developed by Islam an co-workers in Ref.[1]. The **simulated annealing** method is used to simulate amorphous Li_xS compounds for a range of compositions x, and the resulting OCV profile is compared to that in Fig. 3 in Ref.[Page 757, 1].

Note: Fig. 3 in Ref.[1] was made using data from a hybrid grand canonical Monte Carlo/molecular dynamics (GC-MC/MD) method, which is currently not available in QuantumATK. Instead of using the GC-MC to place Li atoms into low energy sites, we use here a simulated annealing method.

Theoretical definition of the open-circuit voltage

Neglecting enthalpic and entropic energy contributions, the OCV is calculated from total-energy differences:

$$\mathrm{OCV} = -\frac{E_{\mathrm{Li}_x\mathrm{S}} - nE_{\mathrm{Li}} - mE_{\mathrm{S}}}{n},$$

where n (m) is the number of lithium (sulfur) atoms in the Li_xS compound (such that $x = n/m$), and E_{Li} and E_{S} are the total energies per atom of the pure Li and S crystals, respectively.

Outline

We first consider $Li_{0.4}S$ and describe all steps needed to compute the open-circuit voltage for partial lithiation of pure S to $Li_{0.4}S$:

- *Amorphous Li0.4S compound*
- *Simulated annealing*
- *Open-circuit voltage*

ATK Python scriting is then used for more automated simulations for a range of Li_xS compositions. The full OCV profile is computed and radial distribution functions for different compositions are investigated:

[1] MdăM. Islam, A.ăOstadhossein, O.ăBorodin, A.ăT. Yeates, W.ăW. Tipton, R.ăG. Hennig, N.ăKumar, and A.ăC.ăT. van Duin. ReaxFF molecular dynamics simulations on lithiated sulfur cathode materials. *Phys. Chem. Chem. Phys.*, 17:3383–3393, 2015. doi:10.1039/C4CP04532G.

- *Full open-circuit voltage profile*
- *Radial distribution functions*

Tip: QuantumATK Python scripts are provided for download throughout this tutorial. You may also download all of them in a single ZIP file: `scripts.zip`.

Note: This is an advanced tutorial – certain basics of operating the **ATK-ForceField** calculator and the **QuantumATK analysis tools** are not explained in great detail. Please see the tutorial *How to Setup Basic Molecular Dynamics Simulations* if needed.

Amorphous $Li_{0.4}S$ compound

The cahtode material is not expected to be in a perfect crystalline phase under battery operating conditions; it is most likely amorphous. QuantumATK offers several different tools for generating amorphous structures, for example the **Amorhpous Prebuilder** and the **PackMol** tool. We use here the latter.

Open QuantumATK and create a new project, preferably in a new directory on your harddrive. The open the

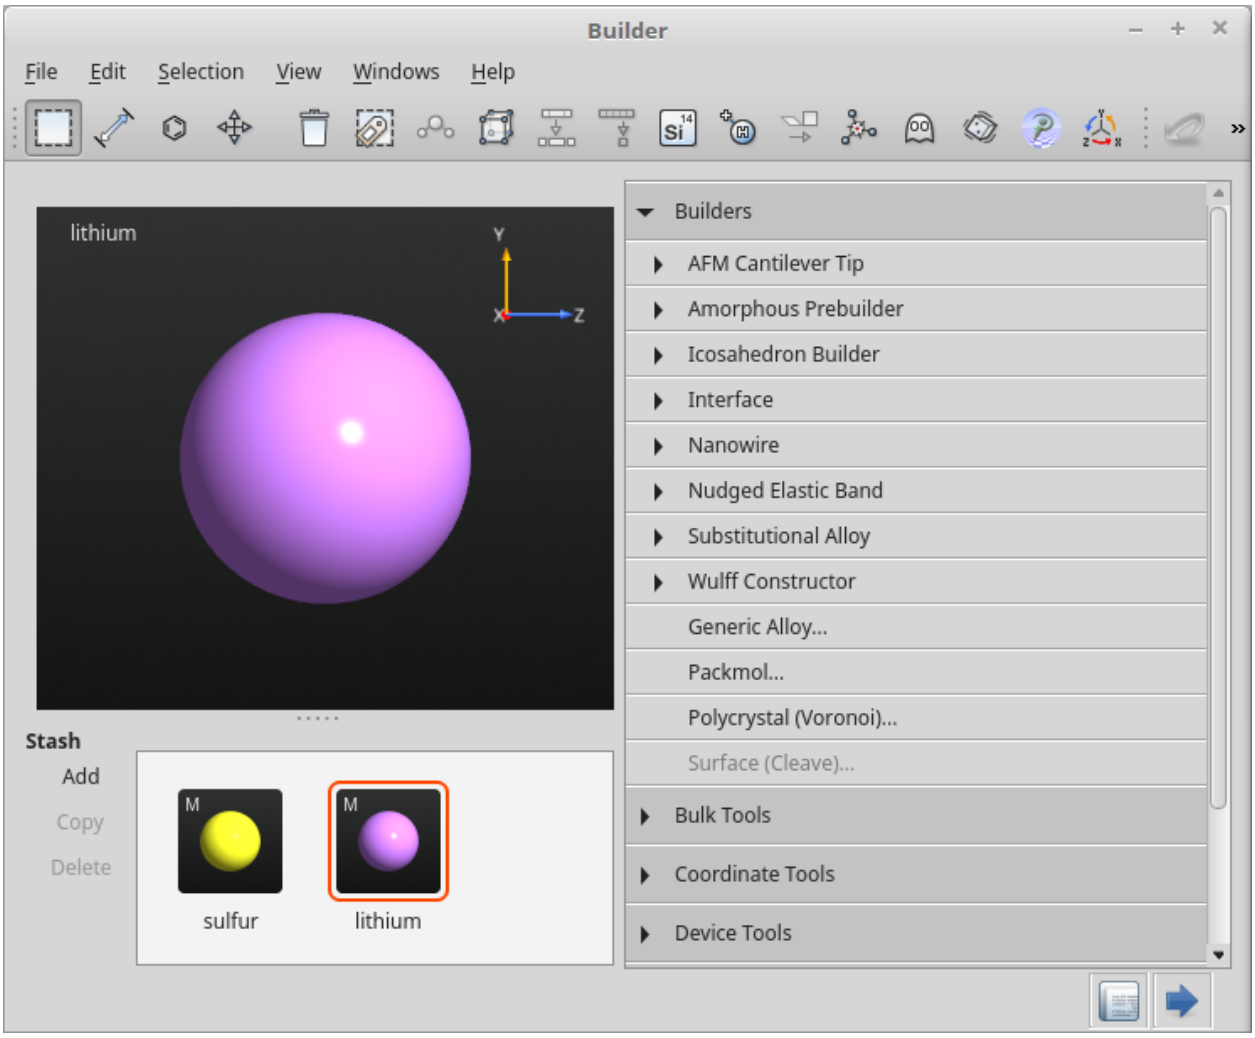
Builder.

PackMol

The initial structure of the amorphous $Li_{0.4}S$ compound is here generated using **PackMol**, which randomly mixes input **molecule** configurations into a reasonable amorphous **bulk** configuration. You therefore need to first add atomic sulfur and atomic lithium to the Builder Stash:

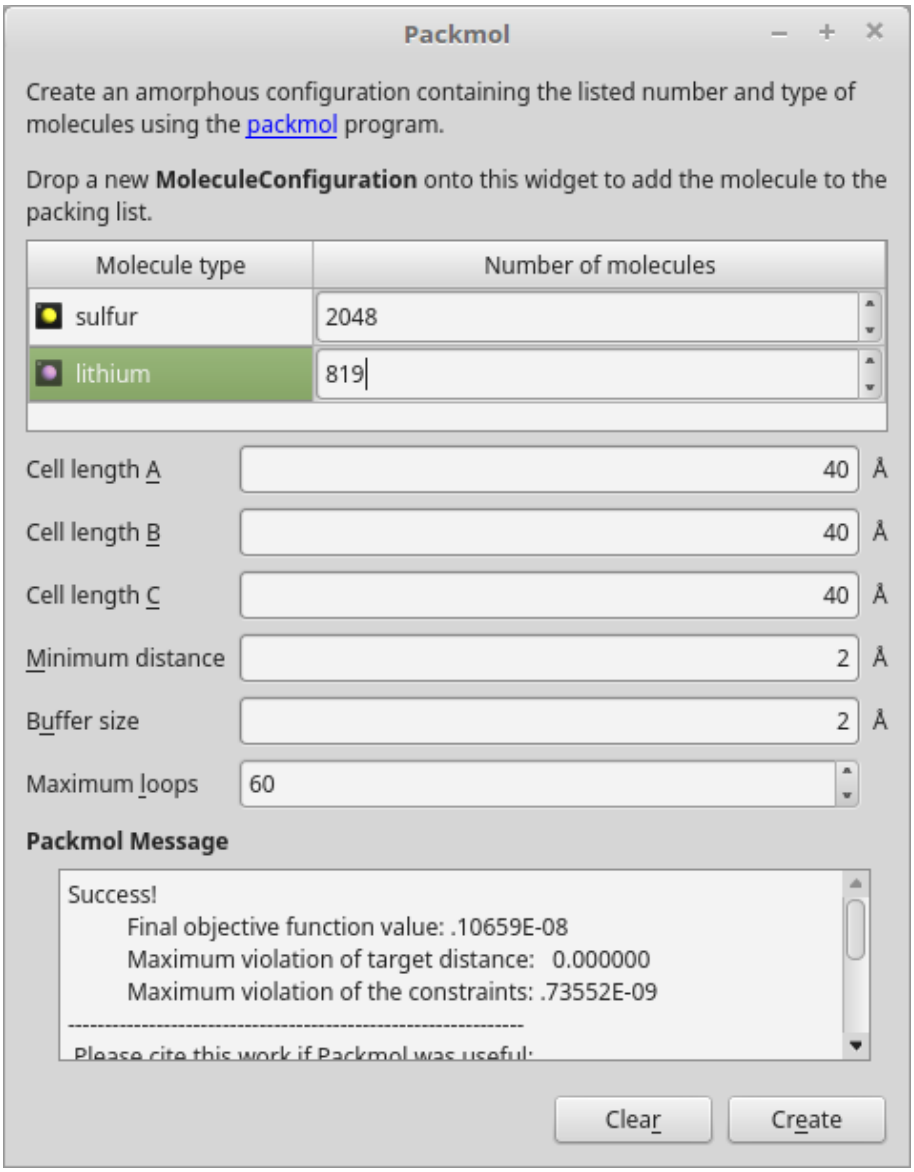
- In the **Stash**, click *Add* → *New Configuration* to add a hydrogen atom in a molecule configuration.
- Select the H atom and use the

tool to turn the H atom into S.
- Repeat the two steps above to create also a lithium atom.
- Rename the Stash items sulfur and lithium, respectively.

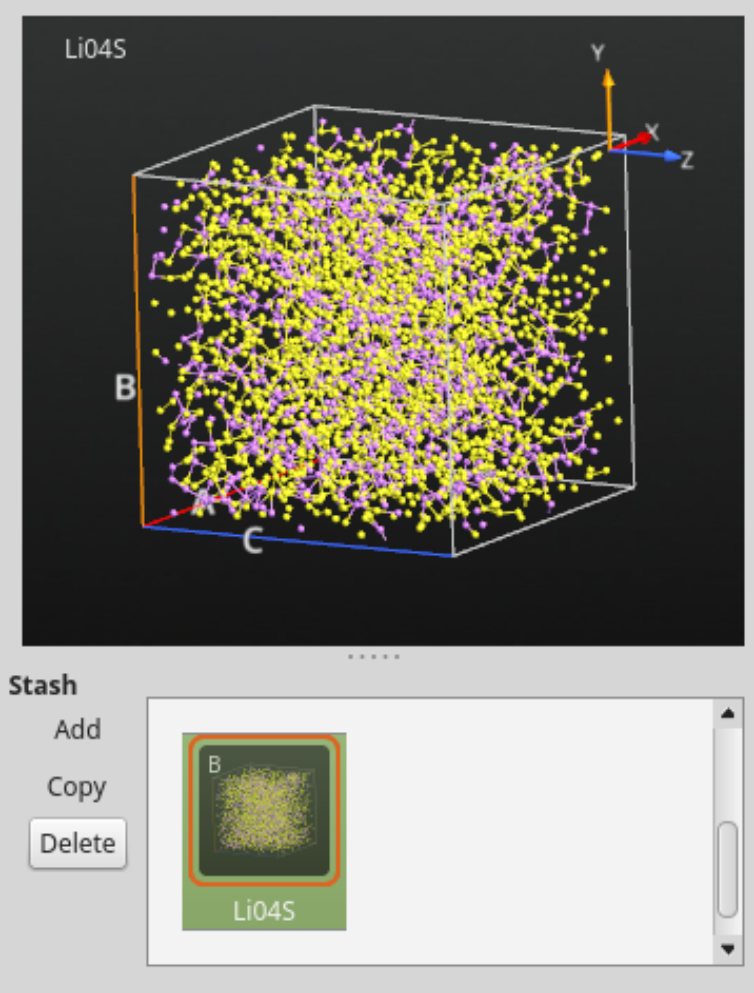


Navigate to the *Builders* → *PackMol* plugin and click it. The **PackMol** widget should now open. Do the following to create a $Li_{0.4}S$ amorphous crystal containing 2048 sulfur atoms.

- Drag-and-drop the sulfur and lithium atoms from the **Stash** onto the **PackMol** widget. The configurations will be added to the Molecule type list.
- Increase the number of sulfur entities to 2048, and the number of lithium entities to 819 (computed from 2048 $\times 0.4 =$ 819).
- Leave all other settings at their defaults, and click **Create**.



The amorphous $Li_{0.4}S$ structure is automatically added to the Stash. Rename it Li04S.



Geometry optimization

The amorphous structure produced by **PackMol** is guarenteed to have some minimal distance between all mixed entities (2 Å by default), but the structure may still be far from equilibrium. It is therefore a good idea to run an optimization of the atomic coordinates and lattice vectors before heating the system to a high temperature using MD.

- Send the Li04S configuration to the **Script Generator** and add the **New Calculator** and **OptimizeGeometry** script blocks.
- Open the calculator block, and select the **ATK-ForceField** calculator. The *ReaxFF_LiS_2005* force field is automatically selected – it was generated in Ref.[1].
- Open the geometry optimization block, and increase the force tolerance to 0.5 eV/Å and increase the maximum number of optimization steps to 1000. Also tick the *Save trajectory* option and enter `Li04S` as the file name for saving the relaxation trajectory.

Save the QuantumATK Python script as `Li04S.py` and run it using either the **Job Manager** or manually in a terminal:

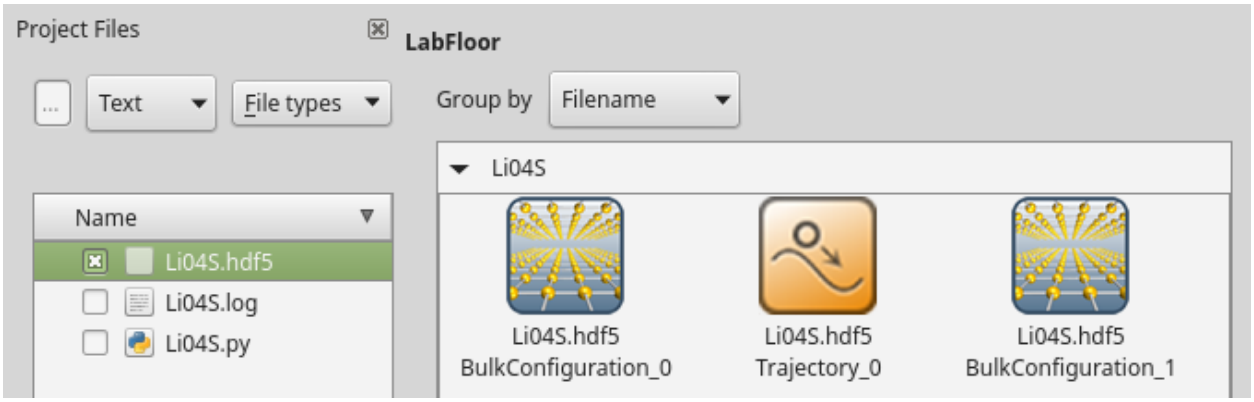
```
atkpython Li04S.py 2>&1 | tee Li04S.log
```

You may also download the script: `Li04S.py`.

Important: Parallelizing ATK-ForceField calculations over more than one physical core is most efficiently done using **OpenMP** threading rather than MPI, see the relevant sections in tutorials on using the Job Manager for *local* and *remote* QuantumATK calculations with threading only.

If running QuantumATK from a terminal, the environment variable `OMP_NUM_THREADS` should either be unset or set to the maximum number of OpenMP threads you intend to use. We recommend to set `MKL_DYNAMIC=TRUE` to allow MKL to dynamically change the number of threads.

The geometry optimization should now have finished, and the output data should be available on the QuantumATK **LabFloor**:



You may use the **Viewer** to visualize the relaxation trajectory; you will see that the unit cell expands a bit upon minimization of atomic forces and stress on the cell.

Simulated annealing

The room temperature structure of the amorphous $Li_{0.4}S$ compound (atomic coordinates and unit cell vectors) is not know *a priori*, so we use the **simulated annealing** method to find it. The basic idea is to heat up the system 1600 K and then slowly cool it down to 300 K using molecular dynamics, all at fixed pressure but allowing the unit cell volume to adapt (NPT dynamics).

The computational workflow is this:

1)Equilibrate the system at 1600 K.

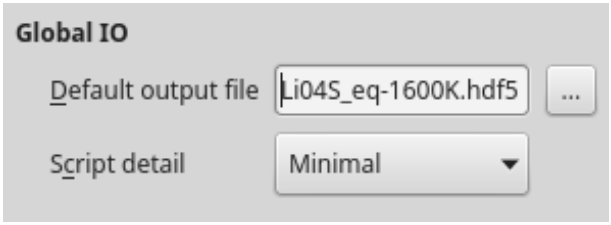
2)Slowly cool down the system from 1600 to 300 K.

3)Equilibrate the system at 300 K.

Equilibration at 1600 K

The bulk configuration labeled *BulkConfiguration_1* on the **LabFloor** (saved in `Li04S.hdf5`) is the optimized one. Select it and drop it on the **Scripter**. The appropriate ATK-ForceField calculator block is automatically added, so add just the **MolecularDynamics** script block.

First, set the default output file name to `Li04S_eq-1600K.hdf5`:



Then open the MD script block and adjust the settings:

•Select the NPT Berendsen MD type.

•Increase the number of MD steps to 50000.

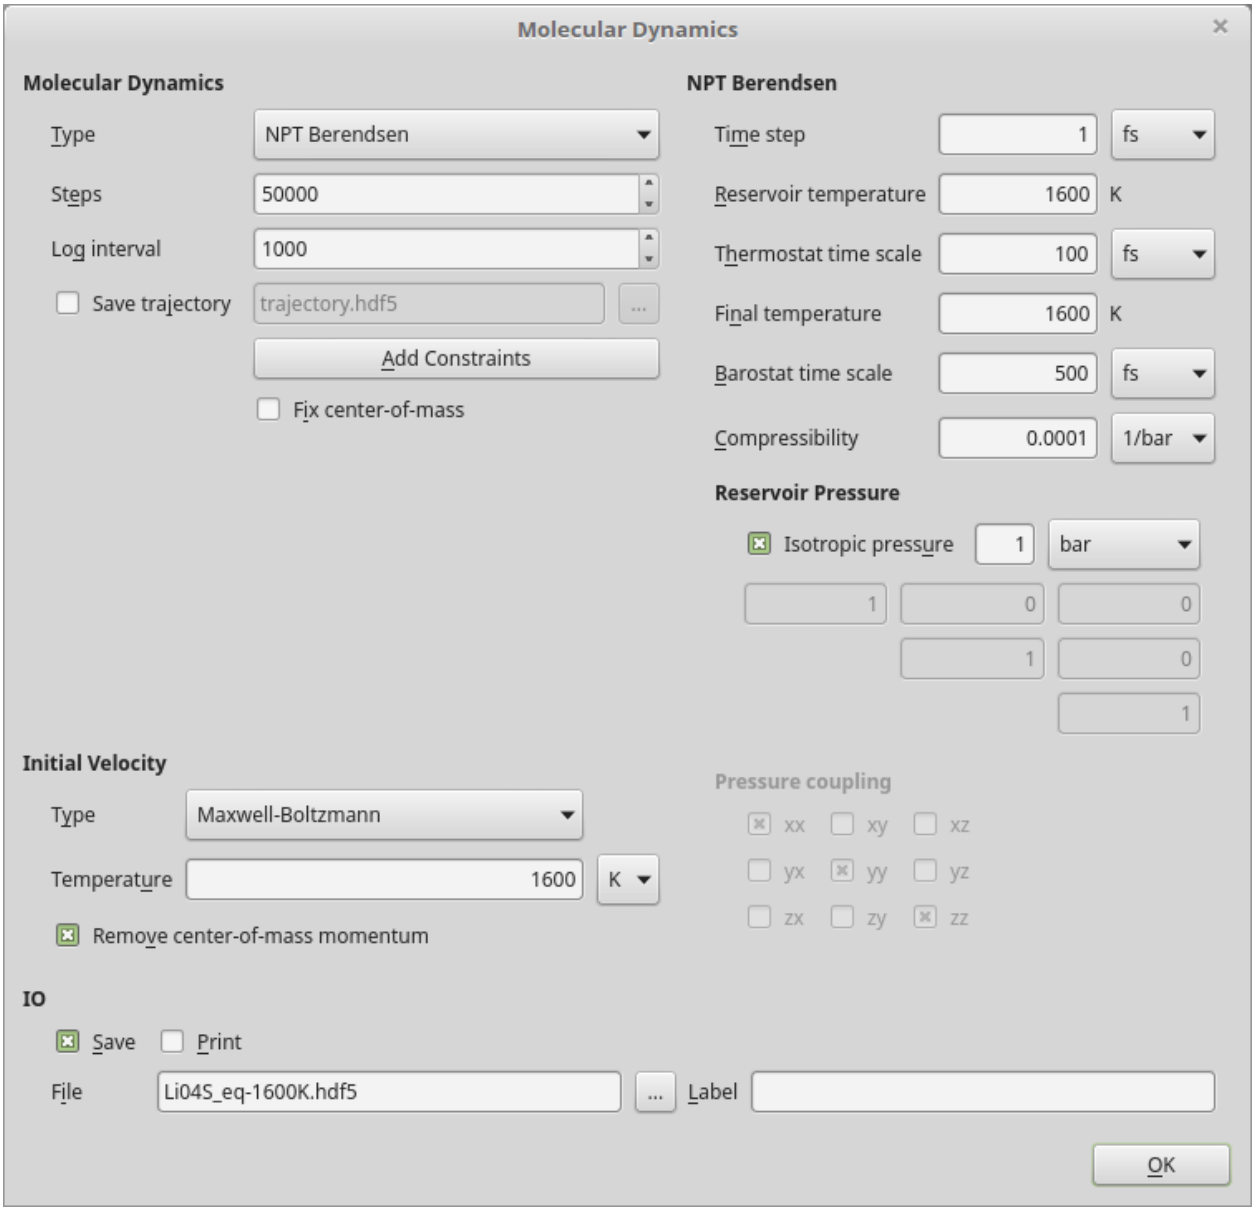
•Increase the log interval to 1000.

•Set the both reservoir temperature and the final temperature to 1600 K.

•Set also the temperature for the Maxwell–Boltzmann distribution of initial particle velocities to 1600 K.

•Optional: Untick the *Save trajectory* option.

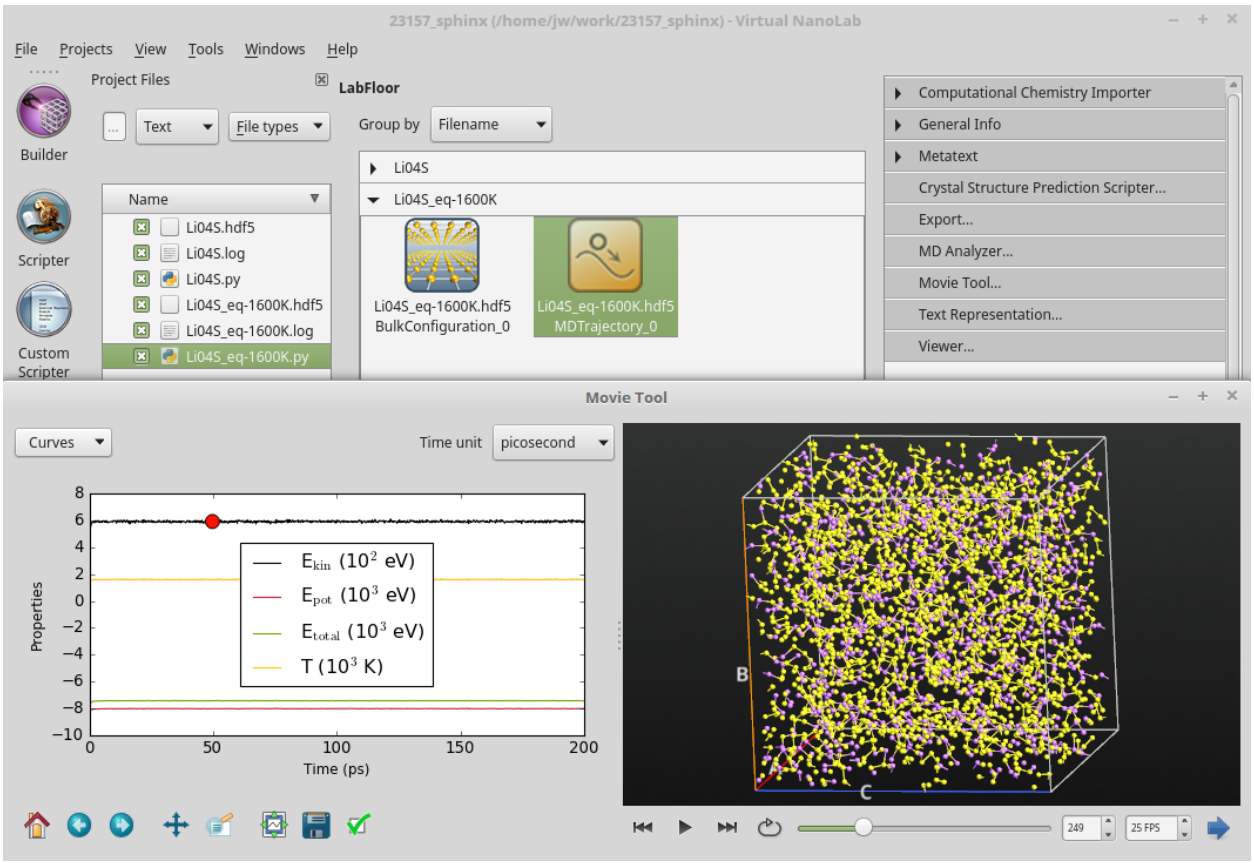
•Click **OK** to save te settings.



Save the script as `Li04S_eq-1600K.py` and run it. Depending on the computational resources (number of OpenMP threads), the job may take up to an hour to finish.

You may also download the QuantumATK Python script: `Li04S_eq-1600K.py`.

Once the calculation is done, the resulting MD trajectory should pop up on the **LabFloor**. Use the **Movie Tool** to visualize the progress of the MD simulation. You can use mouse right-click to enable the *Show bonds* option if needed. Note how the temperature and energies stay roughly constant throughout the simulation, and that the unit cell expands significantly at the beginning, but then stays fairly constant while the atoms move around inside it. The configuration is thereby equilibrated at constant temperature.



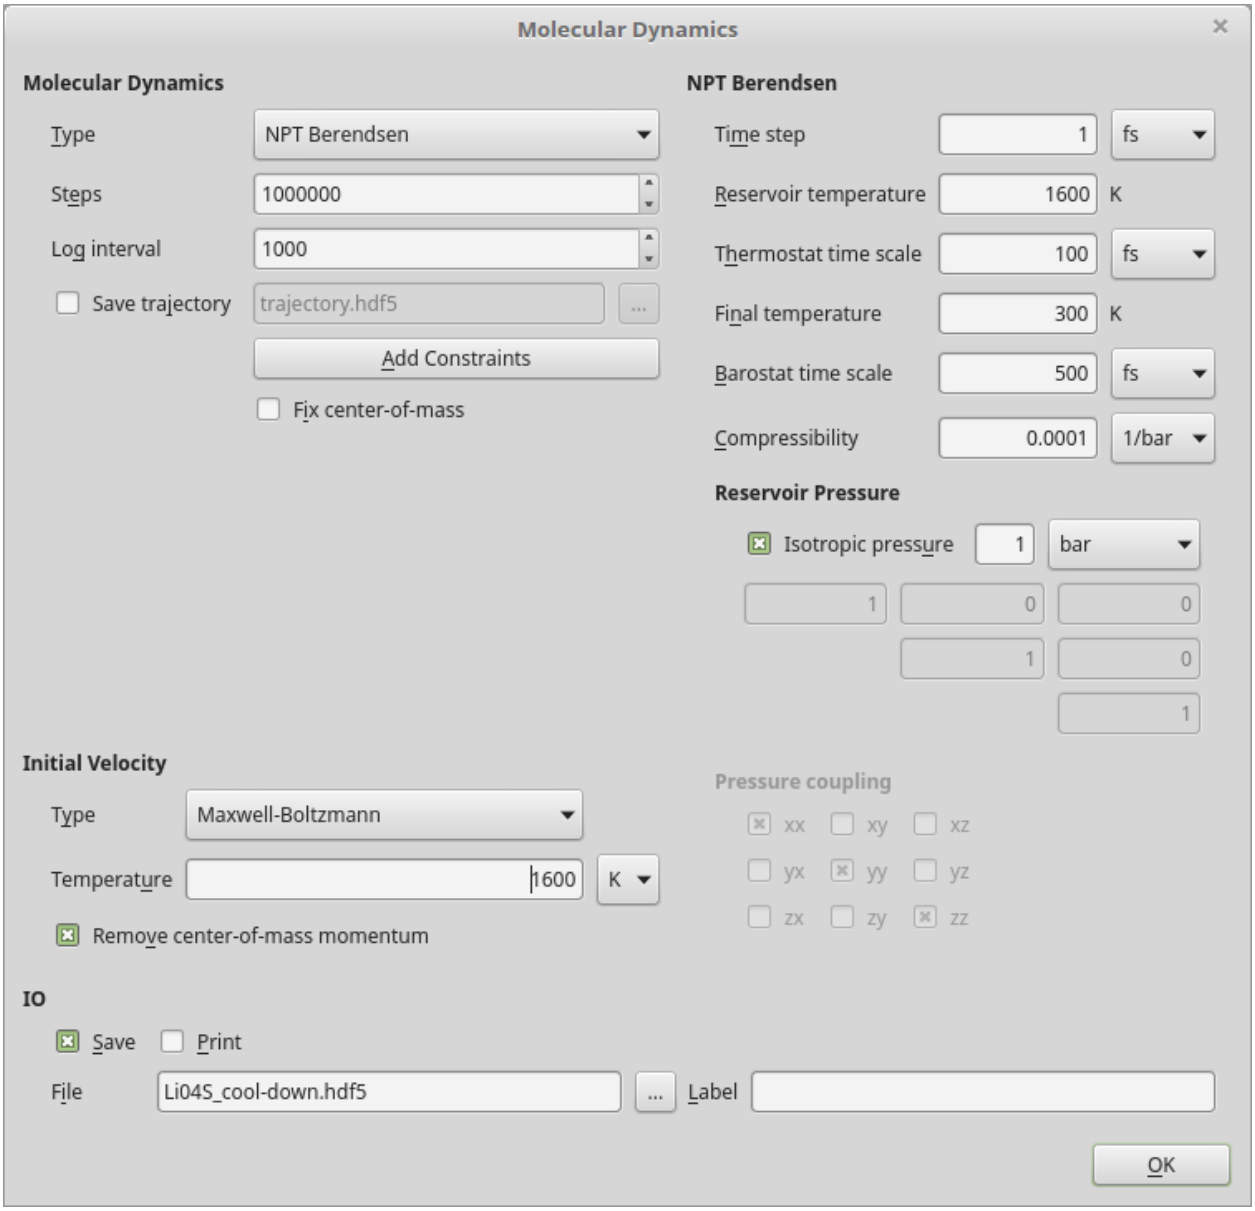
Cool-down from 1600 to 300 K

The $Li_{0.4}S$ configuration is now equilibrated and ready to be cooled down to room temperature. In the **Movie Tool**, use the icon to **transfer the last MD image** in the MD trajectory to the **Scripter**.

Add the **New Calculator** and **MolecularDynamics** script blocks, and select again the ATK-ForceField calculator with the appropriate force field. Then set the default output file name to `Li04S_cool-down.hdf5`, and adjust the settings for the MD block:

- Select the NPT Berendsen MD type.
- Increase the number of MD steps to 1 mio.
- Increase the log interval to 1000.
- Set the reservoir temperature to 1600 K and the final temperature to 300 K.
- Set the temperature for the Maxwell–Boltzmann distribution of initial particle velocities to 1600 K.
- Optional: Untick the *Save trajectory* option.
- Click **OK** to save te settings.

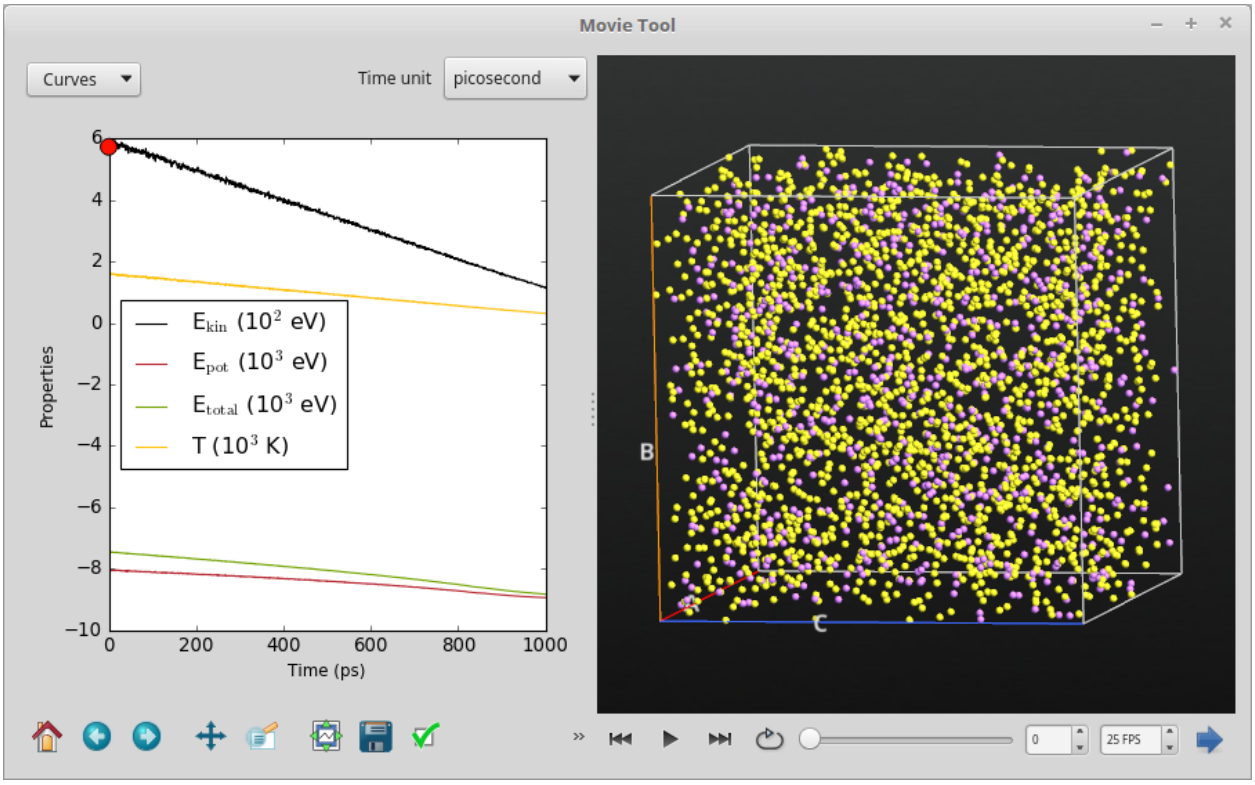
This will result in a **linear temperature ramp** over 1 ns of MD simulation time (10^6 steps $\times 1$ fs/step = 1 ns), and a cooling rate of 1.3 K/ps.



Save the script as `Li04S_cool-down.py` and run it. You may also download the QuantumATK Python script: `Li04S_cool-down.py`.

Warning: The calculation may take a full day if executed on a single core, so it is recommended to use threading when running this job.

Once the calculation is done, the resulting MD trajectory should become available on the **LabFloor**. Use again the **Movie Tool** to visualize the progress of the MD simulation. Notice how the temperature decreases linearly from 1600 K to 300 K, and that the energies of the system decrease as well. Moreover, running the movie from start to end, it is clear that the $Li_{0.4}S$ unit cell shrinks when cooled down, quite as expected.

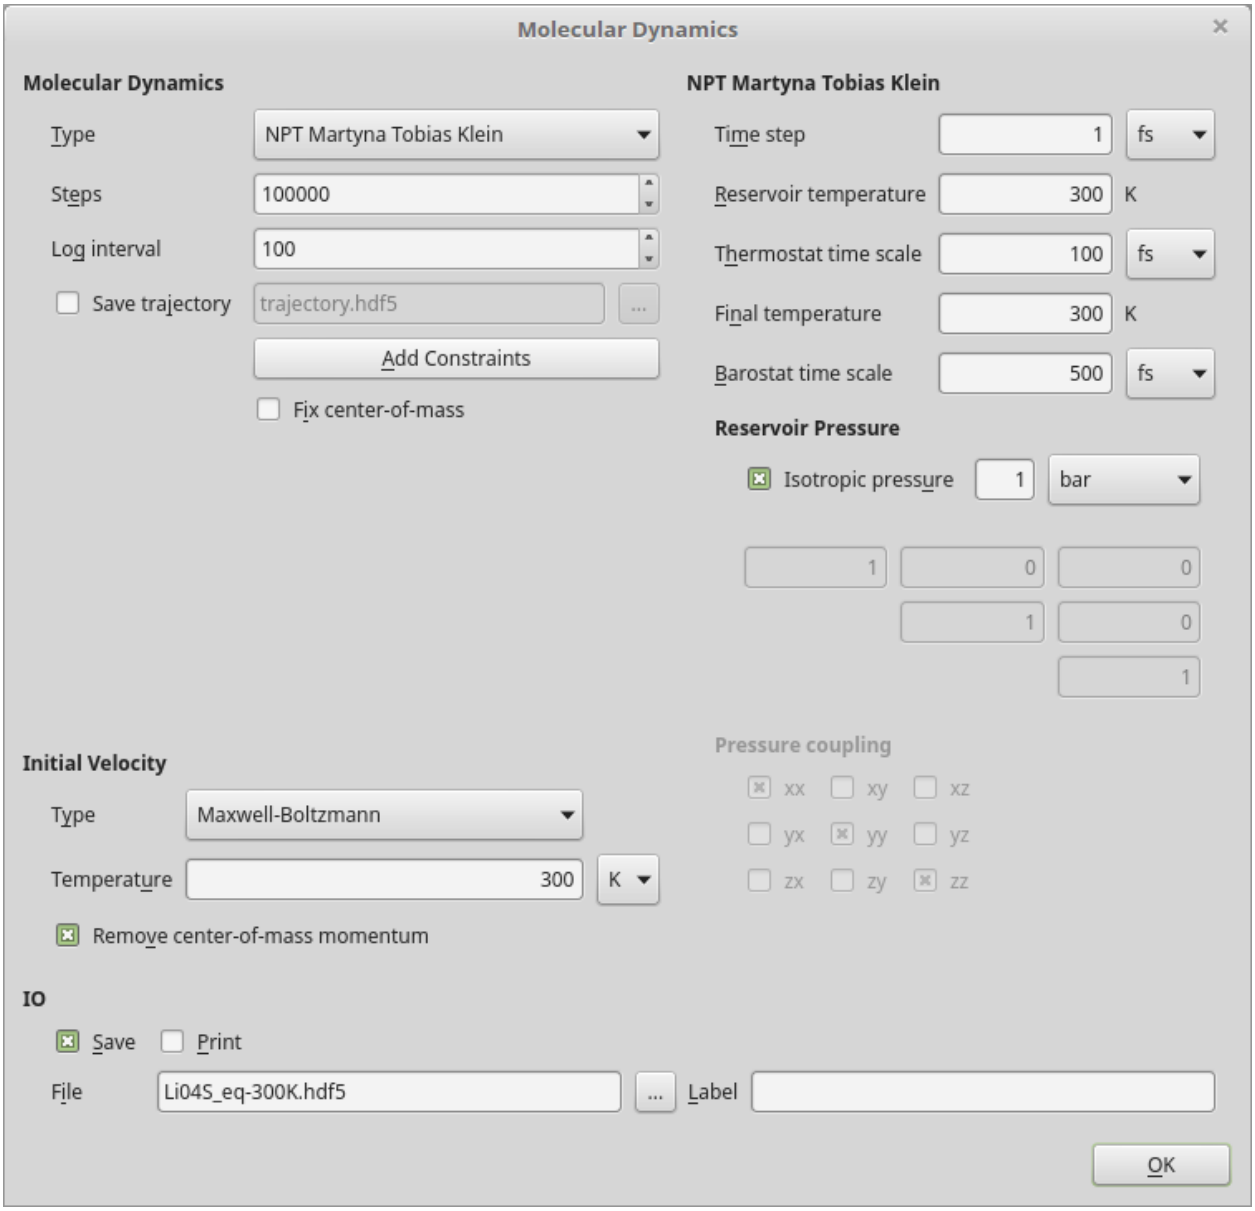


Equilibration at 300 K

Final step is to equilibrate the room temperature amorphous $Li_{0.4}S$ structure. In the **Movie Tool**, use again the icon to transfer the last MD image from the cool-down MD trajectory to the **Scripter**.

Add the **New Calculator** and **MolecularDynamics** script blocks, and select again the ATK-ForceField calculator with the appropriate force field. Then set the default output file name to `Li04S_eq-300K.hdf5` and adjust the settings for the MD block:

- Select the NPT Martyna-Tobias-Klein MD type.
- Increase the number of MD steps to 100000.
- Increase the log interval to 100.
- Set the reservoir temperature to 300 K.
- Set the temperature for the Maxwell–Boltzmann distribution of initial particle velocities to 300 K.
- Optional: Untick the *Save trajectory* option.
- Click **OK** to save te settings.



Save the script as `Li04S_eq-300K.py` and run it. You may also download the QuantumATK Python script: `Li04S_eq-300K.py`.

Once the calculation is done you may use the **Movie Tool** to check that the calculation went as expected (constant temperature, etc.).

The plot below shows the evolution of the total energy per atom and the volume as the MD equilibration progresses. Both energy and volume reaches a stable mean (the black dashed lines), and are thefore well equilibrated after 1000 MD steps. The script `evolution.py` was used to generate the plots.

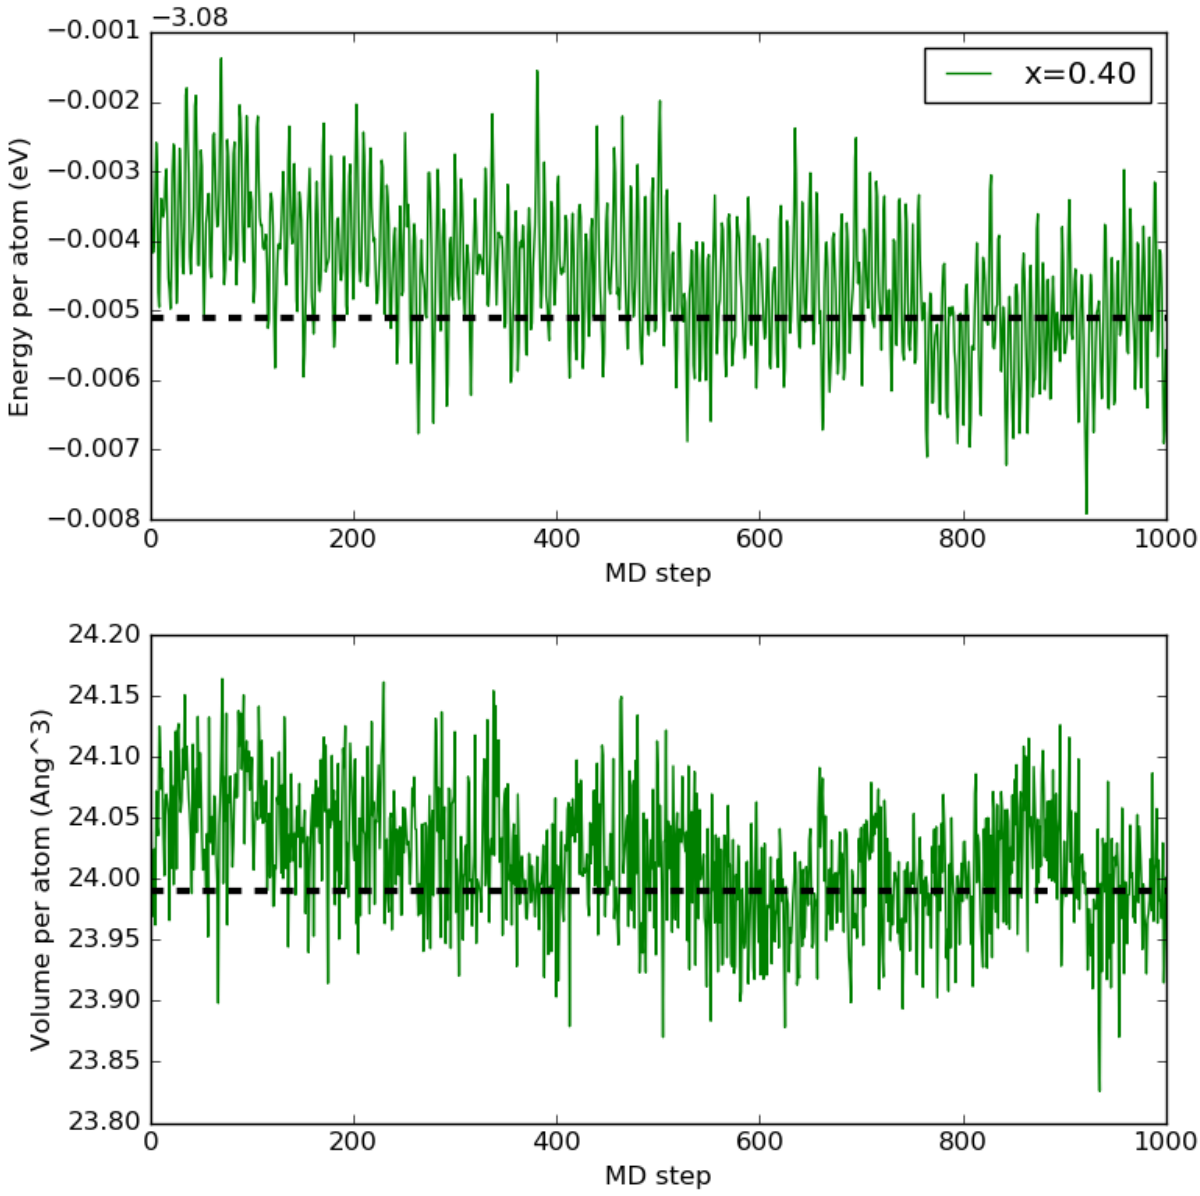


Fig. 3.70: Evolution of the total energy per atom (top) and the volume (bottom) as the MD equilibration progresses. Black dashed lines indicate the average over the last 100 MD images.

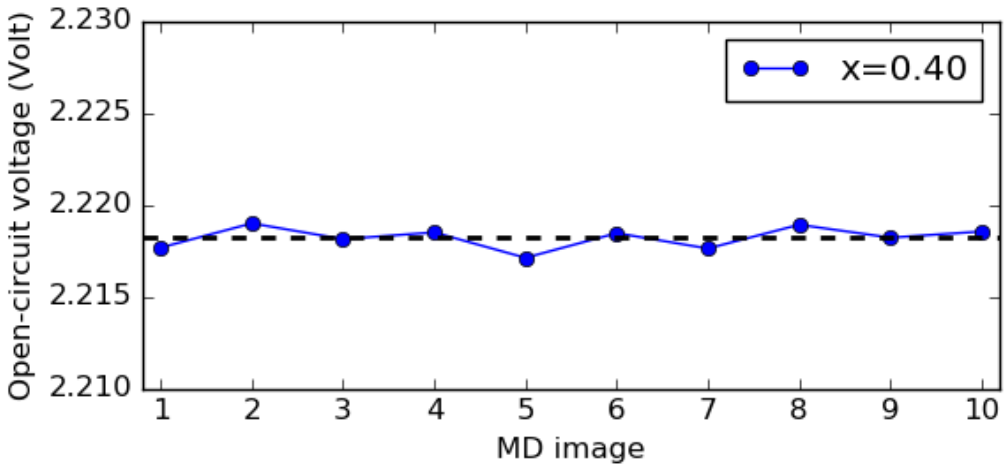
Open-circuit voltage

The OCV is calculated from total-energy differences as discussed in the introduction. Each total energy should be for a geometry optimized structure. To check that the calculated OCV does not depend significantly on the chosen equilibration MD image, you should first perform geometry optimization at fixed unit cell volume for several of the last equilibrated images, and compute the corresponding OCV values. Use the script `Li04S_relax.py` to do this.

You also need the total energy per atom of the pure *BCC* Li and *ORTH* S_8 crystals. The scripts `Lithium.py` and `a-Sulfur.py` perform the required geometry optimizations and calculate the total energies. Run both scripts.

Then calculate and plot the OCV for all the 10 selected $Li_{0.4}S$ MD images using the script `ocv.py`. The plot is shown below. The black line indicates the average OCV, and it is clear that even though choosing different MD images from the equilibration MD simulation results in slightly different OCV values, they are very similar. For each Li_xS composition, we shall below use the average OCV over 10 MD images.



Full open-circuit voltage profile

So far, we have obtained the OCV for $Li_{0.4}S$. To plot the full OCV profile for litiation to the sulfur cathode corresponding to the reduction pathway of S_8 to Li_xS, you should repeat the procedure outlined above for a range of Li concentrations. However, that may be a somewhat tedius workflow – some degree of automation would be useful.

ATK Python scripting is ideal for assembling the different MD scripts given above for $Li_{0.4}S$ into **a single script** that will run all calculations for a given lithium concentration. The script `x0.40_full.py` does this for x=0.4. Download it and use it as a template for running all required MD simulations for each composition:

- Use **PackMol** to generate structures for the desired compositions and save each structure in a separate data file named `x#.##.hdf5`, where `#.##` indicates the Li concentration, e.g. `0.40`.
- Run a separate script for each Li_xS composition (copy `x0.40_full.py` and edit it to use the above generated `hdf5` file as input and output data file.)

Note: Calculations for Li-rich compounds may take several days even if executed on 16 cores using OpenMP threading.

The cool-down MD simulation takes by far the largest part of the job wall-time. You may be able to decrease the time-to-result by decreasing the number of MD steps used in the cool-down from 1600 K to 300 K (and thereby increase the cooling rate), but be careful in doing so, since the cooling rate may affect your results.

Also, it turns out that equilibration often converges faster for Li-rich structures than for dilute Li concentrations, so it may be possible to decrease the number of MD steps for those simulations also.

Finally, plot the OCV profile over the Li_xS compositions using the script `ocv_profile.py`.

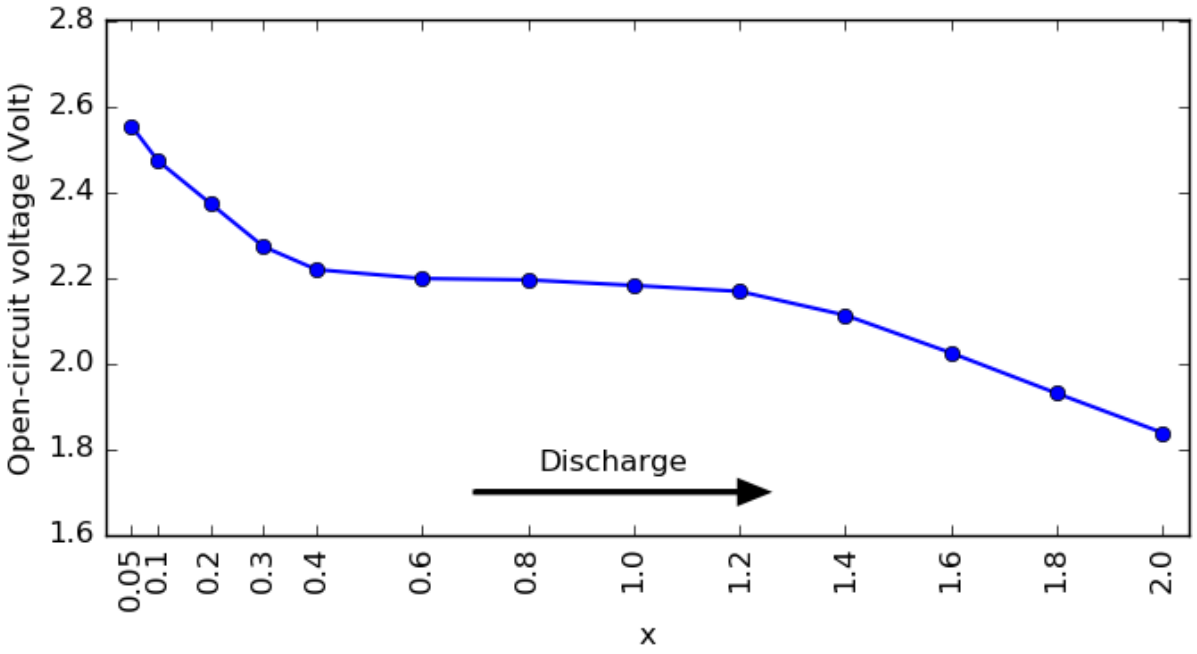


Fig. 3.71: Open circuit voltage profile during lithiation of the sulfur cathode.

This plot shows the full OCV profile and it is almost same as in Fig. 3 in[Page 757, 1]. Typically, experimental discharge voltage profiles for a Li-S battery can exhibit two or three reduction stages depending on the electrolyte. In this case, ReaxFF molecular dynamics calculations predict an initial drop, a flatter region, and again a voltage drop, all in agreement with experiments.

The initial drop may be induced by the formation of high-order polysulfides, *i.e.* sulfur-rich compounds from the S_8 crystal. But it is not stable enough, so it is a fast process. The plateau at ~2.1 V is assigned to a slow process involving the further reduction to low-order polysulfides, *i.e.* Li-rich compounds. Here we only consider the litiated cathode, but in reality, these are very complex processes that may need more detailed understanding depending on the electrolyte composition.

Radial distribution functions

It is also useful to analyze the radial distribution functions (RDFs) for S–S, Li–Li and S–Li in different Li_xS compositions. You may use the following scripts to obtain the plots given below: `rdf_lili.py`, `rdf_ss.py` and `rdf_sli.py`.

The RDFs for Li–Li, S–S and S–Li distances compare well with Fig. 5 in[Page 757, 1], and clearly indicate that 1) Li–Li bonds at ~3 Å distance are formed upon Li uptake during lithiation of the sulfur cathode, 2) short S–S bonds disppear upon Li uptake, and 3) both short and long S–Li distances exist for small Li contents, but the short S–Li bonds (~2.5 Å) dominate at large Li uptake.

3.3.4 Photocurrent in a silicon p-n junction

Version: O-2018.06

In this tutorial, you will learn how to calculate the photocurrent through a device under illumination. We consider a 7.6 nm sized silicon p-n junction, and showcase the Photocurrent Analyzer introduced with the QuantumATK O-2018.06 release.

The photocurrent is calculated by adding the electron-photon interaction to the device Hamiltonian, using first-order perturbation theory, as described in[1] and in the ATK Manual: *Photocurrent*.

Device ground state

At first you will perform the self-consistent device calculation. Then, using the ground-state device Hamiltonian, you will calculate and analyze the photocurrent.

You should use the script `silicon_pn_junction.py` to run the ground-state calculation – both the doped device configuration and the appropriate NEGF calculator are defined in the script. Results are saved in `silicon_pn_junction.hdf5`. Simply download the script and run it using the **Job manager** or from a terminal. Once the calculation is done, you can see the file `silicon_pn_junction.hdf5` on the **LabFloor**. The calculation takes *ca.* 20 mins with 4 MPI processes.

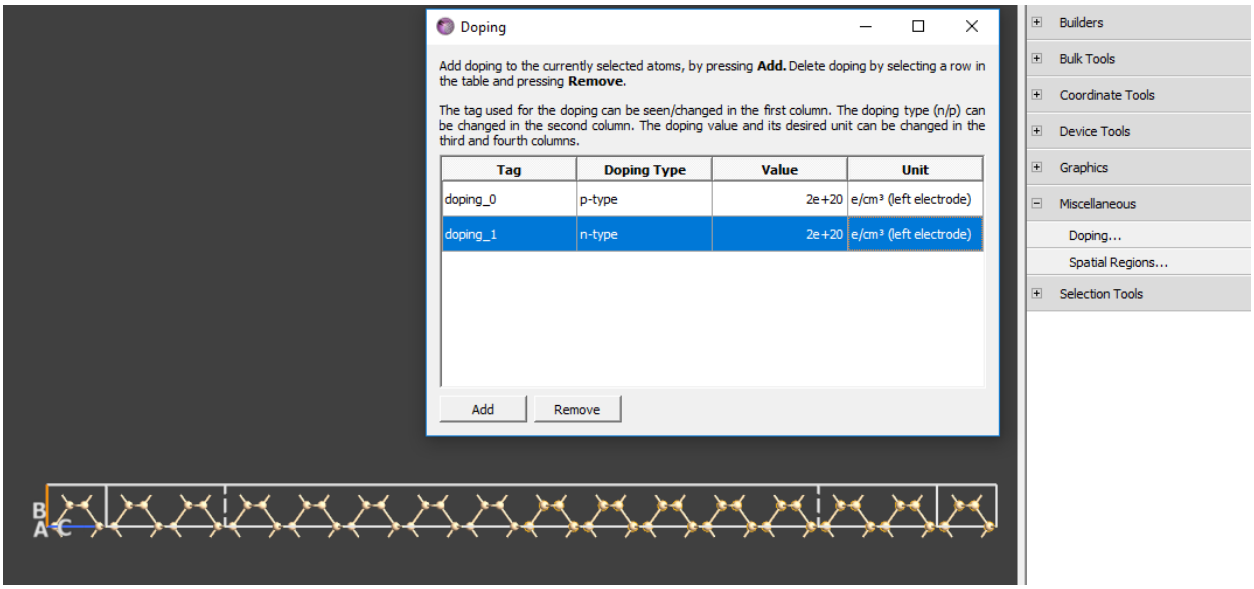
Brief instructions for building the device configuration and setting up the NEGF calculation are also given below.

Silicon p-n junction

The 7.6 nm silicon device should consist of 28 Si layers (76.0284 Å) and 10.8612 Å left and right electrodes. The *p* and *n* doping levels should be both $2*10^{20}$ e/cm^3 for this quite short Si device in order to get a reasonable electronic structure with fairly flat band edges near the electrodes and a small gap from the VBM and CBM to the Fermi level.

If you need more information on how to build a junction, please see the tutorial *Silicon p-n junction*.

[1] Mattias Palsgaard, Troels Markussen, Tue Gunst, Mads Brandbyge, and Kurt Stokbro. Efficient first-principles calculation of phonon assisted photocurrent in large-scale solar cell devices. *arXiv:1801.03683*, 2018. URL: http://arxiv.org/abs/1801.03683.



NEGF calculation

The supplied script `silicon_pn_junction.py` uses a NEGF calculator with the settings given below.

•Basis set: *PseudoDojo* and *Low*.

•Exchange-correlation: *GGA-1/2* and *PBE*.

•k-point sampling: *4 Å* density in the A and B directions.

•Density mesh cutoff: *30 Ha*.

•Default output file: `silicon_pn_junction.hdf5`.

Run the script using the **Job manager** (click the button to start the calculation).

Photocurrent

You are now ready to calculate the photocurrent. Open the **Script Generator** and add a **Analysis from File**.

•Select the file `silicon_pn_junction.hdf5`.

•Make sure the *DeviceConfiguration* object is ticked.

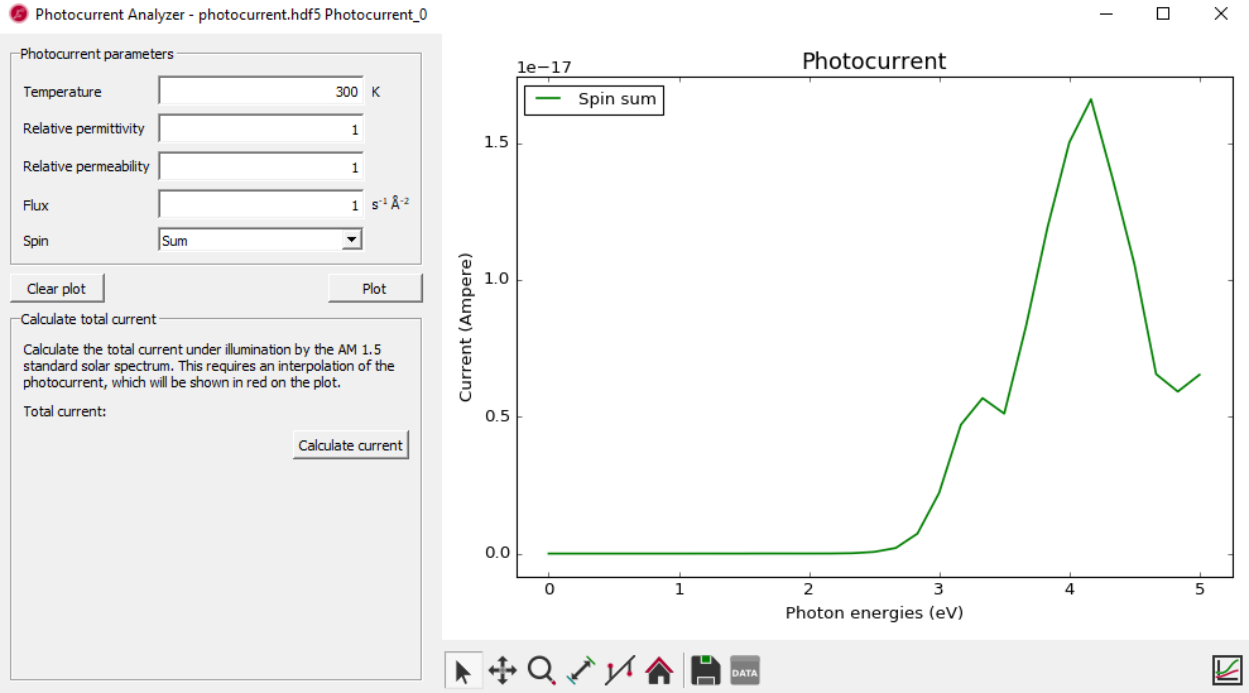
Next, in order to calculate the photocurrent, add the *Analysis* → *Photocurrent* block. Set the photon energy range to 0 – 5 eV with 31 points, and set the k-point sampling to 9 x 9. Keep all other parameters at default values. You can also download the script `photocurrent.py`. Send the script to the **Job manager**, save it as `photocurrent.py`, and click on the button to run the calculation.

Note: The photocurrent calculation takes *ca.* 3.5 hours with 4 MPI processes, so you may consider running the calculation on a remote computing cluster, if possible.

Once the calculation is done, you can see the file `photocurrent.hdf5` in the **LabFloor**. Note that the calculation can be made faster by decreasing the number of photon energies and increasing the `energy_resolution`, leading to fewer electron energy points.

Select the *Photocurrent_0* object of `photocurrent.hdf5` on the **LabFloor**. Open the **Photocurrent Analyzer** in the right-hand panel.

You can easily plot the current *vs.* photon energies by clicking **Plot**. This is shown in the figure below.



You can also calculate the total current based on illumination by the AM1.5 standard solar spectrum obtained from Solar spectra website. Once you click **Calculate current**, the interpolated photocurrent will be indicated by a red line. This interpolated function is multiplied with the flux from the reference spectrum at each photon energy, and the result is then numerically integrated to calculate the total current from the device under the given illumination.

If the photon energies used to calculate the photocurrent do not cover the range of photon energies in the AM1.5 spectrumn, you will see a warning message. In this case, the interpolation will include data outside the data range, so the calculated total current may therefore be inaccurate. We therefore recommend to calculate the total current only from photocurrents covering the full range of the AM1.5 standard solar spectrum, which is 0.3 eV to 4.43 eV. Photocurrents covering a larger range is not a problem, as data outside the range of the reference spectrum simply do not contribute. The figure below shows an example of this.

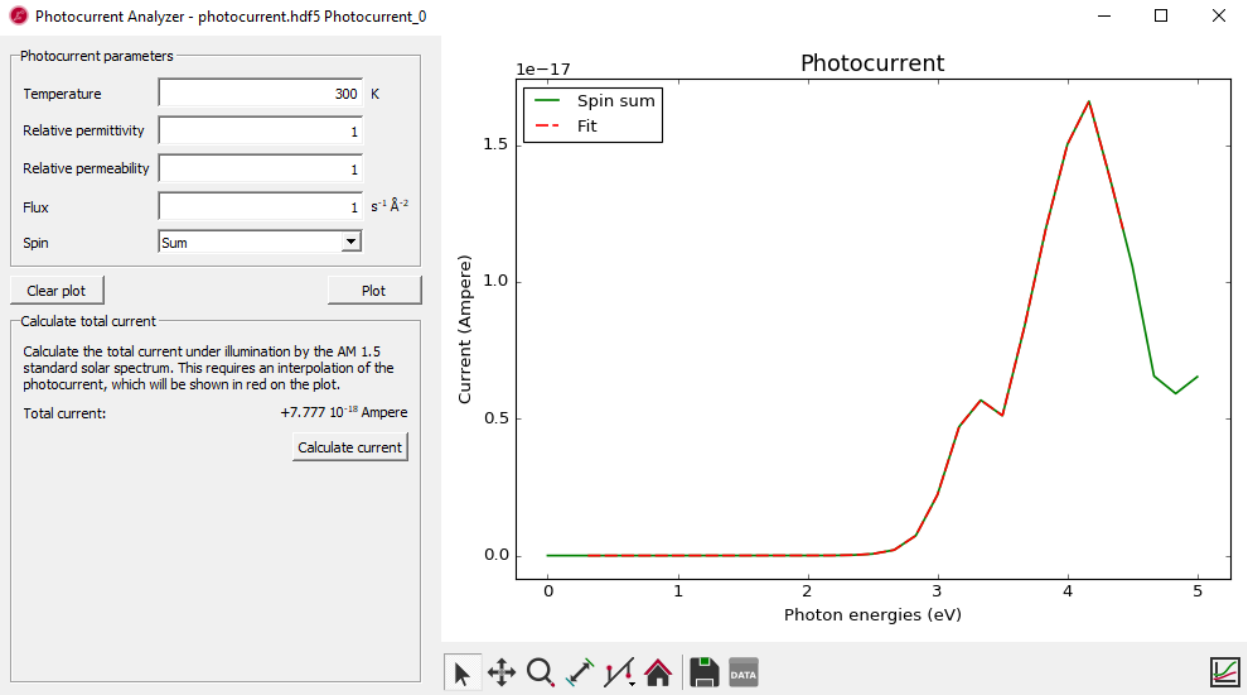


Fig. 3.72: The total current is calcuated as $7.777 \cdot 10^{-18}$ Ampere under the illumination by the AM 1.5 standard solar spectrum.

3.4 Complex Interfaces

3.4.1 Building an interface between Ag(100) and Au(111)

QuantumATK: Interface builder Platforms: *In this tutorial you will learn how to use the interface builder. You will build an interface between an Ag(100) and an Au(111) surface. It is assumed that you are familiar with the basic functionalities of QuantumATK.*

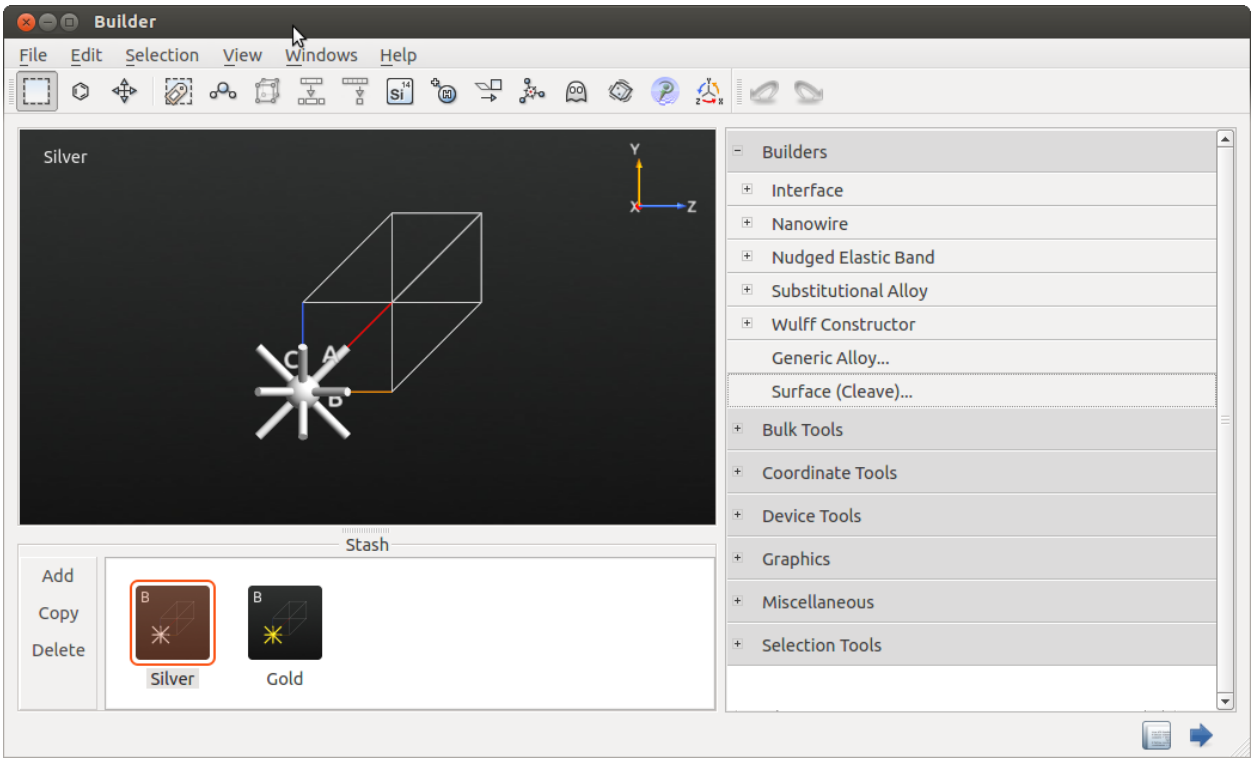
Import silver and gold crystals

Create a new empty project called Ag_Au_interface and open the Builder .

1.Use *Add* → *From database* to import a silver and a gold crystal to the Stash.

2.Double-clisk the Silver Stash item to activate it.

3.Expand the **Builders** group in the right-hand panel bar.



Building the Ag(100) and Au(111) crystals

1.Open the **Surface (Cleave)** tool.

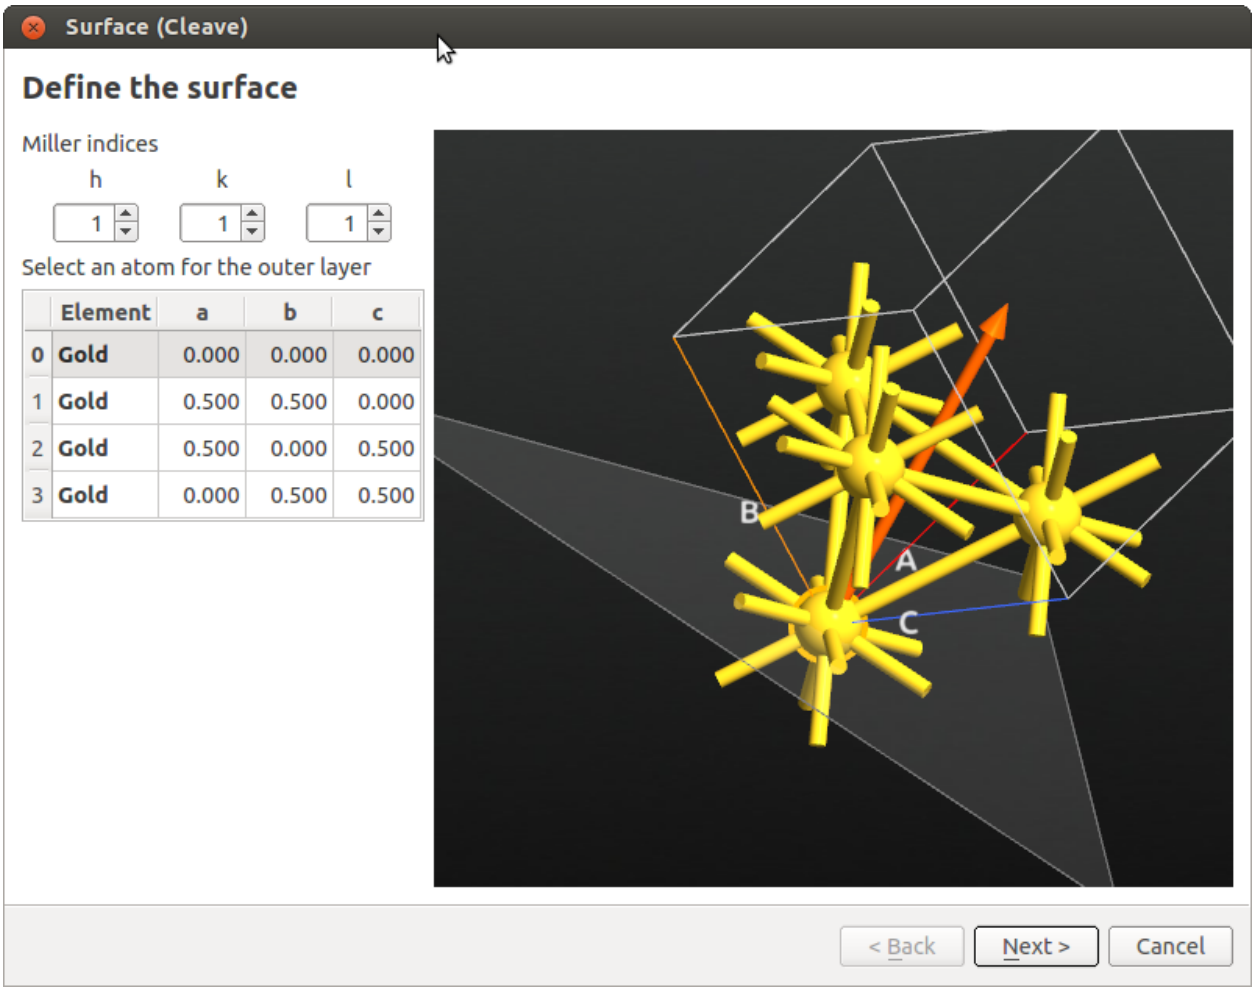
2.Use the default surface direction (100), and click Next.

3.Use the default minimal surface bravais lattice, and click Next.

4.Use the default configuration type, i.e. v3 (C axis) is along z and the structure is periodic.

5.Click **Finish**.

Now do the same for the Gold crystal, but cleave it along the (111) direction.

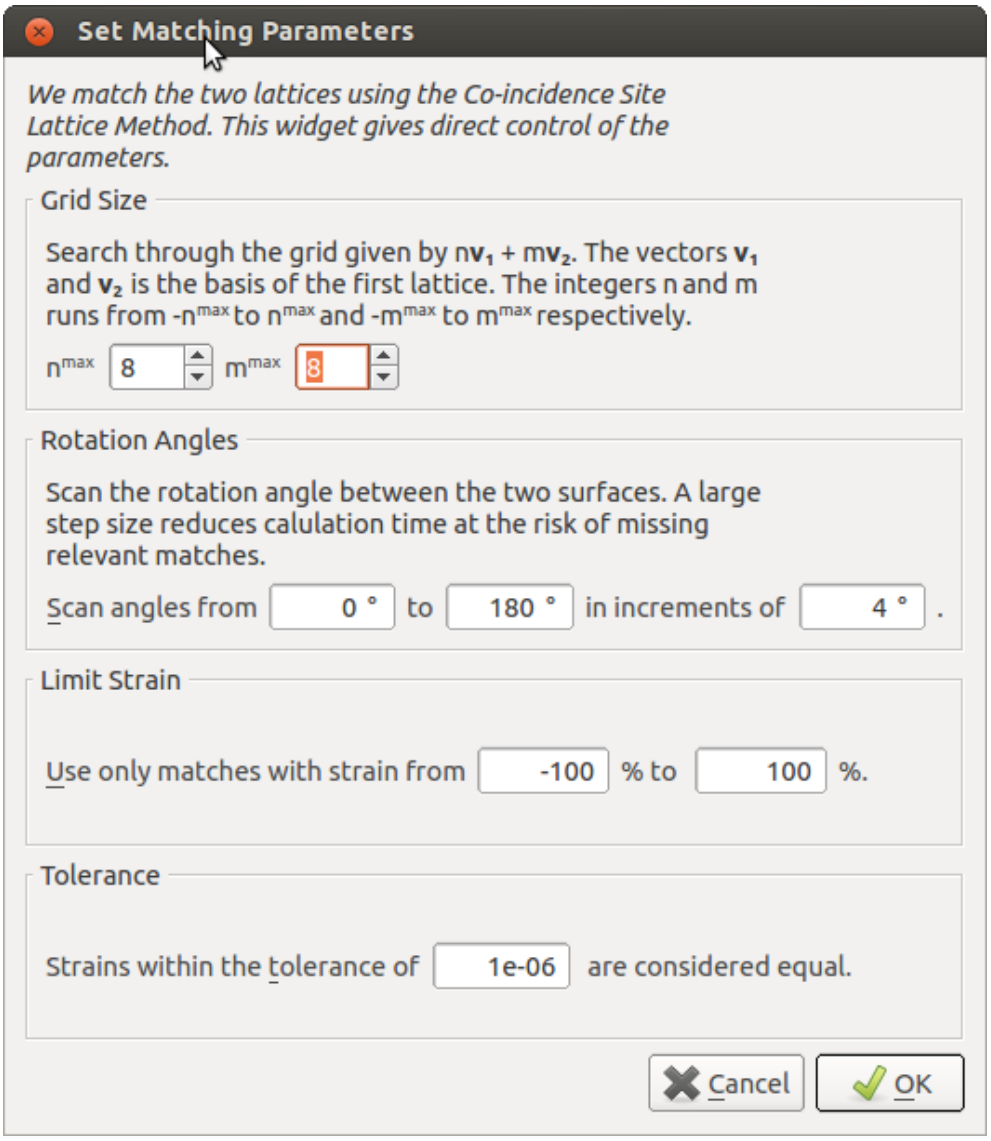


Building the interface

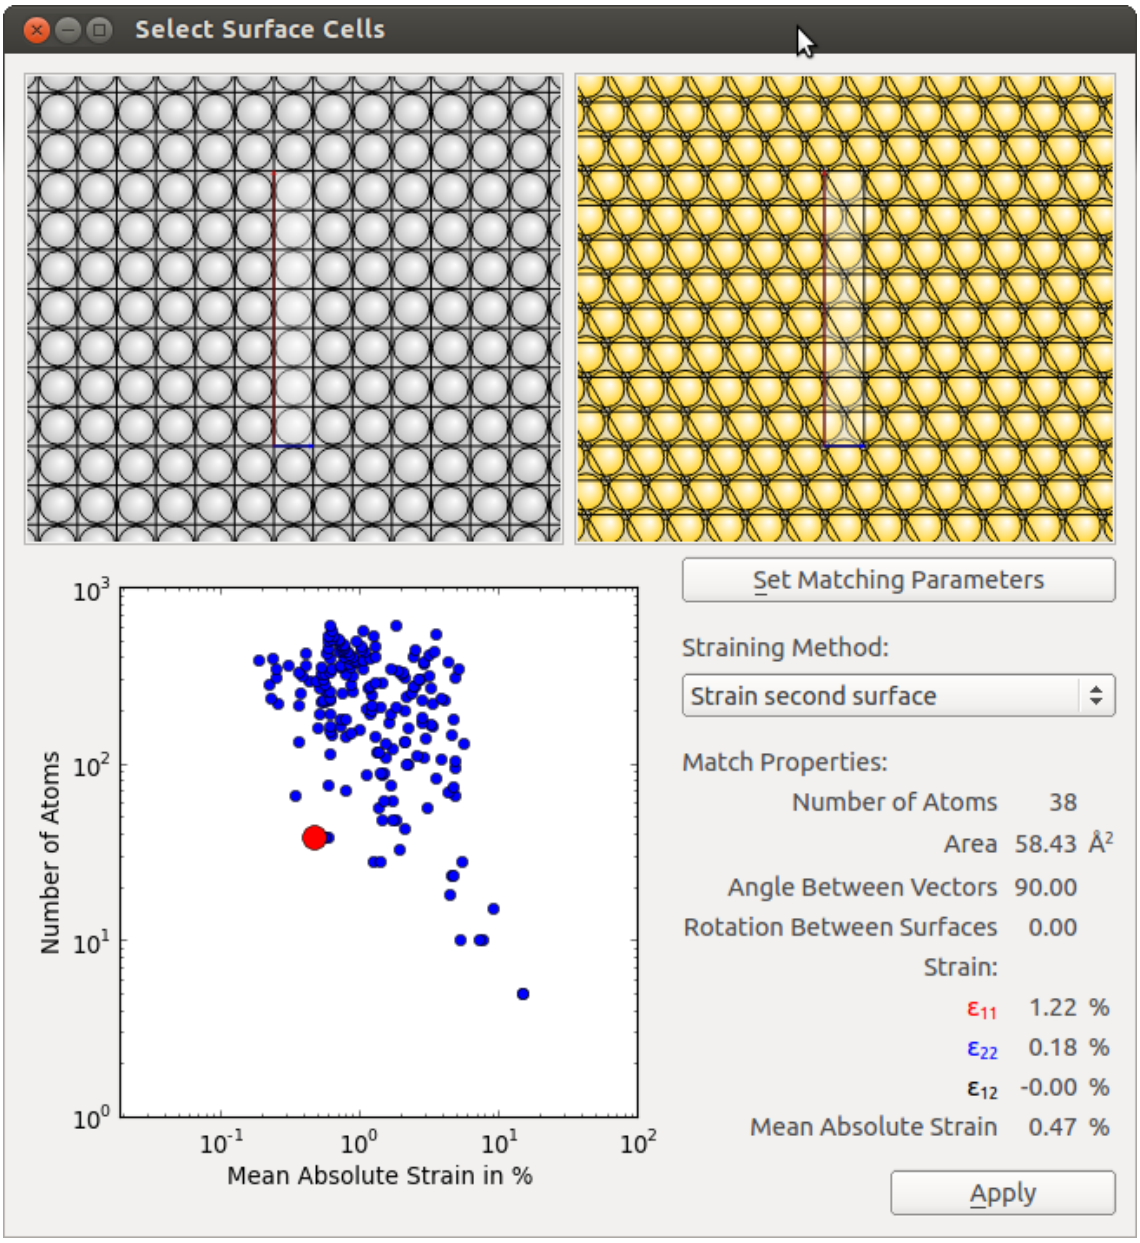
You have now built the Ag(100) and Au(111) supercells. The next step is to combine them into an interface. For this purpose, open the **Interface** plugin from the Builders group in the panel bar. It has two slots. Drop the Ag(100) crystal in the first and the Au(111) crystal in the second slot.

QuantumATK now scans all possible repetitions and rotations of the two surfaces in order to find a common supercell with minimal strain. Open the **Select Surface Cells** menu. The two upper plots show the selected surface cells of the two crystals. The lower left plot shows a number of blue dots, where each dot represents a common supercell for the two crystals.

We will now adjust the algorithm used for matching the two crystals. For this purpose, open the menu called **Set Matching Parameters**. With this menu it is possible to select the number of repetitions included for each cell and which angles are scanned to find a match. Increase n^{max} and m^{max} to 8 in order to search for larger supercells with less stress. Then click OK.



All the matching crystals will now be recalculated. Select the blue point closest to the lower left corner, to obtain a good compromise between a small supercell and a low stress. The supercell has 38 atoms and an average strain of 0.47%. Click Apply.

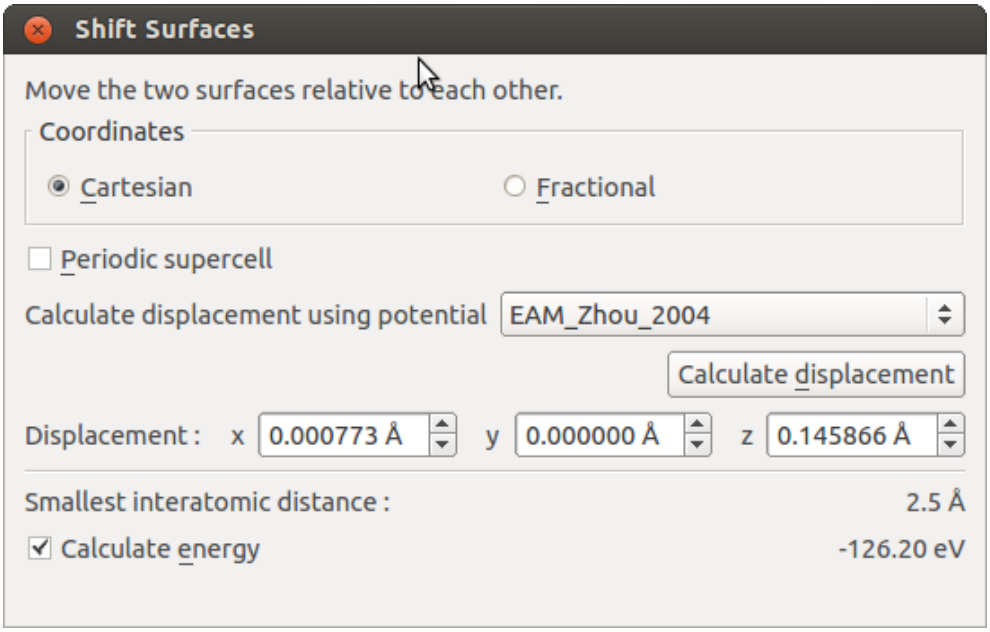


The next step is to define the relative position of the two crystals. For this purpose, open the **Shift Surfaces** menu in the main Interface Builder window. From this menu it is possible to either adjust the relative position of the two crystal manually, or compute the optimal distance using the ATK-ForceField calculator.

1.Select the EAM_Zhou_2004 potential.

2.Check the **Calculate energy** box.

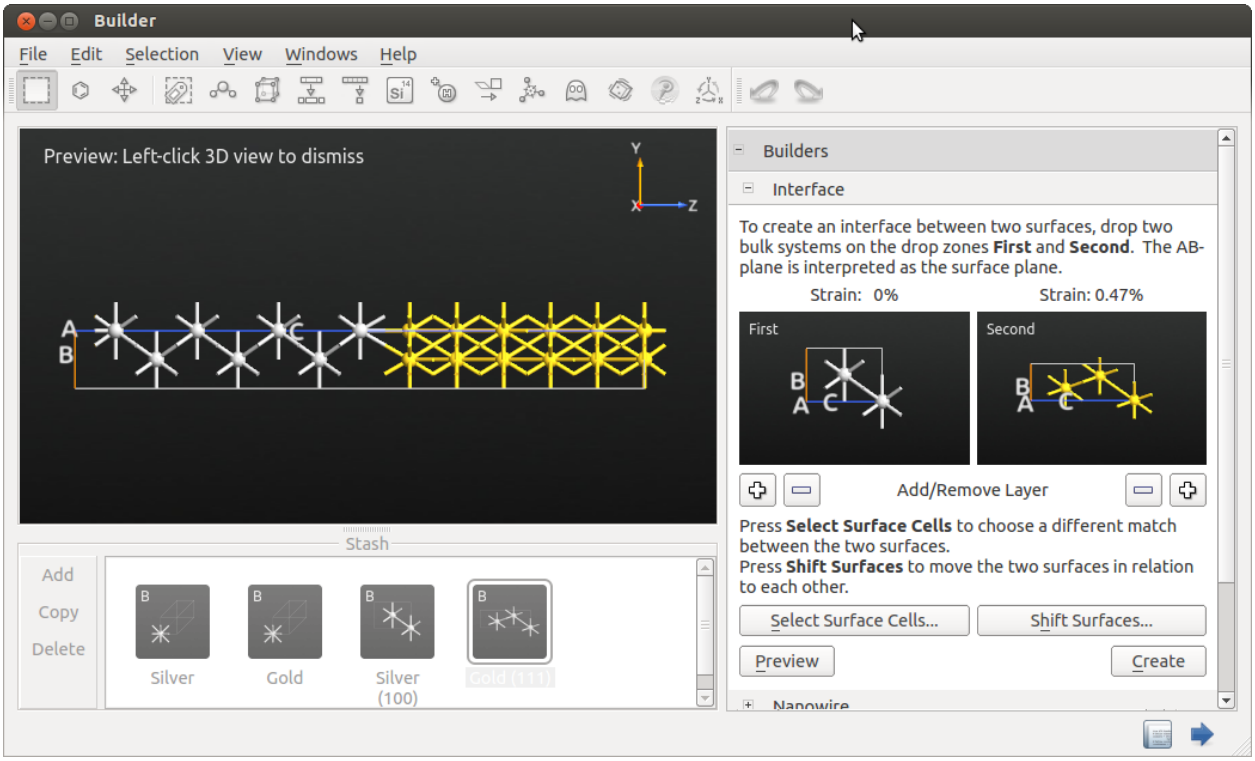
3.Click **Calculate displacement**.



Tip: In this case there are several available potentials. If you are not familiar with any of them, you may just try out different potentials and check if they give consistent results.

Note: For QuantumATK-versions older than 2017, the **ATK-ForceField** calculator can be found under the name **ATK-Classical**.

Close the **Shift Surfaces** menu and return to the main Interface window. Now add 5 silver layers and 3 gold layers using the buttons. Check that there are now 7 layers to the left and 6 layers to the right of the interface (Tip: You can use **Ctrl+r** to resize the plot window). Click **Create** to generate the structure.

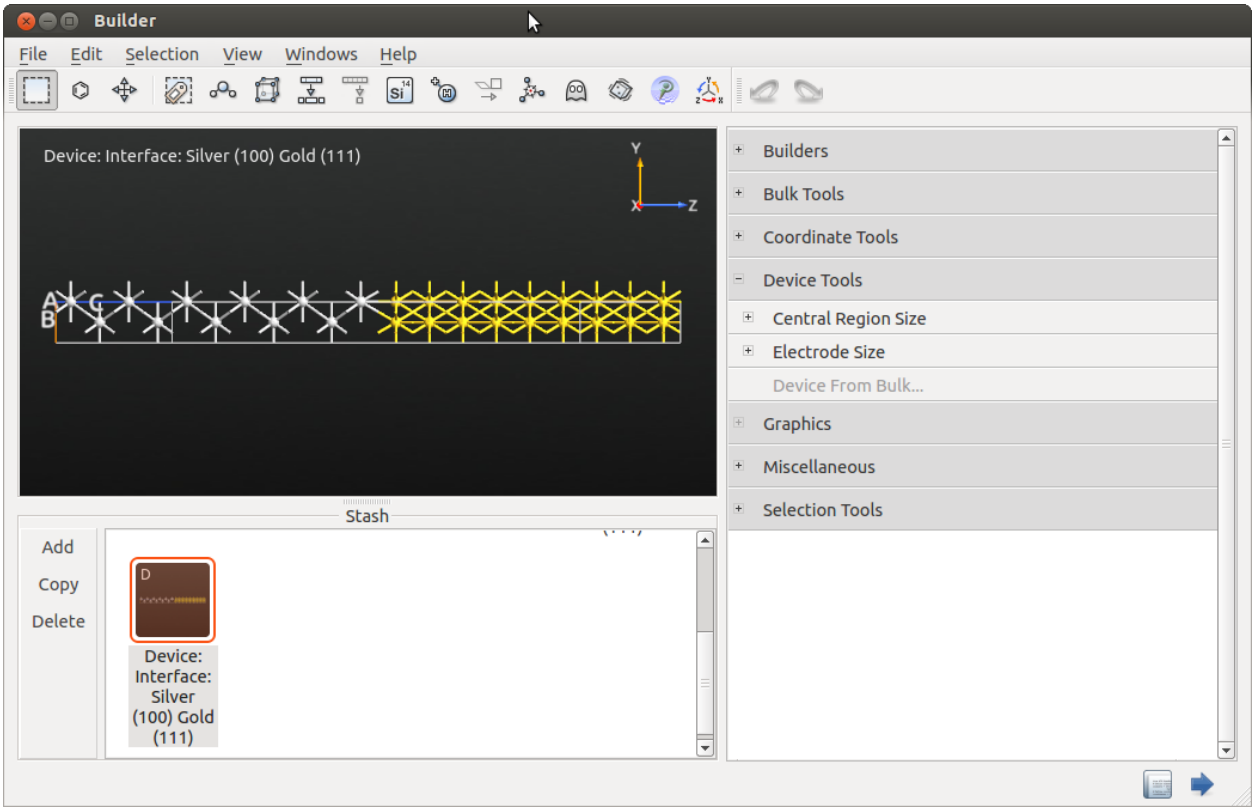


Tip: You can learn more about the Interface Builder in the Technical Notes on *Interface Builder*.

Building the device configuration

The last step is to build a device configuration from the interface structure. Contract the Builders group and expand the **Device Tools** in the Builder panel bar. Select **Device from Bulk**. The tool will try to determine the electrode lengths by looking for repetition matches. Keep the default values and click **OK**. You have now finished the setup.

Save the resulting geometry in the file `Ag_Au_interface.py` by using the **File** menu or by right clicking the Stash item.



3.4.2 Advanced device relaxation - manual workflow

In this tutorial you will learn how to use a combination of Rigid constraints and a simple optimization routine to perform efficient and reliable relaxation of the internal coordinates in a device configuration.

Note: In the O-2018.6 release, we introduced a so-called *Study Object* to automate the workflows described in this tutorial. That is now the recommended way of performing device geometry optimizations in QuantumATK, and if you have access to O-2018.06 or newer, you should go to the corresponding tutorial *Relaxation of devices using the OptimizeDeviceConfiguration study object*. Users of previous versions can still perform the calculations using the more complex workflow, that is described here.

Introduction

Relaxation of the internal coordinates of device configurations can be a tedious and time consuming task. There are two main reasons for this:

The 2-probe configuration consists of three distinct regions: Two electrodes and a central region consisting of electrode extensions and a scattering region. The geometry of each region should be separately optimized in a first-principles manner, but both electrode extensions in the central region must always match the corresponding electrode.

Step 1: Optimize the electrodes. After optimization of the electrodes, it is important to make sure that the electrode extensions in the central region match the optimized electrodes.

Step 2: Optimize the central region. The optimum length of the central region is usually not known *a priori*. In the case of a periodic bulk, one would minimize the stress tensor. However, the stress field is not uniquely defined for a device configuration, so another approach is needed.

In the second step, we must rely on minimizing the device total energy while explicitly preserving the internal coordinates of the electrode extensions. There are at least two different ways to do this using QuantumATK.

BRR method

After building the 2-probe configuration from fully relaxed electrodes, you extract the central region bulk and relax it with Rigid constraints on the atoms belonging to the electrode extensions. The device or interface is then reassembled from the relaxed bulk. This is a computationally efficient approach and will usually capture a large fraction of the required geometry relaxation. We shall refer to this method as Bulk Rigid Relaxation (BRR).

The BBR method does not calculate the total energy using a full device geometry, so the reassembled device may not be exactly in the global minimum-energy geometry. Some types of electronic structure calculations may be sensitive to this difference, others may not.

1D minimization

A somewhat more brute-force approach is to explicitly minimize the device total energy wrt. internal coordinates and the central region length, i.e., do the full 2-probe calculations and vary the central region length. This is a 1D minimization problem with relaxation of the atomic positions at each step, so we shall refer to this method as 1DMIN. We have developed a procedure for doing this as efficiently as possible with QuantumATK, but the computations are in general more demanding than with BRR. It is therefore recommended to use 1DMIN only after pre-relaxing the central region with the BRR method.

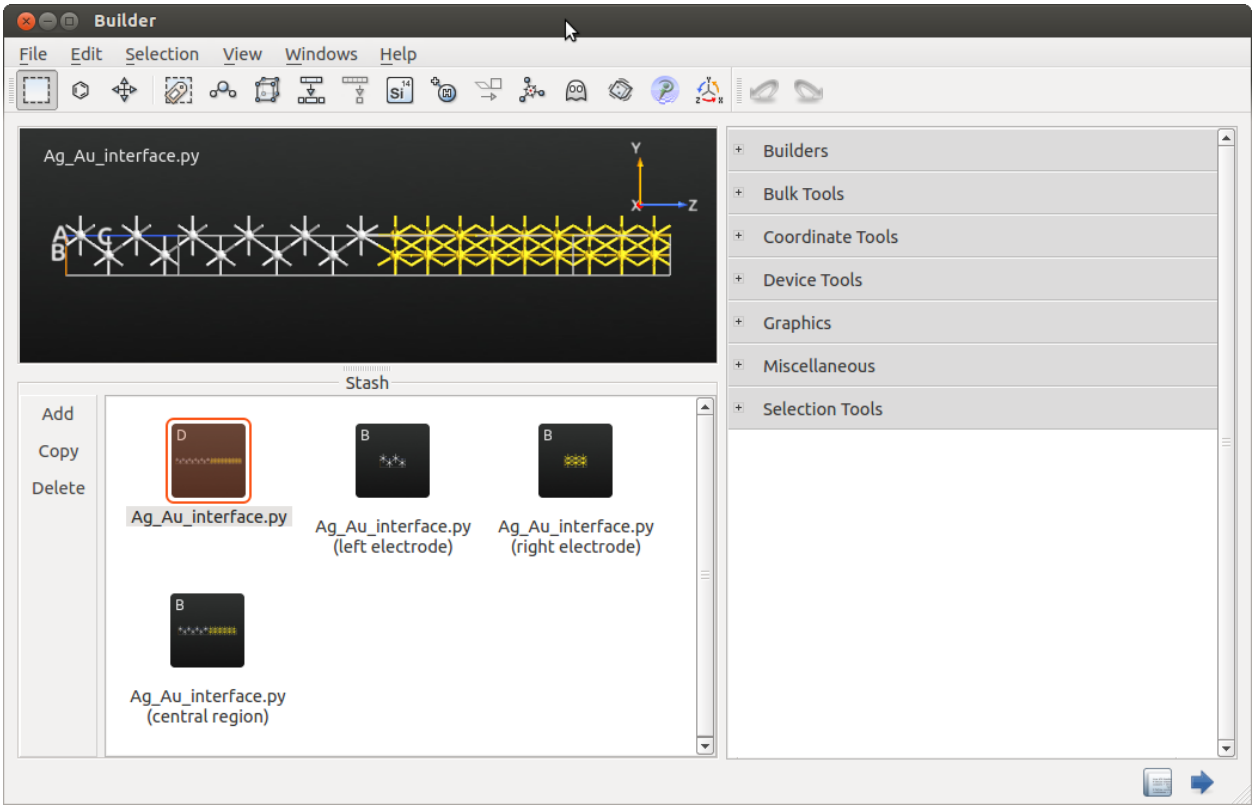
This tutorial introduces the electrode relaxation and the central region relaxation using BRR and 1DMIN methods. The methods are illustrated for relaxing a silver-gold interface using a classical potential. The classical potential is selected for computational convenience, and the same procedure could be used for another relaxation method like DFT. In general we recommend to check ATK-ForceField calculations with DFT calculations.

Preparations

First make a new project called device_relaxation. Our starting point is an unrelaxed 2-probe device configuration. It was created using the QuantumATK Interface Builder follow the tutorial at this link: *Building an interface between Ag(100) and Au(111)*. The geometry can also be downloaded as this file: `Ag_Au_interface.py`.

Save the py-file in your project folder, locate the device configuration on the LabFloor, and drag-and-drop the configuration to the **Builder**.

The 2-probe configuration should look like the one illustrated below. It consists of a left electrode, Ag(100), the central region, and a right electrode Au(111). Use the plugin to split the device into a left electrode, right electrode and central region.



Electrode relaxation

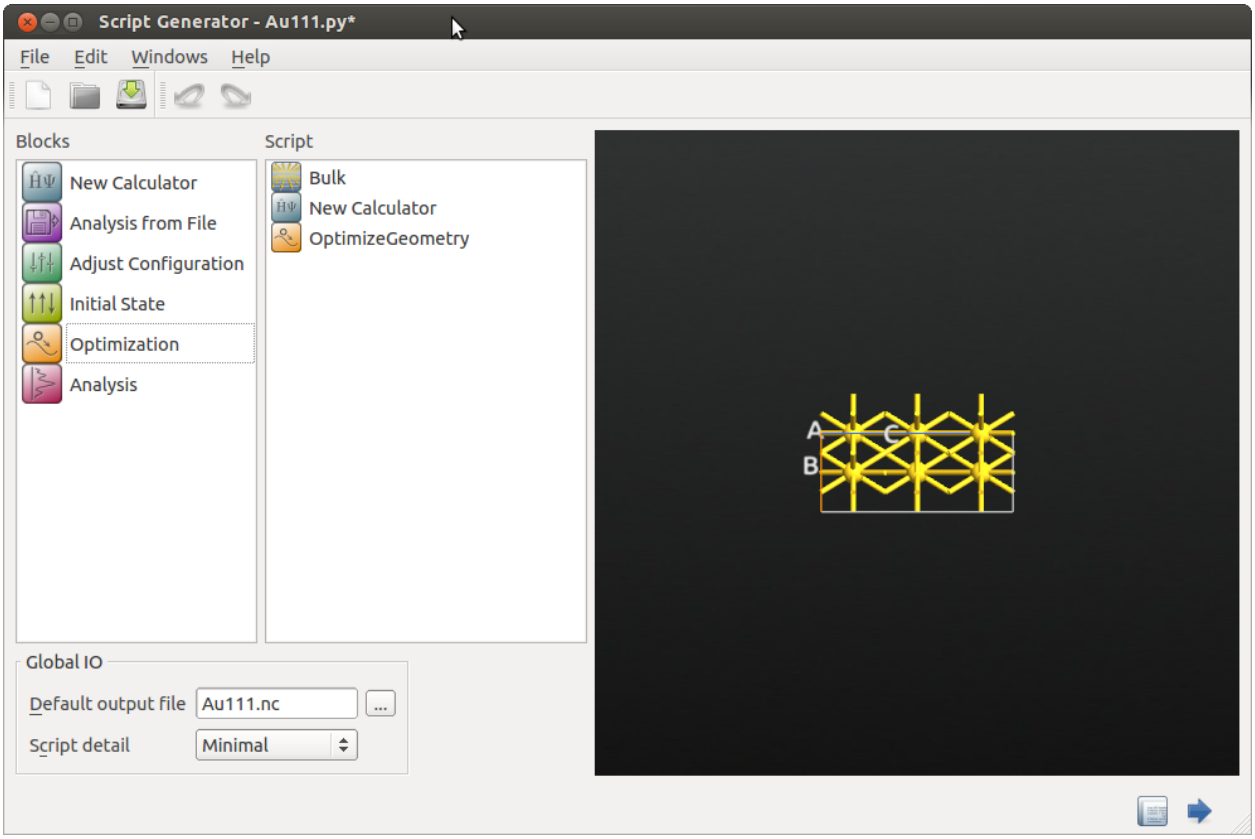
The device geometry was constructed using the interface builder (*Building an interface between Ag(100) and Au(111)*). Prior to building the interface the left and right crystal structures were set up using their experimental geometries. We will assume that the experimental geometry is also the lowest energy structure of the theoretical method we will use for relaxing the device geometry.

In the interface builder we choose Strain second surface upon selecting the surface cell. This means that the Ag(100) surface was kept in its experimental geometry, while the Au(111) surface was strained in the x,y directions upon forming the interface. When the crystal is strained in the x,y directions, it will relax in the z-direction according to the Poisson ratio of the material.

In the following we will apply this relaxation to the Au(111) crystal, by relaxing the stress in the z-direction while keeping the x, y directions fixed. The obtained relaxation of Au(111) will be transferred to the gold atoms in the central region.

Open the builder and change the name of the right electrode to Au111. Double click the geometry to make it active and send it to the **Scripter**. Add the following objects:

- New Calculator
- OptimizeGeometry

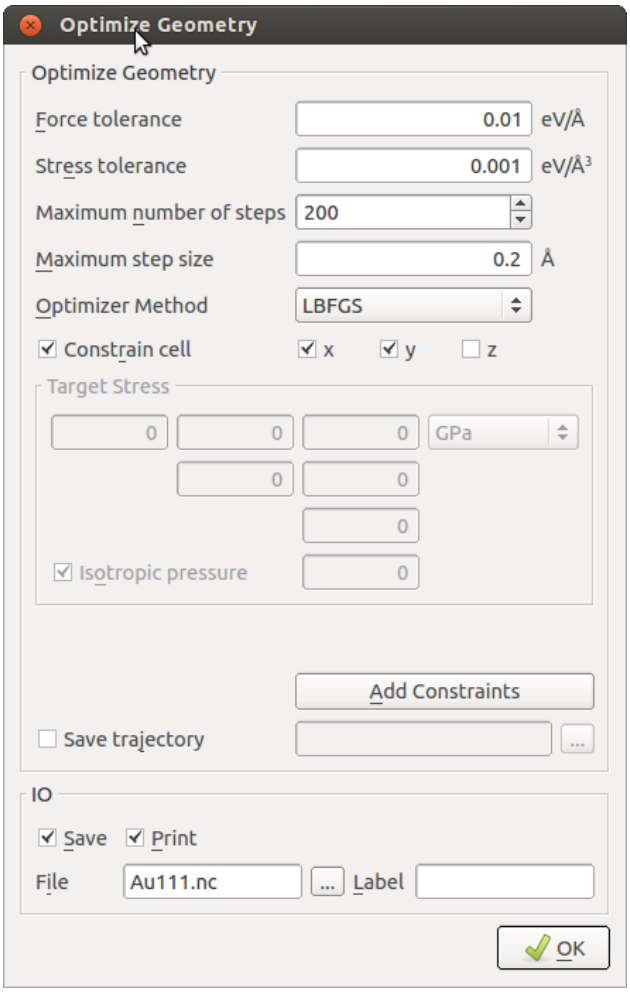


Now open the New Calculator object and select the **ATK-ForceField** EAM_Zhou_2004 potential. Click OK.

Note: For QuantumATK-versions older than 2017, the **ATK-ForceField** calculator can be found under the name **ATK-Classical**.

Next open the Optimize Geometry object:

1. Set the force tolerance to 0.01
2. Set the stress tolerance to 0.001
3. Uncheck z in the Constrain cell checkboxes

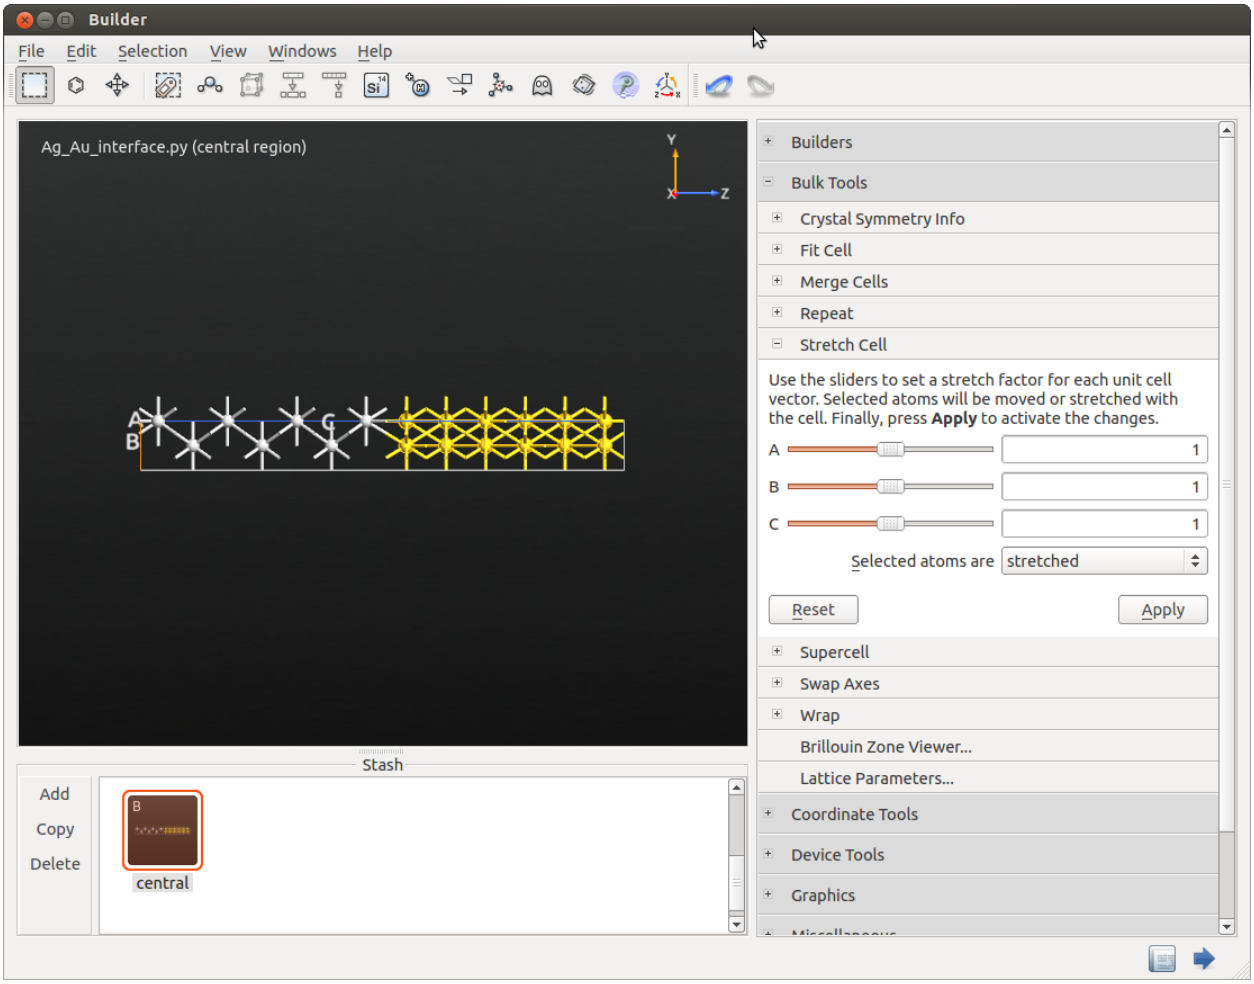


Send the script to the Job Manager and run the relaxation. It should take less than a minute to execute. When finished inspect the log file.

You should now see a new object on the **LabFloor** called Au111.hdf5. It contains two configurations, corresponding to the geometry before and after the relaxation. Select the two geometries and drop them onto the **Viewer**. In the viewer you can hoover the mouse over the unit cell of each configuration and you will notice that the length of the C vector is 7.064 Å before the relaxation and 7.011 after the relaxation. This information could also be obtained from the log file, Au111.log.

The relaxation results in a small compressive strain of 0.75%. To apply this to the central region, open the Builder and double click the central region configuration.

1. Rename the stash item to central.
2. Select all the gold atoms by drawing a rectangle around them.
3. Open the *Bulk Tools* → *Stretch Cell* plugin.
4. Enter 0.9925 along the C axis.
5. Use Selected atoms are *stretched*.
6. Click Apply.



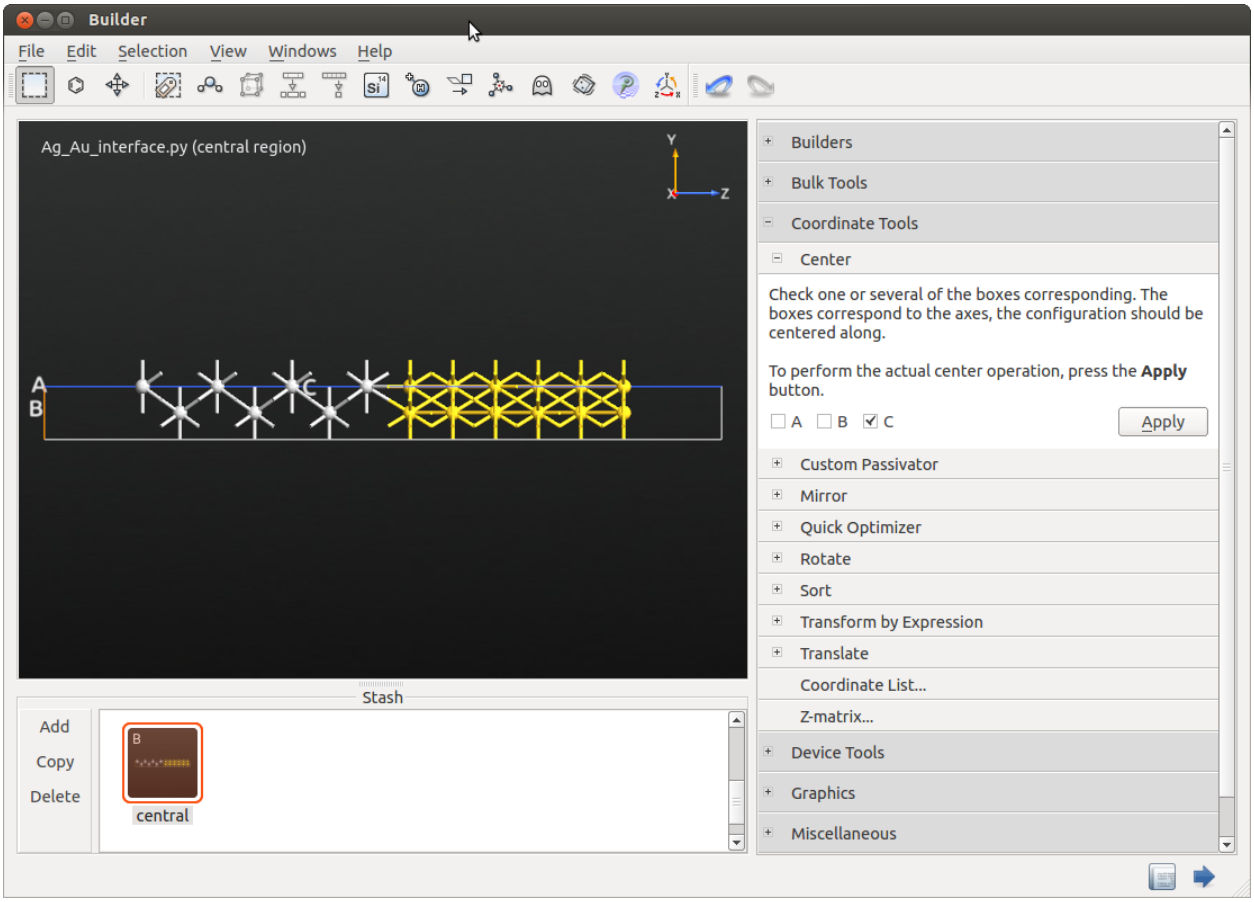
Note: The strain is so tiny that it is not possible to see any visual change in the structure. However, you may open the Lattice Parameters.. plugin and click the and buttons to see how the C cell vector changes when you undo and redo the stretch. Similarly, you can inspect the Coordinate List.

Central region relaxation

You are now going to relax the central region only. We want the electrode extensions to be able to move freely (but rigidly) during geometry relaxation. We therefore add vacuum on both ends:

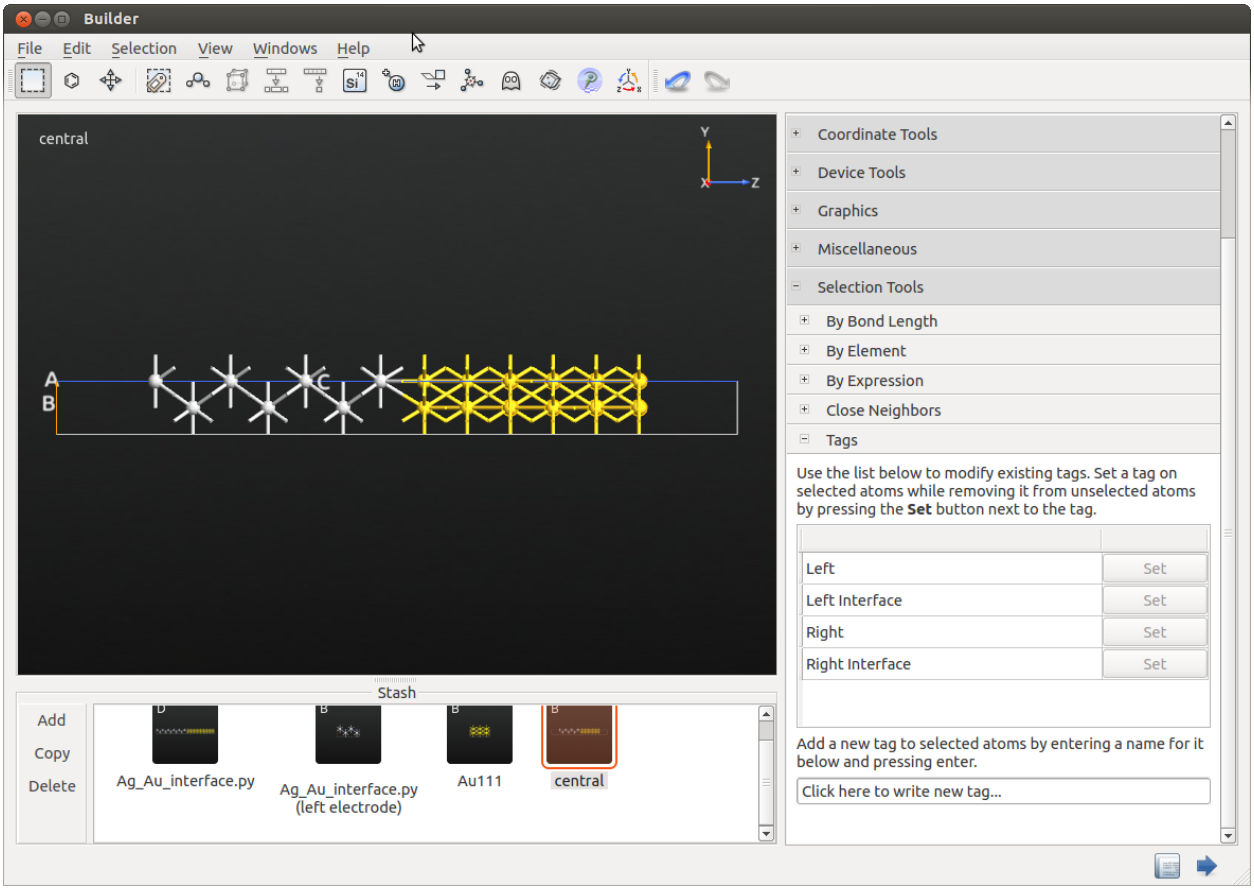
Make sure that no atoms are selected, by clicking the background of the plotting window. In *Bulk Tools* → *Stretch Cell* use the C-vector slider to increase the cell length by 30% or simply type in a multiplication factor of 1.3. The cell is stretched once you click Apply.

Move to *Coordinate Tools* → *Center* and uncheck A and B. Center the central region by clicking Apply.



We want to fix the atoms in the electrode extensions by including an additional layer of the central region. The additional layer will help the *Device from Bulk* tool in QuantumATK to identify the length of the electrode. For this purpose select the 5 outermost silver atoms. Open *Selection Tools* → *Tags*. Enter **Left** in the box named Click here to write a new tag. Press Return.

Next select the 4 outermost gold atoms, and tag them **Right**.



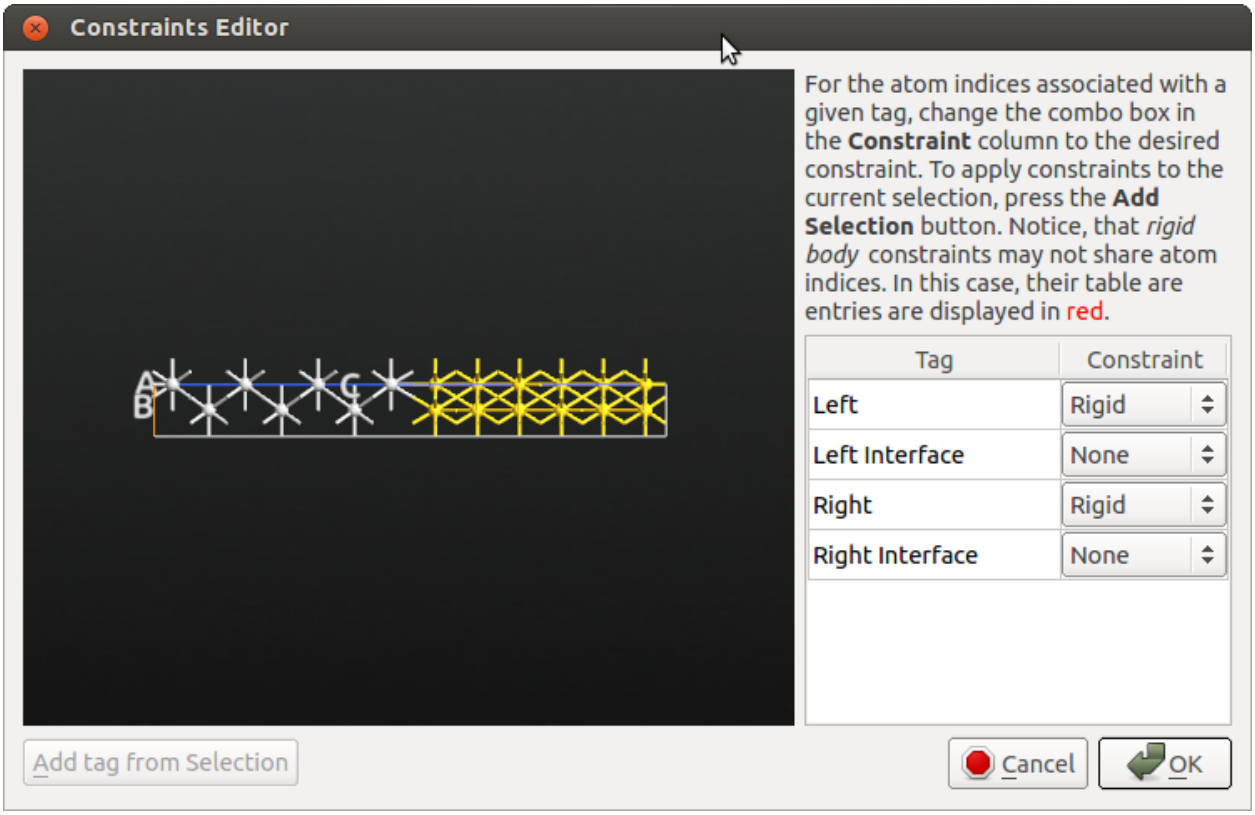
Send the configuration to the **Script Generator** and set up the calculation:

Add a New Calculator and an OptimizeGeometry object.

Choose the ATK-ForceField engine and the EAM_Zhou_2004 potential for these calculations.

Make the following changes to the OptimizeGeometry object:

1. Set the force tolerance to 0.01 eV/Å.
2. Check Save trajectory and set the filename to `central.hdf5`.
3. Click Add Constraints to set up the Rigid constraints on the electrode extensions.
4. Check that the Left and Right tags are assigned to the correct atoms in the configuration. Do this by clicking the tags. Choose Rigid constraints for both tags.
5. Click OK and return to the Scripter.



Note: Choosing instead a Fixed constraint for one of the tagged regions while keeping the other one Rigid, may save BFGS relaxation steps and thereby computational time.

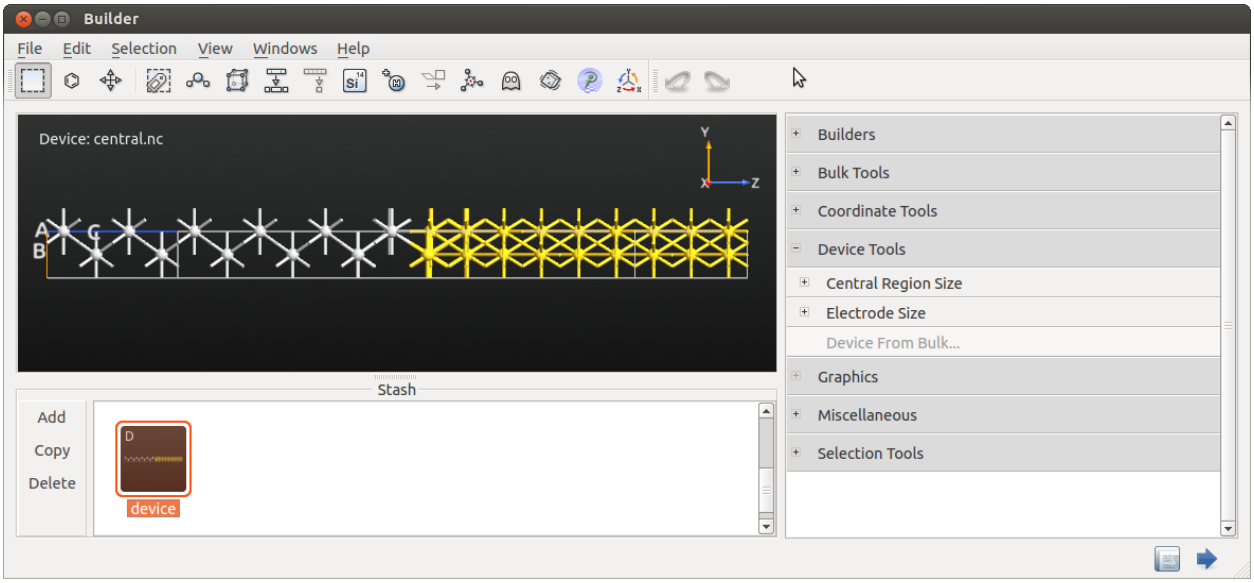
Send the script to the **Job Manager** and run the calculation. It should be very fast. Once finished, the `central.hdf5` output file appears on the **LabFloor**.

You can use the **Viewer** plugin to see the trajectory of the relaxation as illustrated in the animation below.

The relaxed central region is saved in `central.hdf5` as the bulk configuration with id glD002. This is your initial guess for the central region geometry. Drag-and-dro it on to the **Builder**.

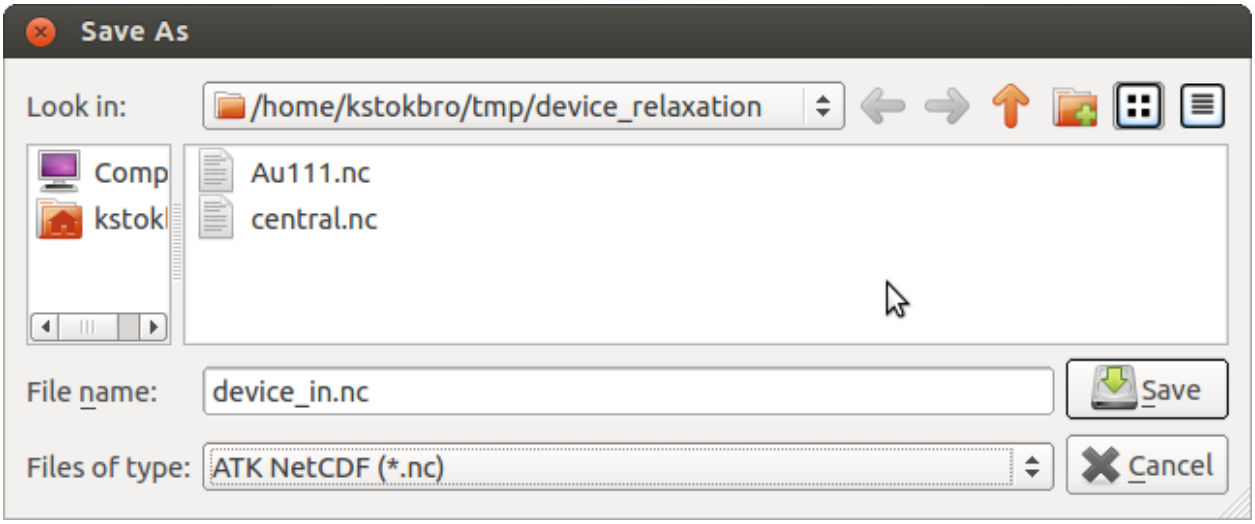
Click *Device Tools* → *Device From Bulk* to turn the `central.hdf5` bulk into a device configuration. You can leave the settings for electrode and central region lengths at default values.

The interface configuration should now look like illustrated below. Rename the configuration to device by using F2 or with a right mouse-click.



1DMIN optimization of the interface using 2-probe calculations

We are now ready to search for the global minimum-energy geometry of the Ag(100)-Au(111) interface. Save the device configuration as a HDF5 file named `device_in.hdf5` by choosing Save as after right-clicking the device Stash item.



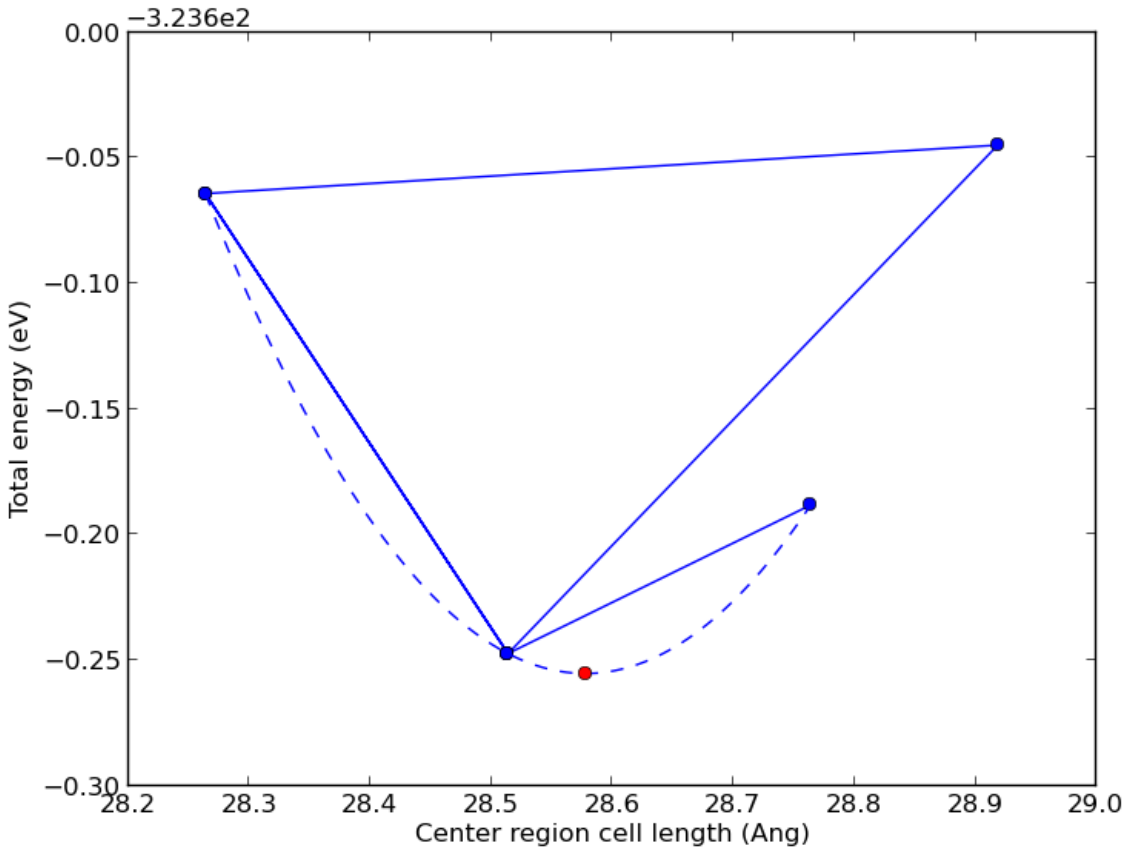
You are now going to apply a simple **SciPy minimization** procedure in search for the central region length that minimizes the interface total energy. The device configuration you just saved in `device_in.hdf5` is the starting point for this.

Two scripts are needed. You can download them here: `device.py` and `optimize.py`. Save both scripts in the folder where `device_in.hdf5` was saved. The first script (`device.py`) reads in the device configuration and sets up and runs the calculation, while the second script (`optimize.py`) contains functions and classes used by `device.py`.

Note: To use the script device.py for other systems you need to edit the script and change the definition of the potential to an appropriate potential for your new system.

Both scripts should now be available in the QuantumATK Project Files list. Drag-and-drop device.py onto **Jobs**. The Job Manager will open. Click to run the script.

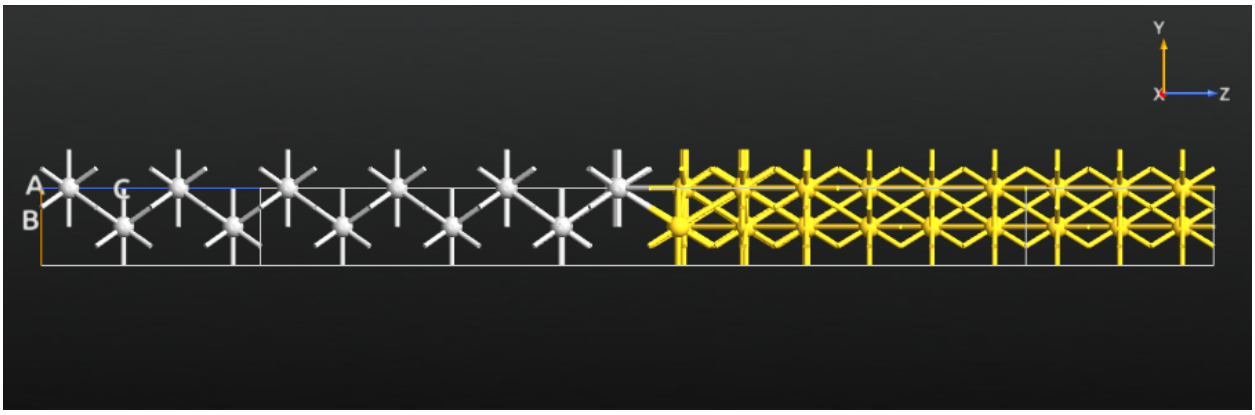
Once finished (its fast!), a window with the figure below will pop up. The blue points are total energies of relaxed interface configurations. The initial cell length is 28.51 Å and the other blue points are trial guesses made by the algorithm. The red point indicates the optimum central region length which is 28.58 Å. The optimization routine simply maps out the illustrated potential-energy surface and finds its minimum!



The job will finish when you close the pop-up window.

The relaxed configurations are saved in the output file `device_out.hdf5` along with the total energies. The configuration corresponding to the red point (the final device or interface geometry) is the latest device configuration (the one with largest id number).

Using the **Viewer** plugin, the minimum-energy interface configuration looks like this:



In this case the change to the structure after the 1DMIN relaxation is minute compared to the BRR relaxation. Often the BRR will be sufficiently accurate and there is no need for the 1DMIN step. The 1DMIN approach is only needed for extreme accuracy.

3.4.3 Relaxation of devices using the OptimizeDeviceConfiguration study object

Version: O-2018.06

This tutorial introduces you to the `OptimizeDeviceConfiguration` study object. For proper optimization of the geometry of a 2-probe device configuration, we recommend the Bulk Rigid Relaxation (BRR) method. However, this can be a complicated task involving several steps. As shown in this tutorial, the `OptimizeDeviceConfiguration` study object automates the BRR method, making it very simple to optimize the geometry of a device.

Note: The **OptimizeDeviceConfiguration** study object was introduced in the O-2018.06 release, and is the recommended way of performing device geometry optimizations in QuantumATK. Users of previous versions can still perform the calculations in a more complex, and manual, workflow, as described here: *Advanced device relaxation - manual workflow*

Introduction

In principle, the complex device structural relaxation can be done manually, as described in the *Advanced device relaxation - manual workflow* tutorial, but the manual BRR procedure requires tedious and time-consuming work. Therefore, we encourage you to use the `OptimizeDeviceConfiguration` study object for relaxing complex device systems. The study object allows for fully automated device relaxation, including automatic identification of the central region atoms that should be allowed to relax. This fully automated procedure is illustrated below, and can be described as follows:

1. **The region of full relaxation is determined.** This happens automatically by first determining which parts of the central region are periodic repetitions of the near-by electrode. The middle point between left and right periodic images is then the center of the region that should be fully optimized, and the region has a user-specified width. Note that the region of full relaxation is not allowed to extend into an electrode extension. If it does, the edge of the region is automatically moved to the border of that electrode extension.

2+3. **Bulk Rigid Relaxation is executed.** The device configuration is converted to a bulk configuration (the electrodes are removed), and the right-hand end of the cell is extended with a vacuum region, in order to allow for contraction

or expansion of the central region during relaxation. Ordinary geometry optimization (force minimization) is then executed while applying a Fixed constraint on the left-hand atoms and a Rigid constraint on the right-hand atoms. See the tutorial *Advanced device relaxation - manual workflow* for more details on the BRR method.

4. **The device configuration is re-assembled.** The vacuum region is removed and the electrodes are attached, resulting in the final geometry optimized device configuration.

ASSEMBLE GEOMETRY OPTIMIZED DEVICE CONFIGURATION

The study object allows you to change certain settings for device relaxation:

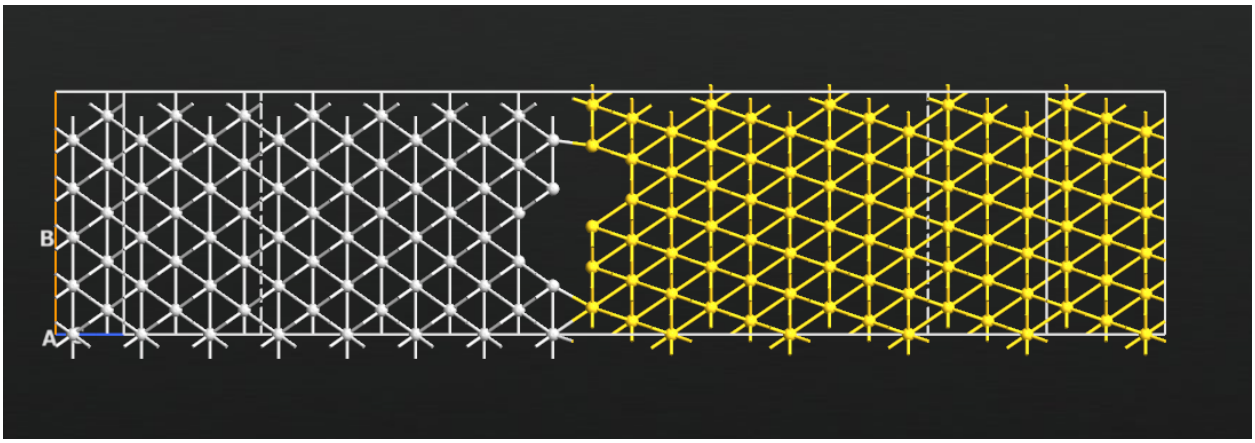
- You may select which part of the central region to fully relax, i.e., you may specify the center and width of the relaxation region.
- The relaxation region may extend to the entire device, except of course the electrodes and their extensions.
- If needed, the left and right surfaces of the central region may be hydrogen-passiovated during steps 2 and 3.
- The usual force convergence criterion for gemoetry optimization may also be tuned.

We will here demonstrate how geometry optimization of a Ag(100)||Au(111) interface can be done using the **OptimizeDeviceConfiguration** study object. For purposes of illustration, a large defect is introduced at the Ag|Au interface in order to enhance the effect of geometry optimization.

Unrelaxed Ag(100)|Ag(111) device

The unrelaxed and defected Ag(100)|Ag(111) device is available as a script: `unrelaxed.py`. Please download it and use it for this tutorial.

The device was built using the **Interface Builder**, as shown in the tutorial *Building an interface between Ag(100) and Au(111)*. The defect at the Ag|Au interface was introduced by simply removing atoms using the **Builder**.



Important: In general, devices should be built from relaxed (unstrained) materials, i.e., the electrodes should be in equilibrium geometries (given the level of theory employed, for example DFT using the PBE exchange-correlation functional, or a particular force field).

This may be crucial, as the theoretically predicted electronic properties of a material will in general depend on the geometry. In particular, the electrode relaxation may have an effect on the band gap and effective masses of the electrode material, which may change IV characteristics of the device. An instructive example of relaxation for strained silicon electrodes is given in *Appendix*.

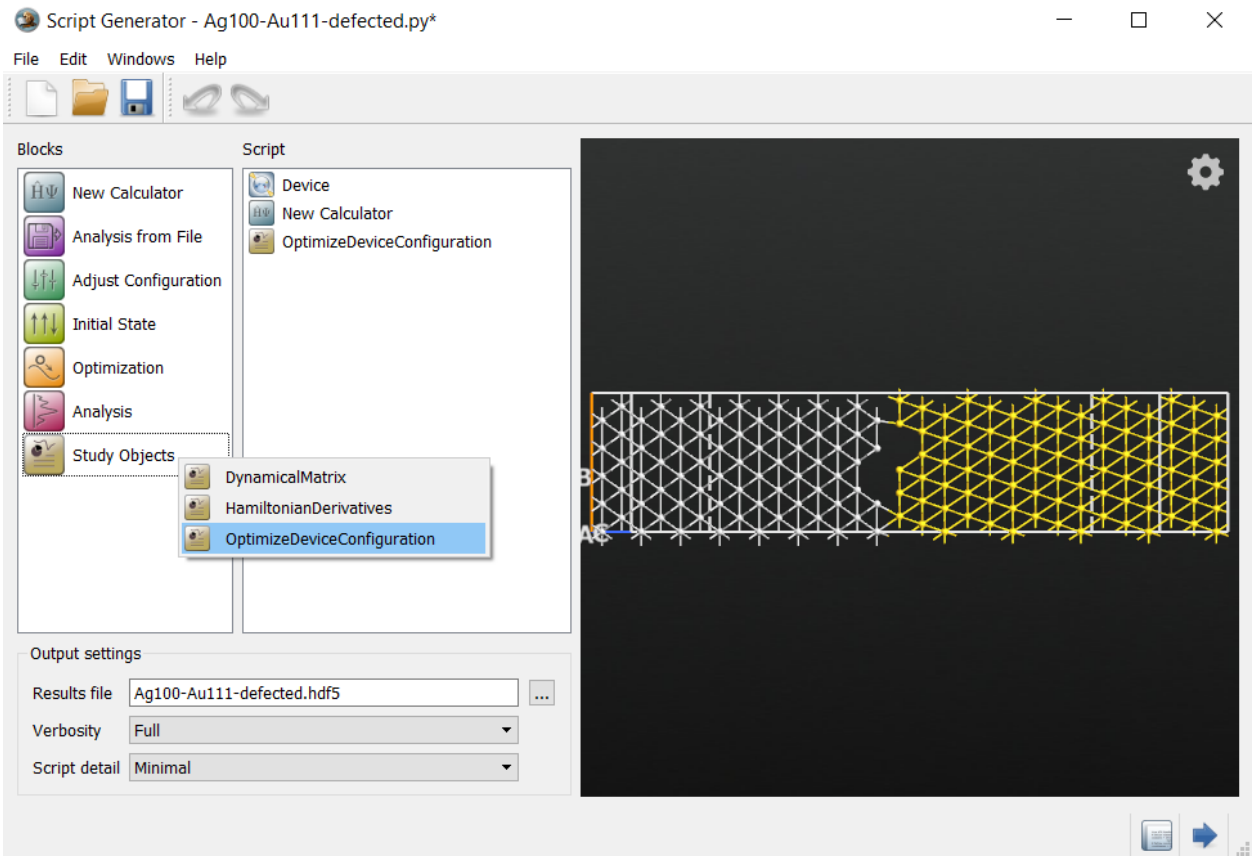
The *OptimizeDeviceConfiguration* study object **does not** relax the electrodes – it is the responsibility of you as a user to make sure the electrode geometries are appropriate before running the device geometry optimization.

Set up and run the device geometry optimization

Send the script `unrelaxed.py` to the **Script Generator**.

You will here relax the device using the ATK-ForceField engine, in order to speed up calculations. In the Script Generator, add the **New Calculator** block, and double-click to open it. Then select the **ATK-ForceField** calculator and choose the **EAM_Zhou_2004** force field.

Next, add the **OptimizeDeviceConfiguration** study object script block, by clicking *Study Objects* → *OptimizeDeviceConfiguration*.

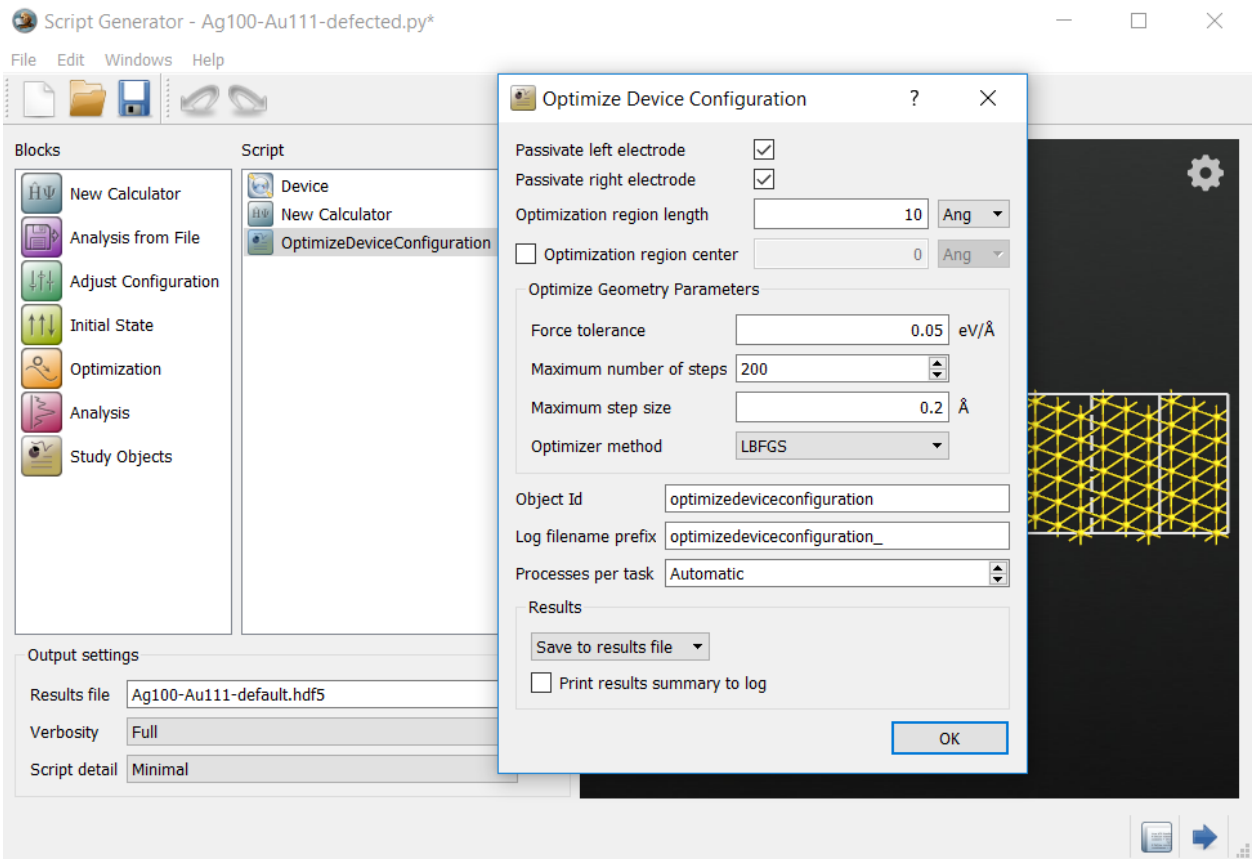


We will run the device geometry optimization using both A) default settings, and B) a custom optimization region.

A) Default settings

Double-click the **OptimizeDeviceConfiguration** block to open it. In principle, none of the settings need to be changed. As you see below, the default width of the optimization region is 10 Å, and the option *Optimization region center* is unticked, so the center is automatically determined, as described above.

Leave the settings at default values, close the widget, and change the name of the output results file to `Ag100-Au111-default.hdf5`, and save the Python script as `Ag100-Au111-default.py`. You may also download the final script: `Ag100-Au111-default.py`.



Note: The options *Passivate left electrode* and *Passivate rigth electrode* are ticked by default, meaning that the `OptimizeDeviceConfiguration` study object will attempt to apply **hydrogen passivation** to the left and right surfaces during the central region bulk relaxation (steps 2+3 in the methodology outlined in the *Introduction*).

This can be of relevance for semiconducting materials, but has no impact on metallic systems such as the Ag(100)|Au(111) interface.

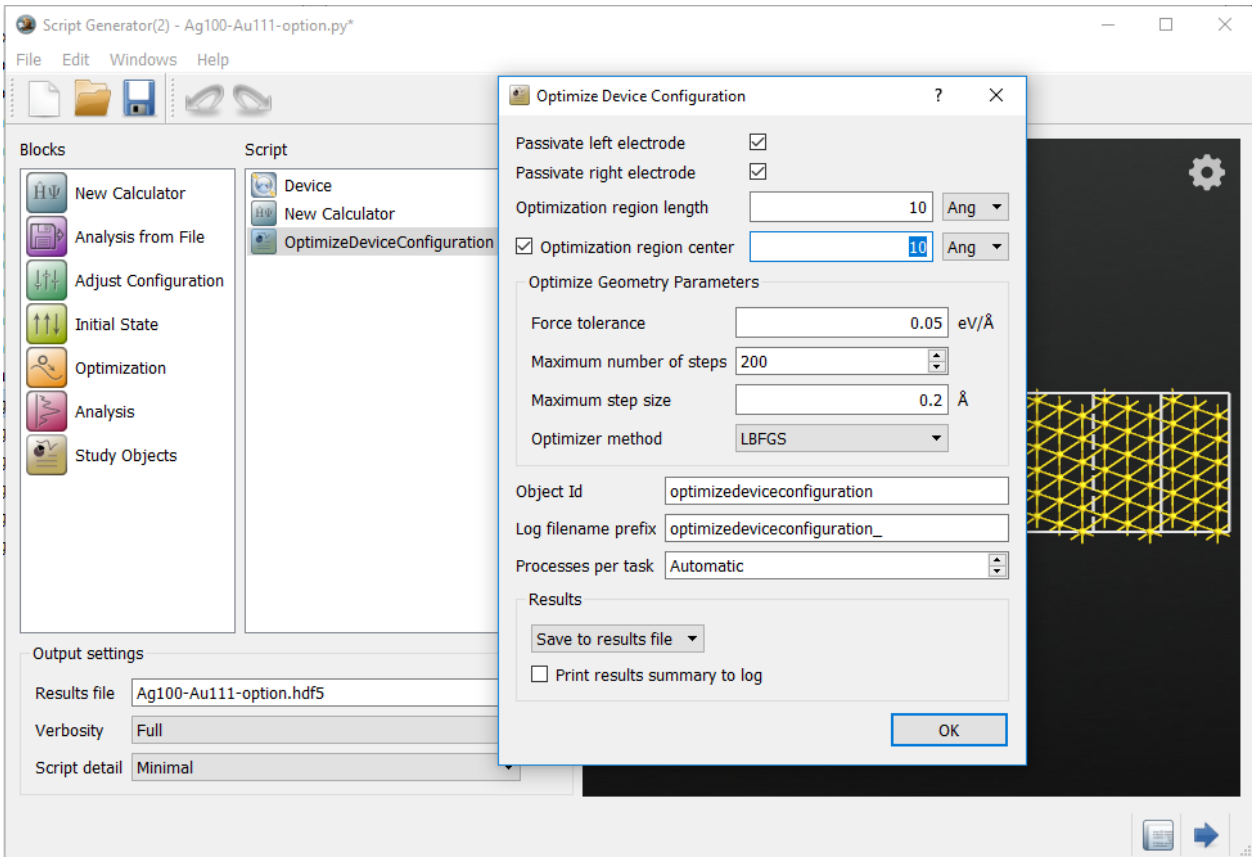
B) Custom optimization region

Open again the **Optimize Device Configuration** widget. For demonstration purposes, you will now specify an optimization region that does not include the Ag|Au interface. The atoms around the interface will therefore not be relaxed.

Tick the option *Optimization region center*, and set the center position to 10 Å, which is measured from the right-hand edge of the left-hand electrode. Keep the optimization region length at 10 Å, such that only atoms within ±5 Å from the center will be allowed to relax.

Note that, since the left electrode extension is of 8.17 Å, i.e., larger than 5 Å, the specified optimization region extends into the electrode extension. This overlap region will not be relaxed because the NEGF method requires that the electrode extension is identical to the electrode.

Finally, close the widget, and change the name of the output results file to `Ag100-Au111-option.hdf5`, and save the Python script as `Ag100-Au111-option.py`. You may also download the final script: `Ag100-Au111-option.py`.



Run the calculations

Run the two **ATK Python** scripts, either using the **Job Manager** or from a terminal:

```
atkpython Ag100-Au111-default.py > Ag100-Au111-default.log
```

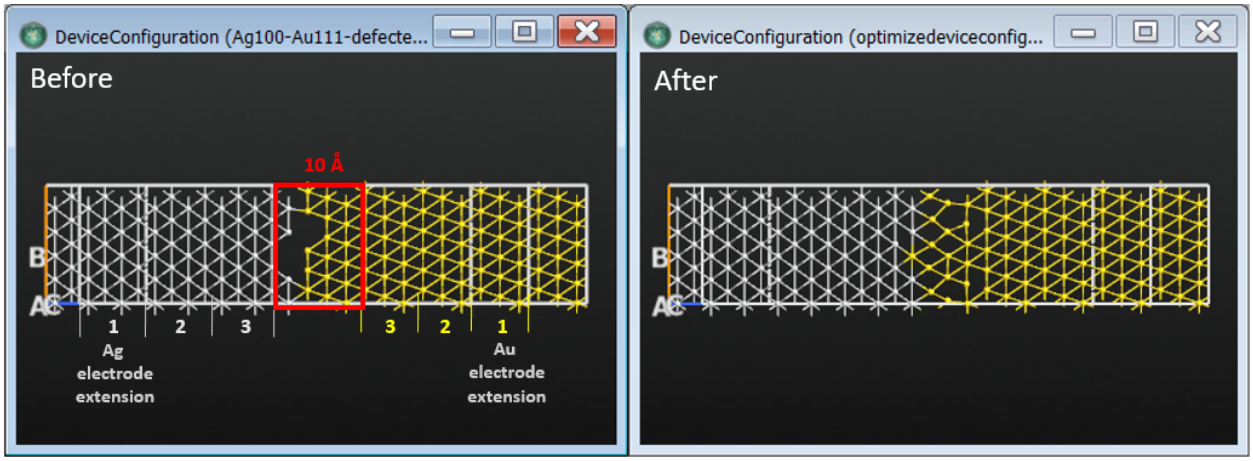
The device geometry optimizations will take only a few seconds to execute.

Relaxed device structures

The **NanoLab LabFloor** should now show the contents of the two saved HDF5 output data files. If not, tick the output files in the left-hand **Project Files** list. Each file contains the *OptimizeDeviceConfiguration* object and the optimized *DeviceConfiguration*.

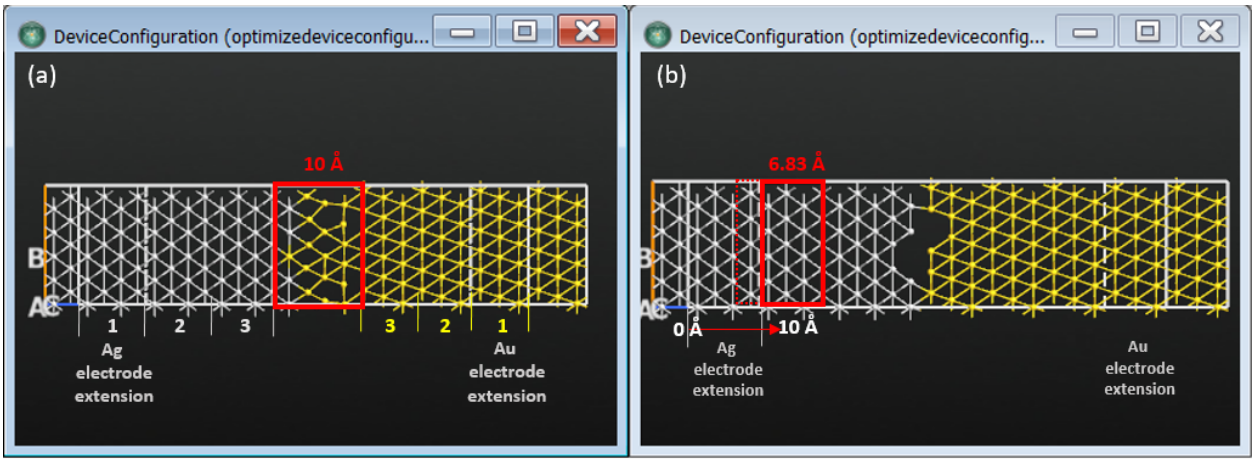
Use the **Viewer** to inspect the optimized devices. You may send the unrelaxed device configuration from the **Builder** to the **Viewer** for easy comparison.

The figure below compares device configurations before and after geometry optimization for **case A** (default settings, `Ag100-Au111-default.hdf5`). You can clearly see the effect of structural relaxation. The periodic repetitions of the left and right electrodes are also indicated, as well as the 10 Å wide region of full atomic relaxation.



The next figure compares the optimized devices from **case A** (default settings) and **case B** (custom optimization region). It is clear that we in case B made a very poor choice of optimization region: Very little relaxation has happened, and the region around the Ag|Au interface is completely unrelaxed. There are two reasons for this:

1. The optimization region **center** is set too close to the left electrode;
2. The optimization region **length** does not cover the interface region with the defects.



The **Text Representation** gives information about the settings used for the OptimizeDeviceConfiguration study object, and a summary of the results. To use it, select one or more OptimizeDeviceConfiguration objects on the **LabFloor**, and click the Text Representation tool in the right-hand plugins bar.

The text representation reports for case A (`Item: 0`) and case B (`Item: 1`) are shown below.

```
+-------------------------------------------------------------------------------+
```

Item 0

For case A, you can see the following information in the text representation:

- The central region includes 135 atoms, and initially had a length of 54.97 Å along the transport direction, which decreased slightly to 54.67 Å during relaxation.
- The length of the left (right) electrode extensions are 8.17 Å (7.06 Å), containing 20 (18) atoms each.
- The optimization region length is 10 Å, and the position of the left (right) optimization region edge is at 24.15 Å (34.15 Å), leading to 21 fully relaxed atoms.
- The left and right parts of the device that are constrained during relaxation are 24.15 Å and 20.82 Å long, respectively, and contain 60 and 54 atoms.

Item 1

For case B, we observe that

1. The length of the optimization region is only 6.83 Å, because it has been automatically reduced in order to avoid relaxing the electrode extension.
2. The right-hand edge of the optimization region is at 15 Å, so the Ag|Au interface is not relaxed.
3. Full atomic relaxation has therefore only been done in a region comprising bulk-like Ag, so very little relaxation has actually happened. This is also indicated by that fact that the central region length did not change at all during geometry optimization.

Conclusions

When using the *OptimizeDeviceConfiguration* study object, you may take full control of what is to be the region of full atomic relaxation, by manually setting the center and width of this region. However, it is important to carefully check the result.

Alternatively, you may choose to let the relaxation region extend over the full device, or simply stick to the default 10 Å width and automatic detection of the region center.

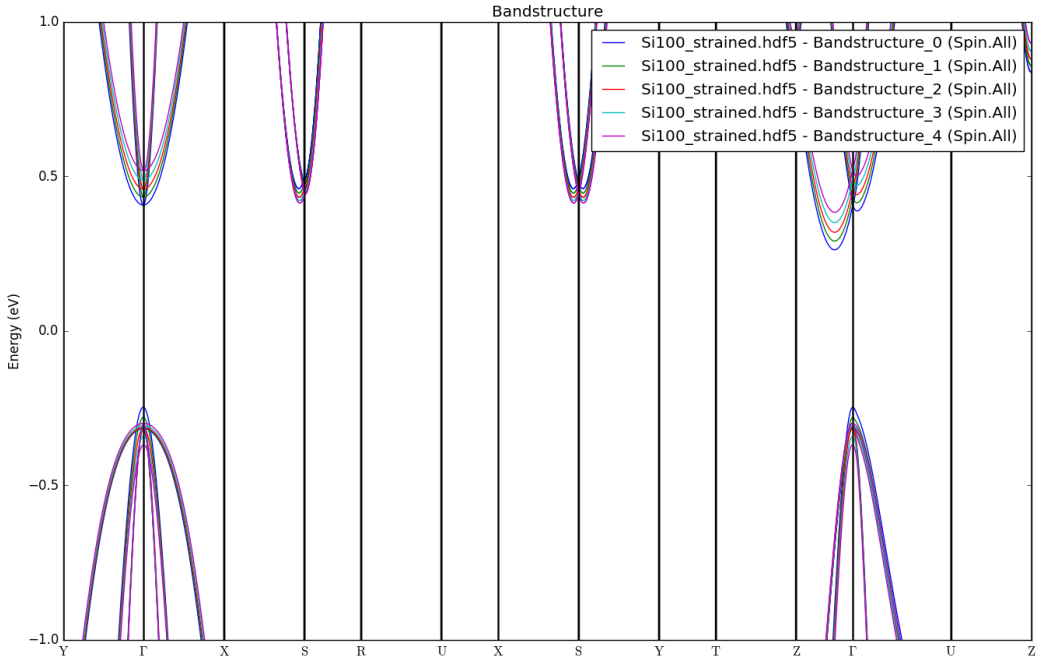
In summary, there are three main modes of operation for the *OptimizeDeviceConfiguration* study object:

- Use default optimization region settings (10 Å width and automatic detection of the region center).
- Manually specify the optimization region center and width.
- Relax all central region atoms (except the electrode extensions) by increasing the optimization region width beyond the central region total length.

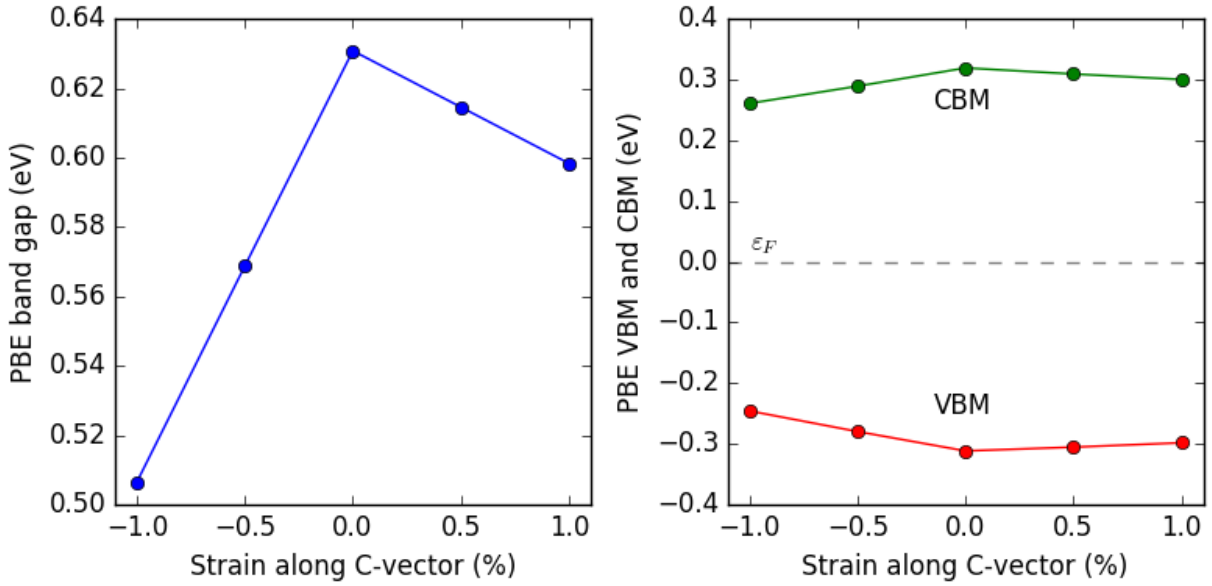
Appendix

As previously mentioned, devices should in general be built from relaxed materials, to avoid effects of stress or strain on the electronic properties. If the starting materials are not relaxed before building the device, geometry optimization of the device may compensate for this by artificially straining parts of the device along the transport direction.

We here show one example of the effect strain on the electronic structure of a semiconductor electrode. The below figure shows the band structure of a Si(100) electrode strained by $\pm 1\%$ along the C-axis, which coincides with the (100) crystallographic direction. By careful inspection one can see that the conduction and valence band energies get slightly shifted.



The figure below shows how the DFT-PBE valence band maximum (VBM) and conduction band minimum (CBM) change upon straining the Si(100) electrode along the C-axis (right-hand panel), and how the silicon fundamental band gap therefore also changes (left-hand panel).



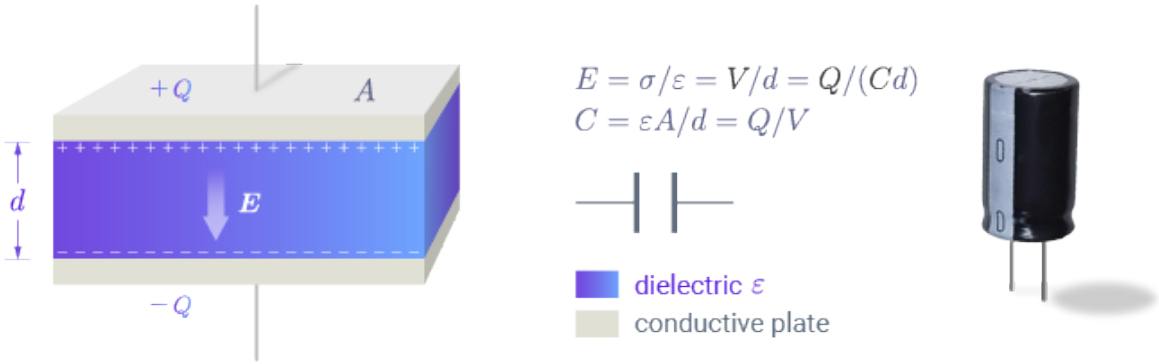
3.4.4 Atomic-scale capacitance

Version: P-2019.03

Downloads & Links

`bias_loop.py` `mulliken-analysis.py` `potential_plot.py` `v-e-plot.py` `v-c-plot.py`

In this tutorial you will perform an atomic-scale simulation of a parallel plate nano-capacitor, which means that the gap between the two parallel metal surfaces is in the nanometer range. This is currently not a realistic device, but the purpose is to show a methodology that can be used to compute the capacitance of other structures, including metal/semiconductor/metal structures.



Attention: Capacitor physics Applying a bias V across the capacitor leads to a build-up of oppositely signed charge Q on the plates, and therefore an electric field E between them. The electric field strength can be written as $E = \sigma/\varepsilon = V/d$, where $\sigma = Q/A$ is the charge density and $\varepsilon = k\varepsilon_0$ is the permittivity of the spacer layer between the plates (vacuum or dielectric). The capacitance can then be calculated from $C = Q/V = Q/Ed = A\varepsilon/d$, where d is the distance between the plates.

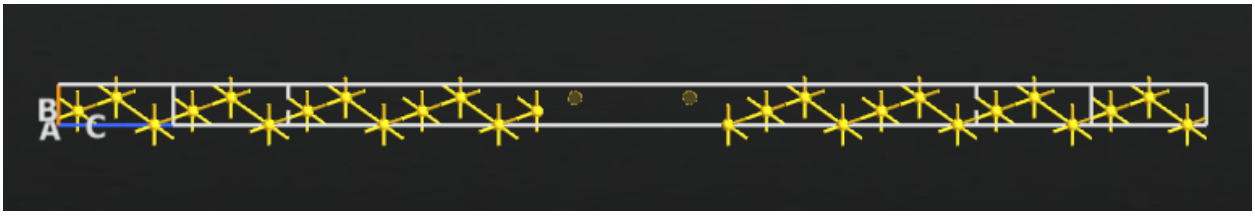
Calculations The equations given above are valid for an ideal macroscopic parallel plate capacitor, but a nano-scale capacitor may in general be quite different. The main method used for computing the capacitance from first principles is to evaluate the electrostatic energy, and from that the capacitance. We will also show a slightly simpler approach based on the Mulliken charge populations of the atoms.

Build the parallel plate capacitor

Open the **Builder** , and do the following:

- Use *Add* → *From Database* to add gold to the Stash.
- Open the *Builders* → *Cleave* plugin, and create a Au(111) electrode by entering the Miller indices as [111].
- Repeat the structure 8 times in the C direction using *Bulk Tools* → *Repeat*.
- Select and delete the two atoms in the middle – they have atom indices 19 and 4.
- Select the surface atoms (indices 10 and 11 after deletion), and turn them into ghost atoms using the toolbar icon .
- Turn the bulk structure into a device configuration via *Device Tools* → *Device From Bulk* and use the default settings.

The result will be the device as shown below.



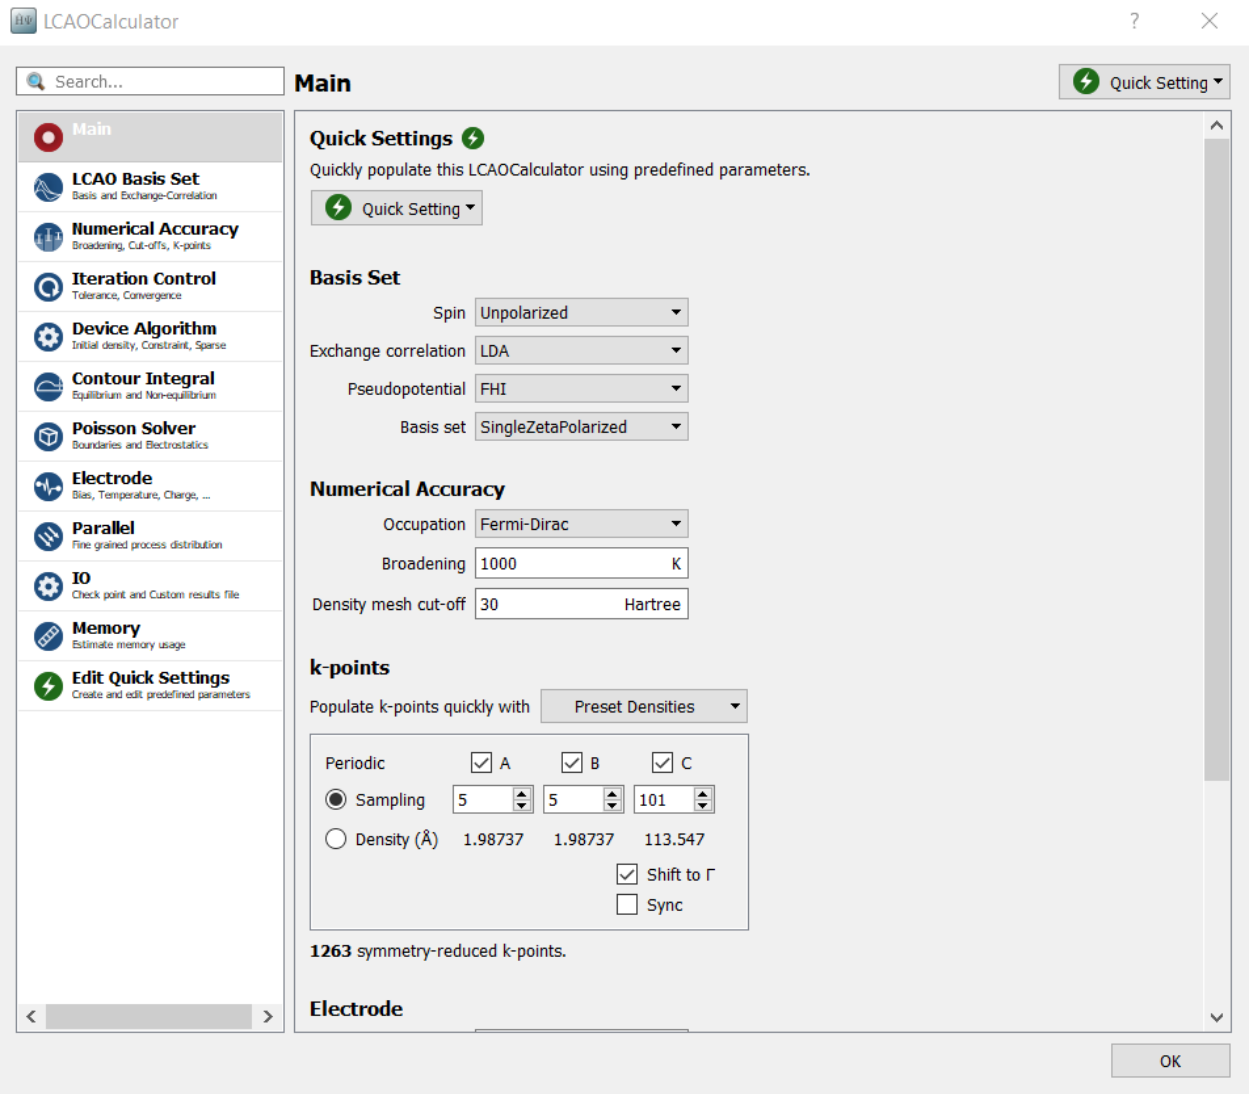
Note: The ghost atoms are used to improve the description of the electron density between the two surfaces. They are simply extra basis sets placed in the empty region. This technique, which is sometimes referred to as a vacuum basis, is also used for calculating the work function of a surface, as explained in a tutorial: *Computing the work function of a metal surface using ghost atoms*.

Calculations

Zero bias

Send the device configuration to the Script Generator by clicking the icon, and set up the script as follows:

- Add an **LCAOCalculator** and use the DFT-LDA engine with a SingleZetaPolarized basis set. Then set a 5x5x101 k-point grid.



•Change the output filename to `au_vacuumgap.hdf5`.

•Save the script as `au_vacuumgap.py`.

Send the script to the **Job Manager** and execute the calculation. It takes 3-4 minutes on a laptop.

Finite bias

To compute the capacitance it is necessary to compute dq/dV, where dq is the induced charge on the surfaces and V the bias voltage. In the bias voltage you will also run the following analysis objects : **MullikenPopulation**, **ElectrostaticDifferencePotential**, and **ElectronDifferenceDensity**.

Use the following script to perform the calculations for bias voltages of 0.25, 0.5, 0.75, and 1.0 V:

```
device_configuration = nlread('au_vacuumgap.hdf5', DeviceConfiguration)[-1]
calculator = device_configuration.calculator()
for voltage in [0.0, 0.25, 0.5, 0.75, 1.0]:
```

(continues on next page)

(continued from previous page)

```
    # Set new calculator with modified electrode voltages on the configuration
    # use the self consistent state of  the old calculation as starting input.
    device_configuration.setCalculator(
          calculator(electrode_voltages=(0.5*voltage*Volt, -0.5*voltage*Volt)),
                     initial_state=device_configuration)
    device_configuration.update()
    nlsave('au_vacuumgap.hdf5', device_configuration, object_id="SCF %s" % voltage)
    # ------------------------------------------------------------
    # Mulliken population
    # ------------------------------------------------------------
    mulliken_population = MullikenPopulation(device_configuration)
    nlsave('au_vacuumgap.hdf5', mulliken_population, object_id="Mulliken %s" % voltage)
    # ------------------------------------------------------------
    # Electrostatic difference potential
    # ------------------------------------------------------------
    electrostatic_difference_potential = ElectrostaticDifferencePotential(device_
↪configuration)
    nlsave('au_vacuumgap.hdf5', electrostatic_difference_potential, object_id="EDP %s" %␣
↪voltage)
    # ------------------------------------------------------------
    # Electron difference density
    # ------------------------------------------------------------
    electron_difference_density = ElectronDifferenceDensity(device_configuration)
    nlsave('au_vacuumgap.hdf5', electron_difference_density, object_id="EDD %s" %␣
↪voltage)
```

You can download the scipt here: `bias_loop.py`. Run it using the Job Manager or execute it from a terminal:

```
$ atkpython bias_loop.py > bias_loop.out
```

It takes about half an hour to finish this calculation on a laptop.

Note: The previously converged calculation is used as an initial guess for the next calculation to speed up the SCF convergence. The `object_id` makes it easier to identify the data in post-SCF analysis.

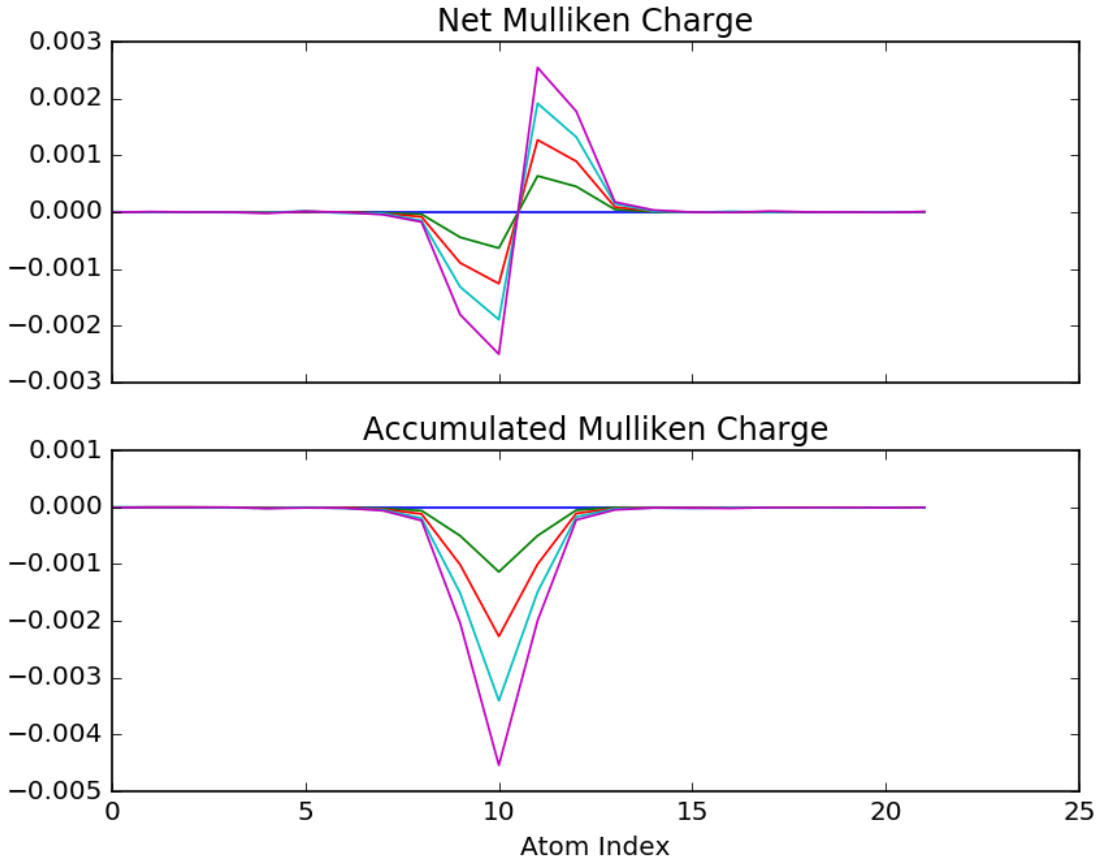
Analysis

We will introduce two different ways to calculate the capacitance:

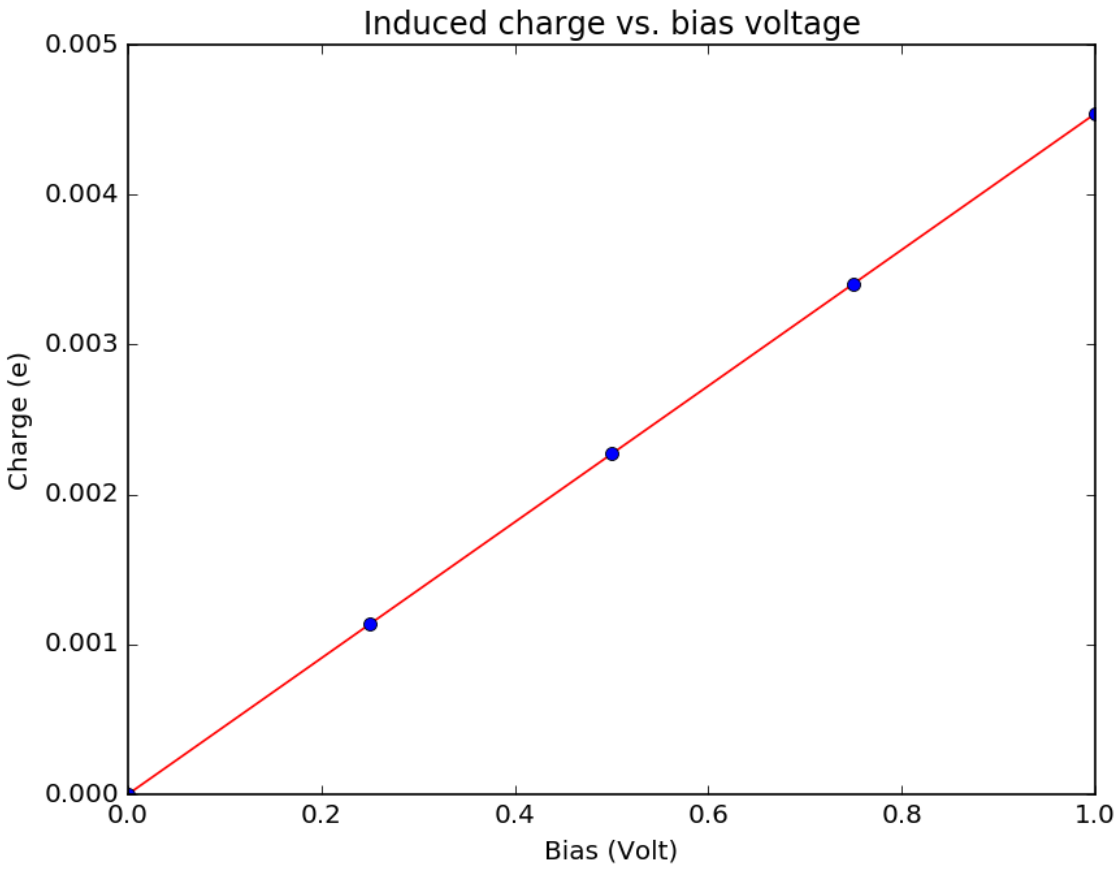
- a simple approach based on the induced charge;
- a more general method based on evaluating the electrostatic energy.

Approach based on the induced charge

The finite bias will build up a net positive/negative charge on the two gold surfaces, as shown in the plots below.



Now, the capacitance can in principle be computed as $C = dq/dV$, where q is the total accumulated charge on one surface as a function of the bias. From the slope of the straight line you can therefore obtain the capacitance of the nano-capacitor:



The plots above, as well as the entire data analysis based on the Mulliken populations, can be achieved by running this script: `mulliken-analysis.py`. It is a long script but a great opportunity to learn about custom data analysis in Python and QuantumATK.

Results

The script reports a capacitance of 7.27*10^{-22} Farad, as computed from fitting a straight line to the data points. To put this number into perspective, consider the capacitance of an ideal parallel plate capacitor, written as $C = \varepsilon A/d$, where $\varepsilon = 1$ for the vacuum permittivity and the area A of each plate can be calculated from the device structure. You can then calculate the parallel plate distance $d = A/C$. This is also done in the script and it reports d=8.77 Å.

Comparing this value with the distance between the surface gold atoms (11.89 Å) the position of the so-called image plane is estimated to be 1.56 Å above the gold surface.

Electrostatic energy analysis

To compute the capacitance using a more general and accurate method, you will need to first calculate the electrostatic energy E as a function of the applied bias V:

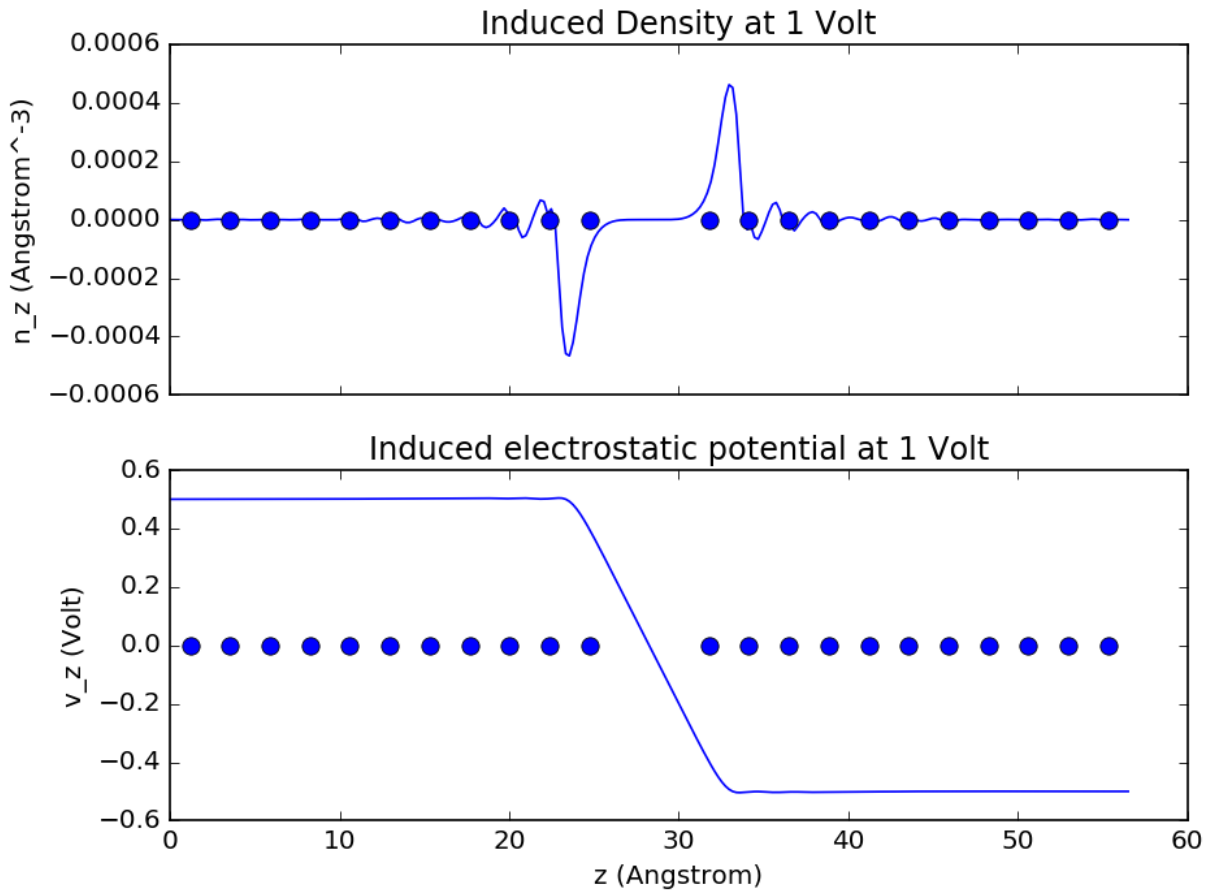
$$E(V) = \frac{1}{2}\int \delta v(\mathbf{r}, V)\delta n(\mathbf{r}, V)d\mathbf{r}$$

where δv is the induced electrostatic potential and δn is the induced density.

The script `potential_plot.py` extracts the potential and density at 1 V bias from the existing HDF5 file and produces the plots of the induced density and electrostatic potential. The script also reports two parameters:

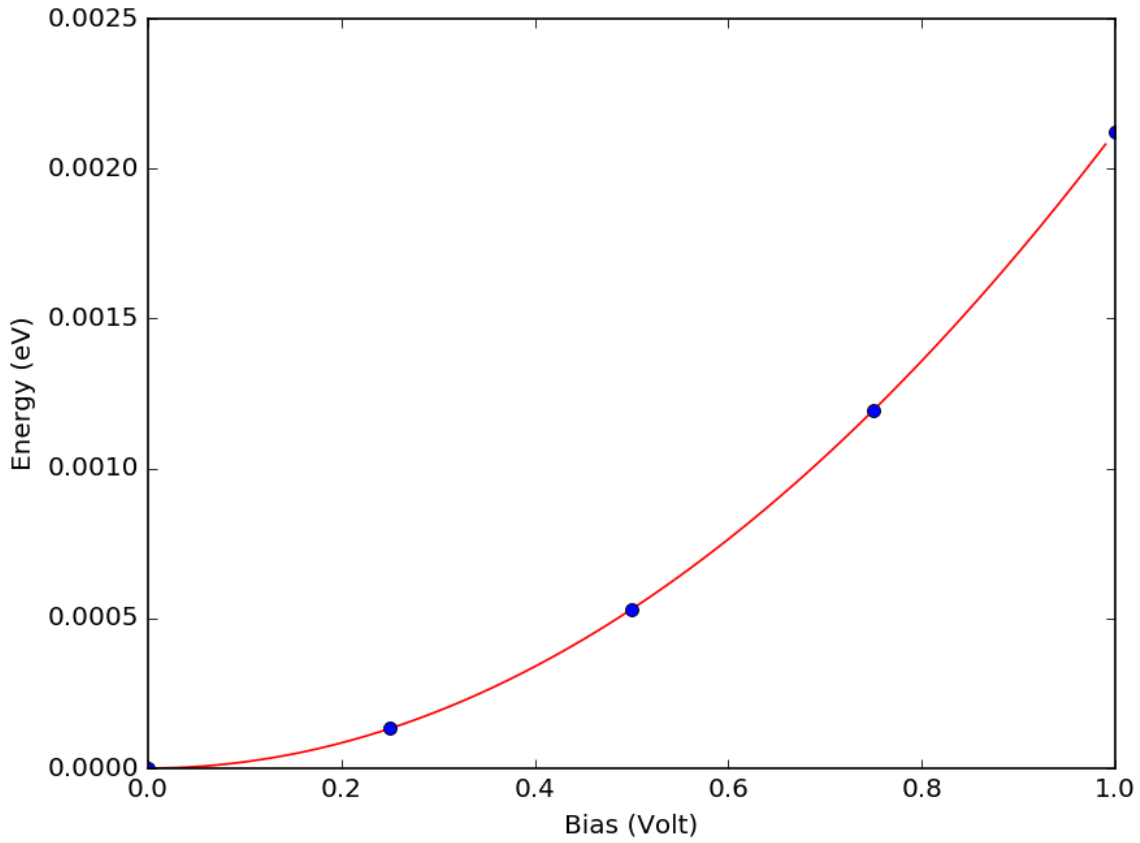
- the electric field in the middle of the vacuum gap E= 0.1127 V/Å;
- the distance between the two image planes d=8.88 Å.

Tip: The position of the image planes is defined as the point where the electric field is zero, that is, where the electrostatic potential becomes flat.



The blue circles correspond to the atom positions. The main charge accumulation takes place in a very narrow region right above the surface, between the outer surface atoms and the ghost atoms.

From this, the capacitance can be extracted by fitting a parabola to the relation $E(V) = CV^2/2$. The script `v-e-plot.py` calculates the electrostatic energy and fits the capacitance as shown below.



Results

The script reports the capacitance C=6.81*10^{-22} Farad, in qualitative agreement with the value obtained from the simple approach using Mulliken charge analysis.

This script also reports d=9.36 Å, corresponding to an image plane at 1.27 Å above the gold surface, in very close accordance with the position of the peak of induced density.

Attention: What is the difference between the two methods? In the Mulliken charge analysis, it is assumed that all electrons on the left surface have the same potential, and similarly for the right surface. When we convolute the electron density and the electrostatic potential we account for the fact that some part of the electron density is located in the region with a finite electric field. The electrostatic energy analysis is therefore more accurate for calculating the capacitance.

The electrostatic energy analysis also has the advantage that it does not require the researcher to separate the atoms as uniquely left and right – this is trivial for the two gold surfaces, but that may not always be the case.

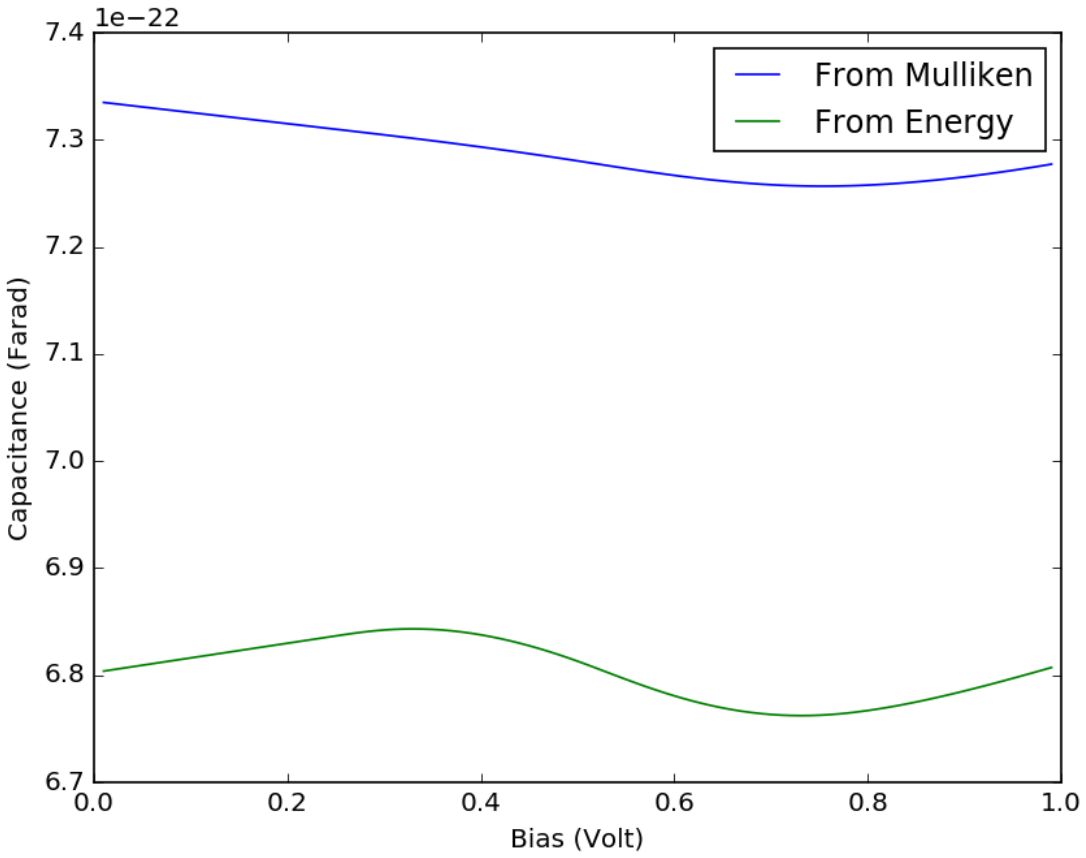
Bias-dependent capacitance

The analysis outlined above is based on the assumption that the capacitance is **independent** of the voltage. However, this is not always the case. A more advanced spline curve fitting allows you to investigate systems whose capacitance does depend on the bias voltage.

Provided that you have already run the scripts `mulliken-analysis.py` and `v-e-plot.py` in the previous section, you can now download and run the script `v-c-plot.py` to perform the fitting.

Note: The data saved by the two scripts are used by the present script to accelerate the analysis.

The computed capacitance is shown below as a function of the bias. As expected, the capacitance changes in this case very little with the bias voltage.



Attention: The present example uses rather few data points to illustrate the method. In general, you should use more than five data points to get an accurate analysis.

Dielectric spacer material

The electric field in the vacuum gap is extremely high (over 900*10^6 V/m at 1 V bias) and would immediately lead to a breakdown discharge in the device. Replacing the vacuum gap between the capacitor plates with a dielectric material can partly solve this.

There are two different ways to do this using QuantumATK:

1. Insert a dielectric material, and explicitly form the two metal–semiconductor–metal interfaces:

- **Spatial region:** Use the QuantumATK Builder to place a dielectric spatial region between the surfaces.

2. Use a cheaper and less rigorous approach, where you simply modify the dielectric constant of the region between the gold surfaces:

- **Implicit solvent method:** Assign a dielectric constant different than 1 to the vacuum region by modifying settings in the Poisson solver.

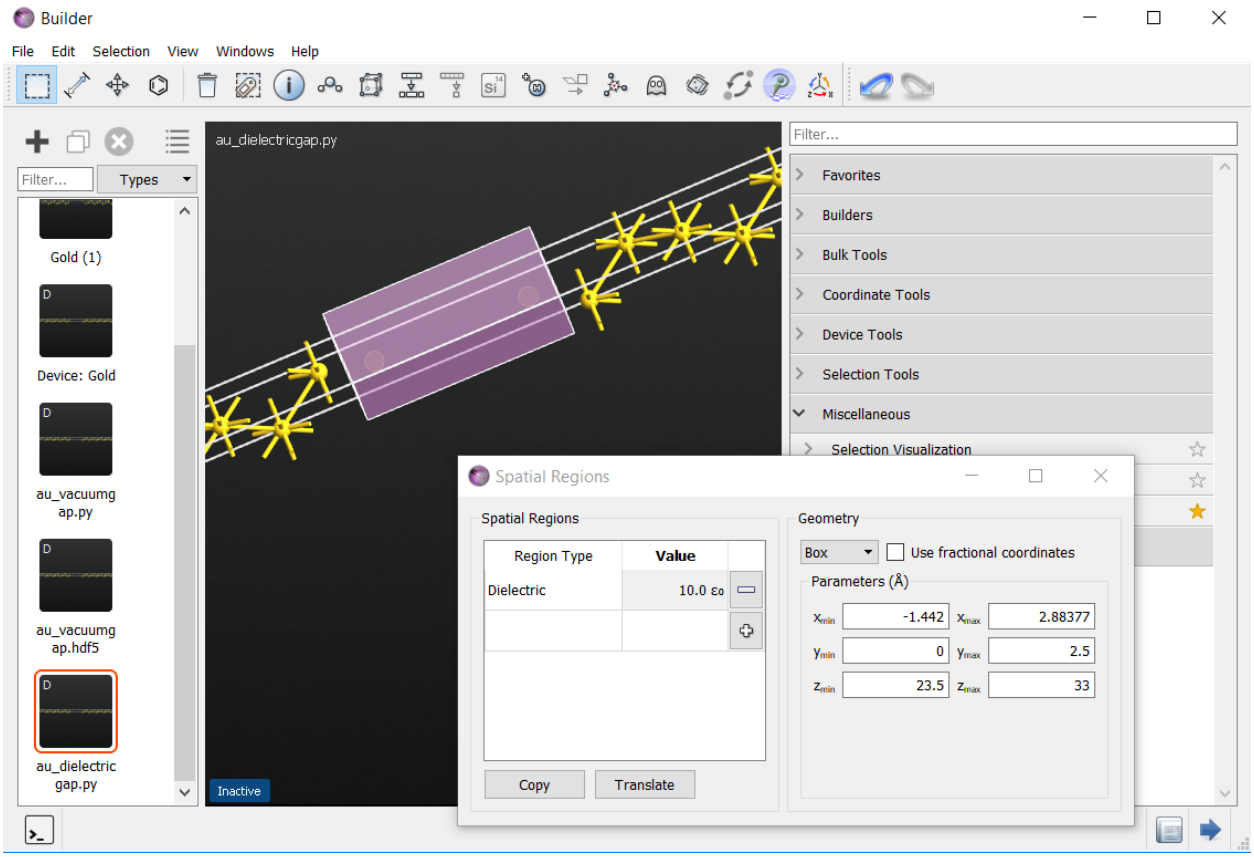
For demonstration purposes, we here go for the first option.

Note: In both cases it is necessary to use the `Multigrid` Poisson solver, but you can still have periodic boundary conditions along A and B.

Dielectric spatial region

Follow the steps that led to calculation of the capacitance from electrostatic energy analysis, but add the dielectric spatial region and change the **Poisson solver** to `Multigrid`.

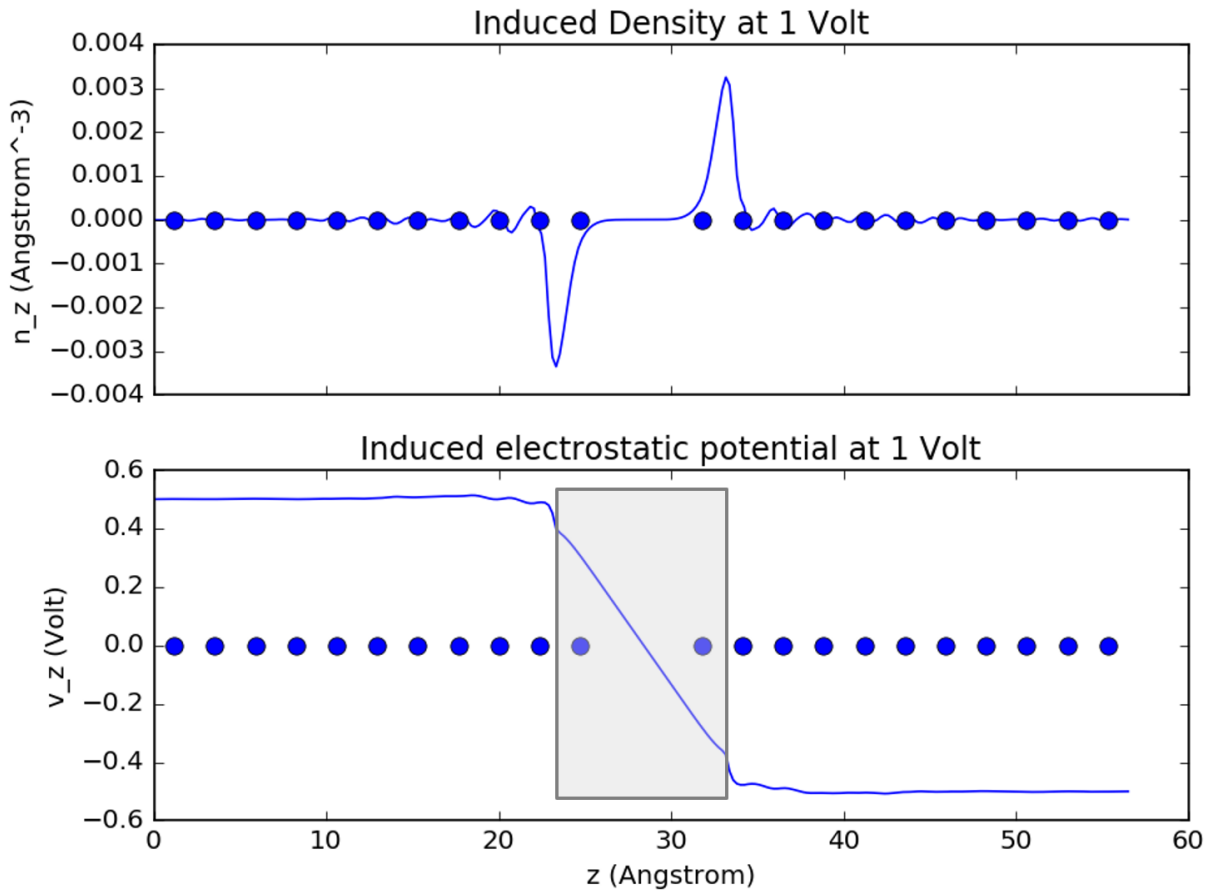
To use a dielectric spatial region, go to the Builder and use the *Miscellaneous* → *Spatial Regions* tool to place between the surfaces a box with a relative dielectric constant of 10:



Note: The dielectric region is a rectangular box, while the unit cell is hexagonal for the present [111] fcc surface. To solve the mismatch, make sure the rectangular box is large enough in the AB plane to extend outside the unit cell. The parts outside the cell will be cut off during the calculation.

Then send the new geometry to the Script Generator and repeat all the steps. Or simply open the structure in the Editor and copy/paste the relevant parts of the scripts you already have, and change the names of the output files.

The results are illustrated below. The position of the dielectric region is indicated by the grey shading. You can clearly see the expected discontinuity of the electric field near the edges of the dielectric region, and you will find that the capacitance has significantly increased.



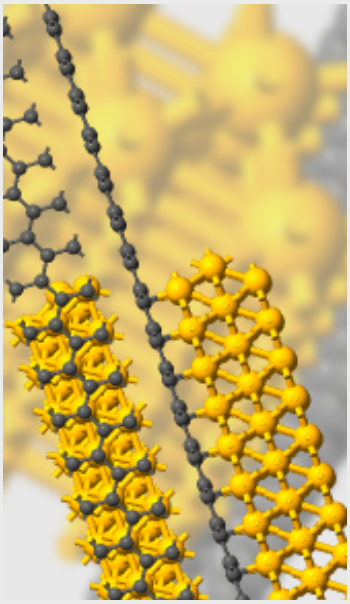
Note:

- The scripts used in the electrostatic energy analysis are self-contained and generic. They can be used to analyse other systems as well, after suitable modification of the file names.
- The scripts used in the Mulliken charge analysis need to be modified before they can be used for other systems, to account for geometry changes.
- These approaches are valid only if the current through the device is very small. For example, the transmission is extremely small (its a capacitor – not a diode!). You can verify that the transmission is extremely small for this large vacuum gap, of the order 10^{-23}.

Tip: What next? Another interesting example of a nano-scale capacitor would be a one formed by *Carbon Nanotube Junctions*.

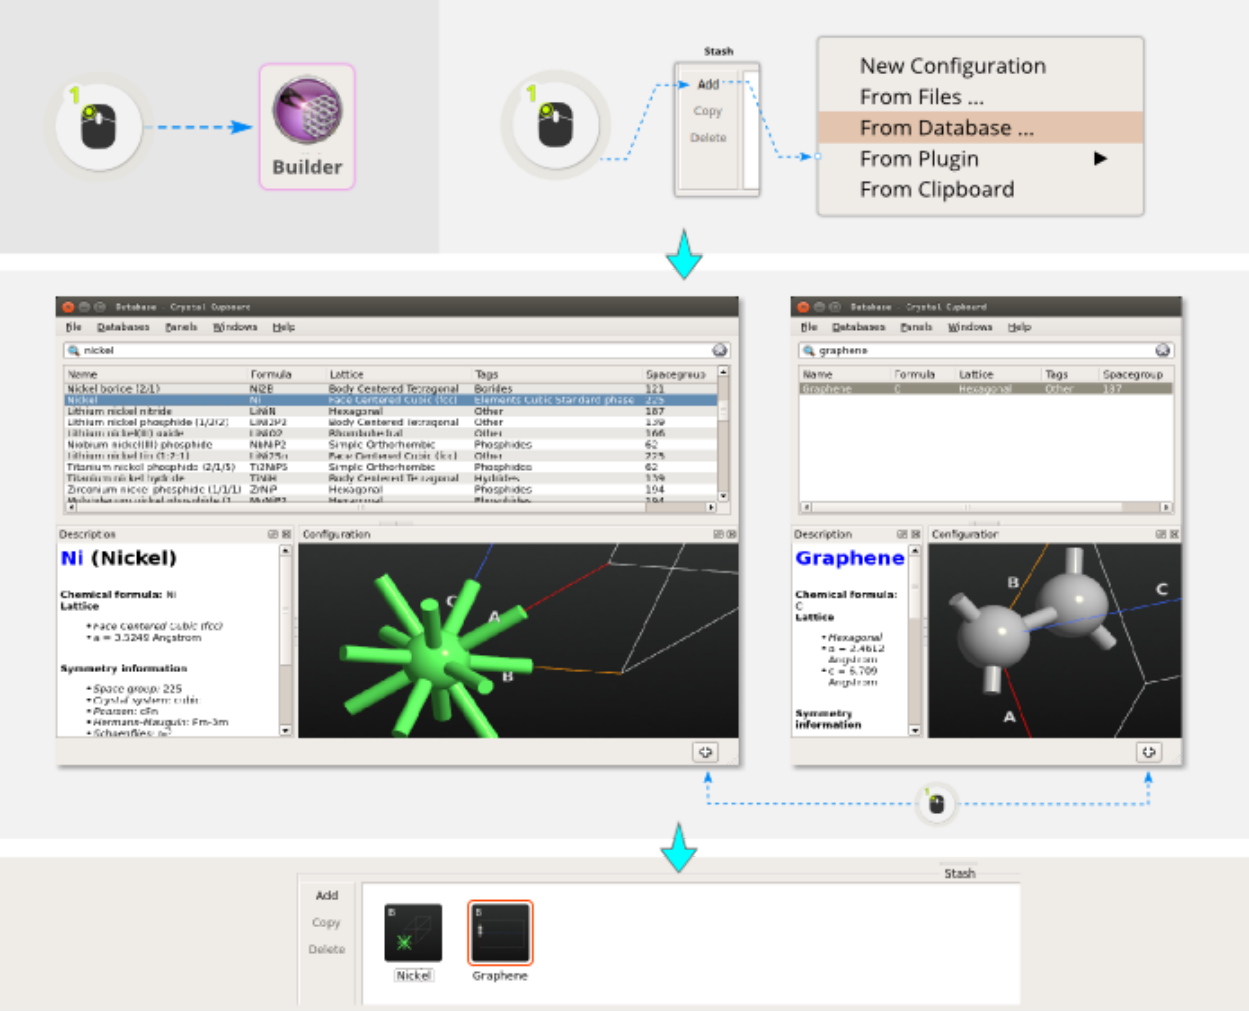
3.4.5 Graphene–Nickel interface

QuantumATK: Interface Platforms: Links: *ATK can easily handle heterogeneous systems, where the two electrodes are not the same, as demonstrated in the above publication. Here you will learn how to build a similar system.*

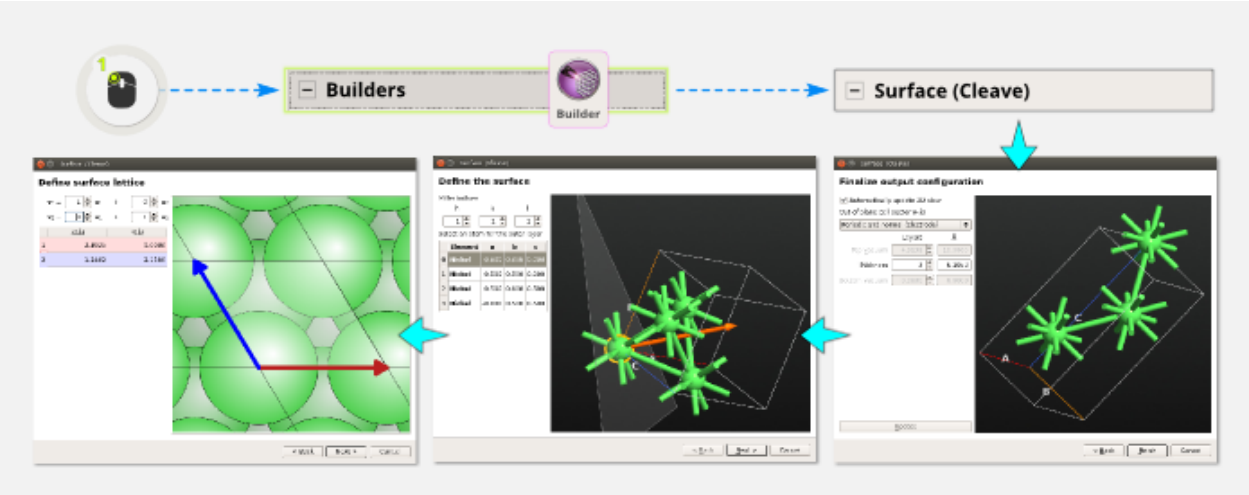


Creating the structure

- **Step 1:** Click *Add* → *Add From Database*. Locate nickel and add it to the Stash. Then also add graphene from the crystal database.



•**Step 2:** Graphene fits very nicely onto Ni(111), so thats the surface well consider. Use the cleave tool *Builders* → *Surface (Cleave)* to cleave the crystal along the (111) plane and make a 3-layer electrode cell.

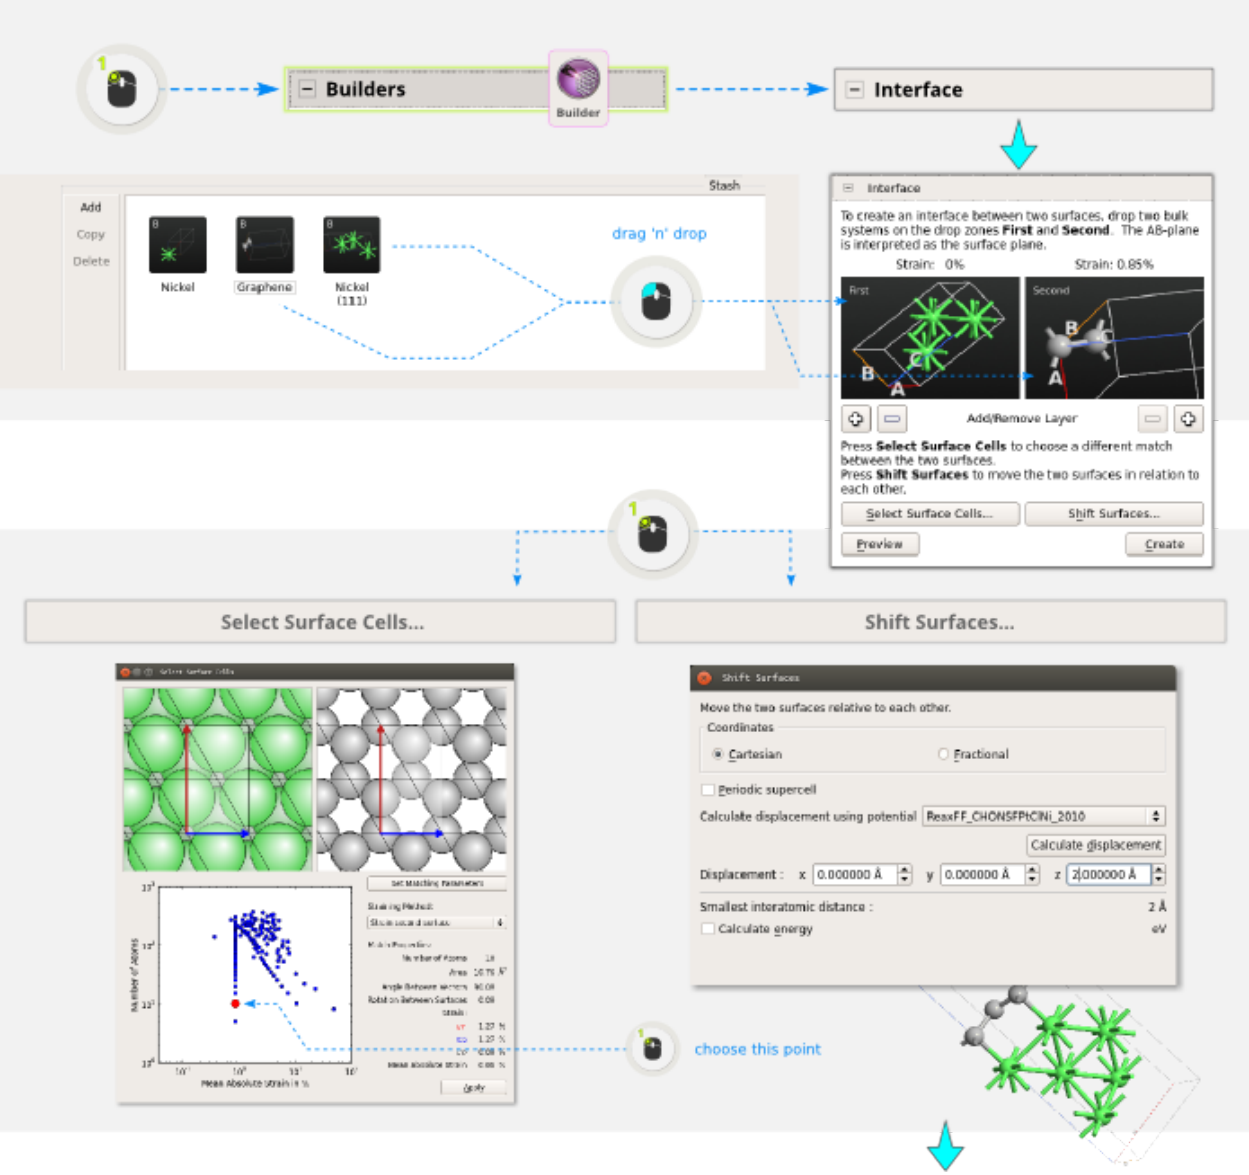


•**Step 3:** Make an interface between the two system by opening *Builders* → *Interface*. Drag the Ni(111) configuration to the first slot and graphene to the second slot.

•**Step 4:** The suggested choice of cell is the minimal commensurate cell. This cell has hexagonal symmetry, but for this

calculation it is more convenient to work with a rectangular cell. Therefore, click **Select Surface Cells**, and pick the cell with a slightly larger number of atoms but the same strain, as shown in the picture below. To choose this cell, click the corresponding point in the plot at the bottom left.

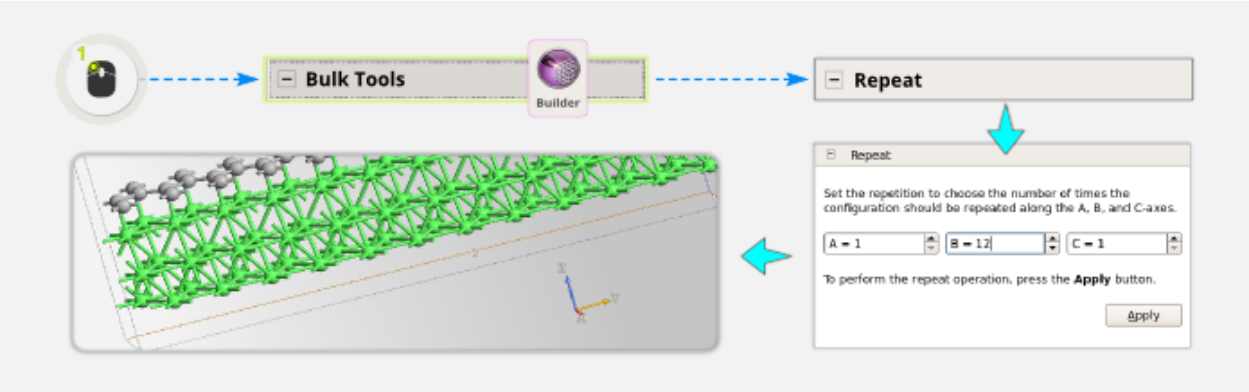
•**Step 5:** Click **Shift Surfaces** and add 2 Angstroms to the Z position.



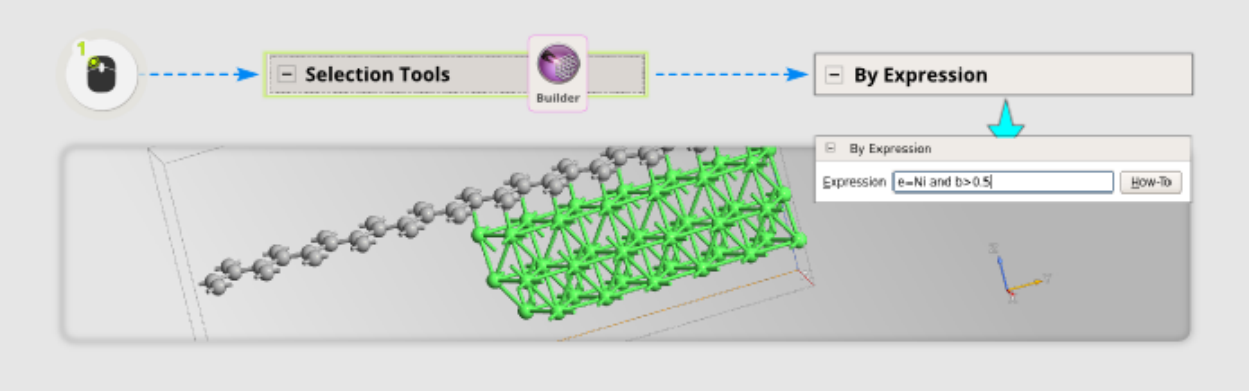
Tip: You can learn more about the Interface Builder in the Technical Notes on *Interface Builder*.

More configurations

•**Step 5:** Use *Bulk Tools* → *Repeat* and repeat the structure 12 times in the **B** direction to make a larger sheet of graphene on an extended Ni(111) surface.



•**Step 6:** Open *Selection Tools* → *By Expression* and enter **e=Ni and b>0.5**. Press Enter or Tab, and then Delete. This cuts away half of the Ni slab.



•**Step 7:** Decide how large a Ni–graphene interface you want, and then use the mouse to select and delete the superfluous carbon atoms.

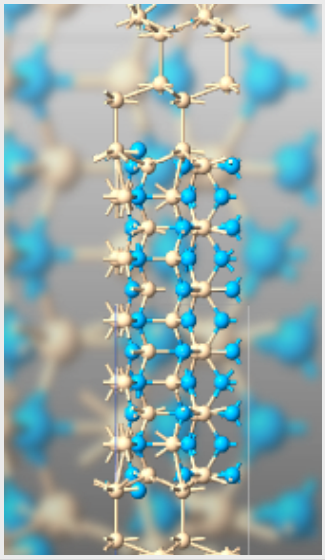
•**Step 8:** If you want to saturate the dangling bonds of the edge carbon atoms (cf. the article – you may or may not want to do this), select the edge atoms and use the passivation tool .

•**Step 9:** The system needs to be re-oriented, since the transport direction is always along Z. Use *Bulk Tools* → *Swap Axes* to swap **B<->C**, and **Y<->Z** (you should normally always swap twice to get a right-handed system).

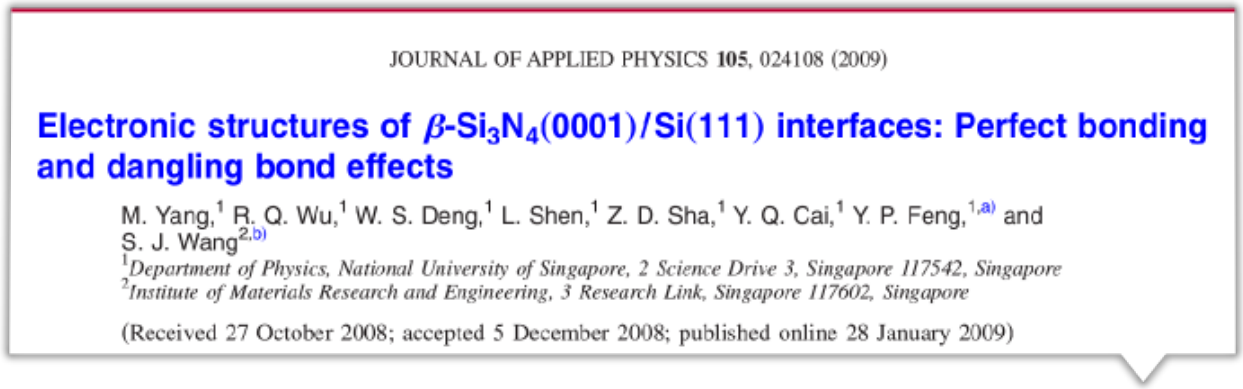
•**Step 10:** Finally, use *Device Tools* → *Device From Bulk* to convert the structure to a device configuration; default option are fine so just click OK.

3.4.6 Building a Si-Si_3N_4 Interface

QuantumATK: Complex Interface Platforms: Links: , `AMS_DATA.cif`, `Si3N4.cif` *In this tutorial you will learn how to build a complex interface using QuantumATK. In particular, we will consider an interface between silicon and silicon nitride.*



Note:



JOURNAL OF APPLIED PHYSICS **105**, 024108 (2009)

Electronic structures of β-Si_3N_4(0001)/Si(111) interfaces: Perfect bonding and dangling bond effects

M. Yang,[1] R. Q. Wu,[1] W. S. Deng,[1] L. Shen,[1] Z. D. Sha,[1] Y. Q. Cai,[1] Y. P. Feng,[1,a)] and S. J. Wang[2,b)]

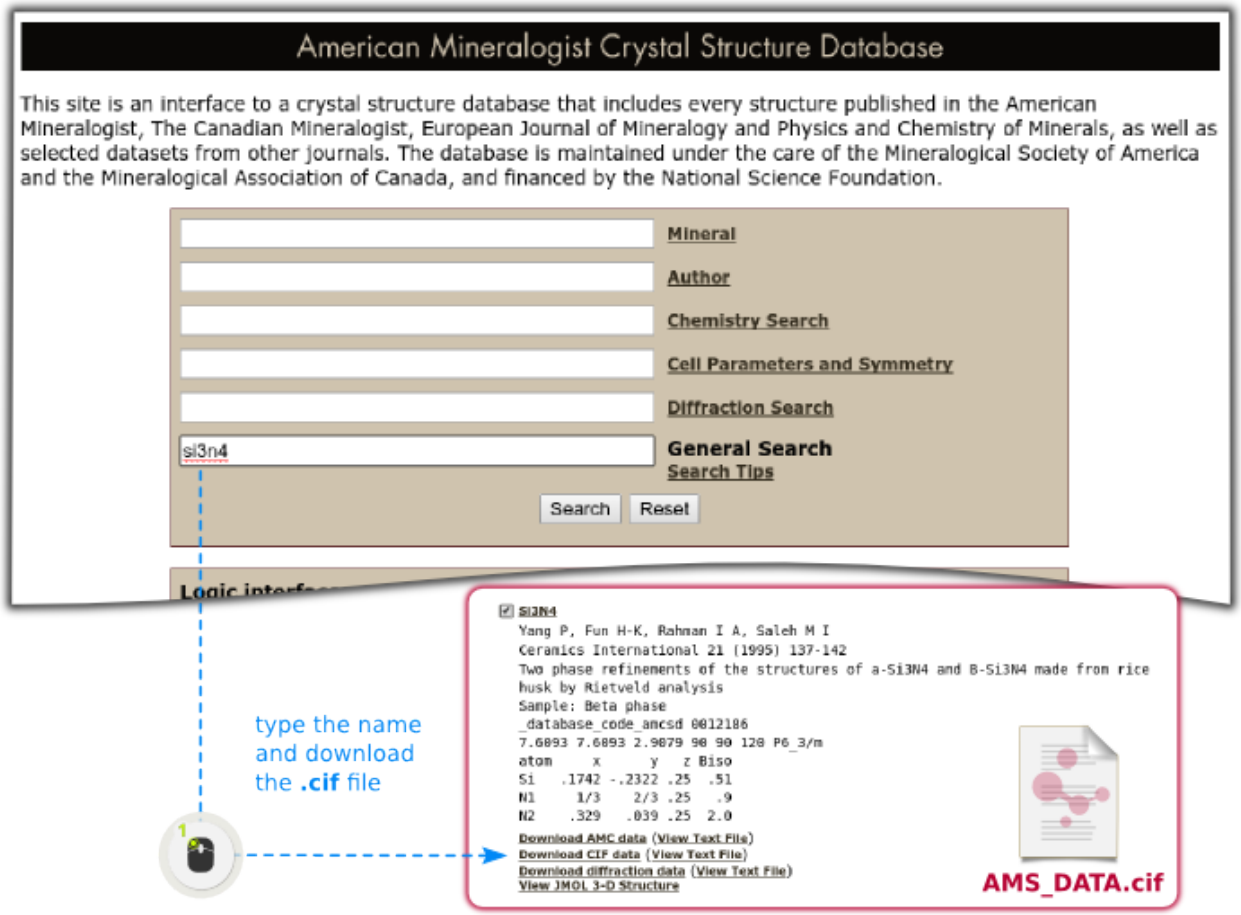
[2]*Institute of Materials Research and Engineering, 3 Research Link, Singapore 117602, Singapore*

(Received 27 October 2008; accepted 5 December 2008; published online 28 January 2009)

The -Si_3N_4(0001)/Si(111) interface was as studied in detail in Ref.[1], and we will use the geometry proposed in that work. An earlier model for the crystalline interface of -Si_3N_4(0001)/Si(111) was proposed by , but that model contained dangling bonds, which is not consistent with . The interface you will build here has all bonds saturated.

To find an appropriate input structure for -Si3N4, visit the and enter si3n4 in the General Search box. This will return three matches - the one entitled Si3N4, by P. Yang *et al.*, is the -Si3N4 you are looking for (the other two are nierite, -Si3N4). Click Download CIF data and save the CIF file in a convenient location.

[1] M.ăYang, R.ăQ. Wu, W.ăS. Deng, L.ăShen, Z.ăD. Sha, Y.ăQ. Cai, Y.ăP. Feng, and S.ăJ. Wang. Electronic structures of -Si3N4(0001)/Si(111) interfaces: Perfect bonding and dangling bond effects. *Journal of Applied Physics*, 2009. doi:10.1063/1.3072625.



Alternatively, you can use the , and enter si3n4 in the text search field.

In either case, be sure to download the structure with space group P 63/m. Rename the downloaded file to `Si3N4.cif`, to make it easier to identify it.

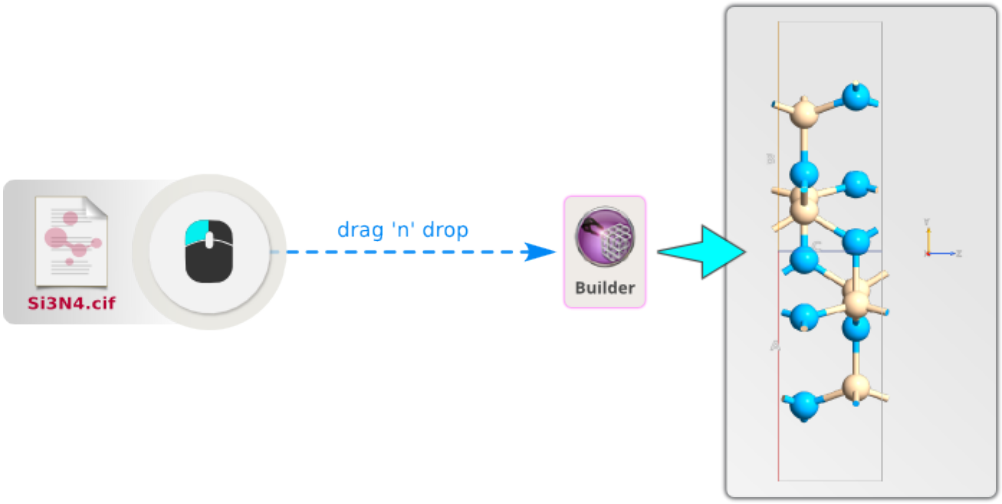
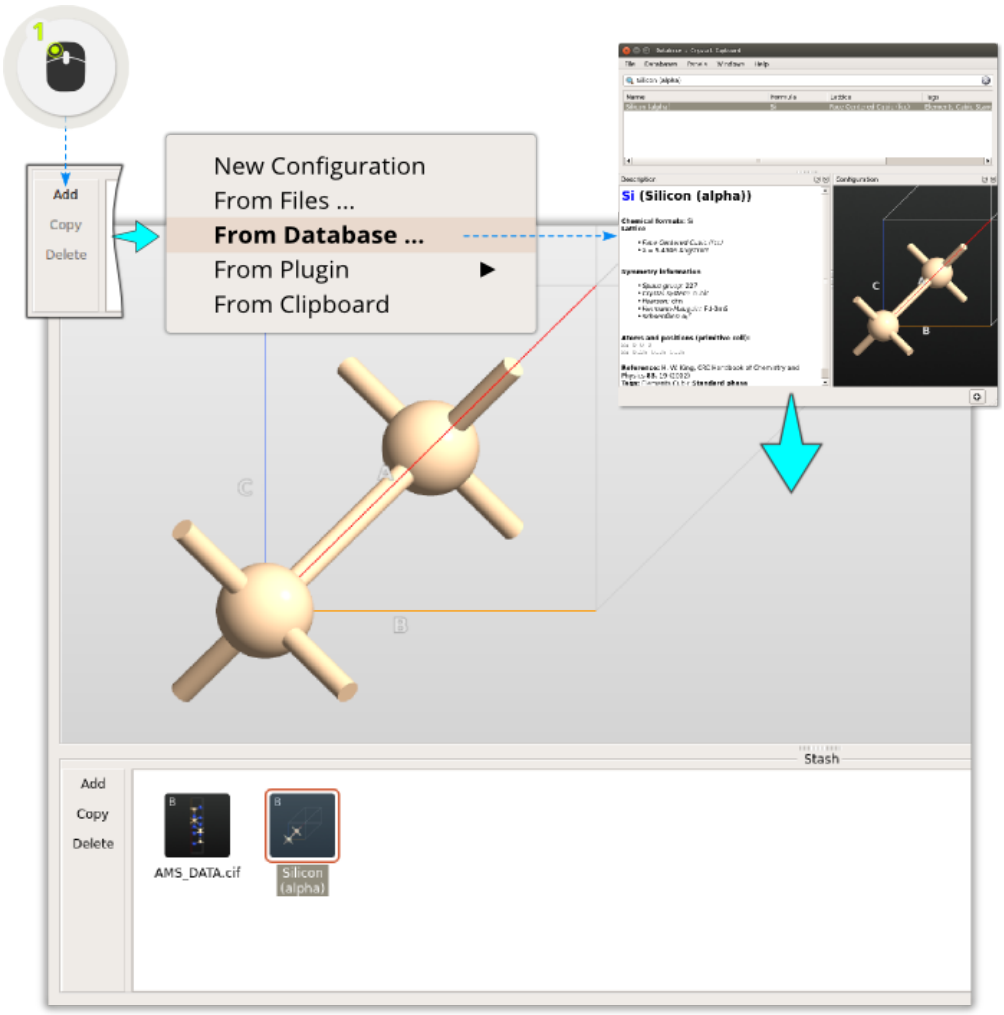
Preparations: Two crystals

•**Step 1:** In QuantumATK, open the Builder and click *Add* → *Add From Files* to import the downloaded CIF file (you can also just drop the file on the Builder). The orientation of the crystal is already appropriate, with the Z axis pointing along 001 (the crystal C axis), as appropriate for the Interface Builder.



•**Step 2:** Next, click *Add* → *Add From Databases* in the Builder, and locate **Silicon (alpha)** by for instance entering silicon in the search filter box. Click the icon in the lower right-hand corner to add the Si crystal to the Builder Stash.



•**Step 3:** The Si crystal needs to be **cleaved** to create a (111) interface:

–Open *Builders* → *Surface (Cleave)* in the right-hand plugin panel. Then enter Miller indices **h=1, k=1, l=1**. This will define the surface C axis, which will be set parallel to Z.

–Additionally, the surface model requires that we have a long bond (along C) at the terminating Si interface, and therefore you should select the atom with index 1 in the list; this atom will define the outermost surface layer.

–Click *Next* → *Next* → *Finish* (the additional options in the Cleaver are not relevant for the present case).

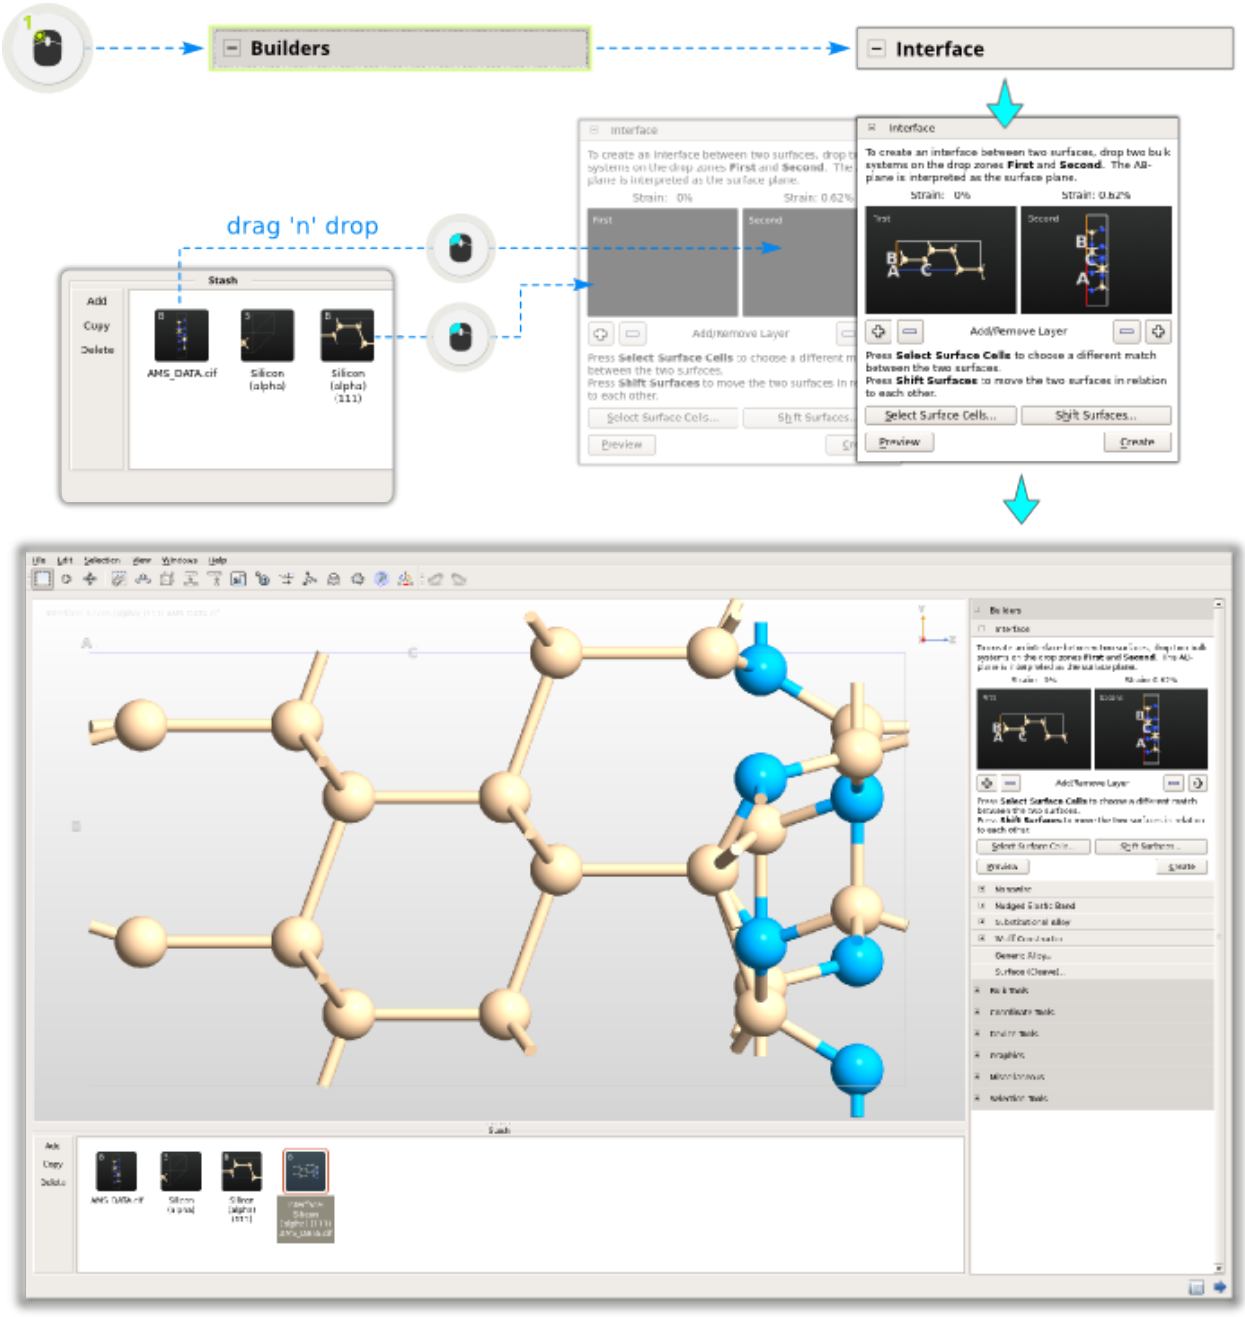
Builder

You now have the two building blocks - its time to put them together.

Building the interface

•**Step 4:** As you will see, the Interface Builder automatically figures out that it needs to repeat the hexagonal Si(111) surface cell 2x2 in the AB plane to fit the hexagonal Si_3N_4 cell. Once it has done so, the strain is extremely small (less than 1%), which of course is why this is an interesting interface. Therefore, no adjustment is needed of the surface cells, but for a general case you can click Select Surface Cells to explore possible choices.

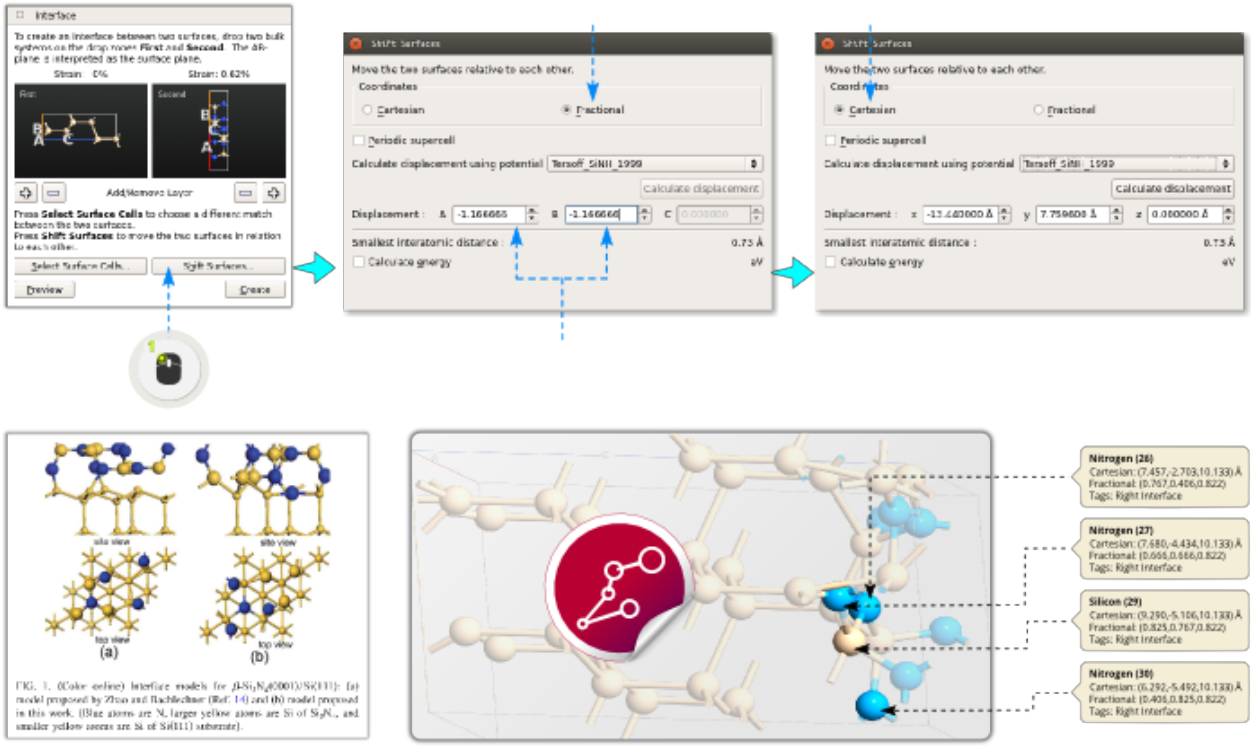


•**Step 5:** The two surfaces do however need to be shifted with respect to each other in the A/B plane. To achieve this, click **Shift Surfaces**, switch to fractional coordinates, and enter -0.16666666 for both A and B. The preview of the model will update right away in the Builder 3D window:

Tip: You can learn more about the Interface Builder in the Technical Notes on *Interface Builder*.

Tip: Looking at the article, you will realize that the Si triangle in the bottom Si_3N_4 layer (the layer closest to the interface, atoms 26, 29, 30 (hold the mouse over the atoms to see the numbers in the tooltip) should be ligned with the last Si(111) atom, sitting on the long bond along C, such that they form a tetrahedron. This arrangement means that the Nth atom (atom number 27) which is currently located in the middle of that triangle, at fractional position (2/3, 2/3), should sit right above that Si atom, which has coordinate (1/2, 1/2). Therefore, a surface shift of (-1/6, -1/6) is needed.

Dont close the Shift Surfaces widget yet. As you can see, the two surfaces are also a bit too close to each other. A suitable shift is 0.7 Angstroms (you need to change back to Cartesian coordinates for this one), which gives similar Si-Si and Si-N bond lengths across the interface as in the two respective bulk materials



Close the Shift Surfaces dialog.

•**Step 6: Add two more layers** of Si(111) by clicking twice for Add/Remove layer under the First window. Similarly, for the Si_3N_4 **add at least four layers** (it must be an even number of times), depending on how thick you wish to make the Si_3N_4.

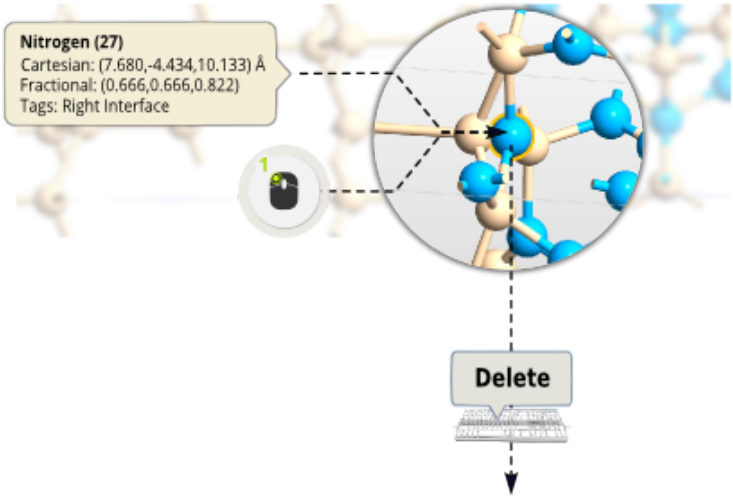
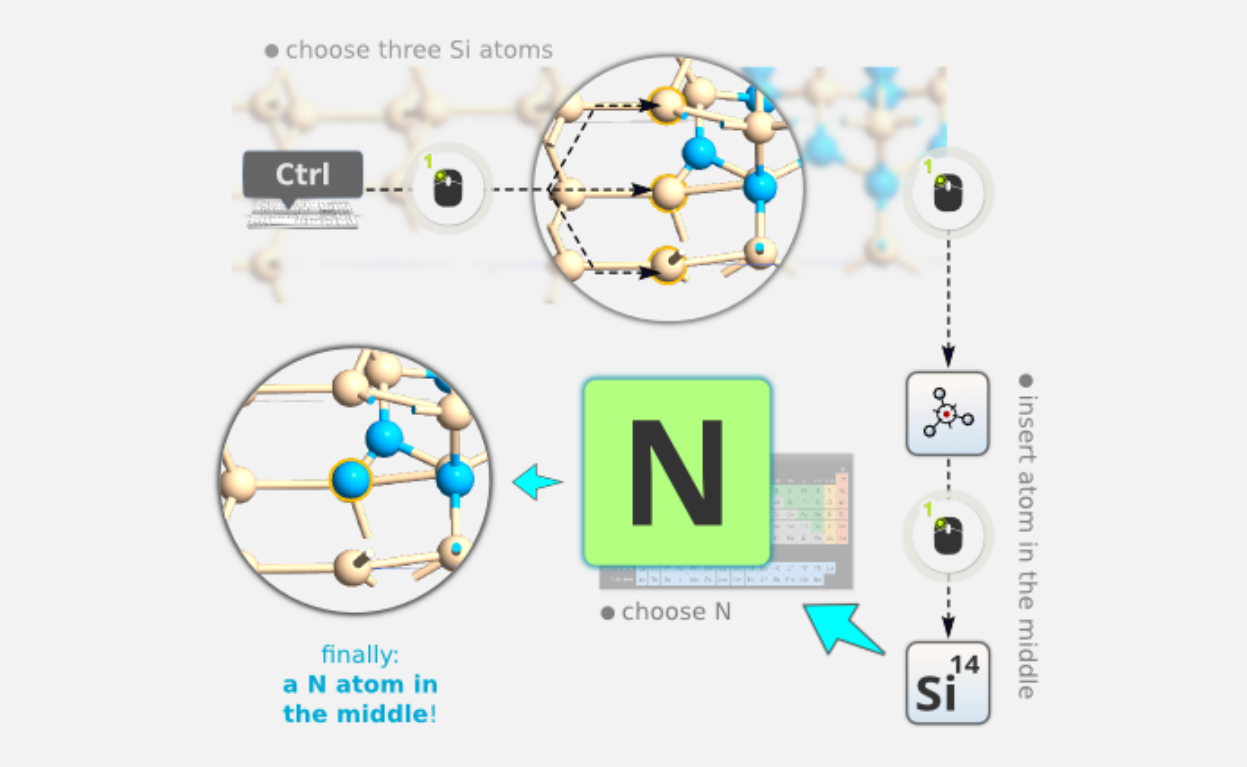
Final adjustment

You are not quite done yet. The crucial observation of Yang **et al.** was that **one N atom in the interface needs to be moved**, in order for all bonds to be saturated. The atom in question is none other than the one you used for the surface shift, sitting in the middle of the Si triangle (atom number 27).

•**Step 7:** Delete this atom by clicking it to select it, and press Del on the keyboard:



•**Step 8:** Insert a **new atom in the middle of the Si triangle in the top layer of the Si (111)**, by selecting the three atoms (click the first one, then hold down Ctrl when clicking the two others; the atoms in questions are numbers 28, 29, 30), and clicking the Centroid plugin in the left-hand side toolbar. The inserted atom has the correct position, but is Si; **change it to N** by using the Periodic Table tool :



At this point you have a single interface between Si(111) and -Si_3N_4(0001), and you may proceed to the next section.

Doubling down: Buried layer model

Tip: One can also take the procedure one step further and create a thin layer of -Si_3N_4(0001) embedded in Si(111), i.e. a double interface model. This is fairly easily acieved by mirroring the single interface.

•**Step 9:** Depending on how many Si_3N_4 layers you added, the size of the current model will be different.

1. Place the mouse over the last layer in the C direction and make a note of the Z-coordinate of these atoms. In our example here (for Si_3N_4) the value is 20.5382 Angstroms.

2. Open *Coordinate Tools* → *Mirror*. The Z direction is already selected for the normal N, but to get a correctly mirror-symmetric configuration you should place the point P in the last layer. Therefore, enter the value from the previous step into the third box for P, then tick Copy, and click Apply.

3. Next, adjust the cell by using *Bulk Tools* → *Fit cell*. Before clicking Apply, make sure only C is ticked, you dont want to change anything in A or B.

4. In the reference layer used for the mirror operation, all atoms are now doubled. Therefore, as the final touch, use *Selection Tools* → *Close Neighbors* to select all overlapping atoms and delete them.

Interface as a device model

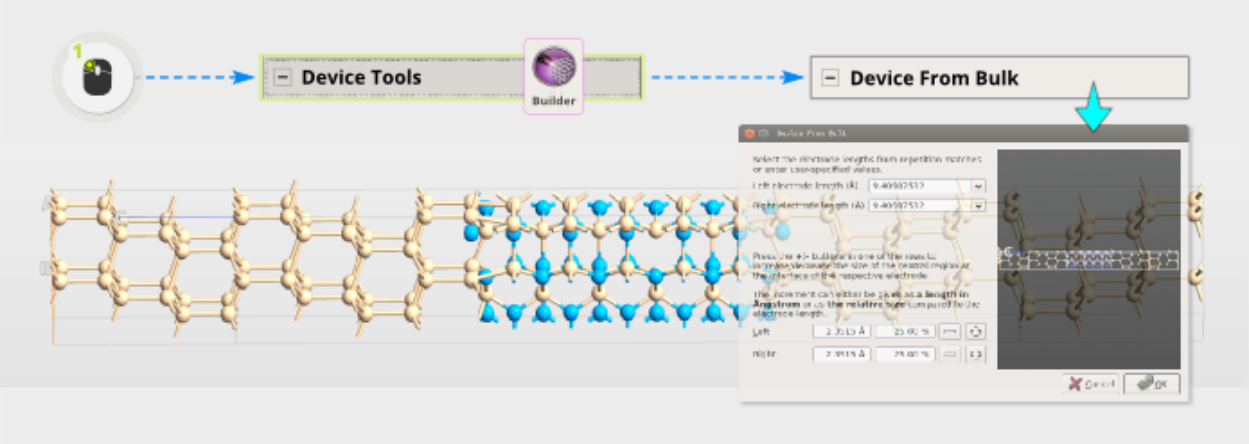
Irrespective of whether you chose the single or double interface model, the geometry is still represented as a periodic structure. In QuantumATK, you can however compute **electronically open systems**, as opposed to the periodic models used in other materials science software packages. This means you can compute the properties of a single interface (or two), rather than a periodically repeated stack of different materials.

Open boundary condition calculations are in QuantumATK carried out using so-called **device configurations**. To convert the current structure into a device:

•Open *Device Tools* → *Device From Bulk*.

•Since you added a few Si (111) layers, the tool can automatically find the electrode lengths, since there is a repetitive pattern.

•Click OK to create the device.



Note: As a final note, although it will not be covered here, it should be pointed out that the geometry needs to be optimized, especially the Si atoms in the interface. If you do that, you will see the formation of fully saturated bonds for all Si atoms. To see it in the unrelaxed structure, send the structure to the Viewer, and increase the range for bonds to be plotted to 1.3 Angstroms, and you will see that all Si atoms have 4 bonds.

3.4.7 Determination of low strain interfaces via geometric matching

Version: 2017.1

This tutorial introduces the new **GeneralizedLatticeMatch** method for combining two bulk crystals into an interface.

On many occasions, one is interested in creating a realistic interface between two materials, even without having precise structural informations on the two surfaces that form the interface. The **GeneralizedLatticeMatch** method facilitates this process, by automatically finding all the possible interface supercells between the two crystals based only on their bulk crystalline structure. The method is an optimized version of the algortihm described in[1]. Compared to the lattice-matching method used in the **Interface Builder**, described in *Interface Builder*, the present method is unbiased as it considers all the possible surfaces of the two crystals forming the interface.

[1] Line Jelver, PeterăMahler Larsen, Daniele Stradi, Kurt Stokbro, and KarstenăWedel Jacobsen. Determination of low-strain interfaces via geometric matching. *Phys. Rev. B*, 96:085306, Aug 2017. doi:10.1103/PhysRevB.96.085306.

A number of structural parameters are calculated for each interface, which allows one to easily analyze the matching pattern and choose the most appropriate interface to be used for further studies. The structure of the desired interface can then be easily created using the **Interface Builder** implemented in **QuantumATK**.

Method description

The following describes in the main steps of the algortihm used in the **GeneralizedLatticeMethod** method, which is very similar to that used in the **Interface Builder** (see *Interface Builder*).

1. Initially, the possible surface vectors $[\mathbf{a}_1, \mathbf{a}_2]$ of the first of the two materials forming the interface are constructed, starting from a linear combination of the Bravais vectors of the primitive cell:

$$\mathbf{a}_1 = \sum_{i=1}^{3} c_i \mathbf{u}_i \quad c_i \in \mathbb{Z},$$
$$\mathbf{a}_2 = \sum_{i=1}^{3} c'_i \mathbf{u}_i \quad c'_i \in \mathbb{Z},$$

and by a subsequent projection of the resulting vectors from $\mathbf{R}^3$ to $\mathbf{R}^2$. A similar procedure is applied to construct the surface vectors $[\mathbf{b}_1, \mathbf{b}_2]$ of the second surface. As it will be shown in the Section *Input and output description*, the number of generated surface cells can be limited by specifying:

- The maximum value of the Miller indexes $[h, k, l]$ that define each surface;
- The maximum length of the lattice vectors $[\mathbf{a}_1, \mathbf{a}_2]$ and $[\mathbf{b}_1, \mathbf{b}_2]$.

2. Each couple of surface cells is matched by using the same lattice-match method as used in the **Interface Builder**, and described in the technical note *Interface Builder*.

3. The average strain is then calculated as:

$$\bar{\varepsilon} = \sqrt{\frac{\varepsilon_{11}^2 + \varepsilon_{22}^2 + \varepsilon_{11}\varepsilon_{22} + \varepsilon_{12}^2}{4}}$$

where ϵ_{11}, ϵ_{22} and ϵ_{12} are the components of the 2D strain tensor, as defined in the technical note *Interface Builder*.

Note: Notice that this definition of the average strain differs from that used in the *Interface Builder*. The present definition of strain is more appropriate for the present method as it is an invariant of the strain tensor.

Input and output description

In order to use the GeneralizedLatticeMatch method one can set up a simple script as follows:

```
# Read the BulkConfiguration of the primitive cell of the
# first material
configuration_1 = nlread('InAs.py',BulkConfiguration)[-1]
# Read the BulkConfiguration of the primitive cell of the
# second material
configuration_2 = nlread('Al.py',BulkConfiguration)[-1]

# Run the GeneralizedLatticeMatch method
generalized_lattice_match = GeneralizedLatticeMatch(
                            configuration_1,
                            configuration_2,
                            max_strain=0.02,
                            maximum_miller_index=3,
                            longest_surface_lattice_vector=50*Angstrom,
                            max_surface_area=200.0*Angstrom**2,
                            user_given_miller_index=None
                            )
```

The script reads two input files, each one containing a BulkConfiguration of the bulk primitive cell of one of the two materials that form the interface. Then, it applies the GeneralizedLatticeMatch method on these two structures. A number of **input parameters** can be set to control the precision and the extent of the search for possible interface supercells. The full list of input parameters is:

- `configuration_1`: BulkConfiguration of the bulk primitive cell of the first material.
- `configuration_2`: BulkConfiguration of the bulk primitive cell of the second material.
- `max_strain`: Maximum strain applied to each of the two surfaces.
- `maximum_miller_index`: Maximum value of the Miller indexes $[h, k, l]$ that define each of the two surfaces.
- `longest_surface_lattice_vector`: Maximum length of each surface lattice vector $[\mathbf{a}_1, \mathbf{a}_2]$ and $[\mathbf{b}_1, \mathbf{b}_2]$.
- `max_surface_area`: Maximum value of the surface area of the interface supercell.
- `user_given_miller_index`: Predefined Miller indexes of the surface of `configuration_1`.

Note: When the parameter `user_given_miller_index` is set to a value different than `None`, the search for the possible surfaces is restricted to the second material, whereas the surface of the first material is kept fixed. This option will be used in *Example 2: Lattice match between a bulk system with a predefined surface*.

After the possible matches are calculated, the matching results are printed directly in the QuantumATK log file of the calculation. The matches will be listed in order of increasing strain, together with a number of output parameters that characterize each match.

```

(continues on next page)

(continued from previous page)

```
[ 2  2  1] >-< [ 1  0  0]   0.000110      23    163.9      2.2     153.4       26.6
[ 3  3  2] >-< [ 1  1  1]   0.004030      28    170.9      1.2     162.6       60.3
```

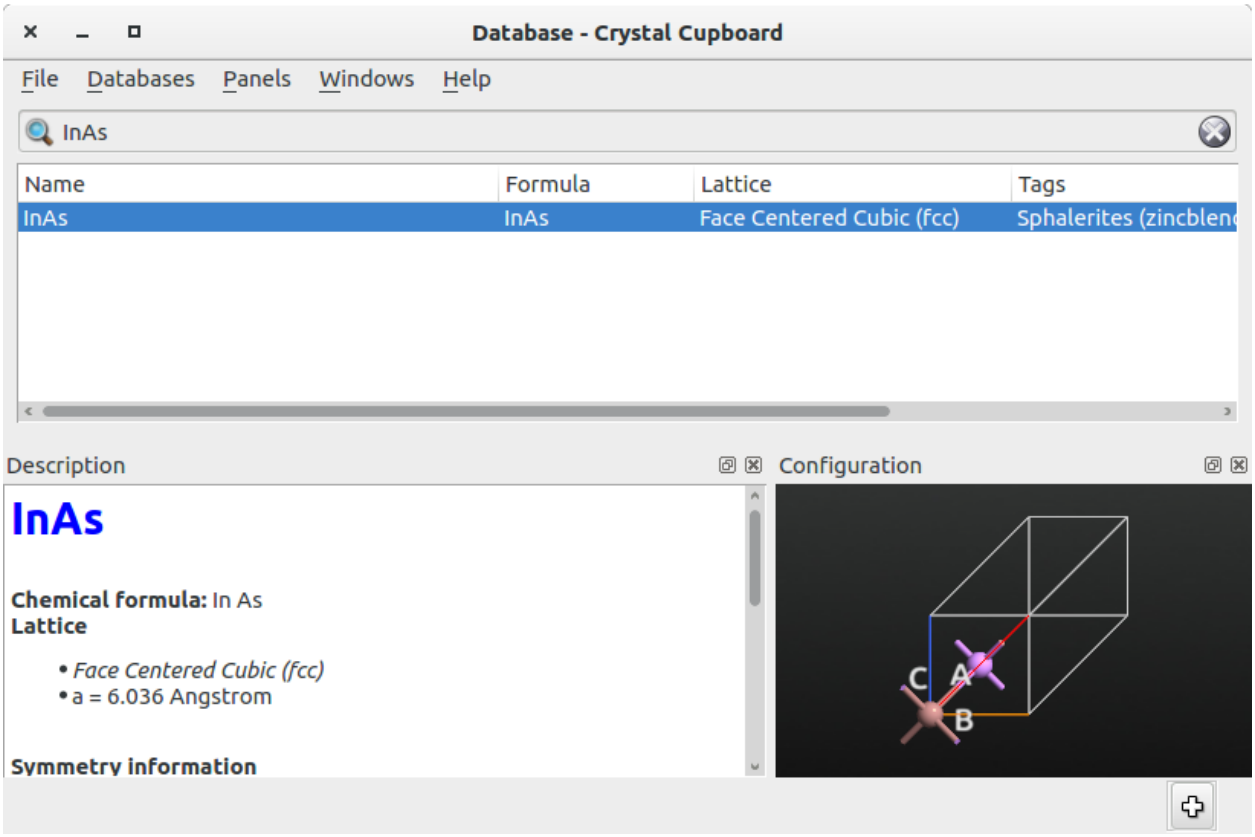
The output parameters are:

- `A`: Miller indexes $[h, k, l]$ of the first surface.
- `B`: Miller indexes $[h, k, l]$ of the second surface.
- `Strain`: Maximum strain of the two surfaces.
- `Atoms`: Total number of atoms in the interface supercell.
- `Area`: Surface area of the interface supercell.
- `Aspect`: Aspect ratio between two surface vectors of the interface supercell. The ratio is calculated by taking the largest vector at the numerator.
- `Angle`: Angle between the two vectors of the interface supercell.
- `Rotation`: Rotation between the two surfaces in the interface supercell.

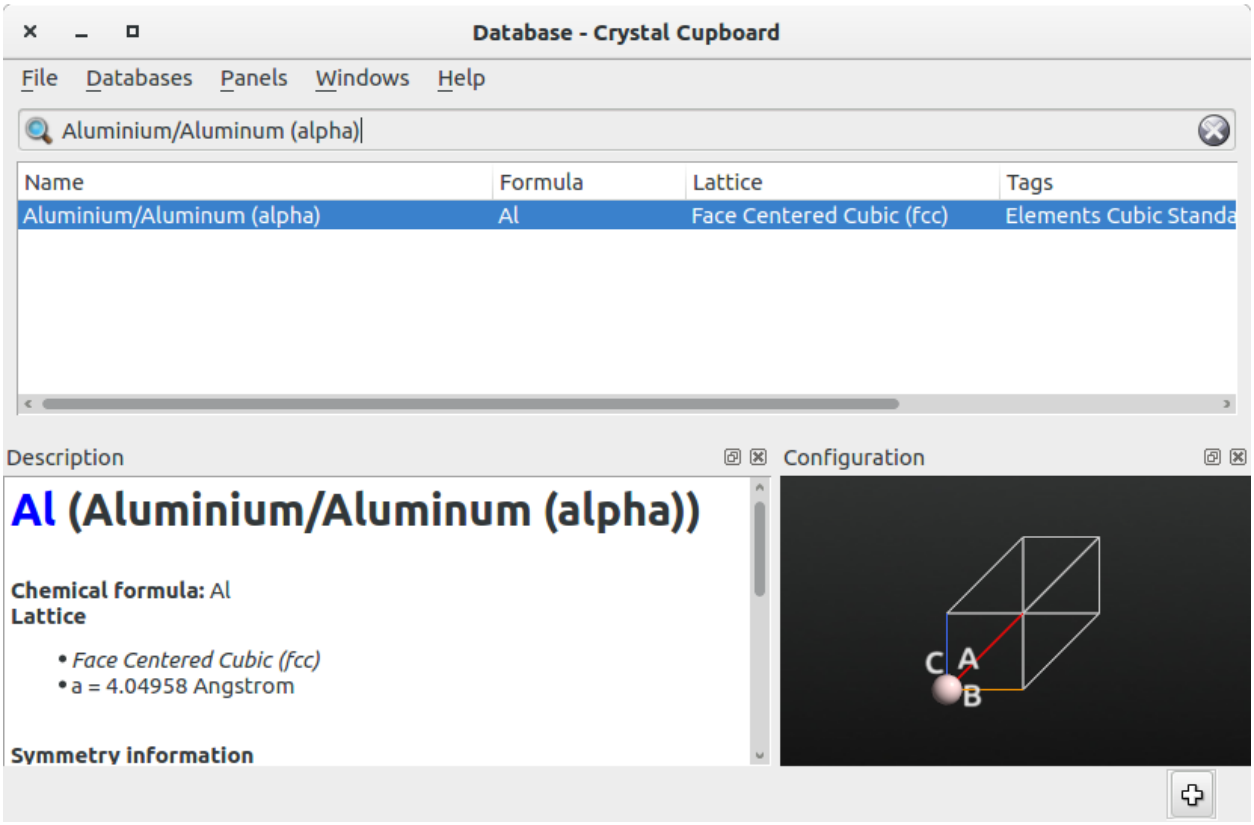
Example 1: Lattice match between two bulk systems

In this first example, you will calculate the possible matches between indium arsenide and aluminum.

To obtain the structure file containing the BulkConfiguration of bulk InAs, open **QuantumATK**, go to the **Builder** and click on *Add* → *From Database*. In the **Database**, select the primitive cell of bulk InAs shown in the figure below, add it to the **Stash** by clicking on the button.



Repeat the same procedure to add to the **Stash** the structure of the primitive cell of bulk Al, which is shown in the figure below.



In the **Stash**, save the two configurations by right-clicking on each structure and selecting *Save as*. Alternatively, you can download the two files from here: `InAs.py`, `Al.py`.

Set up the script for the GeneralizedLatticeMatch method as shown below:

```
# Read the BulkConfiguration of the primitive cell of the
# first material
configuration_1 = nlread('InAs.py',BulkConfiguration)[-1]
# Read the BulkConfiguration of the primitive cell of the
# second material
configuration_2 = nlread('Al.py',BulkConfiguration)[-1]

# Run the GeneralizedLatticeMatch method
generalized_lattice_match = GeneralizedLatticeMatch(
                            configuration_1,
                            configuration_2,
                            max_strain=0.02,
                            maximum_miller_index=3,
                            longest_surface_lattice_vector=50*Angstrom,
                            max_surface_area=200.0*Angstrom**2,
                            user_given_miller_index=None
                            )
```

Alternatively, you can download the script from here: `match_InAs_Al.py`

In this example, the scan will be performed by considering surfaces with a maximum strain of 0.02, with Miller indexes $h, k, l \leq 3$, with a maximum length of the lattice vectors of 50 Å, and with a upper threshold for the surface area of 200 Å^2.

Run the script in the terminal as `atkpython match_InAs_Al.py > match_InAs_Al.log`. The output will look as shown below. There are several possible matches, so for briefness only the first 20 matches are shown.

```

[ 1  0  0] >-< [ 1  1  0]   0.008420      28    200.4      2.2      79.7       38.2
```

Notice how the match with the least strain is that between the $\langle 100 \rangle$ surface of InAs and the $\langle 100 \rangle$ surface of Al.

Example 2: Lattice match between a bulk system with a predefined surface

In some cases, one could be interested in finding the possible matches of a bulk material to a given surface. In this second example, you will investigate how to find the possible matches of bulk aluminium to the InAs(111) surface. InAs nanowires with ⟨111⟩-oriented facets have been synthesized in Ref.[2], and it has been demonstrated experimentally that ⟨111⟩-oriented Al layers can be grown on this surface.

Use the same structure files as in *Example 1: Lattice match between two bulk systems*, and setup the script for the GeneralizedLatticeMatch calculation as follows:

```
# Read the BulkConfiguration of the primitive cell of the
# first material
configuration_1 = nlread('InAs.py',BulkConfiguration)[-1]
# Read the BulkConfiguration of the primitive cell of the
# second material
configuration_2 = nlread('Al.py',BulkConfiguration)[-1]

# Run the GeneralizedLatticeMatch method
generalized_lattice_match = GeneralizedLatticeMatch(
                            configuration_1,
                            configuration_2,
                            max_strain=0.02,
                            maximum_miller_index=3,
                            longest_surface_lattice_vector=50*Angstrom,
                            max_surface_area=200.0*Angstrom**2,
                            user_given_miller_index=(1,1,1)
                            )
```

Notice how the `user_given_miller_index` option, highlighted in yellow, has now been set to `user_given_miller_index=(1,1,1)`. Therefore, in this case only the matches of bulk Al to the InAs(111) surface will be considered. You can also download the script from here: `match_InAs111_Al.py`

Run the script in the terminal as `atkpython match_InAs111_Al.py > match_InAs111_Al.log`. The output will look as shown below. Notice how there are fewer possible matches than those in the output of *Example 1: Lattice match between two bulk systems*. This is because only one surface is now considered for the material denoted `A`.

```

+-------------------------------------------------------------------------------------
↪+
```

In this case, the match to the InAs(111) surface with the lowest strain is that with the Al(111) surface, which is in agreement with the experimentally measured structure reported in Ref.[Page 842, 2].

3.4.8 Modeling metal–semiconductor contacts: The Ag–Si interface

Version: 2016.1

Downloads & Links

`device.py` `c_fit.py` `hdp.py` `hdp_plot.py` `pldos_hdp.py` `IV.py` `IV-n-log.py` `IvsT.py` `arrhenius.py` `spectral_current.py` `barrier_compare.py`

Contacts between metals and doped semiconductors are ubiquitous in modern technology and find applications in several important areas, e.g. photovoltaics. QuantumATK provides an excellent toolbox to study such interfaces, because it correctly accounts for the semiconductor band gap and doping, and describes the interface using the physically correct boundary conditions.

This case study shows how the properties of metal–semiconductor interfaces can be calculated and analyzed using QuantumATK and the NEGF (non-equilibrium Greens function) method. To this end, we will reproduce the main calculations and theoretical analyses reported in the recent publication *General atomistic approach for modeling metal–semiconductor interfaces using density functional theory and non-equilibrium Greens function*[1], which considers the Ag–Si interface. Notice, however, that the methods presented here are completely general and can be applied to any metal–semiconductor interface.

You will be guided through the following steps:

- *Creating the device*
- Calculating and plotting the *projected local density of states*
- Calculating the *ideality factor*
- Estimating and analyzing the *Schottky barrier*

[1] D.ăStradi, U.ăMartinez, A.ăBlom, M.ăBrandbyge, and K.ăStokbro. General atomistic approach for modeling metal-semiconductor interfaces using density functional theory and nonequilibrium Greens function. *Phys. Rev. B*, 93:155302, Apr 2016. doi:10.1103/PhysRevB.93.155302.

•Calculating the *spectral current*

Note: QuantumATK case studies are primarily directed at experienced users of QuantumATK. Instructions are deliberately concise in order to focus mostly on the science.

Warning: If you are running this case study with QuantumATK v2017.2 or higher, be aware that you will have to set explicitly the electronic temperature to $T = 300$ K in all the electronic structure calculations performed for either a `BulkConfiguration` or for a `DeviceConfiguration`, in order to reproduce the results presented in the case study.

Creating the device

Tip: If you wish to skip this part, you can just download the device configuration as an QuantumATK Python script: `device.py`.

The first step is to relax the bulk structures of silver and silicon. Build the structures using the database in the **Builder** and send them both to the **Scripter**, one at a time. In both scripts, add a **New Calculator** block with the following settings:

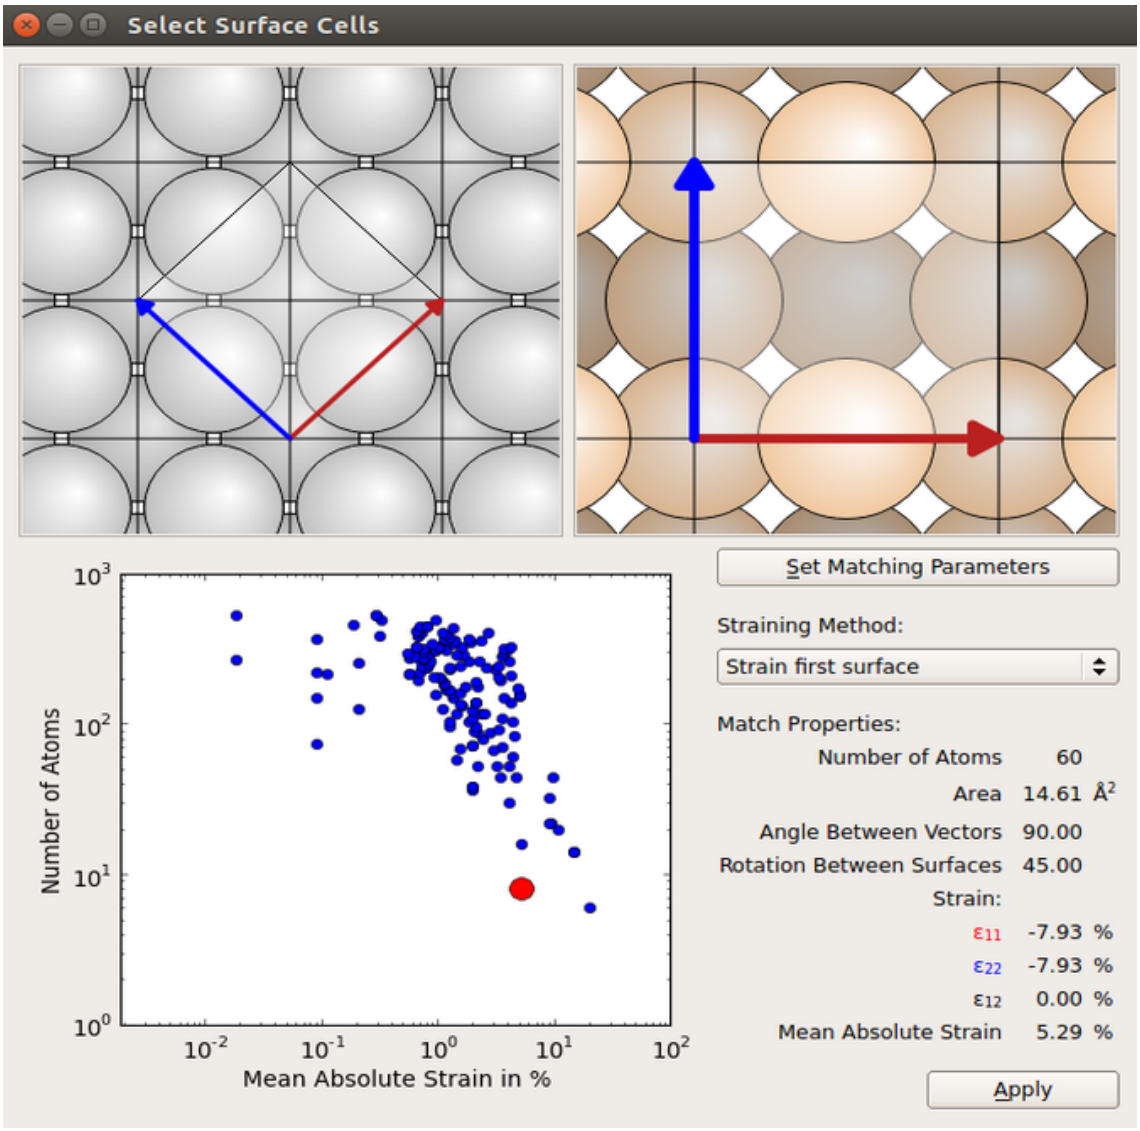
•ATK-DFT

•LDA exchange-correlation functional

•11x11x11 k-point sampling

Also add the **OptimizeGeometry** block, set the force and stress tolerances to 0.01 eV/Å and 0.001 eV/Å^3, respectively, and uncheck the *Constrain cell* box. Run both scripts to obtain the optimized structures. The calculations can easily be run on your local machine.

The Ag and Si (100) surfaces can now by created using the **Surface (Cleave)** tool in the Builder, and from these you can create the interface as explained in the tutorial *Building an interface between Ag(100) and Au(111)*. You should include 6 layers of Ag and 9 layers of Si. Choose *Strain first surface* in the **Select Surface Cells** window under *Straining method* and choose the cell shown in the figure below.

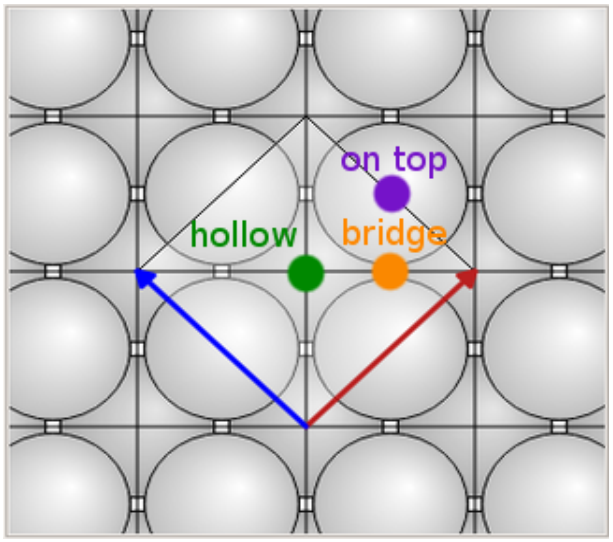


Tip: You can learn more about the Interface Builder in the Technical Notes on *Interface Builder*.

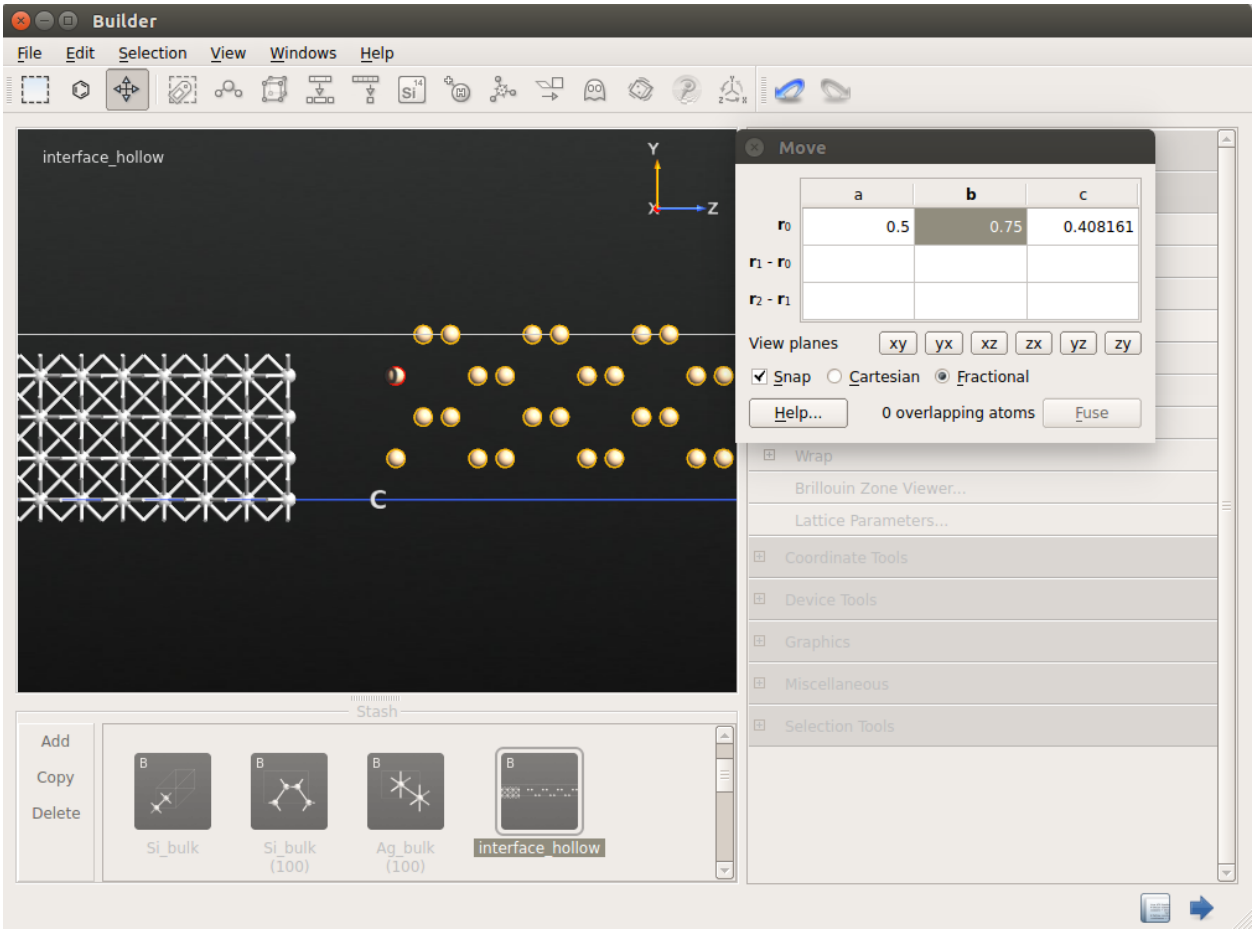
Initial guesses for the interface structure

Use the **Repeat** tool to repeat the interface 2 times along the B-direction. Next, add some vacuum around the configuration by first using the **Stretch Cell** tool to stretch the C-vector by 30%, and then use the **Center** tool to center the atoms along the C-direction only.

At the Ag–Si interface, the Si dangling bonds are initially placed near the hollow site of the Ag(100) surface. In order to find the most stable interface structure, you should investigate the on top and bridge sites as well.



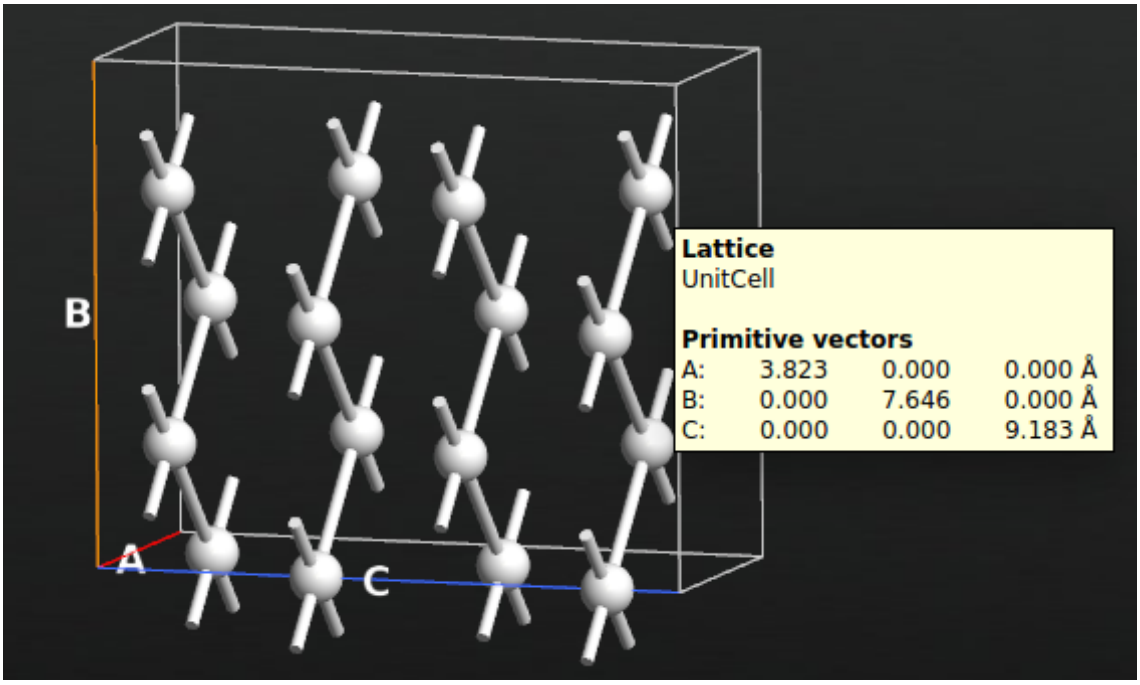
Select all the Si atoms and open the **Move** tool. Choose the topmost of the Si atoms farthest to the left as an anchor by double-clicking it. Then shift the Si(100) surface 4 Å away from the Ag(100) by increasing the c-value in the Move window, and rename the structure `interface_hollow`. Make a copy of the structure and use the **Move** tool again. This time, choose the *Fractional* option and enter a=0.5 and b=0.75 (see image below). Name this structure `interface_ontop`. Finally, make a new copy, set a=0.25 and b=0.625, and name the structure `interface_bridge`.



Note: Repeating the structure is not necessary in the general case. We do it here in order to obtain the structural model considered in[1].

Electrode relaxation

Next, you should relax the Ag electrode in the z-direction. The electrode was strained in the x and y directions when building the interface and should therefore be allowed to relax in the z direction according to the Poisson ratio of the material. You can obtain the electrode by first creating a device configuration (apply the **Device From Bulk** plugin to one of the interfaces created above), and then split it using the icon. Use an ATK-DFT calculator with LDA and a 6x3x1 k-point grid, and use the same force and stress tolerance as for the bulk relaxations above. You will find that the length of the electrode C-vector increases by 9.57%. To be consistent, you should apply the same elongation to the Ag part of the three interface configurations. Use again the **Stretch Cell** tool: Select all the Ag atoms, enter 1.0957 for the stretch along C, and choose *Selected atoms are stretched*.



Central region relaxation

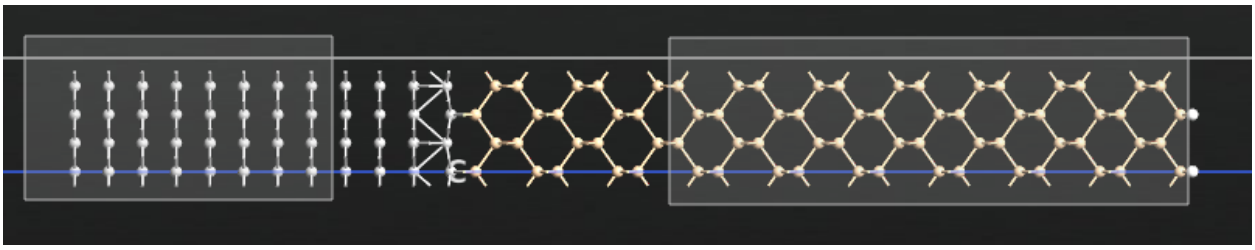
General procedures for relaxing a device configuration is explained in the tutorial *Advanced device relaxation - manual workflow*. Here, you will first relax the three interface structures as bulk configurations (i.e. relax the device central regions) in order to determine which of them is the most stable.

First, add some extra vacuum to all three interface structures by using the **Lattice Parameters** plugin to increase the C-vector length by 30%. Then use the **Center** tool to center the configurations along C only. Finally, use the **Hydrogen passivation** tool to passivate the dangling bonds on the Si(100) surface farthest from the interface. Note that this may add H atoms to the left of the silicon part as well as to the right. Any hydrogen placed in the interface should obviously be removed.

You are now ready to relax each configuration. Use the same calculator settings as for the Ag electrode relaxation, and use the following parameters in the **OptimizeGeometry** block:

- 0.02 eV/Å force tolerance.
- Do not enable stress minimization.
- Use the **Add Constraints** widget to set a *Fixed* constraint for the Ag atoms indicated in the image below, and a **Rigid** constraint for the indicated Si (and H) atoms.

Finally, add also the **TotalEnergy** analysis block to the scripts.



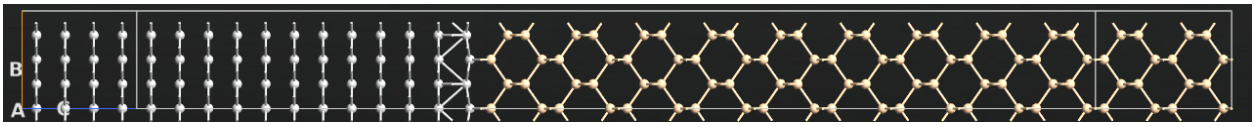
Run the calculations. They are a bit demanding and require roughly 20 hours on a 16-core node. You should find that the structure where the silicon connects to the Ag(100) hollow sites is the most stable (it has the most negative total energy, see below). In the following, only this configuration will be used.

	Total Energy (eV)
hollow	-76536.37
on top	-76535.46
bridge	-76535.40

Device relaxation

Remove the passivating hydrogen atoms from the optimized hollow interface structure, and build a device using the **Device From Bulk** plugin. This final device relaxation should use the same calculator and geometry optimization parameters as for the bulk relaxation above, except that the k-point sampling along C must be increased to 401 (use a 6x3x401 grid).

The calculation takes about 2 hours on 16 cores. If you do not intend to run the calculation, you can download the relaxed device configuration here: `device_hollow.py`.



Fitting the TB09-MGGA c-parameter

We use the TB09 meta-GGA functional[2] to calculate the projected local density of states and transmission spectrum of the device. In order to obtain an accurate description of the Si side of the interface, the TB09 c-parameter is fitted to match the silicon band gap. Details about this procedure can be found in the tutorial *Meta-GGA and 2D confined InAs*. The calculations are quite fast and can be run locally.

Follow these steps:

1. Compute the band structure of the optimized silicon bulk using ATK-DFT with the TB09-MGGA functional and 11x11x11 k-points. You should obtain a band gap of 1.16 eV and a self-consistently determined c-parameter of 1.0841.

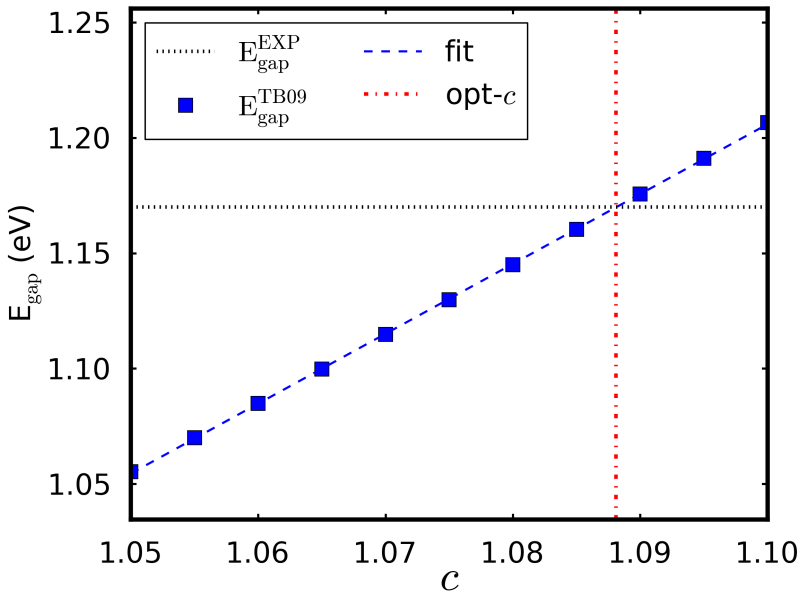
2. Do similar calculations with fixed c-values around 1.0841. This can be done in a single QuantumATK Python script by looping over the different c-values. Use the **Editor** to insert the loop:

```
for tb09 in (1.05,1.055,1.06,1.065,1.07,1.075,1.08,1.085,1.09,1.095,1.1):
    # ------------------------------------------------------------
    # Calculator
    # ------------------------------------------------------------
    #-------------------------------------
    # Exchange-Correlation
    #-------------------------------------
    exchange_correlation = MGGA.TB09LDA(c=tb09)
```

   Remember that the *Bandstructure* block should be included in the loop, just below the *Calculator* section. Use `nlsave('Si_bulk_fitc.nc', bandstructure)` to save all the band structures in a single data file.

3. Fit the c-value to the experimental band gap of 1.17 eV[3] using the script `c_fit.py`. It needs three input parameters; a list of the used c-values (`tb09`), the name of the .nc file containing the bandstructure calculations (`fname`), and the experimental band gap (`SK`).

   The optimal c-value should be around 1.0881.



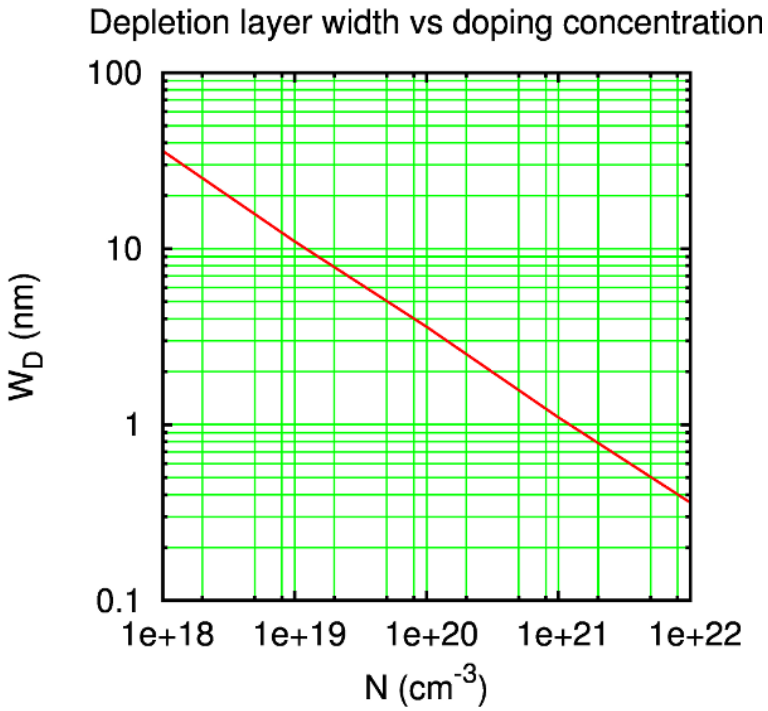
[2] F.ăTran and P.ăBlaha. Accurate band gaps of semiconductors and insulators with a semilocal exchange-correlation potential. *Phys. Rev. Lett.*, 102:226401, 2009. doi:10.1103/PhysRevLett.102.226401.

[3] C.ăKittel. *Introduction to Solid State Physics*. Wiley, 8th edition, 2004.

Silicon doping and depletion layer length

You are now ready to dope the silicon part of the device. Open the relaxed device configuration in the **Builder**, select all the silicon atoms, and use the **Doping** plugin to apply an n-type doping concentration of 10^{19} e/cm^3 to the right electrode.

It is important to consider the length of the depletion layer in your device: The device needs to be longer than the screening length of the semiconductor so that the potential on the silicon side at the boundary with the silicon electrode resembles that of bulk silicon. This can be done by studying the convergence of the Hartree potential with respect to the length of the silicon central region. For a good starting guess, you can consult some typical depletion layer lengths for metal–semiconductor interfaces[4]; a doping of 10^{19} cm^{-3} corresponds to a depletion layer length of around 100 Å.



Tip: You only need to converge the length of the silicon side of the interface, since the metal have a much shorter screening length. The 6 atomic layers of Ag will be sufficient.

Note: In QuantumATK versions 2015 and older, the HartreeDifferencePotential analysis object was called ElectrostaticDifferencePotential.

Increase the length of the silicon part of the central region by using the **Central Region Size** plugin. Use lengths of 80 Å, 100 Å, 120 Å, and 140 Å, and send each device configuration to the **Scripter**. Use a calculator with the same parameters as for the device relaxation, and add the HartreeDifferencePotential block.

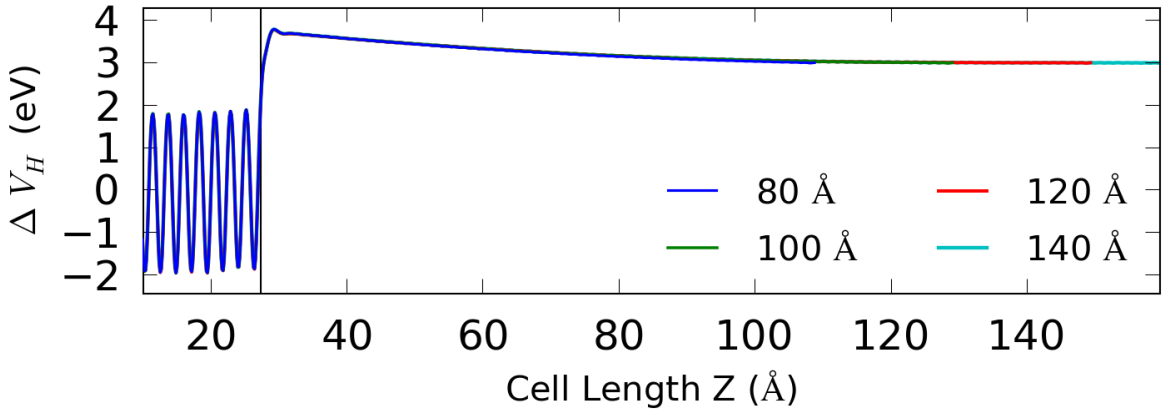
Note that the calculations become increasingly difficult to converge as the length is increased. At 120 Å and more, you will need to adjust the *Iteration Control Settings* in your calculator: In the **Scripter** window, change the **Script detail**

[4] E.ăKasper and D.ăJ. Paul. *Silicon Quantum Integrated Circuits*. Springer-Verlag Berlin Heidelberg, 2005. doi:10.1007/b137494.

to *Show defaults*, and send the script to the **Editor**. In the *Iteration Control Settings* block, change the values of `damping_factor`, `number_of_history_steps`, and `max_steps` used in the device calculation:

```
device_iteration_control_parameters = IterationControlParameters(
damping_factor=0.05,
linear_dependence_threshold=0.0,
algorithm=PulayMixer(),
preconditioner=Preconditioner.Off,
start_mixing_after_step=0,
number_of_history_steps=12,
max_steps=400,
tolerance=0.0001,
mixing_variable=HamiltonianVariable,
)
```

The calculation for the largest device requires around 13 hours on 16 cores. When all calculations have finished and the results appear on the **LabFloor**, you can plot the potentials along the Z-direction using the **1D projector** analysis tool. The potential should be flat in the vicinity of the boundary with the silicon electrode.



The wiggles of the potential can make it hard to see if it has converged to the electrode value. The **macroscopic average** of the potential, $\langle \Delta V_H \rangle$, smoothens out the wiggles. Use the script `hdp.py` to calculate the macroscopic average of the Hartree potential along the z-direction[5]. The script needs to be edited, as it contains some input parameters specific to the interface structure:

gauss_left
Distance along Z (in Å) between two consecutive atomic layers in the left electrode material.

gauss_right
Same as above, but for the right electrode material.

zcoord_int
Z-coordinate of the interface position (in Å) calculated as the midpoint between the last atom in the left-hand material and the first atom in the right-hand material.

fname
Name for the output .dat file containing the averaged potential.

[5] A.ăBaldereschi, S.ăBaroni, and R.ăResta. Band Offsets in Lattice-Matched Heterojunctions: A Model and First-Principles Calculations for GaAs/AlAs. *Phys. Rev. Lett.*, 61:734–737, Aug 1988. doi:10.1103/PhysRevLett.61.734.

Once you have edited these parameters, run the script once for each of the the .nc files containing the HartreeDifferencePotential analysis for the different configurations:

```
atkpython hdp.py device.nc
```

where `device.nc` should be changed to the actual .nc file name.

You can use the script `hdp_plot.py` to compare the resulting .dat output files. Modify the following input parameters:

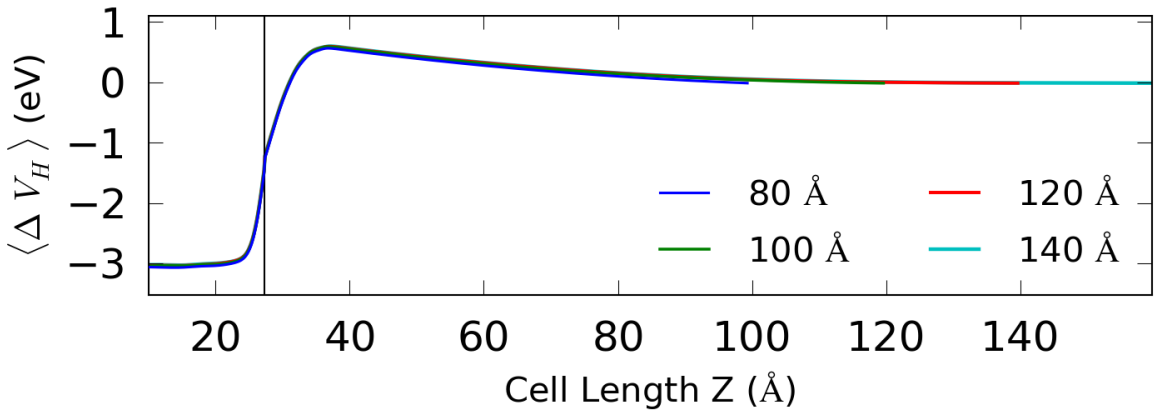
fnames
Names of the .dat files.

names
Lenghts of the silicon central region.

zcoord_int
Same as explained above (input for `hdp.py`).

Edit the script and run it to produce the figure below:

```
atkpython hdp_plot.py
```



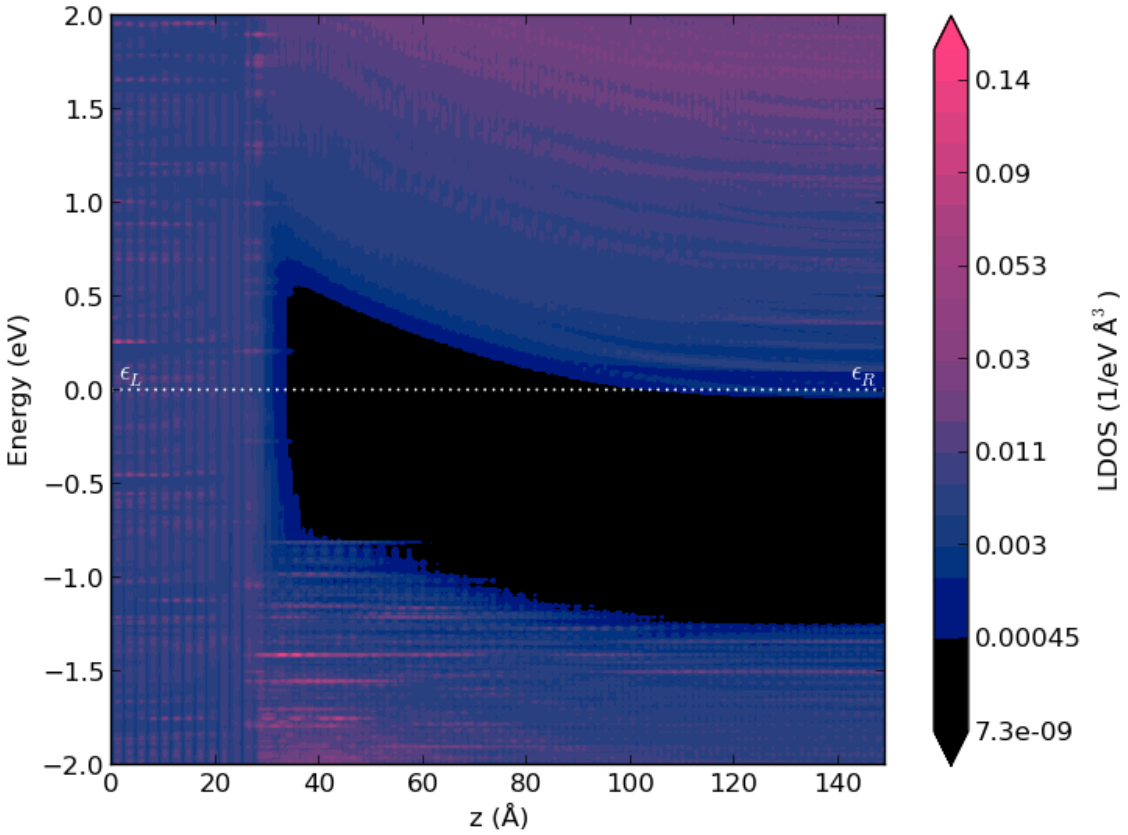
We may conclude from the plot that a silicon central region length of 120 Å should be sufficient. Note that the depletion layer length could change slightly with the bias. You now have the final `device.py`.

Note: The kink at the interface border in the plot above is due to the averaging procedure, where Gaussians of different widths are matched at the Ag–Si border.

Projected local density of states

The projected LDOS (PLDOS) offers a highly useful visualization of the band diagram of the interface. Use the **Analysis from File** block in the Scripter to load the saved device configuration and the converged calculator attached to it. Then add the **ProjectedLocalDensityOfStates** block and edit the settings: Energy range between -2 and +2 eV using 401 energy points and a 18x9 k-point grid. Save the results in the .nc file from which you load the configuration.

The calculation will take around 7 hours on a 16-core node with 64 GB of memory. When the calculation is finished and the results are on the **LabFloor**, you can use the **Projected Local Density of States** analysis plugin to plot the PLDOS along the device transport direction:



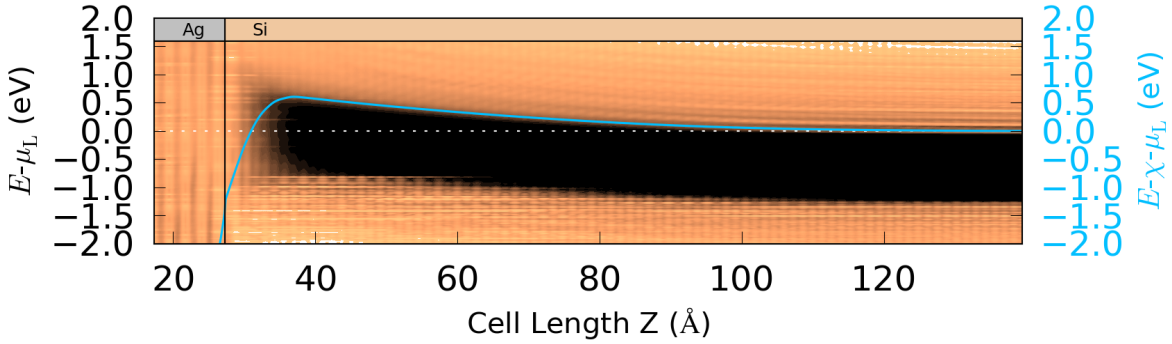
You can also plot the averaged Hartree difference potential along with the PLDOS using the script `pldos_hdp.py`. It requires the .nc file containing both the HartreeDifferencePotential and ProjectedLocalDensityOfStates analysis items, and the same input parameters as `hdp.py`, along with some plotting preferences:

leftname
Name of the left-hand interface material.

rightname
Name of the right-hand interface material.

lenleft
The amount of left material shown in the plot (in Å).

Run the script as `atkpython pldos_hdp.py device.nc` using the generated .nc file.



In this plot, you can easily see the **metal-induced gap states** to the right of the interface border. Moreover, the averaged potential nicely follows the conduction band minimum, both at the interface and far from it. We can therefore estimate the **Schottky barrier**, Φ^{pot}, by calculating the difference between the chemical potential of the left electrode, μ_L, and the maximum of $\langle \Delta V_H \rangle$. The plotting script returns this value together with the plot. You will get a barrier of around 0.606 eV, which is in agreement with experimental results, see[6] and[7]. The script also returns the position of the conduction band minimum with respect to μ_L. You will need this value later on for analyzing the *spectral current*.

Finite-bias calculations

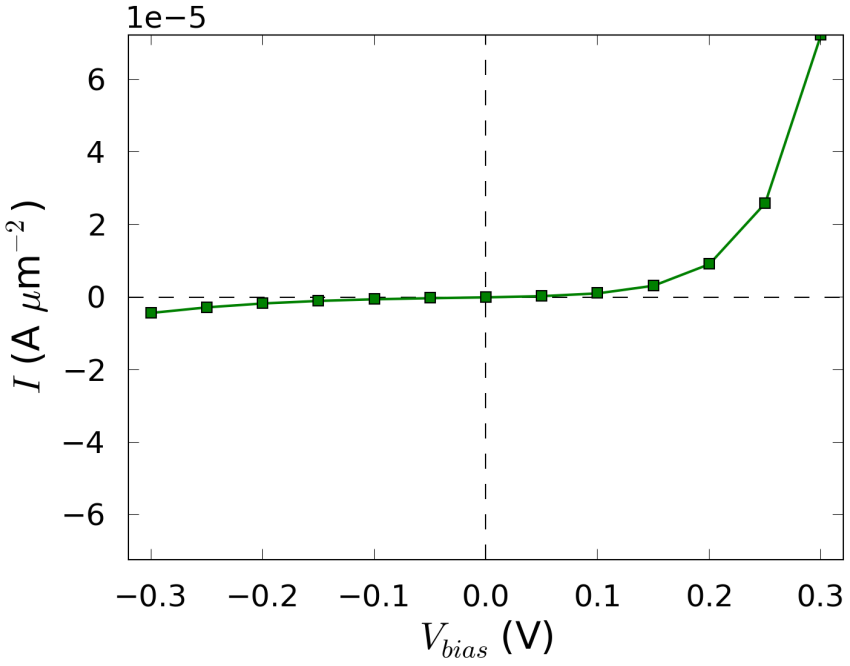
We will investigate the I–V characteristics next. Use the **Analysis from File** functionality and the **IVCurve** analysis block. Choose the following settings for the analysis:

- -0.3 to +0.3 V bias range with 15 points.
- -2 to +2 eV energy range with 401 points.
- 18x9 k-point grid.

The calculation will require around 15 hours on 16 cores. You can use the **IV-Plot** plugin to plot the calculated current vs. bias, or use the script `IV.py` to plot the current density against bias. The script requires a .nc file containing the device configuration and I–V curve items.

[6] R.ăBalsano, A.ăMatsubayashi, and V.ăP. LaBella. Schottky barrier height measurements of Cu/Si(001), Ag/Si(001), and Au/Si(001) interfaces utilizing ballistic electron emission microscopy and ballistic hole emission microscopy. *AIP Advances*, 3:112110, 2013. doi:10.1063/1.4831756.

[7] J.ăJ. Garramone, J.ăR. Abel, I.ăL. Sitnitsky, and V.ăP. LaBella. Hot-electron transport studies of the Ag/Si(001) interface using ballistic electron emission microscopy. *Journal of Vacuum Science & Technology A*, 28:643, 2010. doi:10.1116/1.3397795.



The interface shows Schottky diode-like behavior, with a large increase in the current at forward bias but a rather small increase at reverse bias.

Note: The computed current is significantly lower than the current reported in the publication[Page 843, 1]. See the *Note on the variation of the current* for an explanation.

Ideality factor

Thermionic emission theory describes the I–V characteristics of a Schottky diode as[8]

$$I = I_0 \mathrm{e}^{\frac{qV_{bias}}{nk_BT}} \left(1 - \mathrm{e}^{-\frac{qV_{bias}}{k_BT}}\right),$$

where q is the elementary charge, k_B is the Boltzmann constant, T is the temperature, I_0 is the saturation current, and n is the so-called ideality factor. The ideality factor is a measure of how much the interface resembles an ideal Schottky diode, where a value of n=1 represents the ideal case. Using a log-plot of $I/(1 - \mathrm{e}^{-qV_{bias}/k_BT})$ against V_{bias} you can extract the value of the ideality factor from the slope. Use the script `IV-n-log.py` to create such a plot and calculate the ideality factor. You should edit a few input parameters:

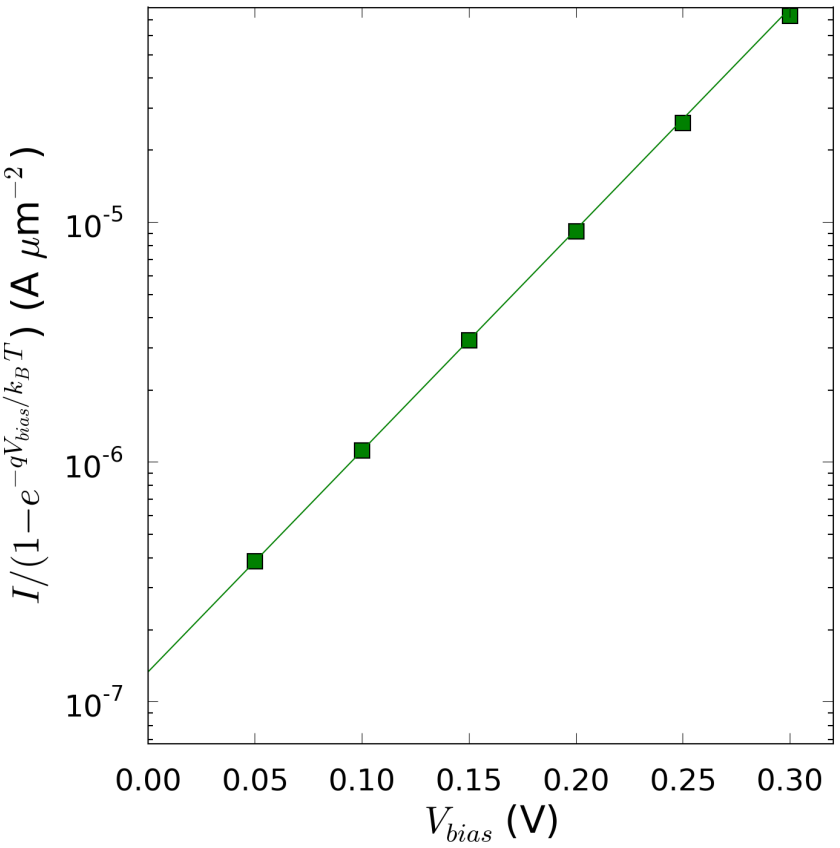
filename
The same .nc file as for `IV.py`.

T
The temperature at which the calculations have been run.

numpoints
The number of bias points to include in the fit used to find the ideality factor.

[8] S.ăM. Sze and K.ăN. Kwok. *Physics of Semiconductor Devices*. Wiley, 3rd edition, 2006.

Running the script, you should get a value around n=1.8208, which means that the system deviates significantly from the ideal Schottky diode behavior.



Schottky barrier

The Activation Energy (AE) method[8] is a widely used experimental procedure for extracting the Schottky barrier. The method extracts the Schottky barrier from an Arrhenius-like plot of $\ln(I/T^2)$ vs. $1/T$,

$$\ln(IT^2) = \ln(AA^*) - \frac{q}{k_B}\left(\Phi^{AE} - \frac{V_{bias}}{n}\right)\frac{1}{T} \Rightarrow$$

$$\phi^{AE}(V_{bias}) = \Phi^{AE} - \frac{V_{bias}}{n} = -\frac{k_B}{q}\frac{\mathrm{d}[\ln(I/T^2)]}{\mathrm{d}(1/T)}.$$

Use the script `IvsT.py` to calculate the transmission at each applied forward bias in a range of temperatures between 250 K and 400 K. The transmission is calculated in a linear-response fashion using the Landauer–Büttiker expression for the current,

$$I = \frac{2q}{h}\int T(E,\mu_L,\mu_R)\left[f\left(\frac{E-\mu_L}{k_BT}\right) - f\left(\frac{E-\mu_R}{k_BT}\right)\right]\mathrm{d}E,$$

where the transmission coefficient $T(E,\mu_L,\mu_R)$ has been evaluated self-consistently at a temperature of 300 K during the the IVCurve calculation.

The script needs three inputs to run:

fname
The .nc file containing the *IVCurve* analysis.

Tmax
Maximum temperature used in the calculations (in K).

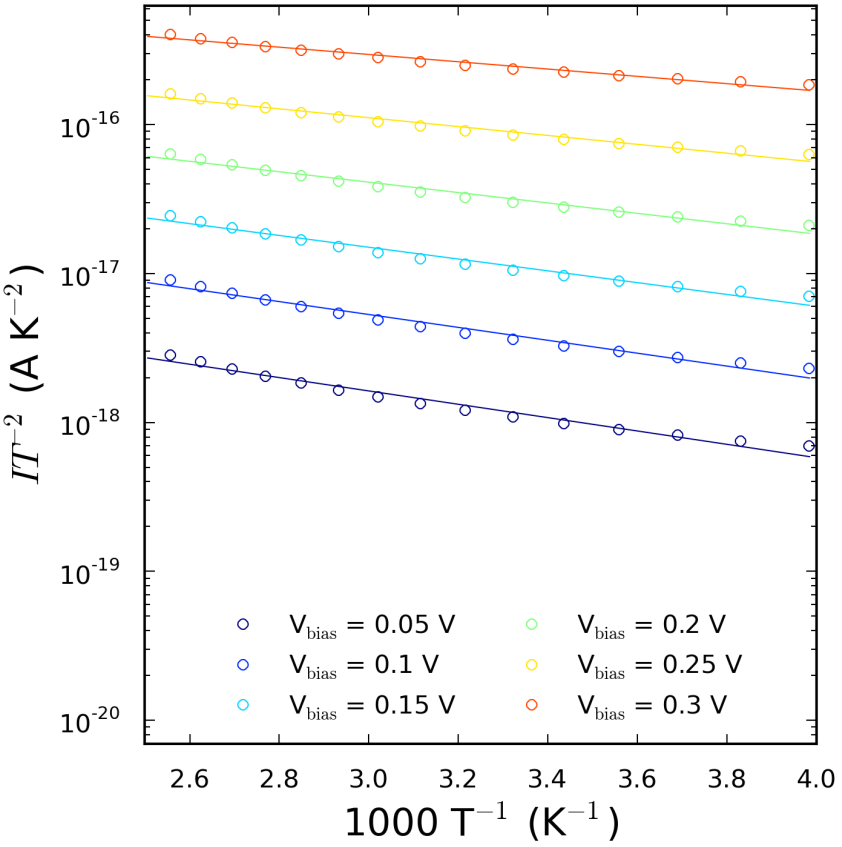
Tmin
Minimum temperature used in the calculations (in K).

Running the script produces a .dat file containing the I–T characteristics for each of the forward bias points. From these files, you can create the simulated Arrhenius plot using `arrhenius.py`. It requires the **Tmax** and **Tmin** inputs, and also the following:

IF
The calculated ideality factor from `IV-n-log.py`.

voltages
Forward biases for which the calculations have been performed (in V).

fname
Name of output file containing the effective barrier height (in eV).



The script produces the plot above, and also returns the Schottky barrier height Φ^{AE} and the effective barrier height $\phi^{AE}(V_{bias})$ for each applied bias (ϕ^{AE} is the barrier from the conduction band minimum of the bulk silicon electrode to the maximum of $\langle V_H \rangle$). The effective barrier height is exported as a .dat file for later analysis. You will find that the Schottky barrier increases with bias voltage. This is unphysical and should not occur, which suggests that the AE method provides only a limited description of this interface.

Spectral current

The final analysis is an investigation of the spectral current,

$$I(E) = \frac{2q}{h} T(E, \mu_L, \mu_R) \left[f\left(\frac{E-\mu_L}{k_B T}\right) - f\left(\frac{E-\mu_R}{k_B T}\right) \right].$$

We will plot the spectral current and the averaged Hartree difference potential together in order to compare the energy of maximum spectral current with the barrier of the Hartree potential.

The starting point is to calculate the Hartree potential at the different biases considered. Do this using **Analysis from File** and load the configurations saved in the file `ivcurve_selfconsistent_configurations.nc`, which was created by the **IVCurve** calculation, and add the **HartreeDifferencePotential** block for each configuration. The calculations should be very fast and can be run locally. You can then reuse `hdp.py` to calculate the average of each of the potentials.

Use the script `spectral_current.py` to plot the averaged potential together with the spectral current. You need to edit a few parameters:

fname
The .nc file containing the IVCurve analysis.

hdp_files
The .dat files containing the averaged potentials.

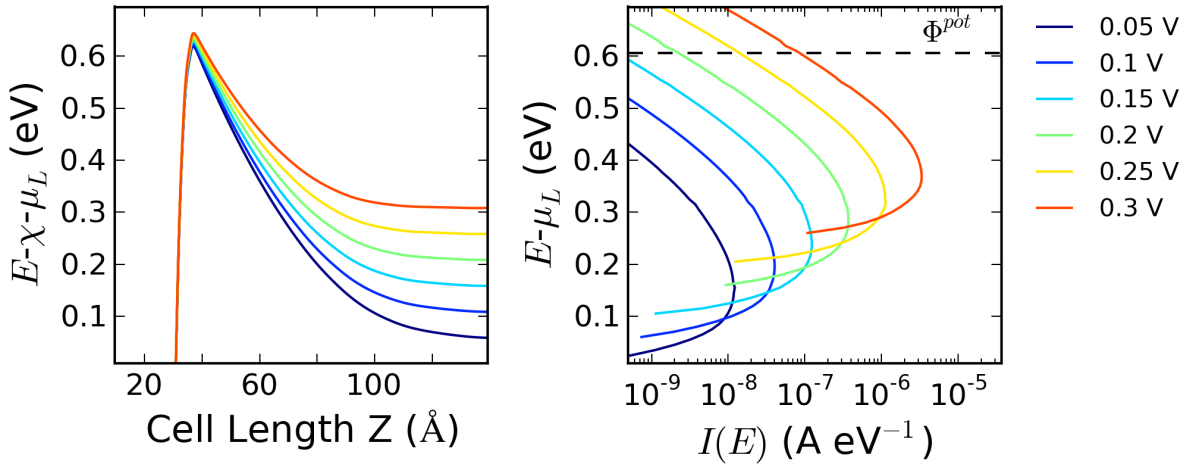
phipot
Schottky barrier calculated with `pldos_hdp.py` at zero bias (in eV).

CB_min
Conduction band minimum of the bulk Si electrode with respect to μ_L, calculated above with `pldos_hdp.py` (in eV).

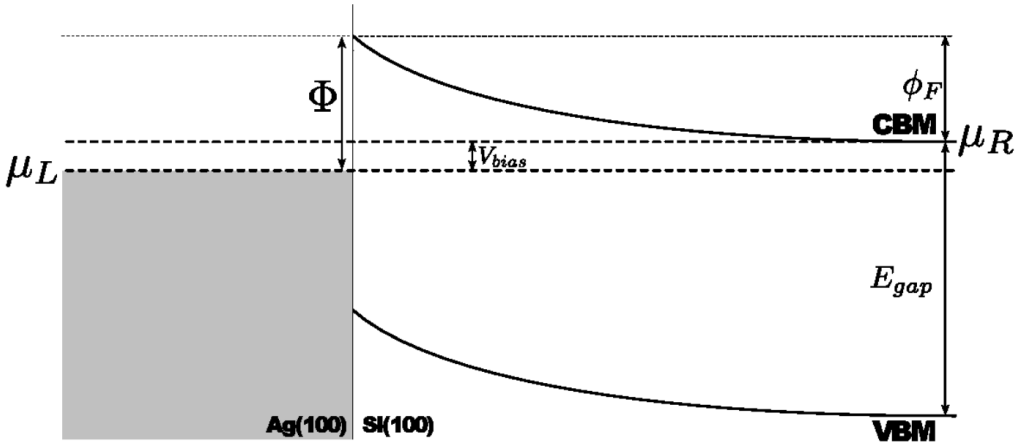
fname2
Name of the output file containing the barriers associated with the thermionic emission process (in eV).

fname3
Name of the output file containing the energy of maximum spectral current (in eV).

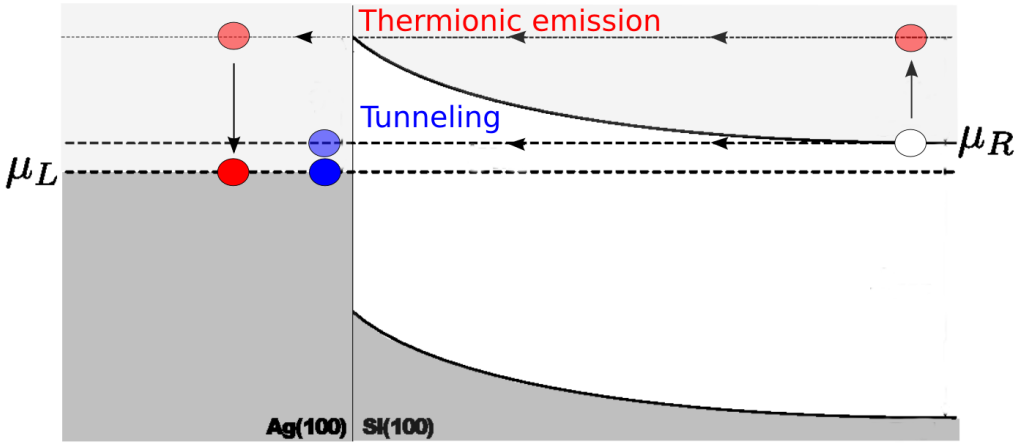
Running the script should produce the figure below.



The script also returns the estimated barrier for thermionic emission, ϕ_F, and the energy of maximum spectral current for each bias as .dat files. The energy axis of the two plots is aligned by plotting the averaged potential relative to the electron affinity of bulk Si (estimated by `pldos_hdp.py`) and μ_L and the spectral current relative to μ_L.



Transmission through the device can occur through two different processes; either by thermionic emission or by tunneling through the Schottky barrier. If the transmission occurs solely by thermionic emission, the spectral current would be zero below Φ^{pot}. This is definitely not the case. In fact, the energy of maximum spectral current is below the thermionic emission barrier for each bias, revealing that the dominant transmission process is tunneling!



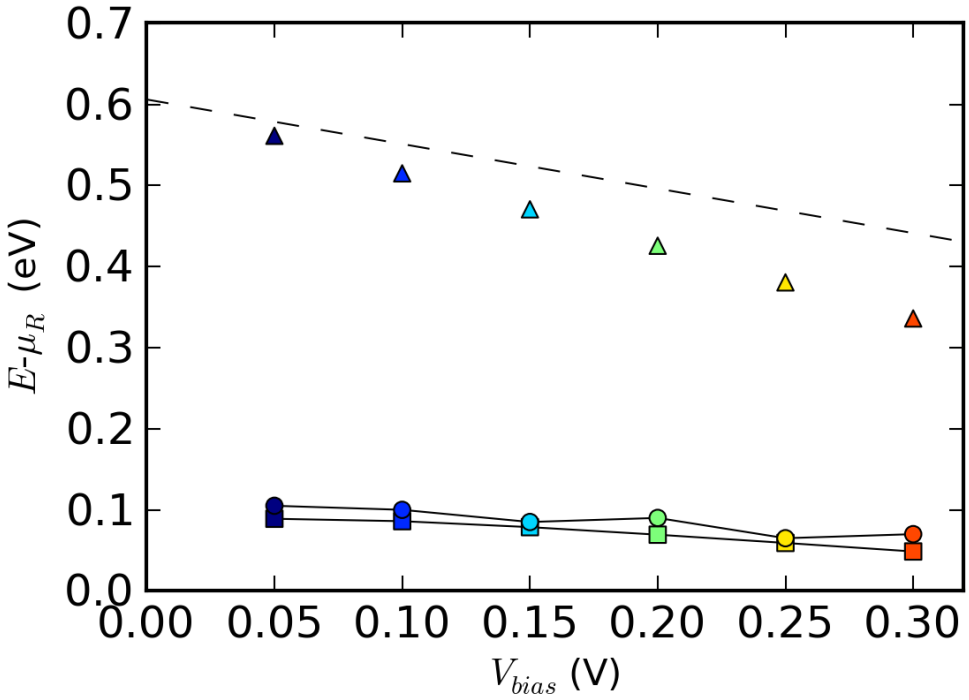
Summing up the results

We compare the finite-bias results by plotting the following:

- The energy of maximum spectral current from `spectral_current.py` (circles).
- The thermionic emission barrier ϕ_F from `spectral_current.py` (triangles).
- The effective AE Schottky barrier $\phi^{AE}(V_{bias})$ from `arrhenius.py` (squares).
- The bias dependence of the AE Schottky barrier predicted by $\phi^{AE}(V_{bias})$ by using $\Phi^{AE} = \Phi^{pot}$ (dashed line).

Create the plot using `barrier_compare.py`. It requires the .dat files created by `arrhenius.py` and

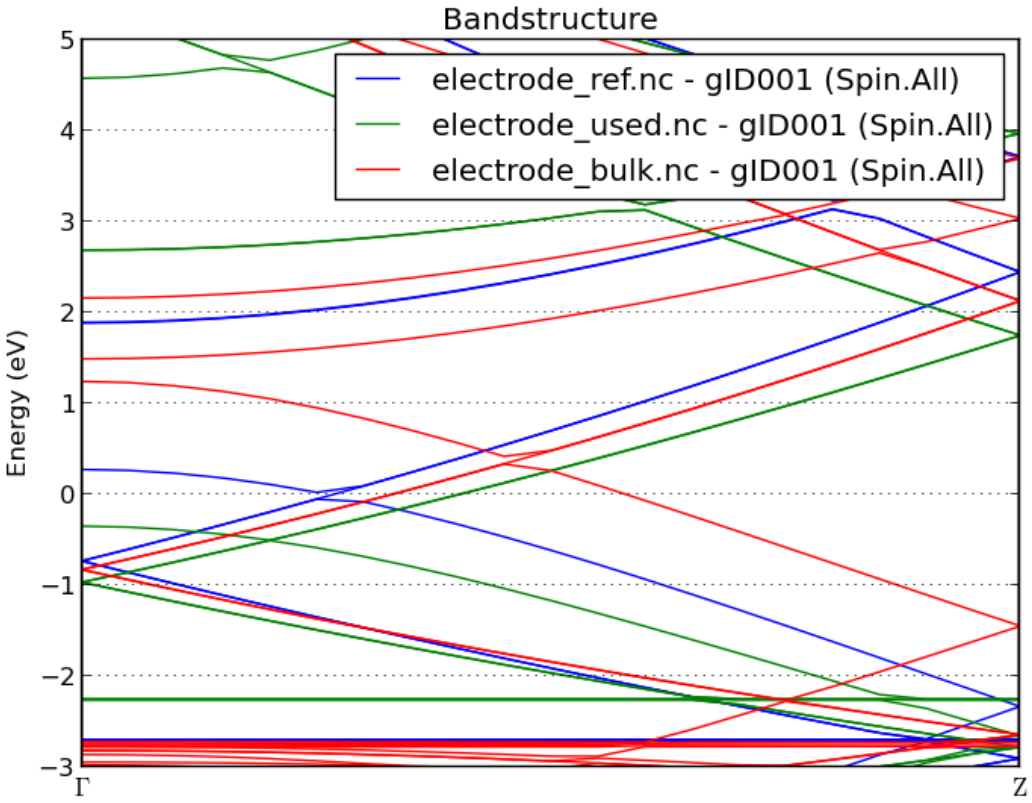
`spectral_current.py` along with the calculated ideality factor from `IV-n-log.py` and the estimated Schottky barrier at zero bias, Φ^{pot}, from `pldos_hdp.py`.



The plot shows that the estimated AE Schottky barrier (squares) lies below the thermionic emission barrier (triangles) for each bias point. This is because the AE method neglects contributions from tunneling and thereby implicitly assumes that the maximum spectral current (circles) will occur at the energy of the barrier height. Furthermore, we see that the analytical bias dependence of the thermionic emission barrier (dashed line) is in good agreement with the calculated barrier heights (triangles).

Note on the variation of the current

The calculated current is two orders of magnitude lower than the current reported in the publication[Page 843, 1]. This is due to the use of two slightly different Ag electrodes: The silver electrode used in the article was not relaxed after matching the two surfaces at the interface – that electrode is therefore compressed as compared to the Ag electrode used in this case study. This has an impact on the electronic structure of the electrode, which can be shown by comparing the electrode bandstructures:



In the figure above, electrode_ref.nc is the electrode used in the article, while electrode_used.nc denotes the electrode used here, and electrode_bulk.nc is a completely unstrained silver electrode. Comparing the first two, we see that the elongation of the electrode generally results in lower energy levels. The electrode used in this case study has fewer k-points (and thereby states) available in the bias window, which results in smaller transmission and thereby a lower current. However, if we compare the first two bandstructures to that of unstrained silver, we see that the main features around the Fermi level are preserved with both the electrode used here and the one used in the publication.

Transport calculations with QuantumATK

The bulk resistivity is an intrinsic property quantifying how strongly a material disrupts a flux of electronic current. In pristine metals, the main cause of the resistivity at room temperature is electron-phonon interaction, i.e., electron scattering due to the interaction with the vibrations of the lattice. The higher the temperature, the larger becomes the

vibrational amplitude of the lattice and hence the scattering probability, leading to linear increase of the resisitivity to the temperature.

This case study aims at introducing the **MD-Landauer** method, which is a conceptually simple methodology for calculating the temperature-dependent resistivity based on combined molecular-dynamics (MD) and electronic-transport calculations within the framework of the Landauer formalism (check the tutorial *Transport calculations with QuantumATK*). Despite its simplicity, the MD-Landauer method has several advantages over other more rigorous methods to calculate bulk resistivities (see, e.g., Refs.[1] and[2], and also the tutorial *Phonon-limited mobility in graphene using the Boltzmann transport equation*), as it takes naturally into account the anharmonic effects in describing lattice vibrations, and is applicable to non-crystalline systems as well.

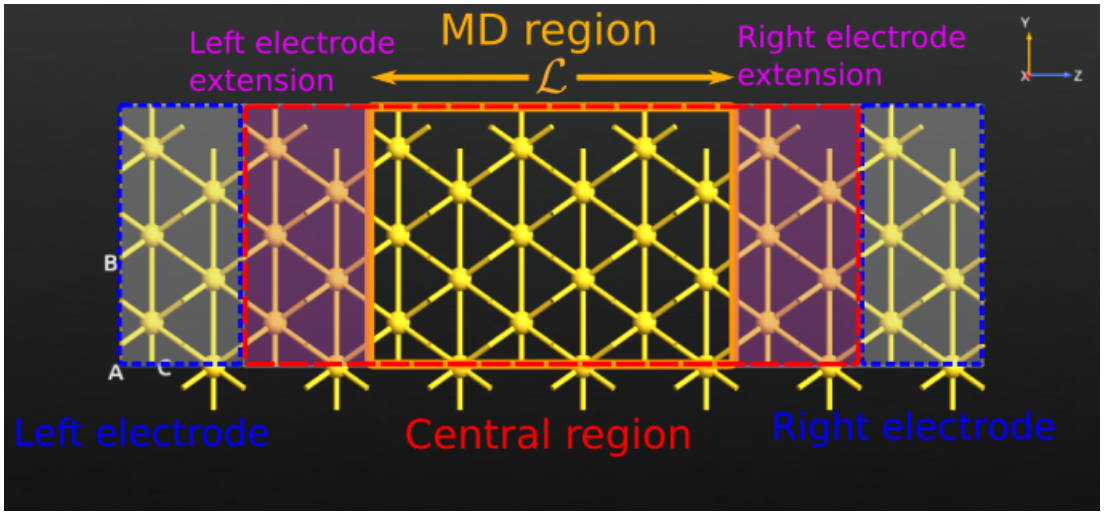
The case study consists of three sections, through which we reproduce some results for bulk gold recently reported in the paper *Electron-phonon scattering from Greens function transport combined with Molecular Dynamics: Applications to mobility predictions*[3]. Section *1. Theory and numerical procedure* provides some theoretical and methodological details. Section *2. Calculation setup* then describes how to setup an MD-Landauer calculation in **QuantumATK**. Finally, Sec. *3. Data analysis* is devoted to explaining how to analyze the data files and compute the resistivity.

Note: The numerical parameters employed in the calculations below have been tuned to achieve a compromise between computational efficiency and accuracy. The results will hence slightly differ from those presented in Ref.[Page 862, 3].

Note: QuantumWise case studies are primarily directed at experienced users of QuantumATK. Instructions are deliberately concise in order to focus mostly on the science.

---

1. Theory and numerical procedure



The figure above displays an illustrative example of a device configuration modeling bulk gold, for which the MD-Landauer calculations are performed. There are two semi-infinite electrodes and, in between, a **central region** which, importantly, consists of three parts: the **MD region** with length $\mathcal{L}$ and the **electrode copy** on its either side. An

incoming flux of electrons from one of the electrodes interacts with phonons in the MD region, and is transmitted with a certain probability to the other electrode. Assuming that the electrodes and their replicas always remain equilibrium at temperature T, MD calculations are performed by allowing the atoms to move only in the MD region for a few nanoseconds, starting with random initial velocities based on the Maxwell-Boltzmann distribution. At the end of each MD calculations, the transmission coefficient is computed as

$$T[E;\mathbf{x}(T),\mathcal{L}] = \mathrm{Tr}\big\{G^{\mathrm{r}}[E;\mathbf{x}(T),\mathcal{L}]\Gamma_{\mathrm{L}}(E)G^{\mathrm{a}}[E;\mathbf{x}(T),\mathcal{L}]\Gamma_{\mathrm{R}}(E)\big\},$$

where $G^{\mathrm{r/a[E;\mathbf{x}(T),\mathcal{L}]}}$ represents the retarded/advanced Greens function, and $\Gamma_{\mathrm{L/R}}(E)$ is the width in the left/right electrode (see, e.g., Ref.[4] for details of the derivation). Note that the Greens functions and thus the transmission coefficient are both functions of E and parametrically depend on the set of displacement coordinates of atoms $\mathbf{x}(T)$ as well as $\mathcal{L}$. The Landauer formula then provides the conductance as a function of $\mathcal{L}$ and T:

$$G(\mathcal{L},T) = \frac{2e^2}{h}\int \langle T[E;\mathbf{x}(T),\mathcal{L}]\rangle \left[-\frac{\partial n_{\mathrm{F}}(E,\epsilon_{\mathrm{F}},T)}{\partial E}\right] dE,$$

where $n_{\mathrm{F}}(E,\epsilon_{\mathrm{F}},T)$ represents the Fermi-Dirac distribution function with ϵ_{F} being the Fermi energy, and $\langle\cdots\rangle$ means taking average over a set of MD calculations. The resistance is defined as the inverse of the conductance, i.e.,

$$\begin{aligned} 1/G(\mathcal{L},T) &= \\ R(\mathcal{L},T) &\\ &\equiv \\ R_{\mathrm{c}} + \rho_{\mathrm{1D}}(T)\mathcal{L}, & \end{aligned}$$

where the second line defines the one-dimensional (1D) resistivity $\rho_{\mathrm{1D}}(T)$. The bulk resitivity is then given by

$$\rho_{\mathrm{bulk}}(T) = \rho_{\mathrm{1D}}(T)\cdot A,$$

where A is the cross section of the device normal to the transport direction.

Dividing the procedure into three steps as follows will help clarify how to compute the 1D and bulk resistivies:

- **Calculation of the lattice geometries:**
For a given value of T and a set of values of $\mathcal{L}$, several MD calculations with random initial velocities are performed. For each calculation, the last snapshot of the MD run is taken.

- **Calculation of the resistance:**
For each set of snapshots with a given length $\mathcal{L}$, the averaged transmission coefficient is computed, which is then used to calculate the conductance $G(\mathcal{L},T)$ and the resistance $R(\mathcal{L},T)$.

- **Calculation of the finite-temperature resistivity:**
The 1D and bulk resistivities at the temperature T are calculated.

The rest of this case study details each step as well as the procedure to construct a device configuration of bulk gold.

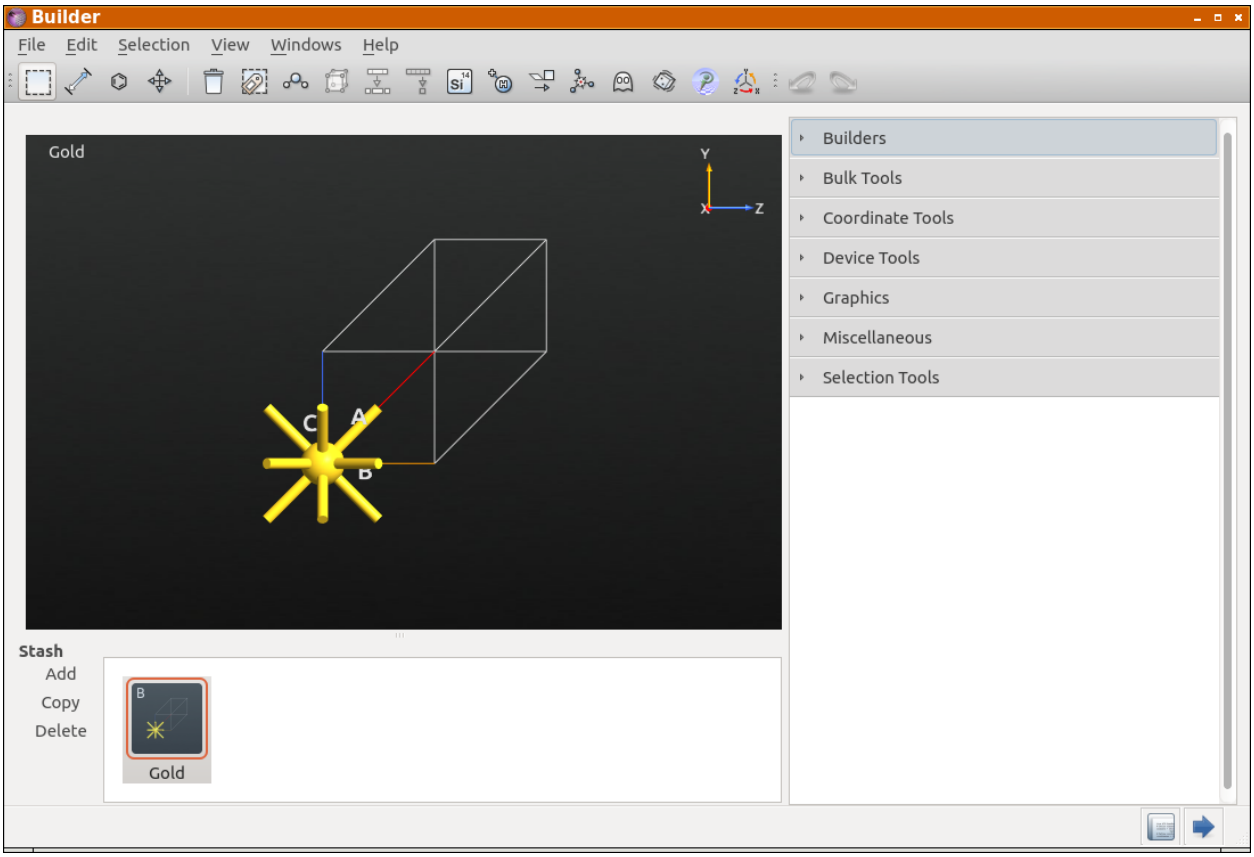
2. Calculation setup

2.1. Construction of the DeviceConfiguration

Tip: This subsection presents a detailed how-to guidline for preparing a device configuation of bulk gold, and finally provides an QuantumATK Python script, `Au100_L3.py`. To save time, one may just download the script and use it.

In the **Builder**, go to *Add* → *From Database* and select *Gold*:

[4] S.ăDatta. *Electronic Transport in Mesoscopic Systems*. Cambridge University Press, 1997. ISBN 0521599431. Cambridge Studies in Semiconductor Physics and Microelectronic Engineering.



Then use the *Builders* → *Surface (Cleave)* tool as follows to create a 3x3 Au[100] bulk supercell with a thickness of 10 layers:

1. Create a [100] surface by setting h=0 and k=l=0.
2. Define the surface lattice vectors by $\mathbf{v}_1 = 3\mathbf{u}_1$ and $\mathbf{v}_2 = 3\mathbf{u}_2$.
3. Select *Periodic and normal (electrode)* and set the thickness to 10 layers.

Finally, use the *Device Tools* → *Device from Bulk* plugin to create a DeviceConfiguration. Set the length of both right and left electrodes to be the minimum value 4.07825 Å.

Save the device configuration as *Au100_L3.py*, where *L3* indicates $\mathcal{L} = 3$ in terms of the number of electrode repetitions. Following a similar procedure, one will be able to easily construct the device configurations for $\mathcal{L} = 4$ and 5, and save them with proper file names.

2.2. Setup of the script

Send the device configuration to **Scripter** by clicking , and add four blocks in the order as follows:

- *New Calculator*
- *Optimization* → *MolecularDynamics*
- *New Calculator*

Note: The choice of the *Krylov* method is of particular importance as it accelerates the convergence in the SCF calculations.

2.3. Edit the python script

Making fully use of GUI supported by **QuantumATK**, the device configuration has been so far constructed with the necessary calculators and analyzer attached. The MD-Landauer method for computing the conductance, resistance, and resistivity, however, requires performing the calculation, for each of given values of $\mathcal{L}$ and T, several times to obtain averaged transmission coefficient $\langle T[E;\mathbf{x}(T),\mathcal{L}]\rangle$. To this end, the python script needs to be slightly modified by hand.

By clicking the icon, send the script to **Editor**. Highlight the whole script and press the `Tab` key on your keyboard to indent every line. Then edit the script as shown below, and save it as *Au100_L3_T300.py* To make sure that there is no mistake in your code, download `Au100_L3_T300.py` and compare the two scripts.

```
# -*- coding: utf-8 -*-

for run in range(0,10):

    # ------------------------------------------------------------
    # Two-probe Configuration
    # ------------------------------------------------------------

    # ------------------------------------------------------------
    # Left Electrode
    # ------------------------------------------------------------

    # Set up lattice
    vector_a = [8.65127469112, 0.0, 0.0]*Angstrom
    vector_b = [0.0, 8.65127469112, 0.0]*Angstrom
    vector_c = [0.0, 0.0, 4.07825]*Angstrom
    left_electrode_lattice = UnitCell(vector_a, vector_b, vector_c)
```

Note: Since the MD and Landauer sections are all placed under a loop, this script evaluates the transmission coefficient 10 times starting with different values of initial velocity, and saves each result with a unique ID number (gIDxxx) attached.

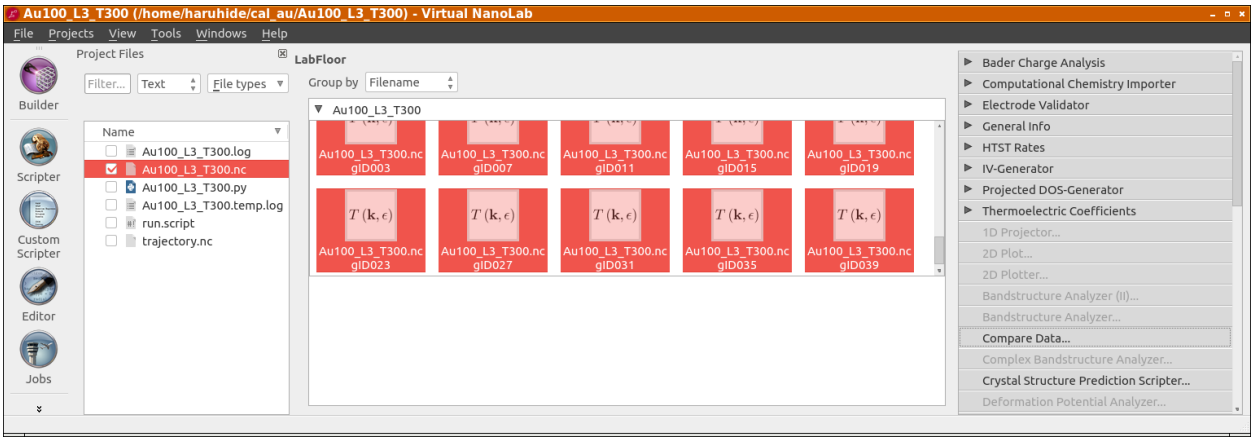
Note: Following exactly the same procedure except employing different values of $\mathcal{L}$, e.g., $\mathcal{L} = 4$ and 5, one can easily prepare the scripts for systematic implementation of the MD-Landauer calculations at T =300 K. To save time, one may download `Au100_L4_T300.py` and `Au100_L5_T300.py`, and use them.

3. Data analysis

Click the icon, send the script to **Job Manager**, and run it. The calculation takes 5-6 hours on 8 cores. The set of transmission coefficients should then be averaged for the analysis. This section hence focuses on how to analyze the results and obtain the 1D and bulk resistivities.

3.1. Transmission functions, conductance, and resistance

QuantumATK provides a useful plugin to make comparison of the transmission functions. Select all the transmission functions $T(\mathbf{k}, \epsilon)$ in **LabFloor** and click the `Compare Data...` button in **Plugin Bar**.



A window will pup up and display all the transmission functions $\{T[E; \mathbf{x}(T), \mathcal{L}]\}_{\mathbf{x}(T)}$ for $T = 300$ K and $\mathcal{L} = 3$.

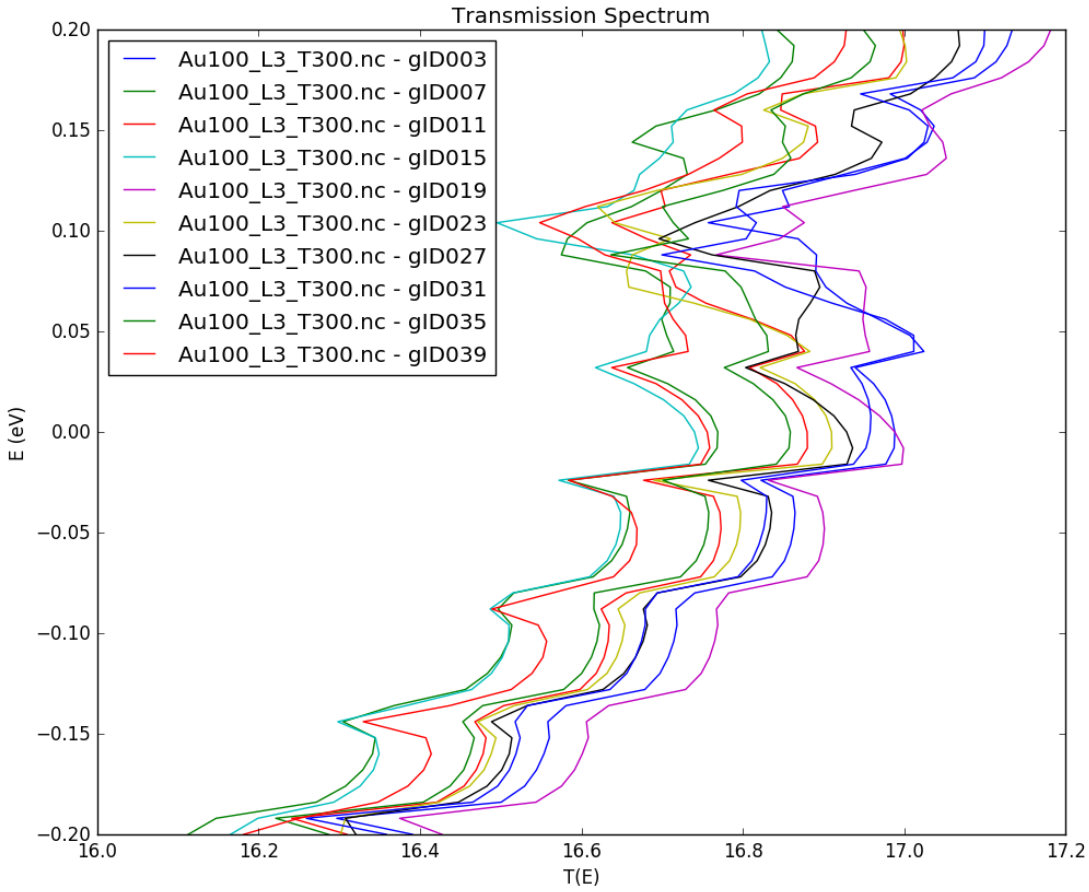
To compute the average of them, download the script `analysis.py` and run it as `atkpython analysis.py` in the same directory of the nc. The analysis will finish in a few seconds, and provide a list of information about the length of the MD-region, and the averaged conductance and resistance:

There also appears a pup-up window, in which black lines show the transmission coefficients as before, and a thick red line represents their average $\langle T[E; \mathbf{x}(T), \mathcal{L}] \rangle$.

3.2. Resistivity

To compute the resistance at $T = 300$ K also for $\mathcal{L} = 0$, 4, and 5, download the scripts `Au100_L0_T0.py`, `Au100_L4_T300.py`, and `Au100_L5_T300.py`. Run them as `atkpython Au100_Lx_Txxx.py`, and analyze the results. One will then obtain a list of resistances, indicating the linear dependence of the resistance on $\mathcal{L}$:

Length of the MD-region, $\mathcal{L}$		Resistance
(# of electrode repetitions)	(Å)	()
0	0	1482.9
3	12.235	1535.1
4	16.313	1555.2
5	20.391	1571.9



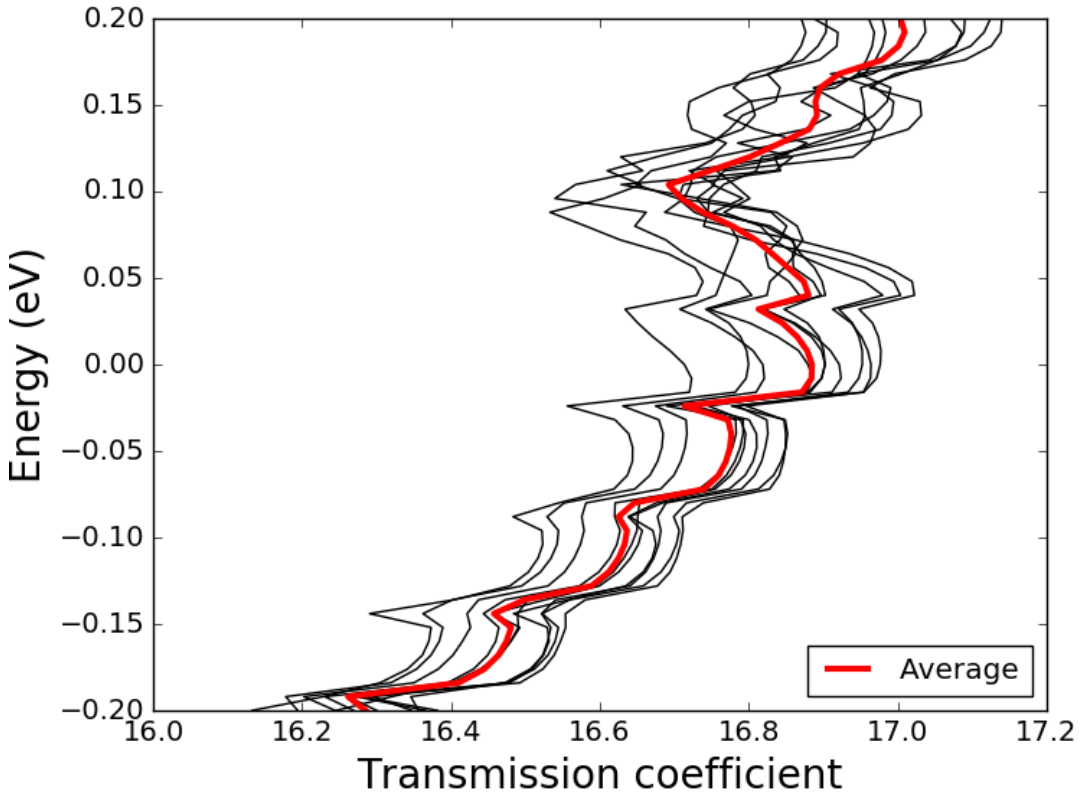
```
LXTerminal
File  Edit  Tabs  Help
Calculating Kinetic Matrix : ================================================

+-------------------------------------------------------------------------+
| MD-Landauer Reprot                                                      |
+-------------------------------------------------------------------------+
| Lenght of the MD region = 12.23475 Ang
| Averaged conductance    = 0.000651443815697 Siemens
| Averaged resistance     = 1535.05179711 Ohm
+-------------------------------------------------------------------------+

Timing:                          Total     Per Step       %

-------------------------------------------------------------------------------

File IO, nlread          :       1.16 s       0.10 s      25.39% |=============|
Loading Modules + MPI    :       1.07 s       1.07 s      23.29% |============|
-------------------------------------------------------------------------------
Total                    :       4.59 s
```



Note: The resistance for $\mathcal{L} = 0$ is computed using the script `Au100_L0_T0.py`, which implements no MD calculation, and because of it, is hence named with *T0*. This script aims at evaluating the contact resistance.

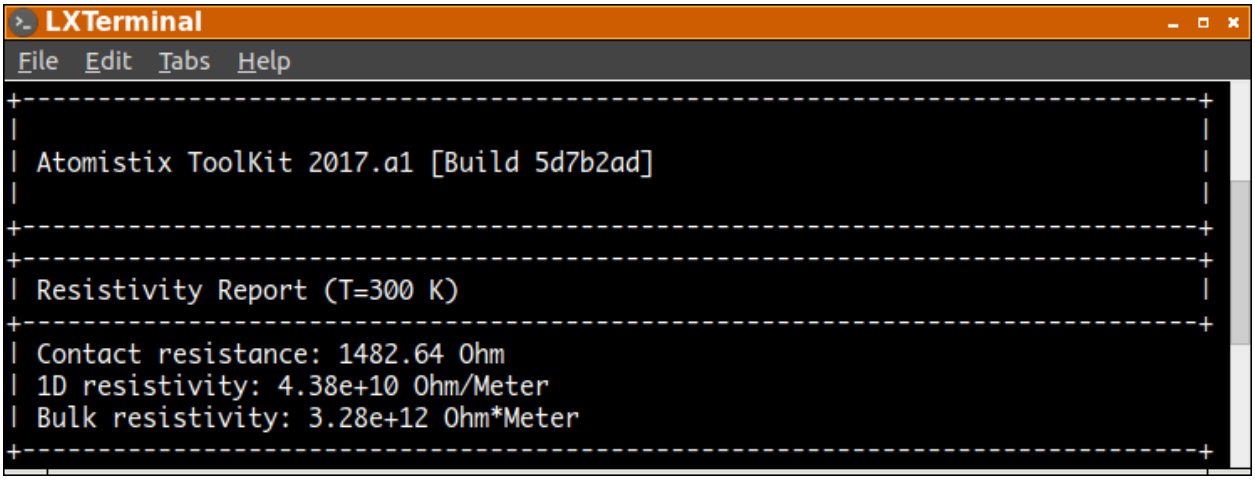
Let us then compute the 1D and bulk resistivities, which requires the value of the cross section. Noting the primitive vectors defined in lines 14 and 15 of *Au100_L3_T300.py*, i.e.,

```
14     vector_a = [8.65127469112, 0.0, 0.0]*Angstrom
15     vector_b = [0.0, 8.65127469112, 0.0]*Angstrom
```

the cross section, in this case, is given by $A = \|$vector_a $\|$Œ $\|$vector_b $\|$= 74.84 Å ^{2}. Using this value, and also the values of $\mathcal{L}$ and resistance listed in the table above, one can evaluate the 1D and bulk resistivities at $T = 300$ K. To this end, download `resistivity.py`, and, after entering the values in the table into the **INPUT SECTION** of the script, run it as `atkpython resistivity.py`.

```
6  #-----------------------------------------------------------------------#
7  #                         INPUT SECTION                                 |
8  #-----------------------------------------------------------------------#
9  cs_area = 8.65127469112**2
10 lengths_list = [0,12.235,16.313,20.391]
11 resistances_list = [1482.9,1535.1,1555.2,1571.90]
12 output_filename = 'resistivity.png'
```

The script interpolates the data points by means of the least squares method and provides the values of the contact resistance, as well as the 1D and bulk resistivities at $T = 300$ K:



LXTerminal

3.4.10 Electron transport calculations with electron-phonon coupling included via the special thermal displacement method - STD-Landauer

Version: 2017.1

Downloads & Links

Silicon device Inelastic current in a silicon p-n junction Transport calculations with QuantumATK SpecialThermalDisplacement ATK Reference Manual

Phonons have a large influence on the electronic transport properties of semiconductors, but most methods for modeling them are computationally very expensive. In a recent paper; *First-Principles Electron Transport with Phonon Coupling: Large-Scale at Low Cost*[1], Gunst et al. proposed a new method, which is computationally equivalent to traditional 0 K calculations. We call this method **STD-Landauer**. In this case study, we will go through the calculations required to produce one of the figures in the paper, explaining how QuantumATK was used to create this research.

[7] D.ăR. Lide. *Handbook of Chemistry and Physics*. New York: CRC Press, 75th edition, 1997.

[1] Tue Gunst, Troels Markussen, Mattias L.ăN. Palsgaard, Kurt Stokbro, and Mads Brandbyge. First-principles electron transport with phonon coupling: Large scale at low cost. *Phys. Rev. B*, 96(16):161404, oct 2017. arXiv:1706.09290, doi:10.1103/PhysRevB.96.161404.

Specifically, we will re-create figure 2c in the paper[1]. This figure shows the IV characteristics of the short silicon p-n junction, comparing the current with no electron-phonon coupling included, and two different methods for including it. It shows how the electron-phonon coupling effects are very important to include for a correct description of the reverse current.

We will compare the new **STD-Landauer** method to the more well-established Lowest Order Expansion (**LOE**) method, and show that the STD-Landauer can achieve comparable accuracy at much lower computational cost in both time and memory.

Note: QuantumWise case studies are primarily directed at experienced users of QuantumATK. Instructions are deliberately concise in order to focus mostly on the scientific content.

Building the device

We will here use a simple silicon p-n junction, and the workflow for building it is already explained in detail in a tutorial: *Silicon device*. If you do not know how to build such a device, you may go through the steps in the tutorial, applying the modifications mentioned below.

Finding the lattice constant of silicon

As is done in the paper, we will model the structural properties, including phonons, with a classical force field. This means that we first need to find the lattice constant for silicon with the *StillingerWeber_Si_1985* force field. Do a geometry optimization with the following criteria for the forces and stress:

```
max_forces=0.001*eV/Ang,
max_stress=0.01*GPa,
```

This will result in a lattice constant of 5.430952 Å, very close to the database value of 5.4306 Å. Use this optimized bulk configuration as the basis for the following.

Building the pristine device

In this case we go with a device which is actually too short, compared to the screening length at the chosen doping level. However, this choice was made in the paper to allow running of the heavy LOE calculations later on. You should therefore choose 24 layers instead of 52, as specified in the tutorial. You can use the same approach for doping, or alternately you can use the doping widget as described in this tutorial: *NiSi2–Si interface*. However, note that the doping should be n-type on the left and p-type on the right.

Tip: For more details on the implementation of doping in QuantumATK, please consult this note: *Doping methods available in QuantumATK*

Applying the special thermal displacement to the atomic positions

Having built the doped pristine device, we now need to apply the thermal displacements to build the device for calculations with the atomic positions at 300 K. This means that we first need to compute the dynamical matrix, which is independent of the temperature and is used to compute the relevant phonon modes. Afterwards, they are weighted using to the procedure of Zacharias and Giustino[2] and the atoms are displaced accordingly. Use the pristine device, again with the *StillingerWeber_Si_1985* forcefield, and calculate the dynamical matrix. You may follow the procedure in this tutorial: *Inelastic current in a silicon p-n junction*, except for these changes:

•Insert an optimize geometry block with a force tolerance of *0.0001 eV/Ang*

•For the Dynamical matrix, change repetitions to *custom* and *3x3*.

Run the script in a folder called `dyn-mat` to calculate the dynamical matrix; it should take no more than a few minutes. You may also download it here: `dyn-mat.py`. Finally, create the device configuration at 300 K using a simple QuantumATK Python script: `build_std_conf.py`. Note that the QuantumATK method is called `SpecialThermalDisplacement` and you may find the manual page here: *SpecialThermalDisplacement*.

```
# -*- coding: utf-8 -*-
filename = 'device-pristine.hdf5'
filename_dynmat = 'ff-device-si.hdf5'
filesave = 'device-std-300K.hdf5'
device_configuration = nlread(filename, DeviceConfiguration)[-1]
dynamical_matrix = nlread(filename_dynmat,DynamicalMatrix)[-1]
T = 300

device_configuration_STD = SpecialThermalDisplacement(device_configuration, dynamical_
↪matrix=dynamical_matrix, temperature=T*Kelvin)
device_configuration_STD.update()
nlsave(filesave,device_configuration_STD)
```

Run it, and you will have both the pristine and thermally displaced configurations ready for the actual calculations. You may also download the pristine configuration as a script: `device_pristine.py` or an .hdf5 file: `device_pristine.hdf5`. You may also download the thermally displaced configuration here as a script: `device_std.py` or an .hdf5 file: `device_std.hdf5`.

Tip: As you can see here, applying the STD method is very simple, and for the actual calculations, we will not not do it in a separate script.

Calculations

There are several ways in which one may approach these calculations, but here we first do the calculations for zero temperature and bias, and then we use those results as basis for the phonon-including calculations at 300 K, using the special thermal displacement (STD) method, and for finite bias in both cases.

Note:

•Be aware that most of the calculations are impractical to perform on a personal computer and requires some sort of dedicated computational server/supercomputer.

[2] Marios Zacharias and Feliciano Giustino. One-shot calculation of temperature-dependent optical spectra and phonon-induced band-gap renormalization. *Phys. Rev. B*, 94:075125, Aug 2016. doi:10.1103/PhysRevB.94.075125.

•The calculations will generate a lot of files, so we recommend that each type of calculation is done in a separate sub-folder. We provide the names we used and which are assumed in the scripts, but you may of course choose other names and then modify the subsequent scripts accordingly.

Calculations at 0 K and zero bias

First we calculate the PLDOS for the np-junction at zero temperature and bias. Do these calculations in a folder named `0K-zero-bias`. Take the relaxed structure from before, and attach a DeviceLCAOCalculator to it, with the following parameters:

•*k-point sampling:* 9 x 9 x 101.

•*Broadening:* 300 K.

•*Exchange-correlation functional:* LDA.PW.

•*Basis set:* SingleZetaPolarized.

•*Density mesh cutoff:* 75 Hartree

•*Poisson solver:* [Parallel] Conjugate Gradient.

•*Iteration control parameters:*

–Maximum steps: 1000

–Tolerance: 0.0000001

–Number of history steps: 10

Add a **ProjectedLocalDensityOfStates** analysis object, with these parameters.

•*Energy interval:* -1 to 1 eV.

•*Method:* Device DOS.

•*k-point sampling:* 21 x 21.

Finally, you need to make a few manual changes to the *device_iteration_control_parameters* of the full device calculation:

•Remove *tolerance=1e-07,*

•Add *damping_factor=0.01,*

You can also download the script here: `0K-zero-bias.py` Run the script, which should take about 20 minutes on a modern laptop.

Calculations at 300 K and zero bias

For the calculations with the STD configuration, we can do things a little simpler, to ensure that we use the same parameters for the calculator. Do these calculations in a folder named `300K-zero-bias`. Make a copy of the previous script and delete everything related to the structure and calculator, leaving only the PLDOS block. Replace the deleted part with this:

```
# -*- coding: utf-8 -*-
# ------------------------------------------------------------
# Two-probe Configuration
# ------------------------------------------------------------
```

(continues on next page)

(continued from previous page)

```
filename = '../0K-zero-bias.py/0K-zero-bias.py.hdf5'
filename_dynmat = '../dyn-mat/ff-device-si.hdf5'
filesave = '300K-zero-bias.py.hdf5'
device_configuration = nlread(filename, DeviceConfiguration)[-1]
dynamical_matrix = nlread(filename_dynmat,DynamicalMatrix)[-1]
T = 300

device_configuration_STD = SpecialThermalDisplacement(device_configuration, dynamical_
↪matrix=dynamical_matrix, temperature=T*Kelvin)
device_configuration_STD.update()
nlsave(filesave,device_configuration_STD)
```

This will read in the previously calculated Dynamical matrix as well as the configuration, including calculator, from the 0 K and zero bias calculation, and create a new configuration with the thermally displaced atoms and the same calculator as for 0 K. You may download the full script here: `300K-zero-bias.py`

Calculations at finite bias

In this case study, we will first do the self-consistent part of the finite bias calculations, and then afterwards calculate the transmissions. We do this because convergence for the 300 K structure can be a little tricky, and it is easier to fine-tune the convergence for difficult bias-points when doing it in this way.

Tip: In QuantumATK we have implemented an object called *IVCurve*, which automatically calculates the transmission at specified bias values. This is very useful for relatively simple systems and not too high bias values, where there are no problems with the convergence of the SCF loop. In this case, the calculations with the thermally displaced device are more difficult to converge, so we will not use the IVCurve object. For more information on how to use it, see *Transport calculations with QuantumATK*.

The script itself is actually fairly simple, as it simply reads in the zero bias calculation to use as a starting point, and then keeps re-using the previous bias-point as an initial state for the next one. Here we show the script for the un-displaced configuration:

```
# Set bias
# Positive: Reverse and Negative: Forward

pos_bias_list = [0.10, 0.20, 0.30, 0.40, 0.50, 0.55, 0.60, 0.70]*Volt
neg_bias_list = [-0.10, -0.20, -0.30, -0.40, -0.50, -0.60]*Volt

# Read DeviceConfiguration
zero_bias_file = '../0K-zero-bias/0K-zero-bias.py.hdf5'
device_configuration = nlread(zero_bias_file, DeviceConfiguration)[-1]

for bias in pos_bias_list:
    if processIsMaster():
        print "Bias is now: ", bias
    # Get the calculator
    calculator = device_configuration.calculator()

    # Set the bias voltage
    calculator=calculator(electrode_voltages=(bias/2, -bias/2))
```

(continues on next page)

(continued from previous page)

```
    # Attach the calculator and use the old initial state
    device_configuration.setCalculator(
      calculator(),
      initial_state=device_configuration)
    device_configuration.update()
    nlsave('device_bias_%.2f.hdf5' % bias.inUnitsOf(Volt), device_configuration)

# Read DeviceConfiguration
device_configuration = nlread(zero_bias_file, DeviceConfiguration)[-1]

for bias in neg_bias_list:
    if processIsMaster():
        print "Bias is now: ", bias
    # Get the calculator
    calculator = device_configuration.calculator()

    # Set the bias voltage
    calculator=calculator(electrode_voltages=(bias/2, -bias/2))

    # Attach the calculator and use the old initial state
    device_configuration.setCalculator(
      calculator(),
      initial_state=device_configuration)
    device_configuration.update()
    nlsave('device_bias_%.2f.hdf5' % bias.inUnitsOf(Volt), device_configuration)
```

Run these 2 scripts, in folders named `0K-iv` and `300K-iv` respectively. The titles should be self-explanatory:

- `0K-iv-scf.py`
- `300K-iv-scf.py`

They should each take a couple of hours on a 16-core node. Afterwards, we want to calculate the transmissions for each of the configurations and the PLDOS for the most extreme bias points. The first is essentially a loop over the previously calculated files, using the same settings for the Transmission Spectrum as before. This should take a couple of hours on a 16-core node. The PLDOS scripts read in the converged calculation and calculates the PLDOS. They should each take 10-20 minutes using 4 MPI processes on a laptop.

- `0K-iv-transmission.py`
- `300K-iv-transmission.py`
- `pldos-0K-forward.py`
- `pldos-0K-backward.py`
- `pldos-300K-forward.py`
- `pldos-300K-backward.py`

Lowest Order Expansion (LOE) Calculations

Finally, we also need to make the LOE calculations, which takes the inelastic contributions into account through an approximation of the full electron-phonon coupling matrix. This approximation is valid when the Density of States (DOS) varies slowly around the Fermi level. For this, we need to calculate the Hamiltonian Derivatives, which is a fairly heavy calculation. We therefore sample the electronic Brillouin zone in the Γ point only. This is a good approximation in this case, as tunneling is the dominant effect and is in turn dominated by transmission at Γ. Note that this reduces the computational time by a factor of 9 compared to using the same k-point density as in the STD calculations.

Afterwards, we calculate the actual electron-phonon couplings, a calculation which can in general be very time-consuming, due to the many possible combinations of k- and q-points.

Tip: For more information on how to calculate the full electron-phonon coupling, see f.ex. the tutorial: *Phonon-limited mobility in graphene using the Boltzmann transport equation*.

We need to set up a calculator similar to before, with only the k-point sampling changed, followed by a calculation of the Hamiltonian derivatives. Do these calculations in a folder named `loe`. You can use a script similar to before, where you read in the calculator and modify it, or set everything up from scratch in a new script. Here we have chosen to read in the configuration from an existing file, but setting up the calculator anew. The Hamiltonian derivatives should look like this:

```
# ------------------------------------------------------------
# Hamiltonian Derivatives
# ------------------------------------------------------------
hamiltonian_derivatives = HamiltonianDerivatives(
    configuration=device_configuration,
    repetitions=(3, 3, 1),
    atomic_displacement=0.01*Angstrom,
    constraints=[0,1,2,3,44,45,46,47],
    use_equivalent_bulk=False,
    )
nlsave(filesave, hamiltonian_derivatives)
```

You may download the script here: `ham-der.py`. Ensure it points at the right files and run it. In our case, it took about 5 hours on a total of 48 cores with 1 TB of total memory.

Afterwards, we need to run the actual LOE calculations. We use only 1 q-point, in accordance with the paper, which is a good approximation in this case, as the tunneling is also dominated by the Γ-point in the phonon Brillouin zone. This also gives a more direct comparison with the STD method. If the goal is to get as accurate LOE calculations as possible, the number of q-points sampled, should always be converged for the system of interest. You may download the script here: `loe.py`. Make sure it points at the right files, and run it. This should take no more than a few minutes on a laptop.

Tip: For more information on the different parameters of the inelastic transmission spectrum or further discussion of the k- and q-dependence of the transmission in this system, you may consult this tutorial: *Inelastic current in a silicon p-n junction*.

Computational timings

The main advantage of the STD method over the LOE method is computational efficiency, and we will therefore present the timings in a more systematic way. In the table, we show the timings for the full IV curve for each method, normalized to the total number of core-hours on equivalent machines.

Table 3.2: Computational timings in core-hours

	Noninteracting	STD	LOE
Time spent on IV Curve:	28 h	129 h	468 h

We see here that the STD method takes longer than the noninteracting calculation, which is mostly due to convergence being more difficult. In this case study, we have chosen a conservative approach which improves convergence, but at the expense of longer calculations. It is probably possible to find other settings which also converge, and use less time. With the parameters we have chosen for the LOE calculation, almost all the time is spent on calculating the Hamiltonian derivatives, and very little is spent on computing the actual electron-phonon interactions afterwards. However, this is in general not true, and the LOE part itself increases very quickly with the number of k- and q-points included. Additionally, as noted above, we have reduced the calculation time for the hamiltonian derivatives by a factor of 9 by reducing the k-point sampling to just the Γ-point.

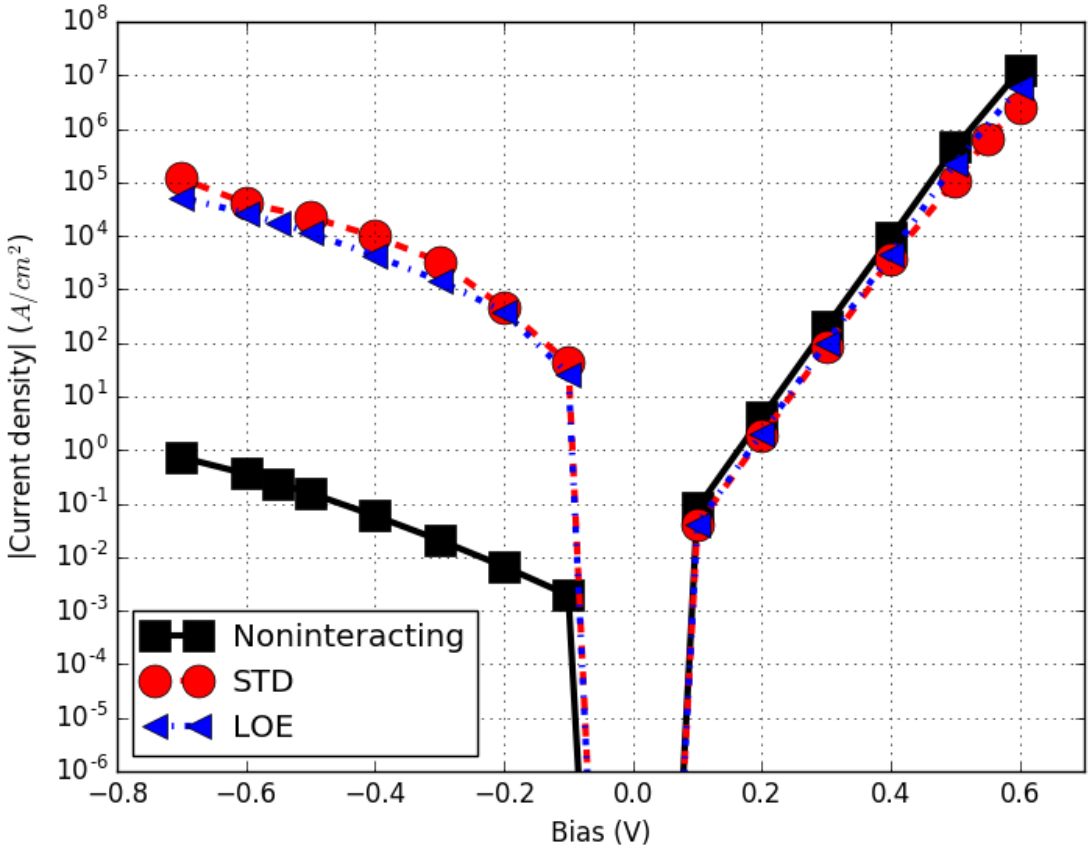
Note: Note that the Hamiltonian derivatives were computed on special nodes with extra memory, which is an added complication of such demanding calculations.

Analysis and discussion

We have now calculated the current as a function of bias using three methods:

- **Noninteracting**: uses a pristine configuration and does not incorporate phonons in any way.
- **SpecialThermalDisplacement (STD)**: Uses a single thermally displaced configuration to account for phonons. This is a new method introduced in the paper this case study is based on.
- *Perturbation Theory (PT)* using the **Lowest Order Expansion (LOE)**: Approximate approach to include the full electron-phonon contribution to the current.

The main point of these calculations is to show that the STD method is as accurate as the LOE method, in this case, but at a much lower computational cost, as there is no need to compute the very expensive dH/dR matrix. We will now plot our data and see how they compare. Download this plotting script, make sure it points at the right files and run it: `plot-iv.py`. You should get a plot looking like this:



We see how inclusion of the electron-phonon coupling (EPC) drastically increases the reverse current. We also see that both the STD and LOE approaches show this increase, and are in clear agreement about the effect and importance of the electron-phonon coupling. Note that for the longer device, which is also treated in the paper[Page 876, 1], the results are also in good agreement with experiments. The increase in current reduces the $I_{\mathrm{ON}}/I_{\mathrm{OFF}}$ figure-of-merit to be on the order of 1 when going below a bias of ± 0.5 V. This means that the current will be essentially the same for both forwards and backwards bias, and the device no longer acts as a diode at low bias. See the table for details:

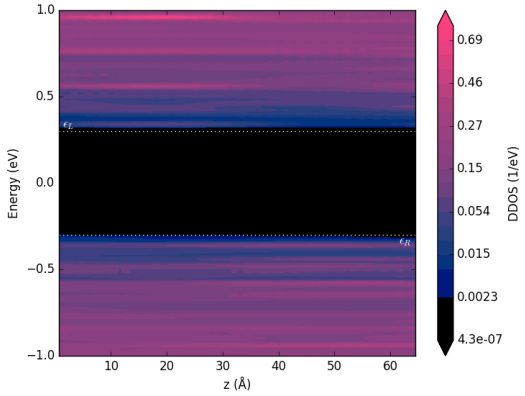
Table 3.3: $I_{\mathrm{ON}}/I_{\mathrm{OFF}}$ figure-of-merit.

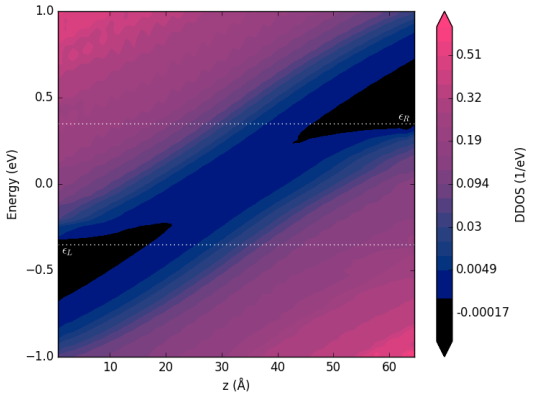
Bias [V]	Noninteracting	STD	LOE
± 0.5	$8 \cdot 10^6$	5	20
± 0.6	$7 \cdot 10^7$	58	200

Note: The $I_{\mathrm{ON}}/I_{\mathrm{OFF}}$ figure-of-merit is a basic property of diodes and describes how effective the diode is at suppressing current at reverse bias. Specifically, it is the current under forward bias divided by the absolute value of the current under a reverse bias of equal magnitude. So if it is 10 at 0.5 V, it means that the current at 0.5 V forward bias is 10 times larger than the reverse current under a reverse bias of -0.5 V.

In order to understand why phonons are very important under reverse bias, and negligible under forward bias, we need to consider the two cases in more detail. Specifically, the mechanism of transport differs between forward and reverse bias. Under forward bias, the bands are essentially flat and carriers can pass unhindered from one electrode to the other. Under reverse bias, there are no states around the Fermi level in the central region and carriers can only travel between

the electrodes by tunneling. This can also be seen from a comparison of the PLDOS at forward and reverse bias, see figures below. We show the PLDOS without electron-phonon coupling included, to make the features more clear. The left/right PLDOS is at forward/reverse bias.





To a first approximation, the band-to-band tunneling probability decreases when $|k|$ increases, and increases when the carrier energy increases. Therefore, the tunneling probability will be higher if the carrier can increase its energy without increasing the momentum. This leads us to the role of phonons. This explains why we can use just the Γ-point for both k- and q-points, as the interaction gives maximum tunneling probability there. The fact that the transmission peaks at the Γ-point, is shown in more detail in the tutorial: *Inelastic current in a silicon p-n junction*.

The STD method compared to the LOE method

In this case study, we have used two quite different methods to account for the electron-phonon interaction. The LOE method uses perturbation theory and Greens functions to calculate the transitions between states with varying k- and q-values. The STD method simply displaces all the atoms according to a weighted average of the phonons, so that the correct thermal average of the current is obtained. It does not model the electron-phonon interactions explicitly. Beforehand, there was no guarantee that the agreement would be as good as shown here, and this will not be true in all cases. Especially if the relevant processes require momentum transfer, the STD method should not be expected to give as good results as the LOE method. However, as the two methods rely on different approximations and assumptions, it is also no guarantee that the LOE method will always give better results than the STD method. Additionally, the STD method is much faster and less memory-demanding.

3.5.1 Transport in graphene nanoribbons

Version: 2016.0

Research on fundamental aspects and device applications of graphene is a very active field. This tutorial illustrates how QuantumATK can be utilized to study various applications related to graphene nanoribbons, ranging from a simple, infinite sheet of graphene to more complex junctions.

The main purpose of the tutorial is to demonstrate the basic work-flow in QuantumATK, how to build systems with nanoribbons and compute fundamental quantities such as band structures and transmission spectra using QuantumATK.

Introduction

The geometry of graphene is simple and regular, and the infinite, planar structure can easily be created, either by hand or by taking a single layer from the crystal structure of graphite.

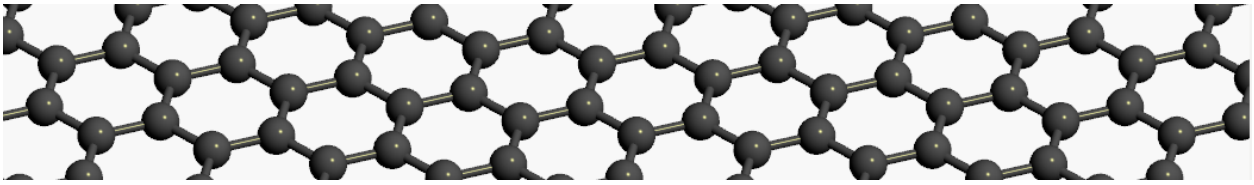

Fig. 3.73: A graphene sheet.

However, to create a device-like structure, the infinite sheet must be cut into a suitable shape. A common shape for electronics applications is a so-called graphene nanoribbon (GNR). These can be quite cumbersome to set up in an effective manner, not least considering the hydrogen passivation of the edges, which is needed in finite structures in order to satisfy all carbon valence electron bonds.

QuantumATK has a specific graphene nanoribbon Builder tool, and you will in this tutorial learn how to use it, and how to customize the structures it produces to make more advanced shapes of graphene. This will allow you to

1. calculate the band structure of ideal, infinite graphene nanoribbons, of either armchair or zigzag type, as a function of the ribbon width;
2. introduce doping or defects, on the edge or elsewhere, and study the influence on the transmission spectrum;
3. use basic ribbons as building blocks for your own device ideas, such as e.g. Z-shaped nanoribbon junctions.

This tutorial will show examples of each type of system.

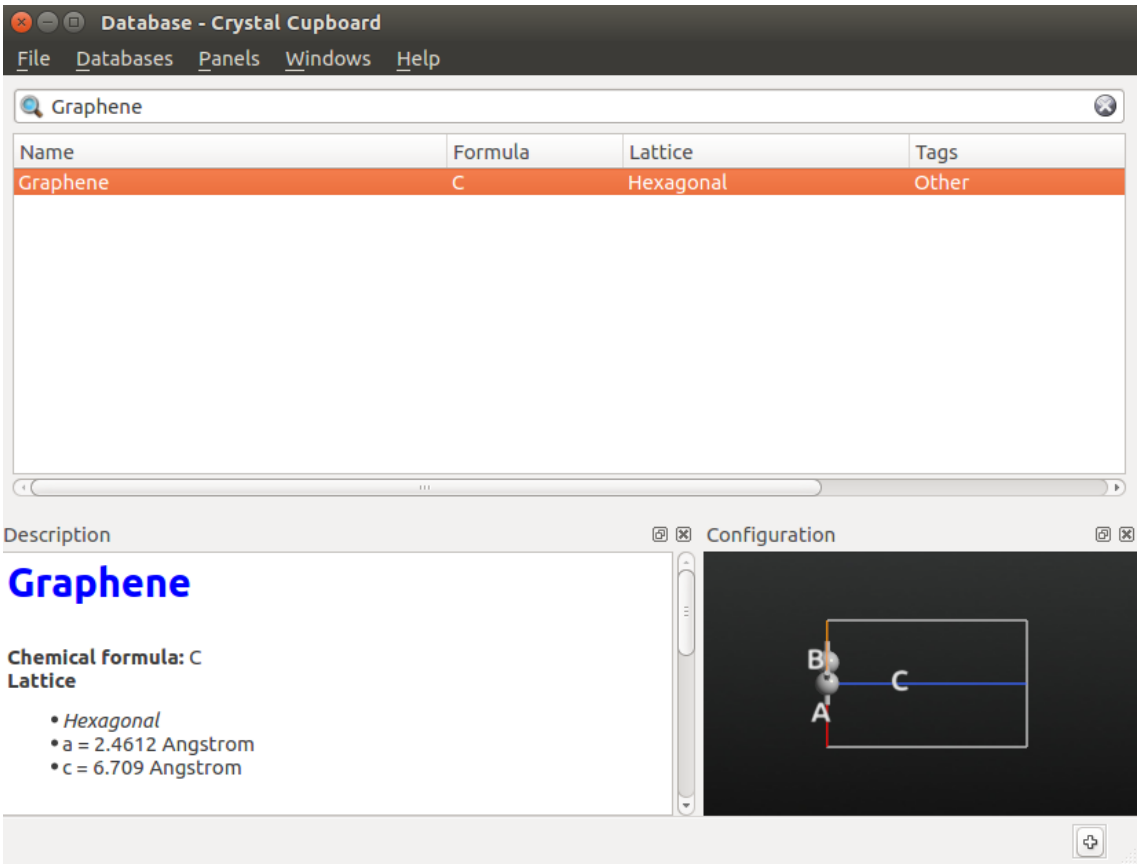
Band structure of 2D graphene

Before starting with the nanoribbons, you will do a quick introductory calculation of the band structure of an infinite 2D sheet of graphene. This will also serve as a way to refresh the basic concepts and work flow in QuantumATK.

Constructing the graphene

Start QuantumATK, create a new project and give it a name, then select it and click **Open**. Launch the builder by clicking the **Builder** icon on the tool bar.

Graphene, and many other crystals, molecules and fullerenes, are available in the built-in database in QuantumATK. In the Builder, click *Add* → *From Database* and locate Graphene (while you are typing, you will see that graphite is included in the database too).



Double-click the line to add the structure to the Stash, or click the in the lower right-hand corner.

Now send the structure to the **Script Generator** by clicking the Send To icon in the lower right-hand corner of the window.

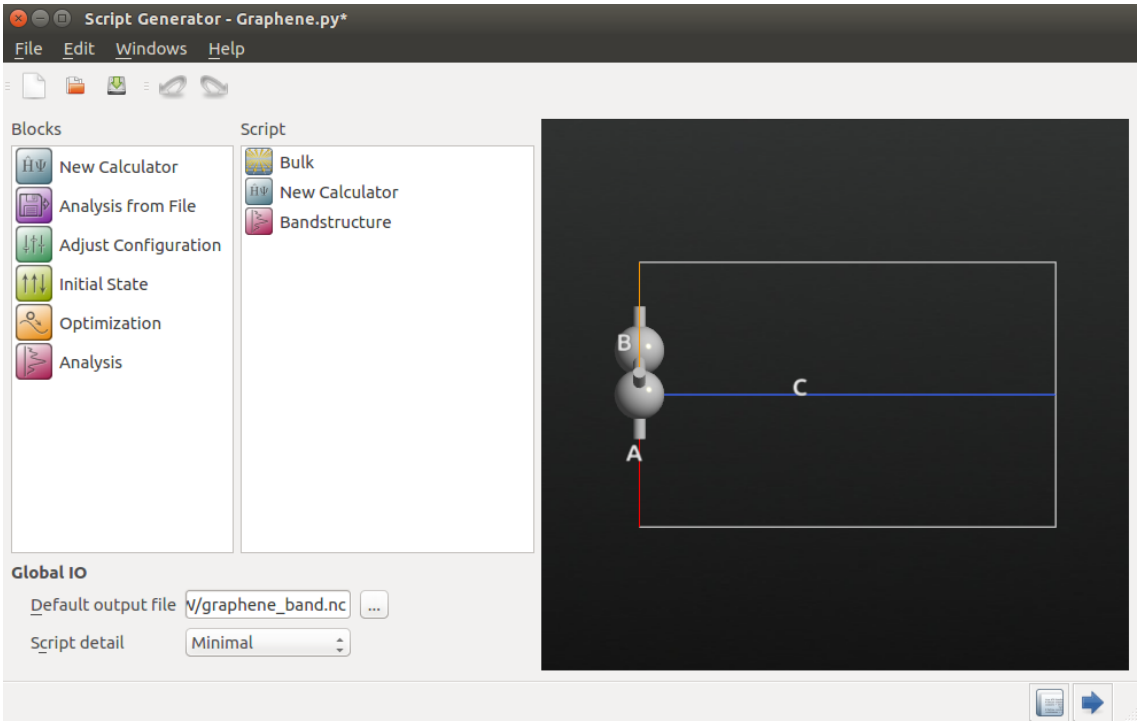
Band structure: k-point sampling

You will now set up the band structure calculation. It is instructional for this particular system to compare the results of a DFT calculation with the semi-empirical method; as you will see, they are very similar.

The first step is to use the Extended Hückel method in the ATK-SE calculator to determine the required k-point sampling. Using this faster method saves time compared to doing the same investigation with DFT. The results should, for this aspect, be very similar.

In the **Script Generator**, change the default output file to `graphene_band.hdf5` and add the following blocks to the script:

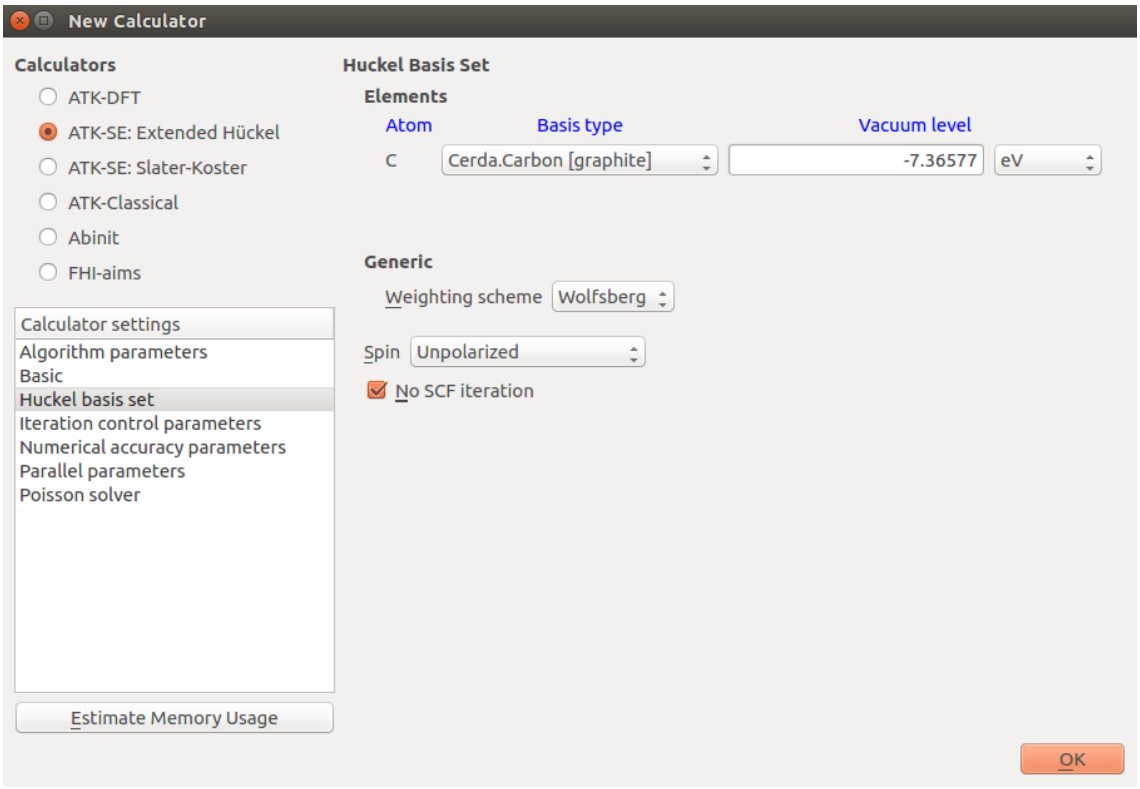
- **New Calculator**
- **Bandstructure**



You should the default parameters, except the for the Hückel basis set parameters: Open the **New Calculator** by double-clicking it.

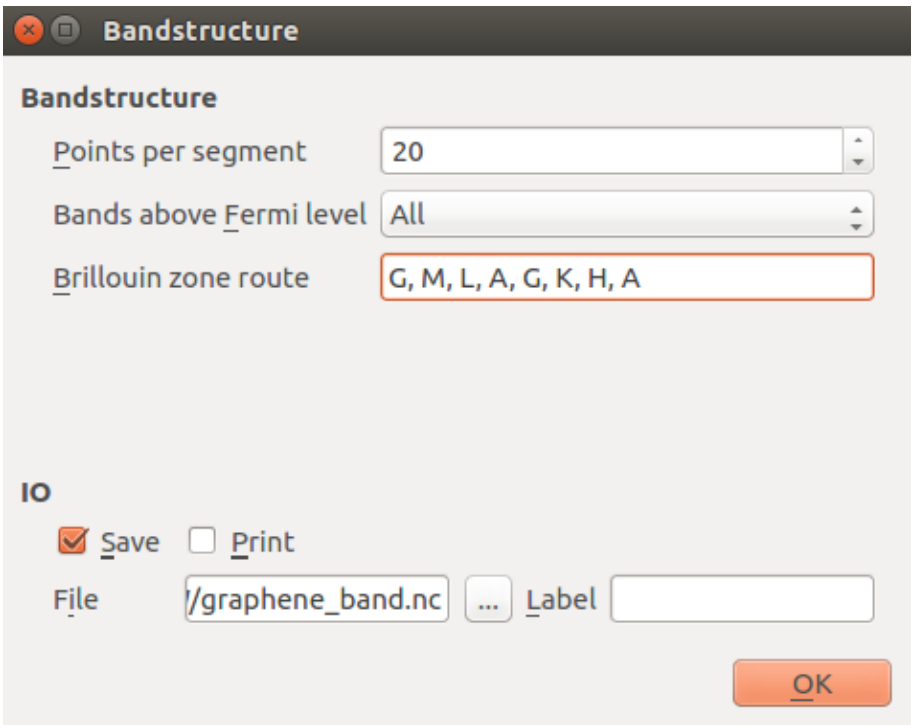
•Select the ATK-SE: Extended Hückel calculator.

•Under **Huckel basis set**, select the Cerda.Carbon [graphite] basis set.



Make sure to use this basis set whenever studying graphene (or carbon nanotubes) with the extended Hückel method. Close the dialogue by clicking **OK** in the lower right-hand corner.

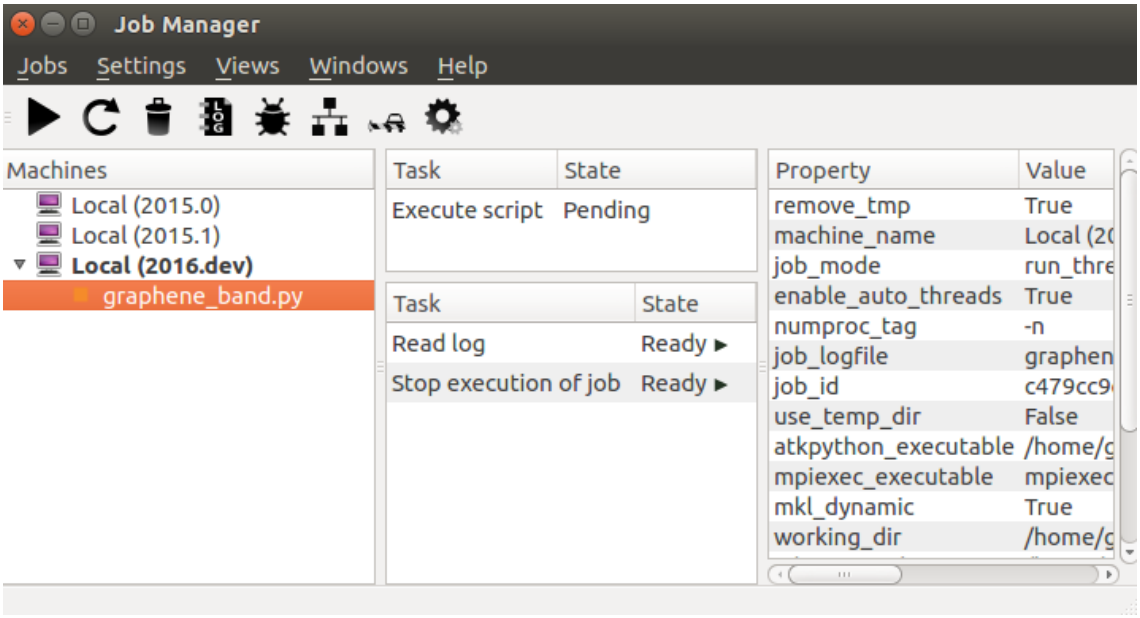
Next, open the **Bandstructure** block. A pre-defined route in the Brillouin zone is set up, corresponding to a three-dimensional hexagonal Bravais lattice. Leave it like that for now; this point will be discussed below.



Note: The different components of the script inherit the global output file name. It is possible to specify a unique file name for each analysis block, but usually it makes most sense to collect all results in the same file.

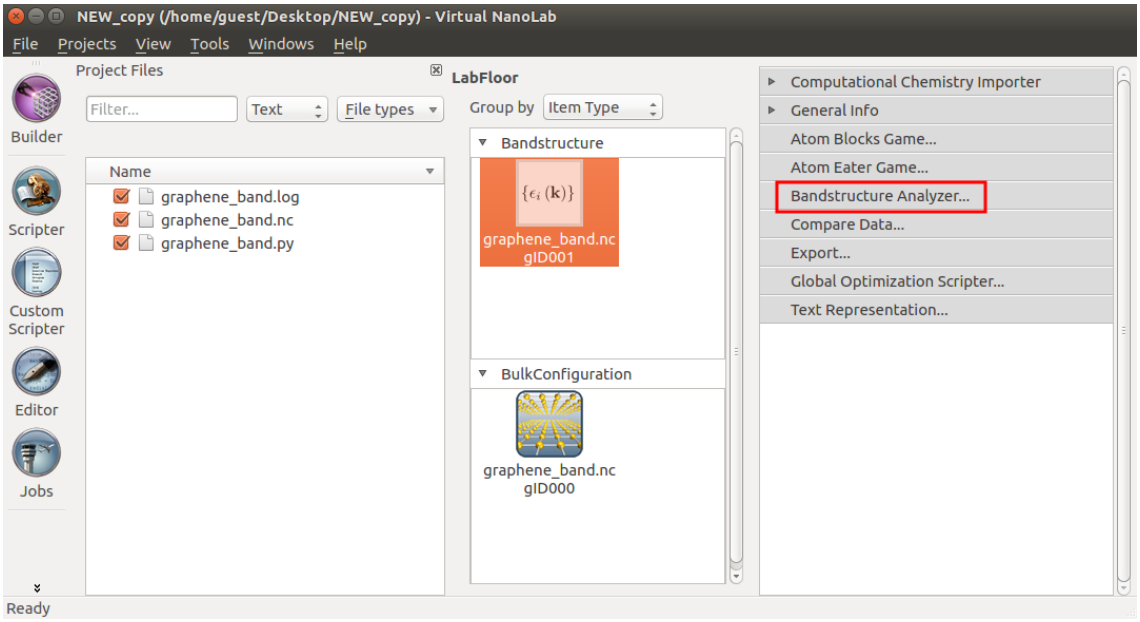
You are now ready to run the calculation: Send the script to the **Job Manager** by clicking the Send To button and by selecting Job Manager in the menu that shows up.

In the Job Manager, click to run the job. The calculation takes only seconds to complete.

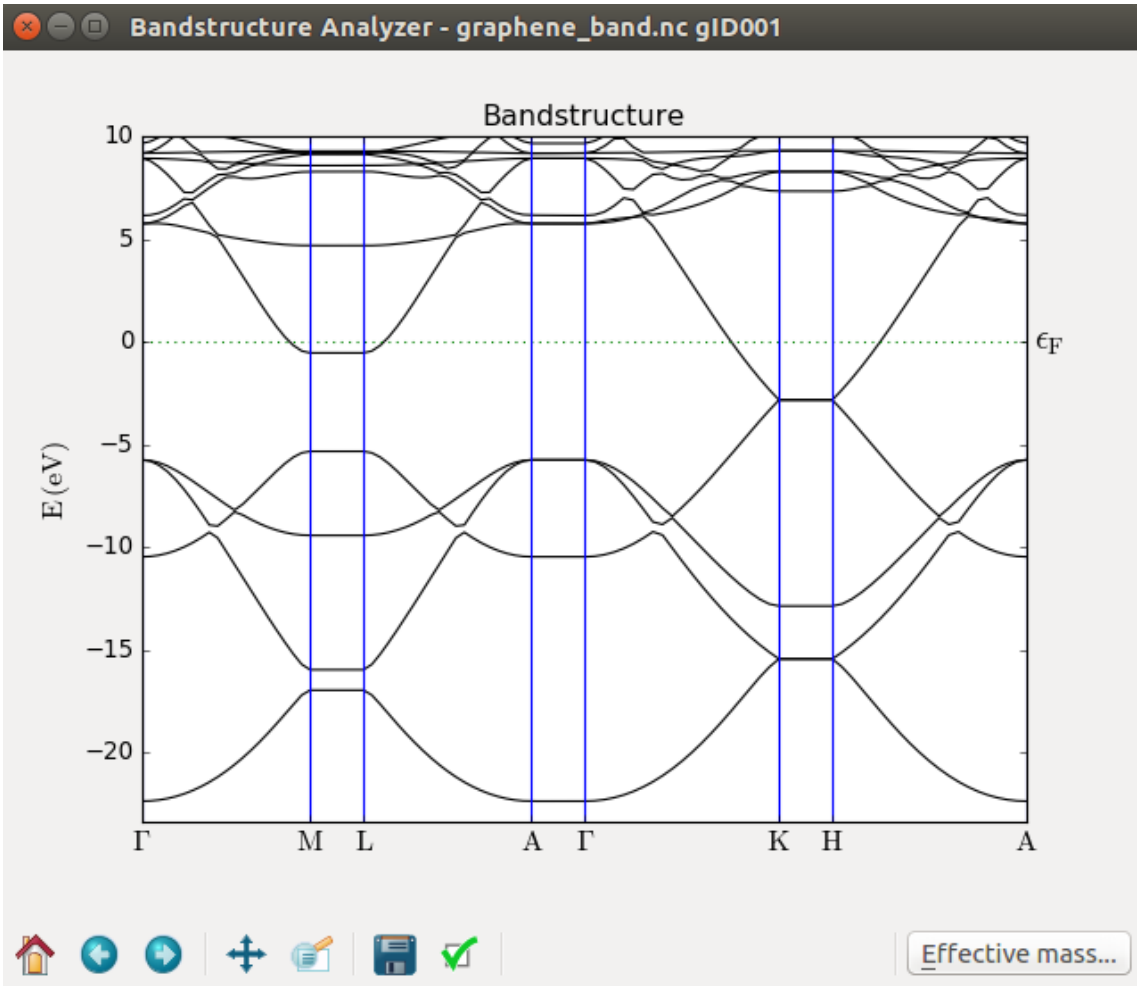


Analysis of the results

Once the calculation is finished, the `graphene_band.hdf5` file should be visible in the Project Files list in QuantumATK. On the **LabFloor**, select Item Type from the drop-down menu as shown in the below figure. Select the Bandstructure item, and click the **Bandstructure Analyzer** button in the right-hand plugins panel.

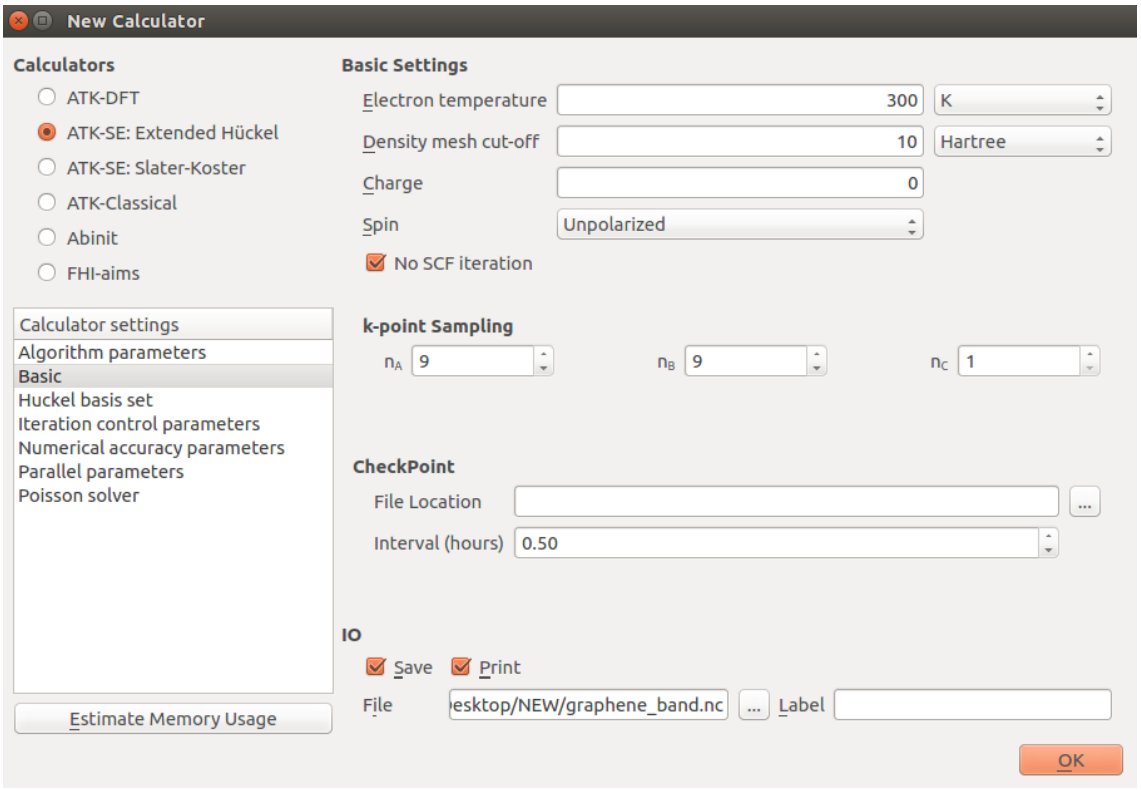


The calculated band structure is visualized. However, on close inspection, you can see that is does not appear to be correct, since the Brillouin zone K point is supposed to coincide with the Fermi level.



The cause of the poor band structure is insufficient k-point sampling; the default is to have just one point in each direction, and this fails to properly describe the graphene electronic structure.

Therefore, open the minimized **Script Generator** window again, open the Calculator block, and enter 9x9x1 k-points under Basic settings.



You should also adjust the symmetry points used for the band structure calculation to avoid the flat segments, which correspond to paths out of the planar graphene Brillouin zone. The only relevant k-points in a 2D hexagonal lattice are G=(0,0,0), K=(1/3,1/3,0), and M=(0,1/2,0), in units of the reciprocal lattice vectors.

This can easily be done in the Scripter (by double-clicking the Bandstructure block and editing the path), but to demonstrate how easy it is to use a script produced by the Script Generator as a template, you will now learn to do that by hand instead!

Send the script to the **Editor** by clicking the icon in the Scripter. Locate the line with the symmetry points, and edit it as shown below.

```
bulk_configuration.setCalculator(calculator)
nlprint(bulk_configuration)
bulk_configuration.update()
nlsave('graphene_band.nc', bulk_configuration)

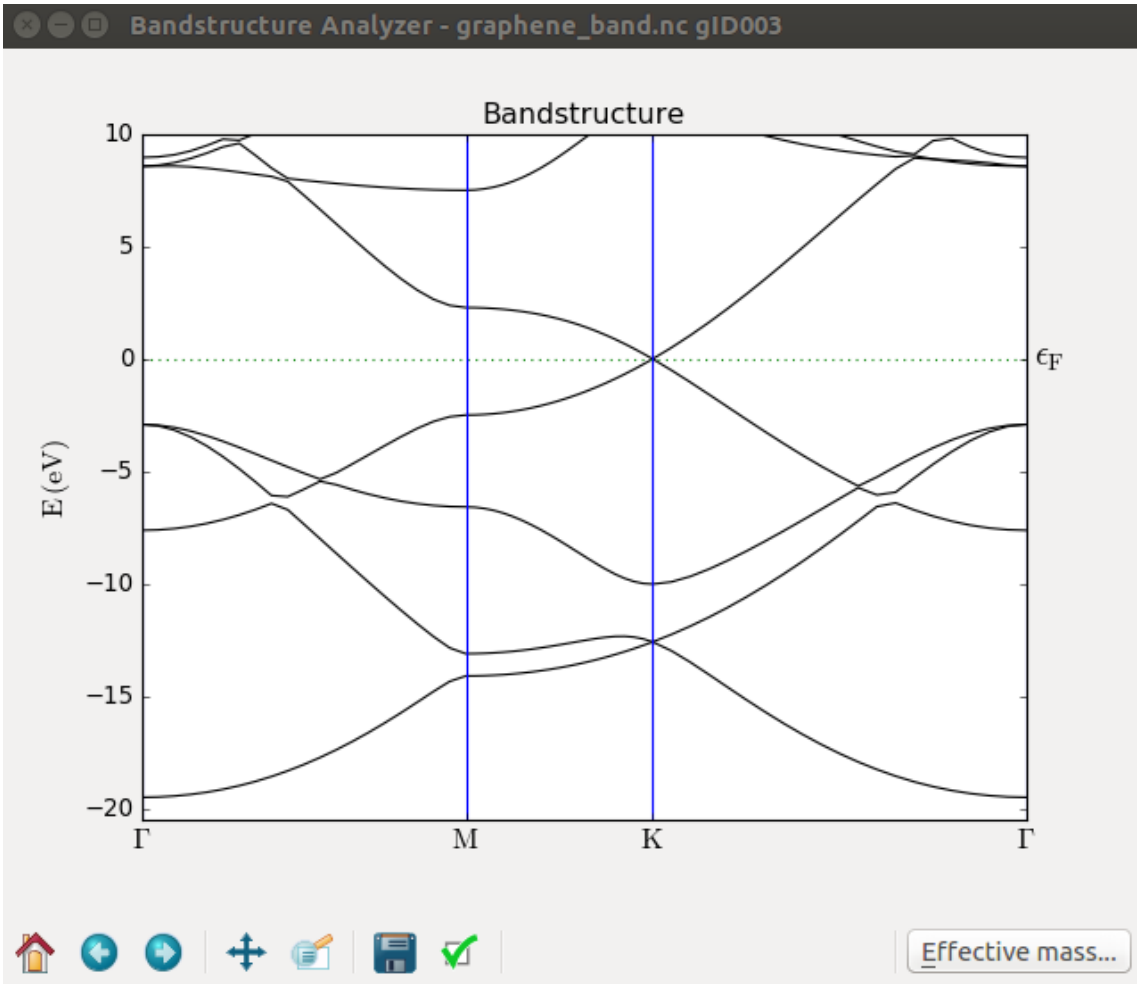
# ------------------------------------------------------------
# Bandstructure
# ------------------------------------------------------------
bandstructure = Bandstructure(
    configuration=bulk_configuration,
    route=['G', 'M', 'K', 'G'],
```

(continues on next page)

(continued from previous page)

```
    points_per_segment=20,
    bands_above_fermi_level=All
    )
nlsave('graphene_band.nc', bandstructure)
```

Run the calculation by sending the script from the **Editor** to the **Job Manager**. When the calculation finishes, a new Bandstructure object will be located on the **LabFloor**. Select it and plot it as before. The Fermi level is now exactly at the K point, as illustrated below.

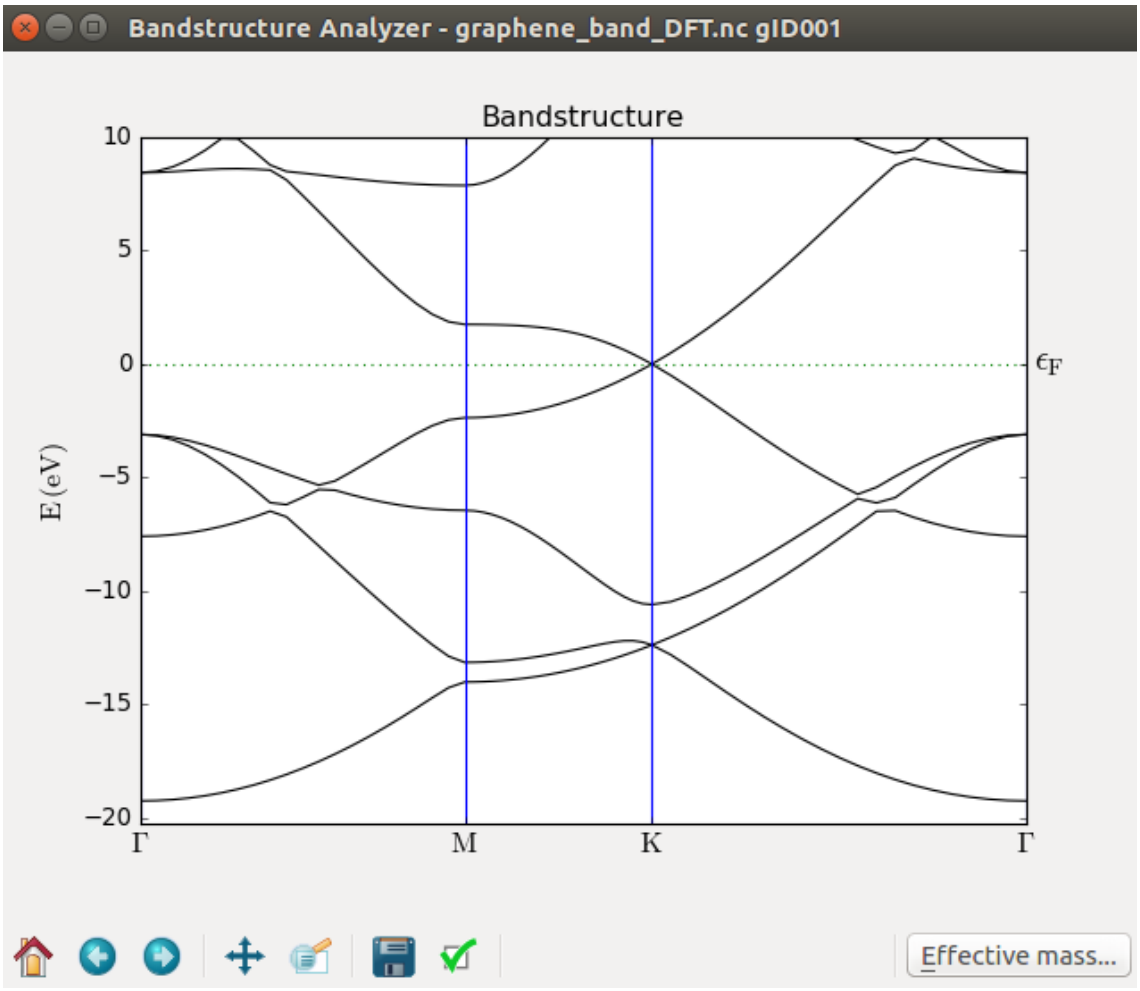


Calculate the band structure using DFT

You now know the required k-point sampling, and you can use this also for the DFT calculation. To switch method, return to the **Script Generator**, open Calculator block, and select the **ATK-DFT** calculator. Set the k-point sampling to 9x9x1, but leave all other parameters at their default values.

Tip: In case you closed the Script Generator window, you can reuse the geometry from the saved HDF5 file by dropping one of the bulk configuration inside it on the Scripter icon on the toolbar.

Keep again the same name for the output HDF5 file, and run the calculation. This will add yet another Bandstructure item to the **LabFloor**, which can be plotted like before. On inspection, you will find that the results are very similar to the Hückel band structure. The Hückel method therefore has good accuracy for this system and will be used for the further examples, mainly to save time; the interested reader is encouraged to verify that the results obtained with DFT are very similar.



Note: As it turns out, getting an accurate alignment of the K point to the Fermi level in graphene is not just a simple matter of having a lot of k-points. The results for 12x12x1 or 13x13x1 k-points are, for instance, considerably worse than those for 10x10x1. There is a general trend that more k-points are better, but on the other hand, 3x3x1 points are better than almost all other values up to 20x20x1. This behavior can be understood by studying how the k-points in the Monkhorst–Pack grids are distributed around K=(1/3,1/3,0); the ideal situation is to have several points close to or at the Fermi level, although the latter is less favorable than having two points close by.

Band structure of an armchair ribbon

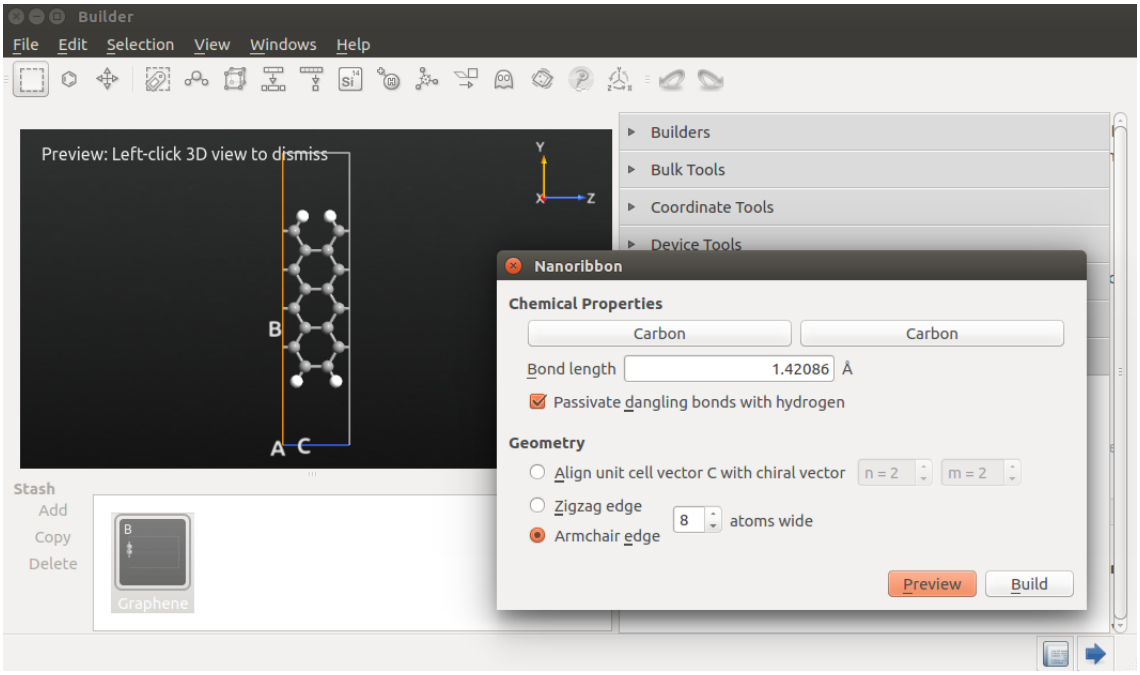
Having investigated the band structure of pure graphene, the focus is now on graphene nanoribbons (GNR), which are finite, narrow strips of graphene cut out from the infinite 2D sheet. There are two primary ways to cut out such a ribbon – these two structures are known as armchair or zigzag ribbons, a nomenclature that refers to the shape of the edges. Notably, an armchair ribbon is an unrolled zigzag nanotube! Armchair ribbons are predicted to be semiconducting, and you will now compute the band structure of such a ribbon to confirm this.

Building the archair ribbon structure

Generating nanoribbons with QuantumATK could not be easier – there is a **Builder** plugin specifically designed for this task. Launch the Builder and click *Add* → *From Plugin* → *Nanoribbon*. This launches the Graphene Ribbon tool.

In the widget that opens, you can design many different types of nanoribbons, not just graphene but also B-N, etc. By selecting a linear combination nA+mB of the two unit cell vectors A and B in the graphene plane, ribbons of any chirality can be constructed (the chirality label comes from the fact that these structure correspond to an unrolled (n,m) nanotube). For simplicty, you can also directly choose to build armchair or zigzag ribbons, and specify their width (which must be even for zigzag ribbons).

Select an armchair ribbon of width 8 (carbon atoms), and click **Builder** to add it to the Stash.

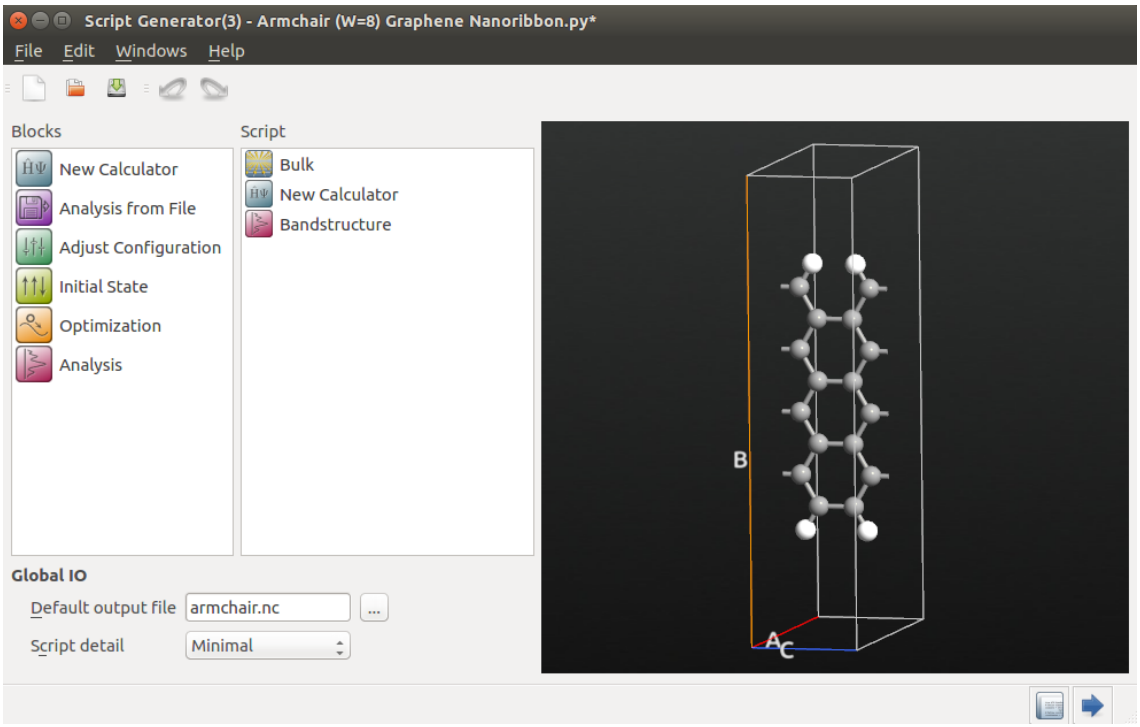


Send the structure to the **Script Generator**.

Band structure

Like before we will use the Extended Hückel method for the calculations. Change the default output filename to `armchair.hdf5`, and add the following two blocks to the script:

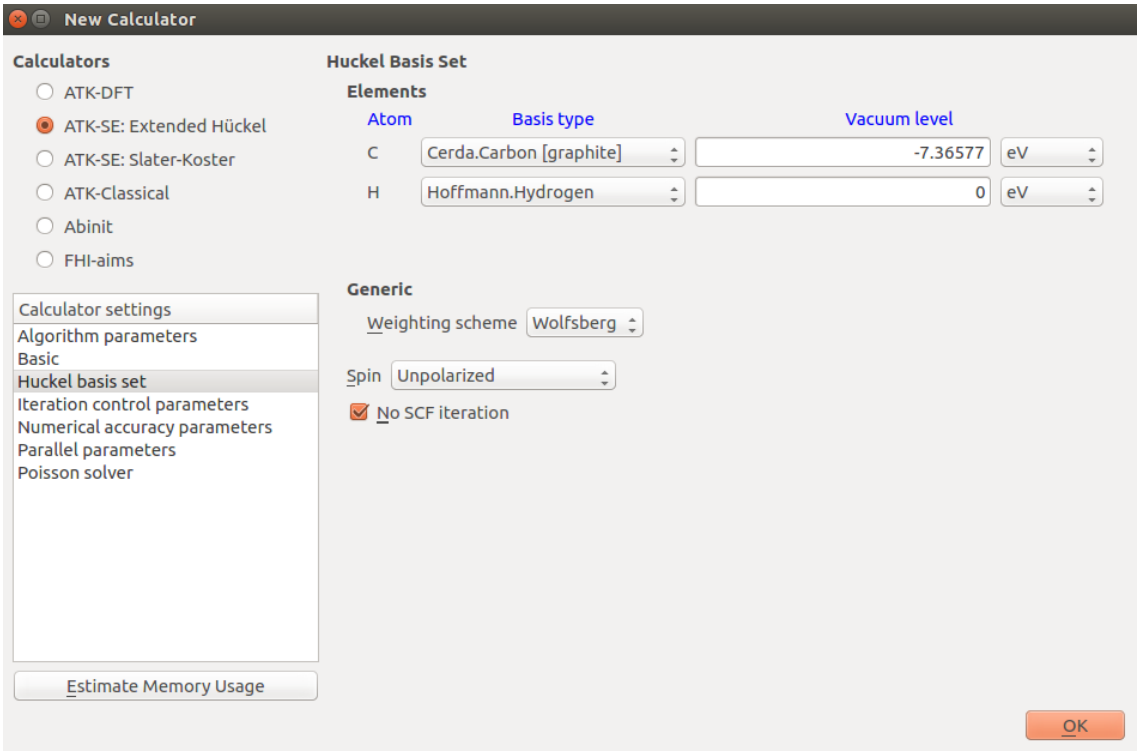
- **New Calculator**
- **Bandstructure**



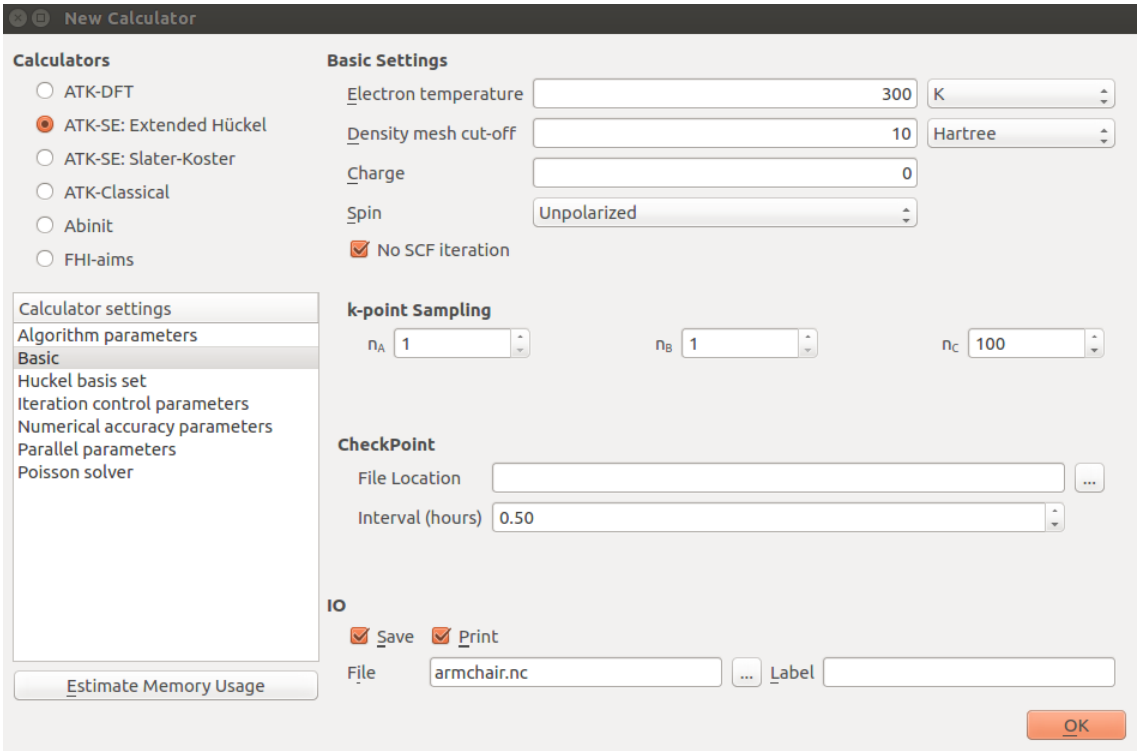
Open the Calculator block to edit it:

•Select the ATK-SE: Extended Hückel calculator.

•Select the Cerda.Carbon [graphite] basis set for carbon. The default Hoffmann basis set should work well for the hydrogen.

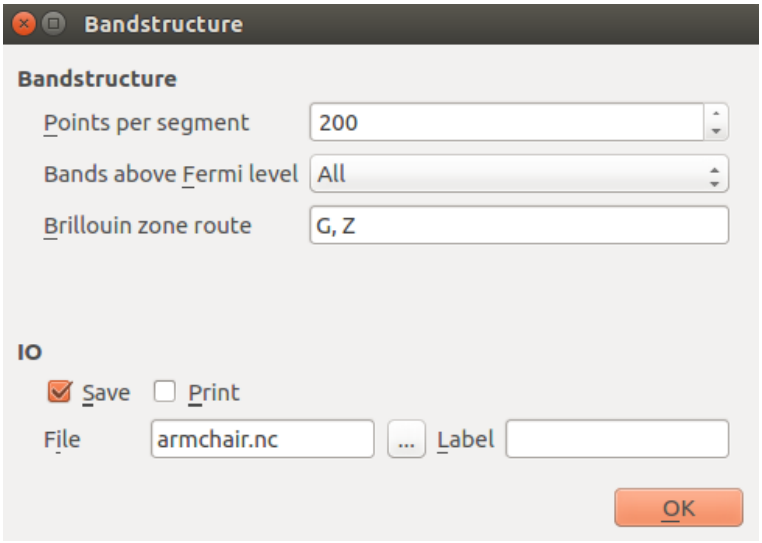


In this case you need only 1 k-point in the directions perpendicular to the direction of the ribbon, since the system is finite in these direction, while the system is periodic in the C direction. A large number of k-points is needed in this direction, since the unit cell is quite short and graphene has a rather peculiar point-like Fermi surface as we saw above; 100 points should be sufficient:



The default suggested route in the Brillouin zone from G=(0,0,0) to Z=(0,0,1/2) for the band structure is indeed the

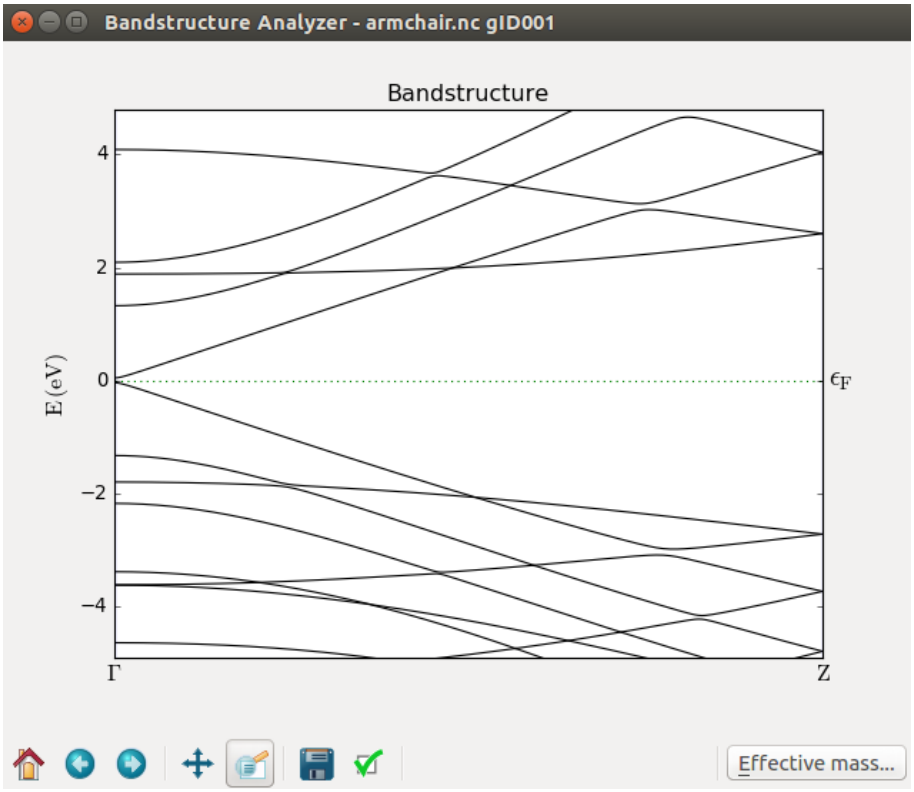
appropriate one, so you just need to increase the number of points to 200 to obtain nicely smooth curves:



Run the calculation using the **Job Manager**.

Analyzing the results

Return to the main QuantumATK window and use the **Bandstructure Analyzer** to plot the Bandstructure item from the file `armchair.hdf5`. The computed band structure is shown in the figure below. By zooming in a bit you should see a small band gap band gap at the point. The armchair nanoribbon is therefore semiconducting.



As an extension of this exercise, you are recommended to redo the calculations for different types of ribbons (armchair/zigzag) and for different widths. The band gap is strongly dependent on both factors!

In the next section, you will investigate a zigzag ribbon, which is metallic rather than semiconducting.

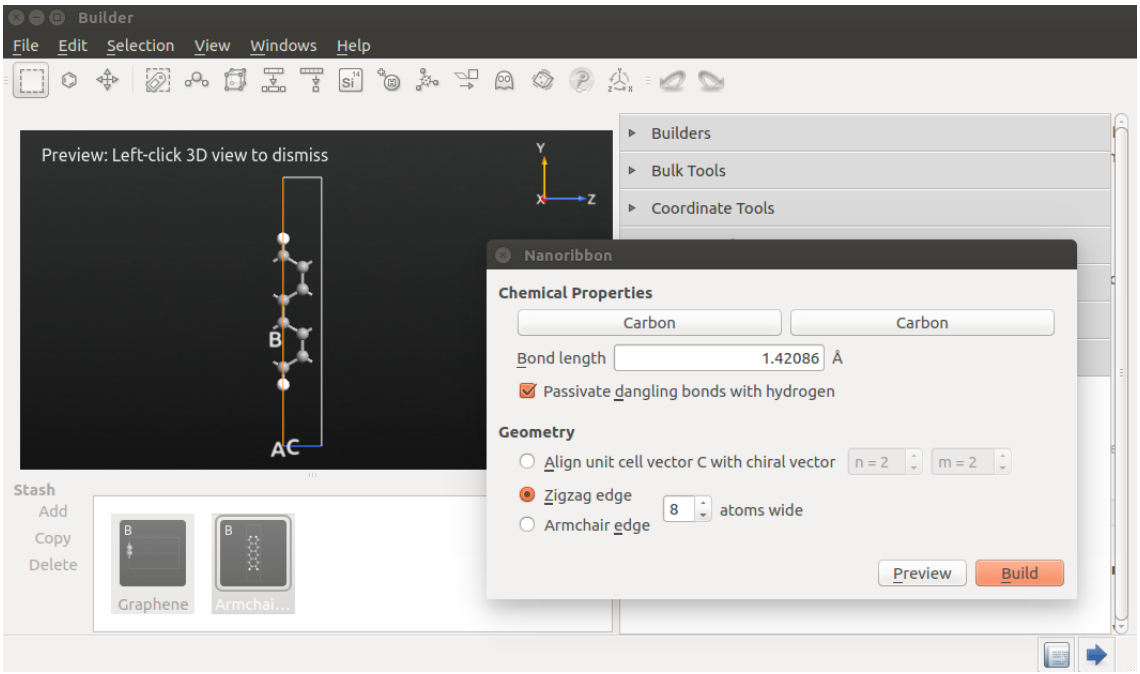
Transport properties of a zigzag nanoribbon

In this section you will do some transport calculations. One of the most basic transport system that can be made with graphene is a perfect, infinite zigzag nanoribbon. Such ribbons are metallic and display no elastic scattering, i.e. perfect conductivity. In the second part you will investigate what happens when scattering is introduced by distorting the edges of the ribbon.

Pristine ribbon

In a pristine device system there is no scattering from the central region and, as illustrated in the following, you can obtain the transmission spectrum from the properties of the electrode.

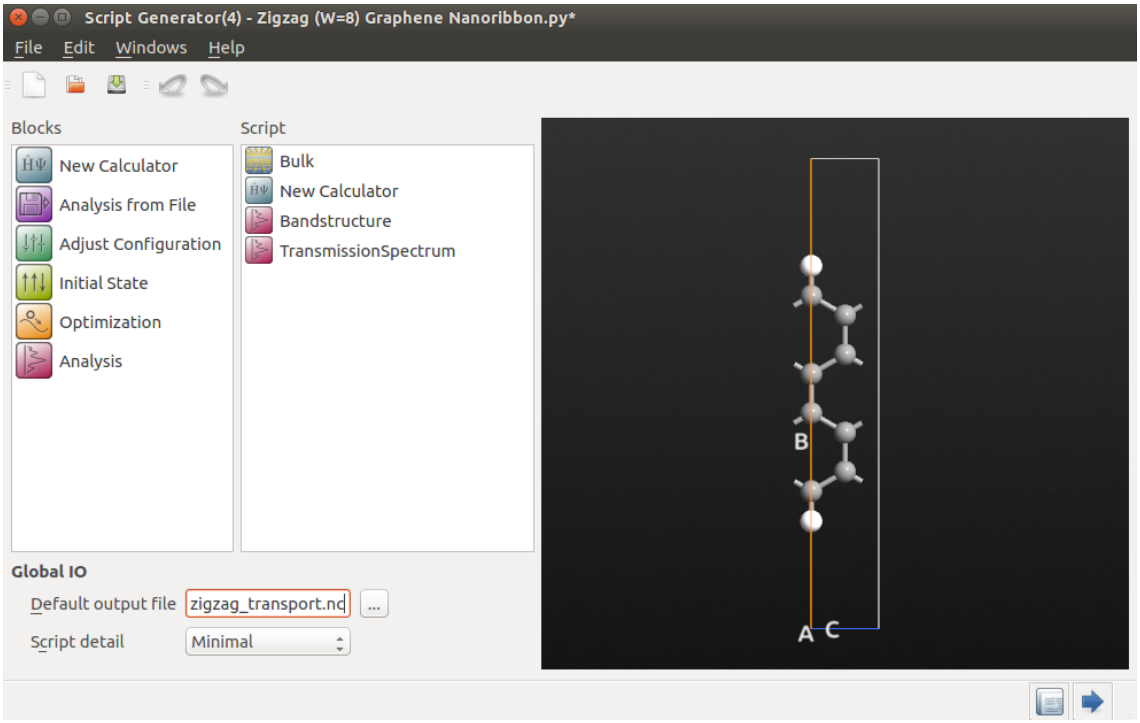
Return to the **Builder** and open the Nanoribbon widget from *Add* → *From Plugin* → *Nanoribbon*. Build a zigzag nanoribbon with a width of 8 carbon atoms.



Transfer the structure to the **Script Generator** and add the following blocks to the script.

- **New Calculator**
- **Bandstructure**
- **TransmissionSpectrum**

Change the default output file to `zigzag_transport.hdf5`.



Edit the Calculator settings:

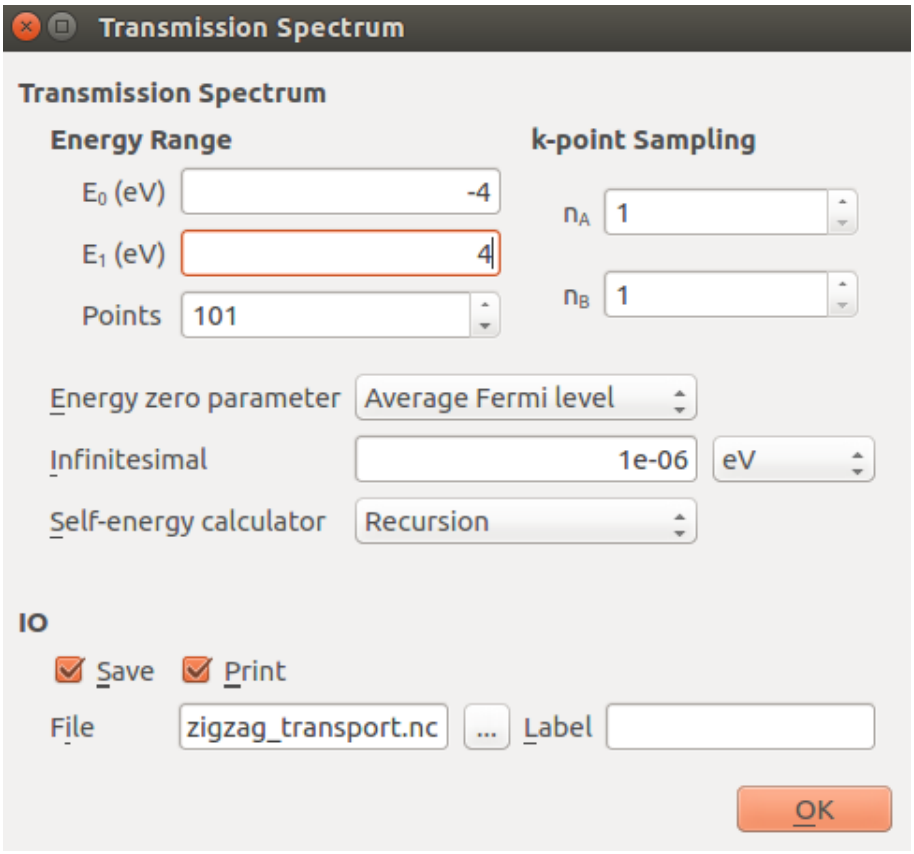
•Select the **Extended Hückel** calculator

•Set the k-point sampling to 1x1x100.

•Change the Hückel basis set to Cerda.Carbon [graphite] for C.

Next, open the the Bandstructure block and set points per segment to 200.

Finally, open the TransmissionSpectrum block and set the energy range from 4 eV to +4 eV.

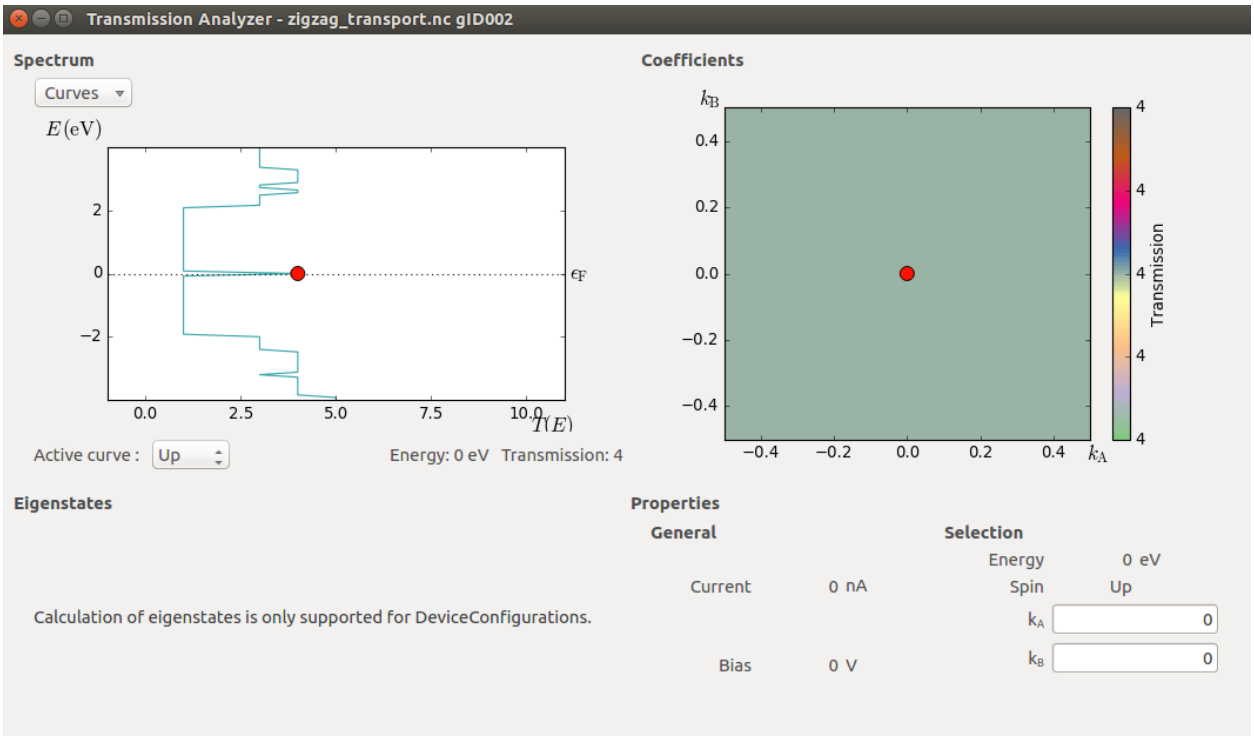


Note: The odd number of energy points ensures that there will be an energy point at the Fermi level.

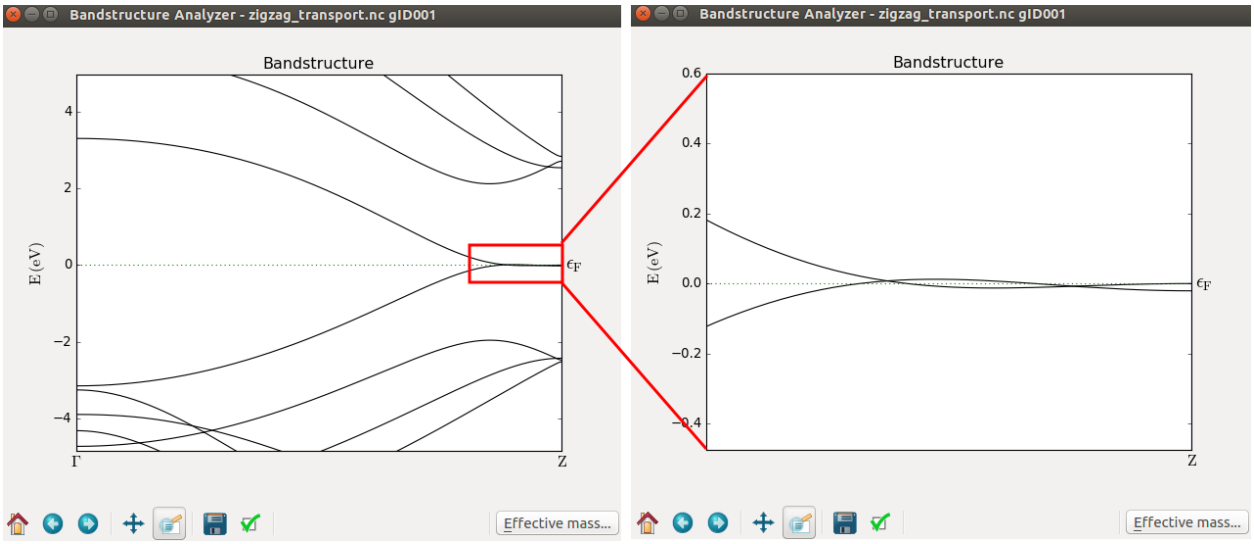
Run the script using the **Job Manager**. It should take only a few minutes to finish.

Analyzing the results

Once the calculation finishes, locate the **TransmissionSpectrum** item on the LabFloor, and open the **Transmission Analyzer** plugin. As expected for a perfect 1D system, the transmission exhibits a sequence of steps with integer transmission.



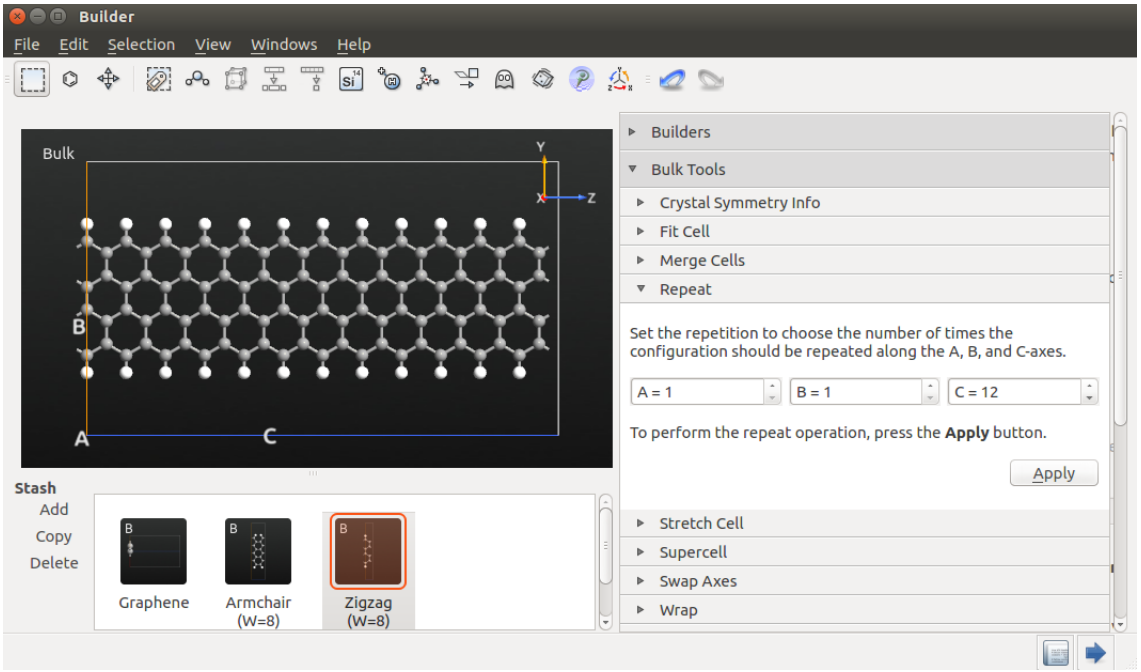
The most prominent feature of the plot is the enhanced transmission around the Fermi level. This is due to a peculiarity in the band structure of the zigzag ribbon (see the band structure below), and interestingly enough, the enhancement is retained even if the ribbon is distorted, at least in the way that will be investigated in the next example.



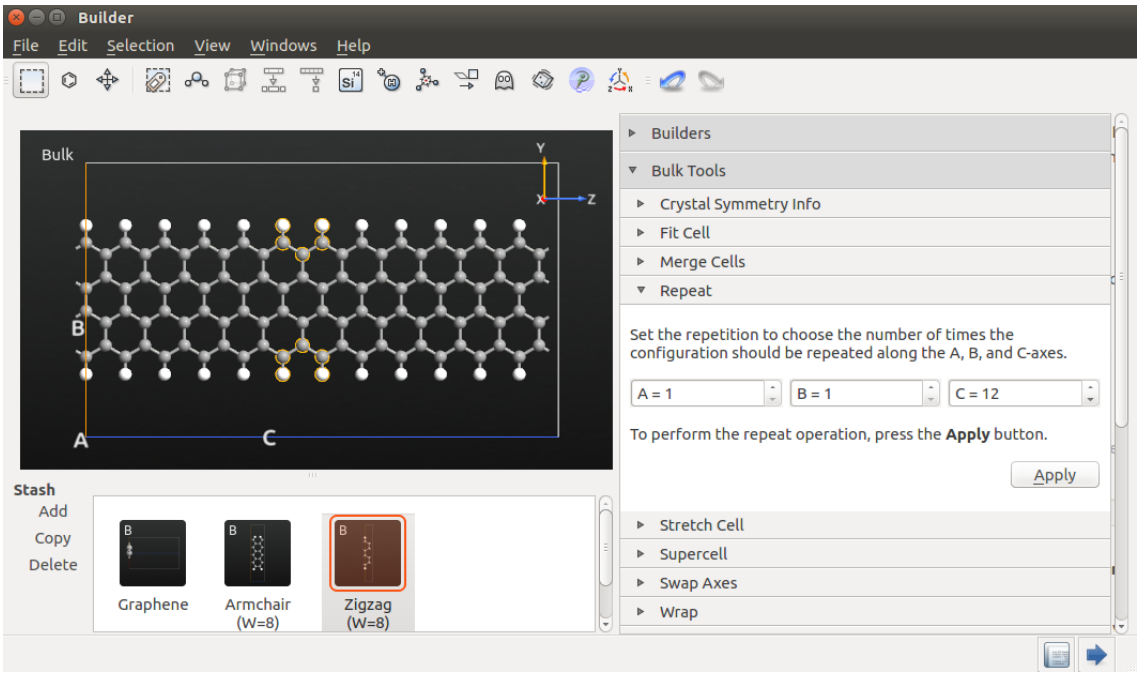
Creating a distortion in the ribbon

So far you have basically just confirmed that armchair ribbons are semiconducting and zigzag ribbons are metallic (at least as long as electron spin is not considered). It is now time to do something a little bit more interesting. The next system you will study is a distorted ribbon; more specifically you will make a constriction in the perfect zigzag ribbon, and see how this influences the transport properties.

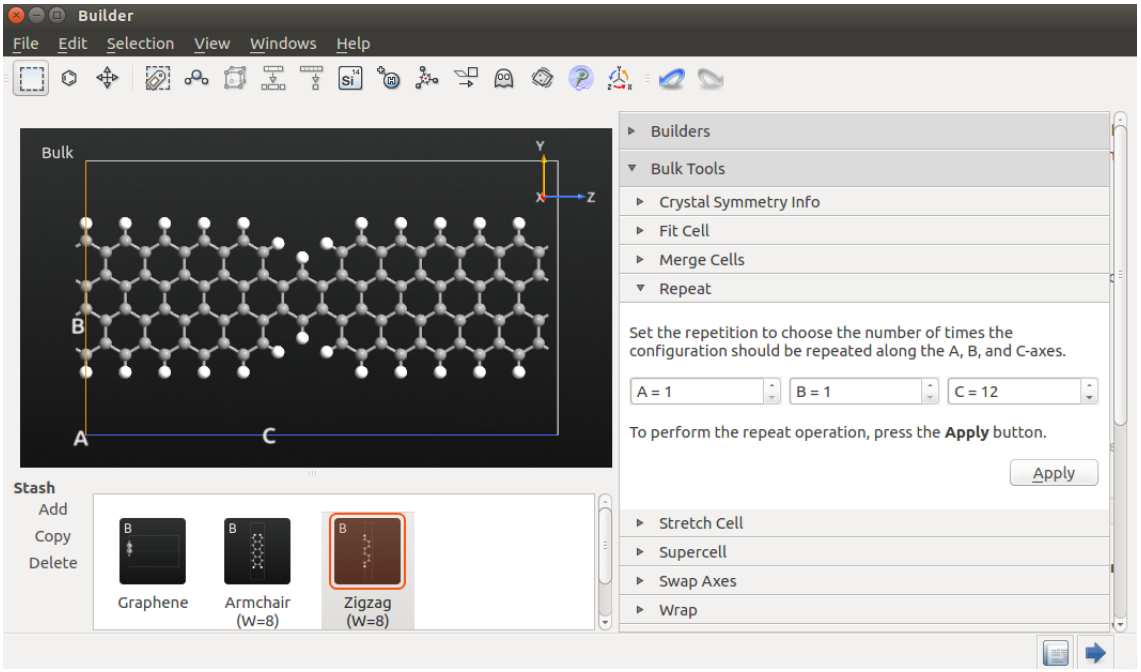
Return to the **Builder** and open the Repeat tool (available from Bulk Tools in the plugin panel). Set C=12 and click **Apply**. Then press `Ctrl`+R to reset the 3D view.



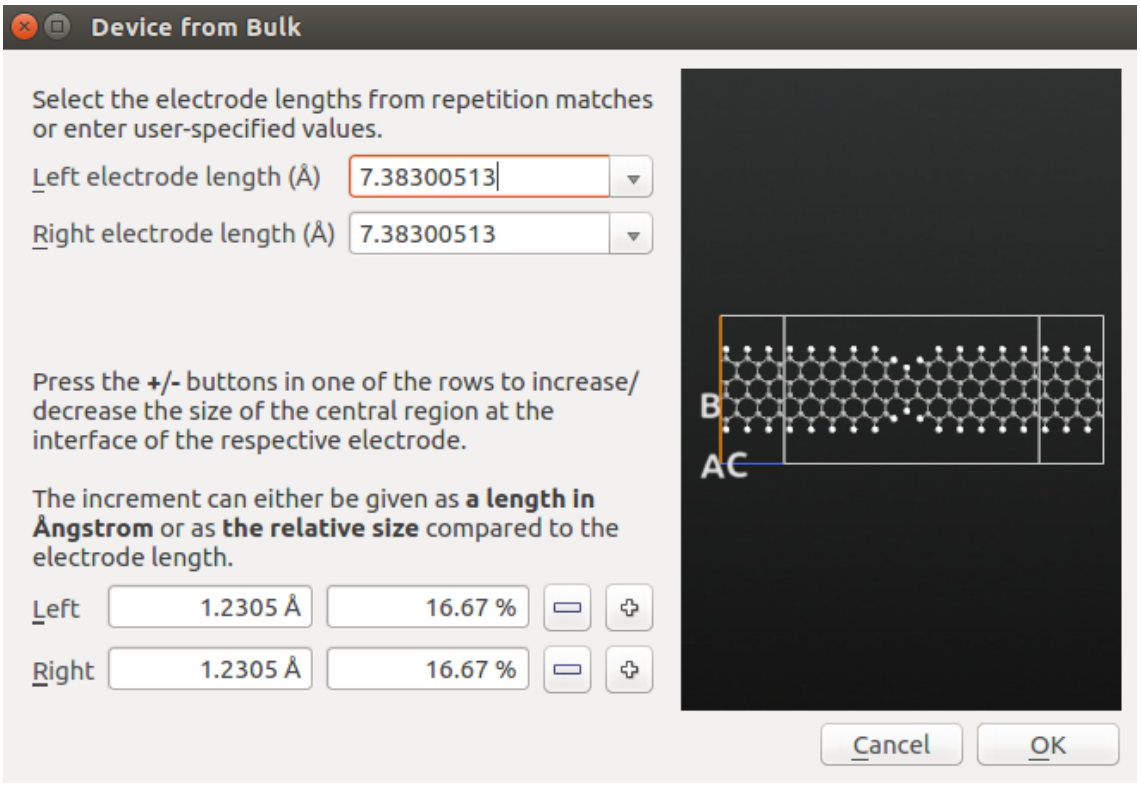
Select the atoms indicated in the figure below by drawing a rectangle with the mouse, while holding down `Ctrl`.



Delete the atoms by pressing the `Delete` key. The dangling bonds that have now been created should be saturated by adding hydrogen atoms. To do this, click the Passivate button on the top toolbar.



Finally, convert the periodic structure to a device geometry by using the *Device Tools* → *Device From Bulk* tool.



The builder will detect any pattern of periodicity close to the edges of the structure, and suggest these as electrodes. You may see these suggestions in the dropdown combo boxes, as indicated in the figure above.

For the current structure, several periodicity patterns can be found, corresponding to a certain number of repetitions of the zigzag unit cell. The suggested value (7.383 Å), corresponds to 3 repetitions, and this is a suitable length. Thus, no further adjustments are needed. Click **OK**, to build the device geometry for the distorted zigzag nanoribbon.

Transport properties of the distorted ribbon

In the following you will learn how to perform the calculation of the zero-bias conductance of the distorted ribbon using open boundary conditions, first non-self consistently and then self-consistently.

Note: Calculations at finite bias must always be performed fully self-consistently, since the non-self-consistent model do not produce a correct voltage drop across the device.

Non-self-consistent calculation

Send the device geometry to the **Script Generator**, and set the default output file name to `zigzag_transport.hdf5` (i.e. the same file name as used for the bulk transmission calculation above, so that the new calculations are saved in that same file).

Then add the **New Calculator** and **TransmissionSpectrum** script blocks.

Set up the Calculator block to use the **Extended Hückel (Device)** calculator with the Cerda.Carbon[graphite] Hückel basis set for carbon. Set also the energy range in the TransmissionSpectrum block to 4 eV to +4 eV.

Run the script using the **Job Manager**. It takes a minute or so, but while it is running you can already proceed and prepare the next step.

Self-consistent calculation

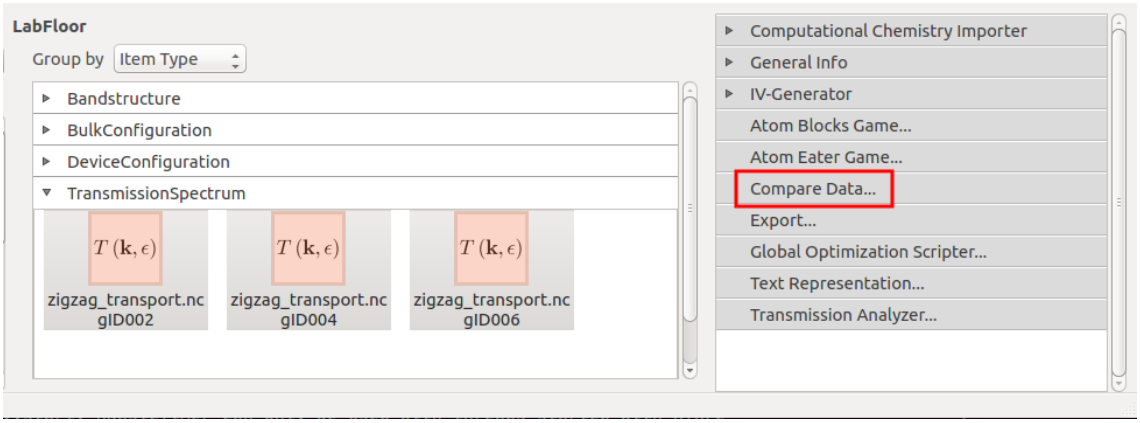
You should also perform a self-consistent calculation with open boundary conditions. This requires only a single change to the Calculator block:

- Remove the tick mark from **No SCF iteration** in the Iteration Control Parameters calculator settings.
- Send the script to the **Job Manager** and run the job.

Run the script using the **Job Manager**. This time the job will take somewhat longer (around 10 minutes).

Comparing the transmission spectra

Let us now compare the computed transmission spectra of the perfect ribbon and the distorted ones. On the **LabFloor**, select **Item Type** in the Group by menu. Then select all three the transmissionspectrum objects and click the **Compare Data** plugin.



Comparing the results you see that the strong transmission at the Fermi level in the perfect ribbon is also present in the distorted ribbon. Apart from this, the transmission spectra for the distorted GRN are strongly suppressed due to scattering by the distortion.

3.5.2 Transmission spectrum of a spin-polarized atomic chain

Version: 2016.3

In this tutorial, you will learn how to build an atomic-chain device, and calculate the spin-polarized transmission spectrum for two cases where the electrodes have parallel and anti-parallel spin-polarizations.

You will use a chain of carbon atoms to make the calculations run fast. Carbon is not naturally magnetic, but when the atom spacing in the chain is large enough – but not too large – the electronic ground state is actually spin-polarized. This system is of course highly artificial, and only chosen for the purpose of illustrating the methodology.

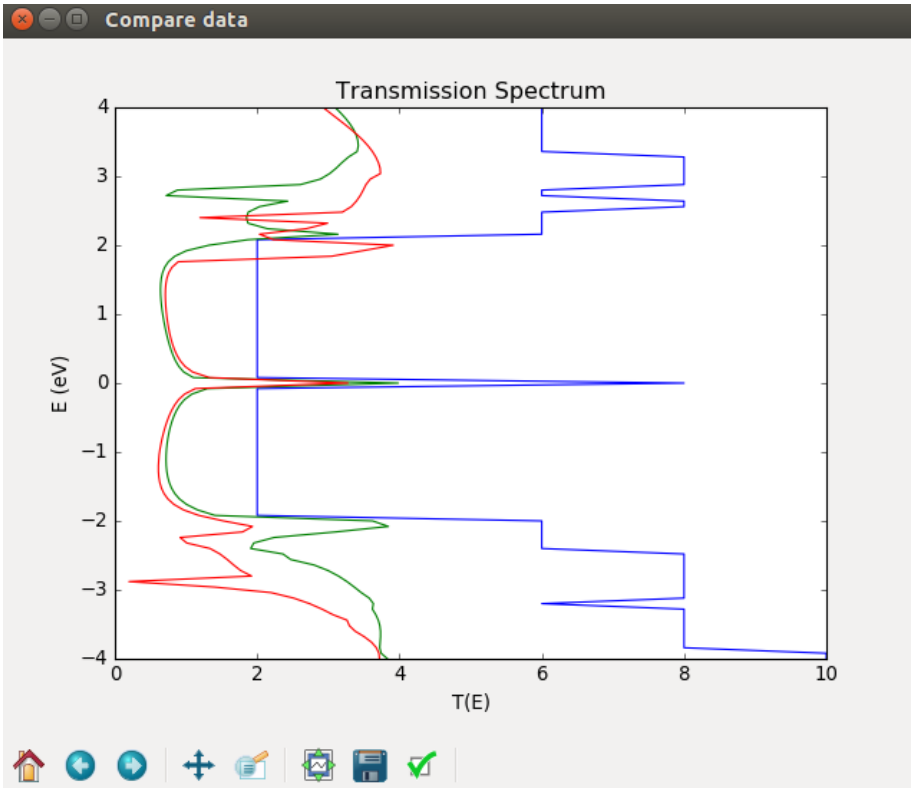


Fig. 3.74: Comparison of the transmission spectra of a perfect ribbon (blue) and a distorted ribbon calculated non-selfconsistently (green) and selfconsistently (red).

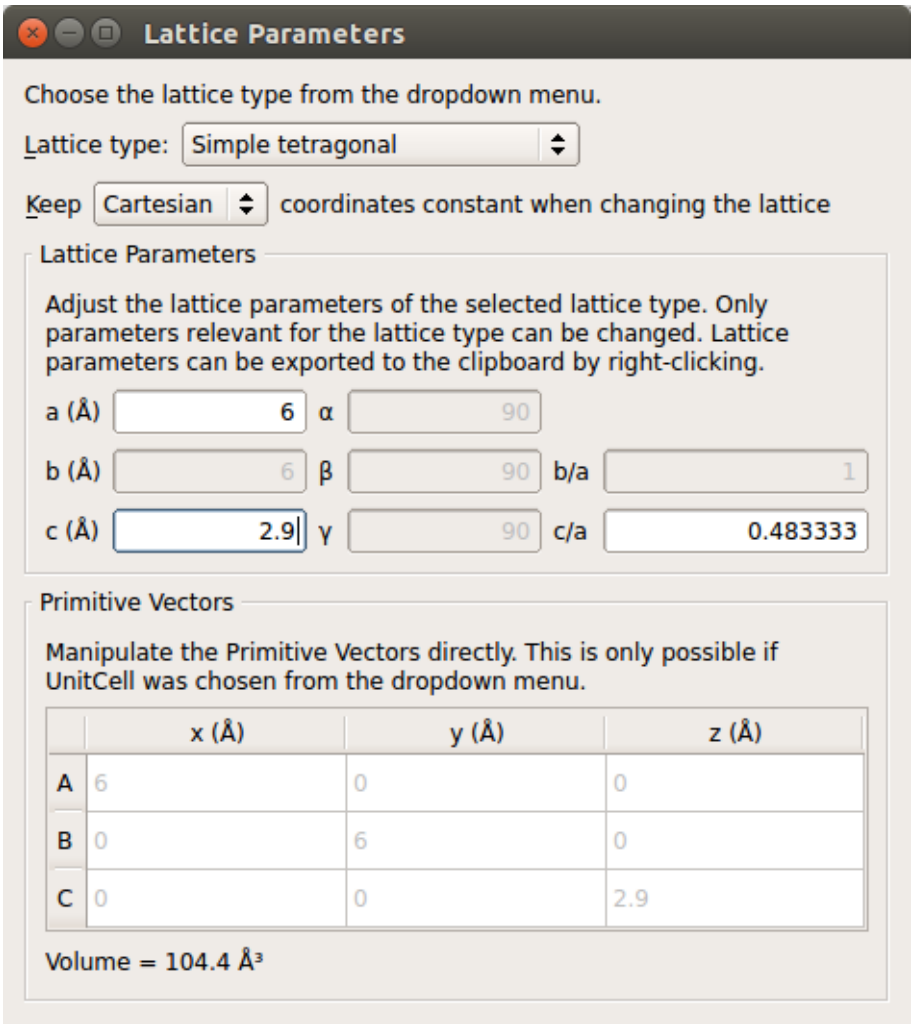
Building the 1D carbon chain

1. Open the QuantumATK **Builder**.

2. In the **Stash**, click *Add* → *New Configuration*. This creates a hydrogen atom.

3. Select the hydrogen atom in the 3D view and use the **Periodic Table** tool to convert the atom to carbon.

4. Open the *Bulk Tools* → *Lattice Parameters* tool and change the lattice type to **Simple tetragonal**. Then set the lattice constants to a = 6 Å and c = 2.9 Å.

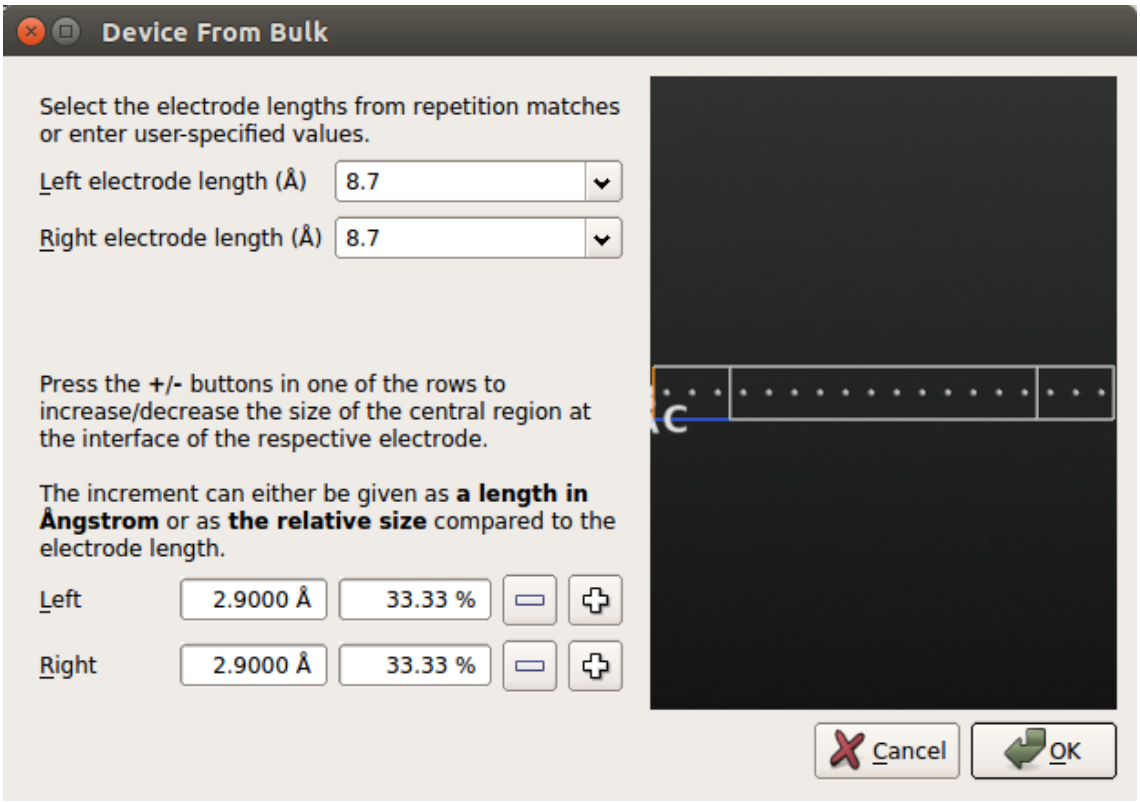


Tip: Periodic boundary conditions will be employed along the A and B directions, so we use the large a = 6 Å unit cell vector to minimize electrostatic interactions between repeated images of the chain along A and B.

5.Click *Coordinate Tools* → *Center* to center the atom in the unit cell.

6.Use the *Bulk Tools* → *Repeat* plugin to repeat the system 12 times in the C direction.

7.Use the *Device Tools* → *Device from Bulk* plugin to create the carbon-chain device. The automatically suggested electrode length of 8.7 Å is adequate, so just click *OK*.



Spin-parallel transmission spectrum

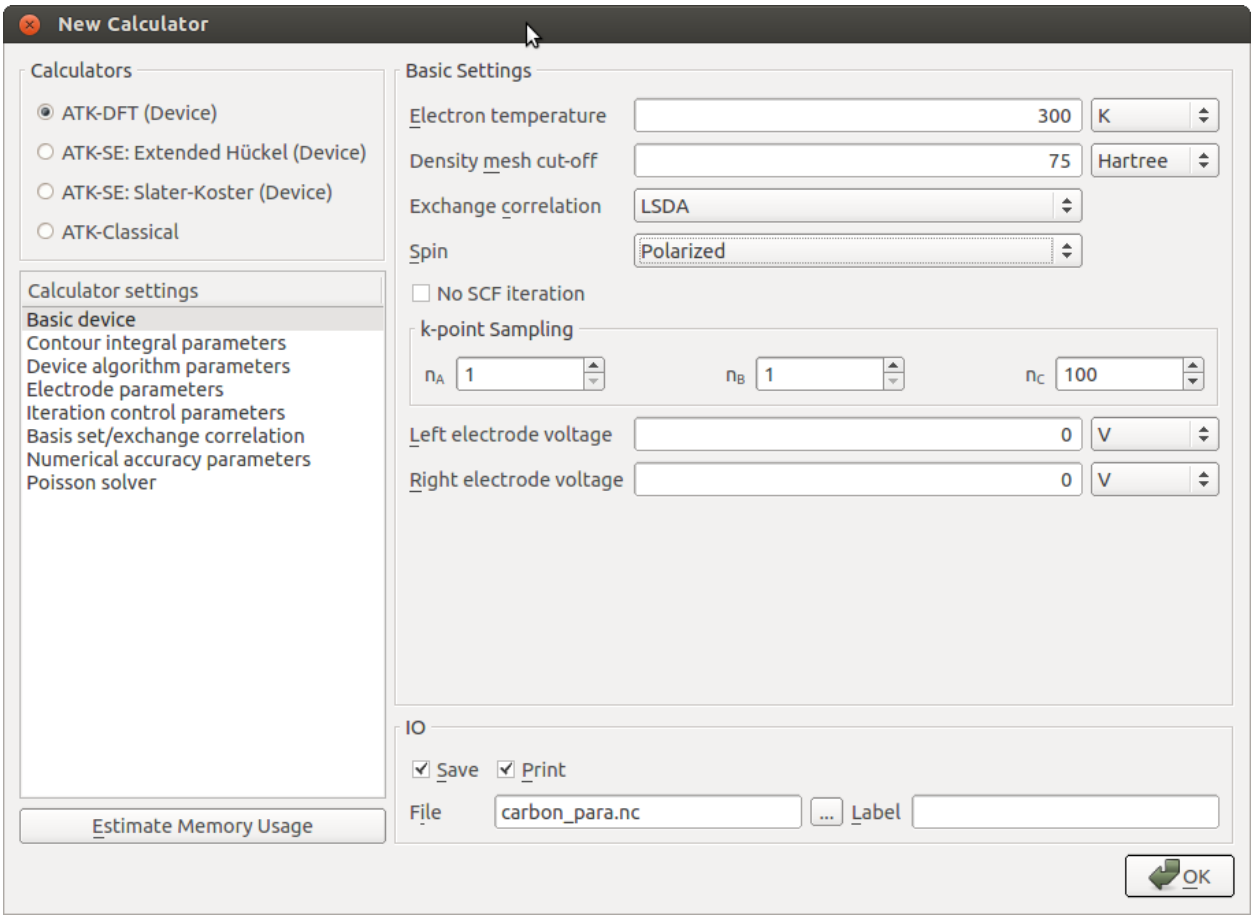
You will now set up a NEGF-DFT calculation with parallel spins throughout the device, and compute the electronic transmission spectrum for this spin configuration.

1.Send the device configuration to the **Script Generator** by using the **Send to** icon in the lower-right corner of the Builder.

2.Set the **Default output file** to `carbon_para.nc`.

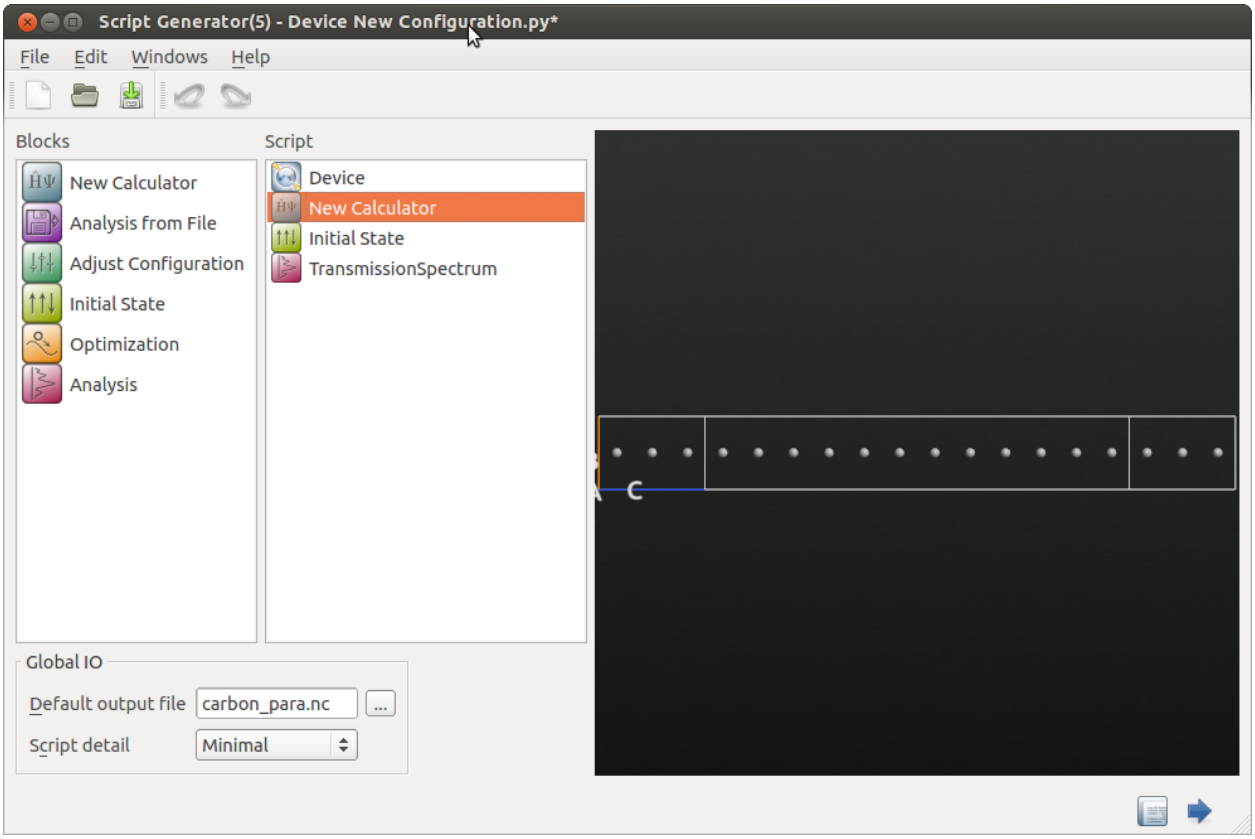
3.Add a New Calculator block to the script, and double-click it to open it.

4.Set the *Spin* to **Polarized**. The exchange–correlation functional will automatically switch to **LSDA**.



5. Add an Initial State block, which defines the initial spin populations. Open it and select **User spin** (all atoms now start out at maximum spin-up polarization).

6. Add a *Analysis* → *TransmissionSpectrum* block. Default parameters are fine for this 1D carbon chain.



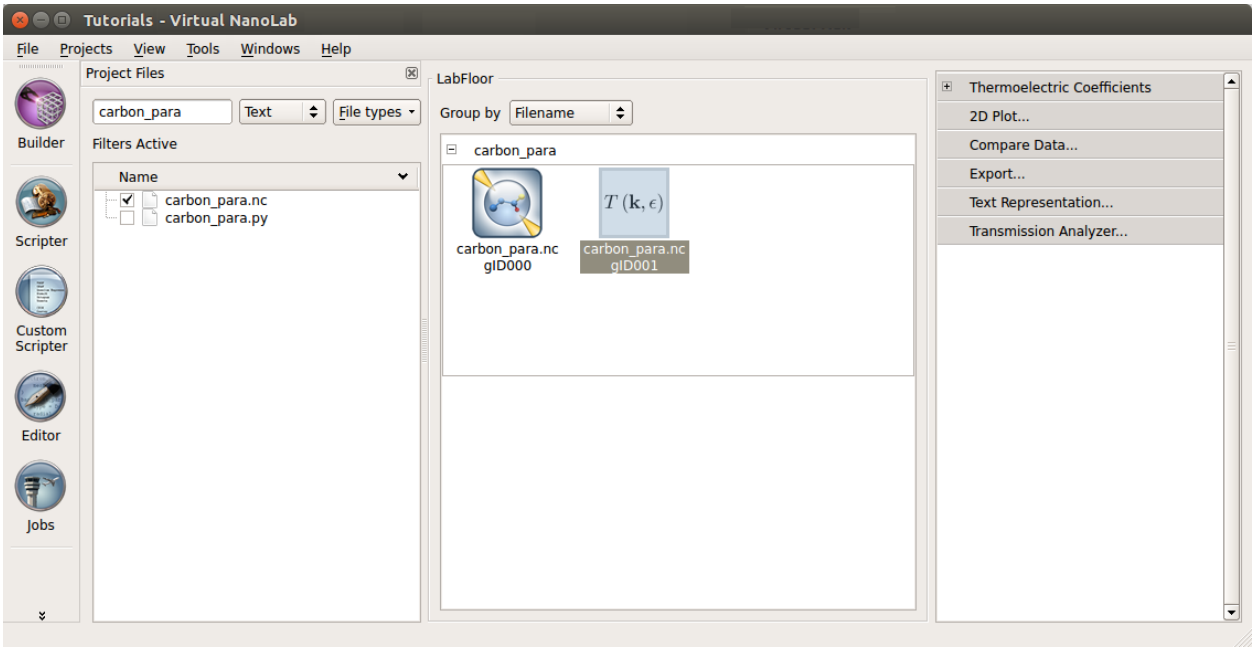
7. The QuantumATK Python script is now ready. Send it to the **Job Manager**, save the script as `carbon_para.py`, and run the calculation – it should only take a few minutes to run.

Note: Do not close the Script Generator window – you will need it later on.

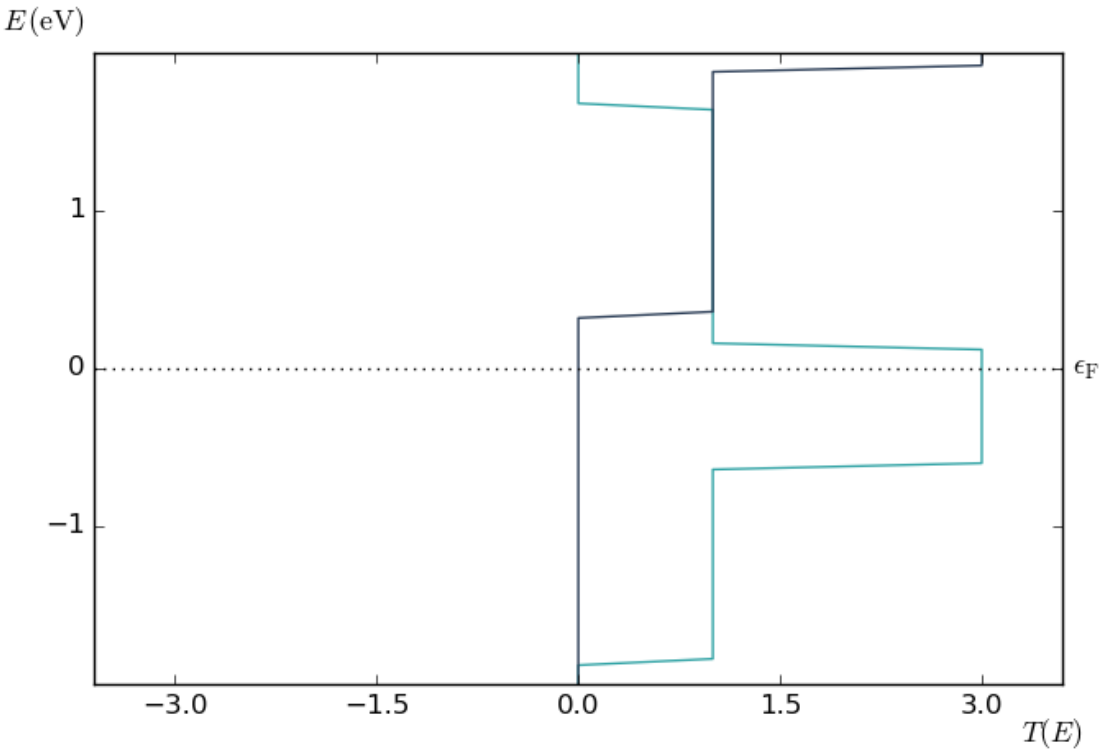
Tip: By inspecting the QuantumATK log file, note that the populations for the up/down (*DM[U]*/*DM[D]*) electronic states are nearly the same on all atoms, as expected in an ideal system. The small differences are primarily due to the fairly low default density mesh cut-off.

Analysis

The calculated **TransmissionSpectrum** analysis object should now be available on the QuantumATK LabFloor.



Select the TransmissionSpectrum and use the **Transmission Analyzer** to plot the spin-parallel transmission spectrum.



Both the up (light blue) and down (dark blue) spin components of the transmission spectrum are plotted, and they are significantly different: The spin-down transmission is zero at the Fermi level, where the (unitless) spin-up transmission is 3.

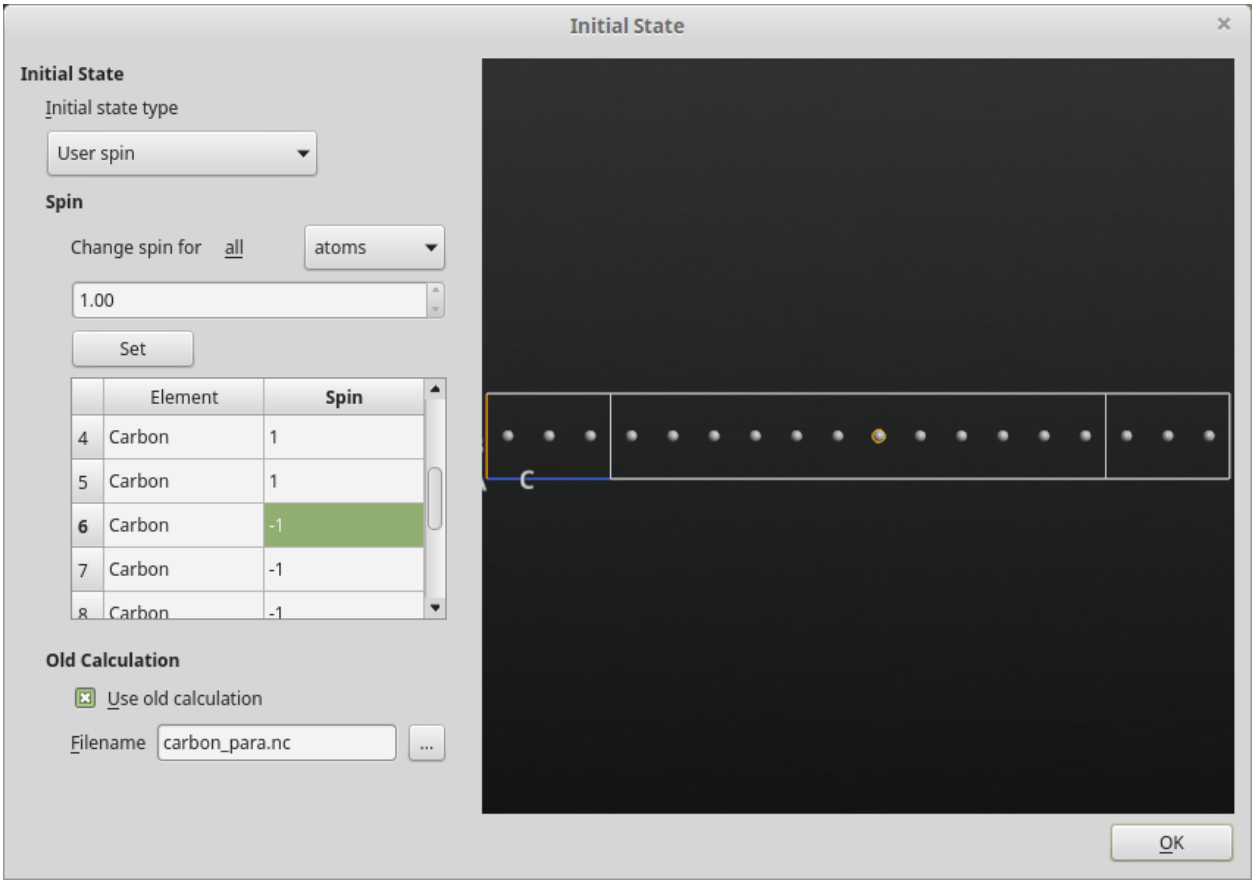
Spin anti-parallel transmission spectrum

You will now do the spin anti-parallel calculation and compare the transmission spectrum to that of the spin-parallel case. The already computed spin-parallel ground state will be used as an initial guess for the anti-parallel calculation.

Return to the **Script Generator** window and modify the settings:

1. Change the **Default output file** to `carbon_anti.nc`.
2. Double-click the InitialState block and modify the following parameters:

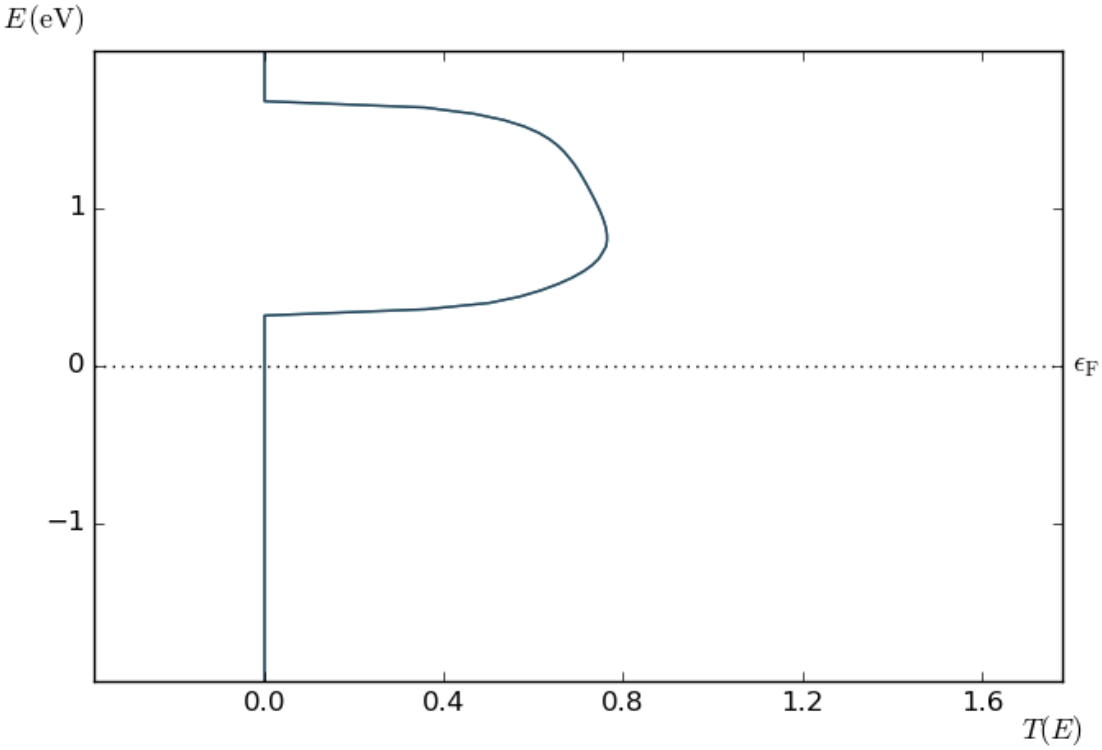
- Set the *initial state type* to **User spin**
- Set the spin on atoms with index 6 to 11 to -1.
- Tick **Use old calculation** and set the *Filename*, from where to read the spin-parallel ground state, to `carbon_para.nc`.



3. Thats it! Save the script as `carbon_anti.py` and run it using the **Job Manager**.

Analysis

When the calculation finishes, use again the **Transmission Analyzer** to plot the transmission spectrum contained in `carbon_anti.nc`. The two spin components have, in this case, identical transmission spectra, as expected from the symmetry of the device.



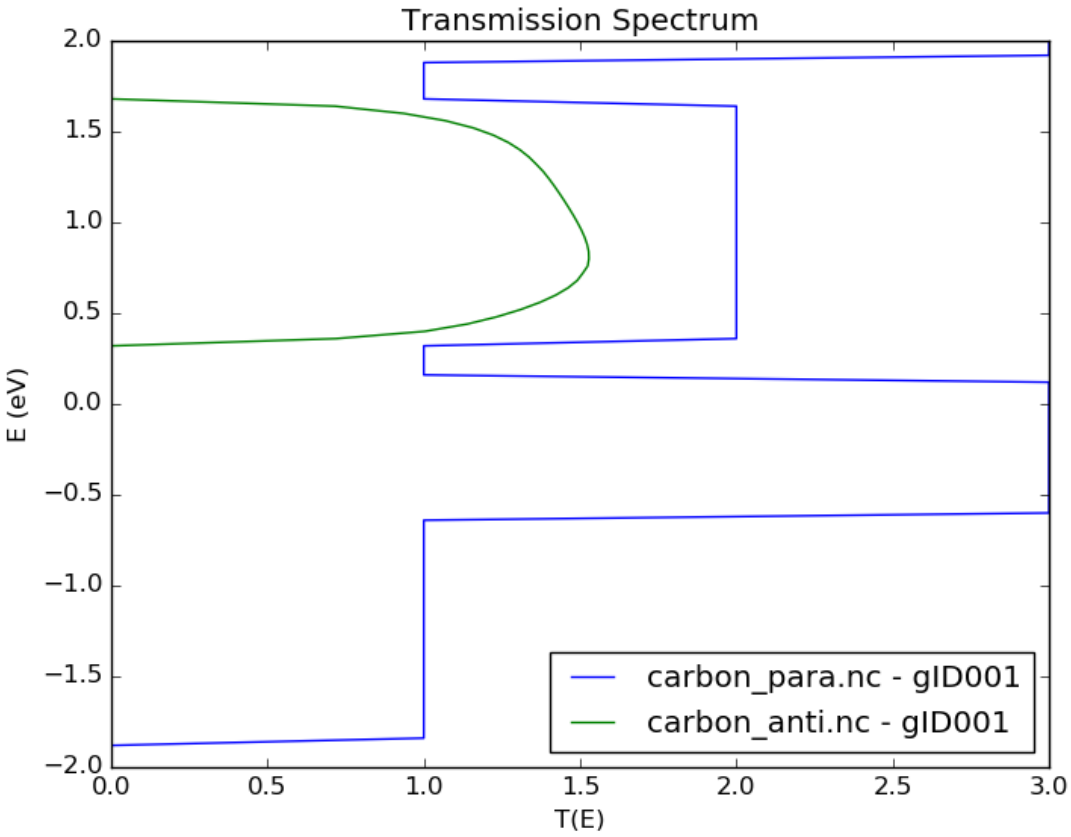
Tip: If you inspect the QuantumATK log file from the anti-parallel calculation, you will see that the spin is indeed flipped in the right part of the device, where the spin-down density matrices, *DM[D]*, have higher occupations than the spin-up ones, *DM[U]*:

```
+-------------------------------------------------------------------------------+
| Density Matrix Report                          DM[U]     DM[D]      DD        |
+-------------------------------------------------------------------------------+
|   0   C   [   3.000 ,   3.000 ,   1.450 ]    2.99639   1.00028  -0.00333     |
|   1   C   [   3.000 ,   3.000 ,   4.350 ]    3.00324   0.99997   0.00321     |
|   2   C   [   3.000 ,   3.000 ,   7.250 ]    2.99536   1.00105  -0.00359     |
|   3   C   [   3.000 ,   3.000 ,  10.150 ]    3.00271   1.00275   0.00546     |
|   4   C   [   3.000 ,   3.000 ,  13.050 ]    2.96897   1.01659  -0.01444     |
|   5   C   [   3.000 ,   3.000 ,  15.950 ]    2.92841   1.08262   0.01103     |
|   6   C   [   3.000 ,   3.000 ,  18.850 ]    1.08262   2.92840   0.01101     |
|   7   C   [   3.000 ,   3.000 ,  21.750 ]    1.01660   2.96897  -0.01444     |
|   8   C   [   3.000 ,   3.000 ,  24.650 ]    1.00275   3.00271   0.00546     |
|   9   C   [   3.000 ,   3.000 ,  27.550 ]    1.00105   2.99535  -0.00359     |
|  10   C   [   3.000 ,   3.000 ,  30.450 ]    0.99997   3.00325   0.00322     |
|  11   C   [   3.000 ,   3.000 ,  33.350 ]    1.00027   2.99629  -0.00344     |
+-------------------------------------------------------------------------------+
```

Regarding the use of the spin-parallel calculation as initial state, QuantumATK will actually flip the density matrix if the

initial spin (which is set in the InitialState block) is less than zero. Also, the spins in both electrodes are automatically set to match the spin configuration in the corresponding electrode extensions.

Finally, mark both the parallel and anti-parallel transmission spectra on the LabFloor, and use the **Compare Data** plugin to directly compare the total transmission in both cases. The transmission in the spin-parallel state (blue) is significantly larger than that of the anti-parallel state (green) over most of the sampled energy window around the Fermi level.

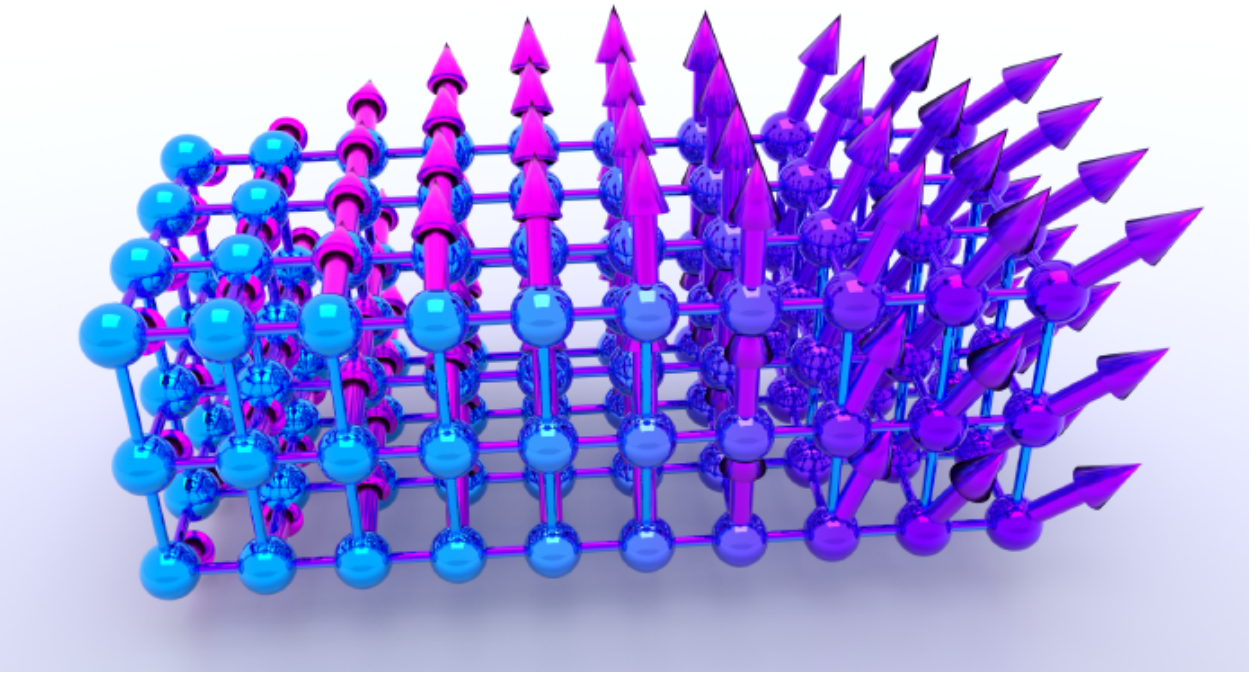


3.5.3 Introduction to noncollinear spin

Version: 2016.3

In standard (collinear) spin-polarized calculations, the spin quantum number (up or down) is added to the electronic states. In contrast, **noncollinear spin** allows the electronic spin to point in any direction. This introduces a few more concepts – and possibilities! – which may be somewhat unfamiliar. This tutorial therefore provides a simple introduction to **ATK-DFT** calculations with noncollinear spin densities.

As briefly stated above, **noncollinear magnetism** refers to situations where the spin direction depends on position in such a way that there is no particular direction in which all the spins are (anti)parallel. Noncollinear spins are quite ubiquitous in nature, and include systems with spin spirals (e.g. chromium) and helicoids, canted spins (e.g. manganites), and most commonly domain walls in ferromagnetic materials. **ATK** allows you to study systems with noncollinear spins from first principles, but it is technically and conceptually quite different from the familiar case of collinear spin.



From collinear to noncollinear spin

It is important to realize that the familiar concept of spin as being either *up* or *down* – and all derived quantities also being labeled by this quantum number – does not work in a noncollinear DFT calculation. Instead, the eigenstate of an atom is a **spinor** with a certain mixing of both spin up and down channels, and many quantities – like the electron transmission spectrum – become a 2x2 matrix rather than two separate numbers (spin up and down transmission).

Another important aspect of noncollinear calculations in practice is that they require in general more CPU time and memory than the corresponding spin-polarized or unpolarized calculation. SCF convergence may also be harder to achieve, since the electronic states have more degrees of freedom.

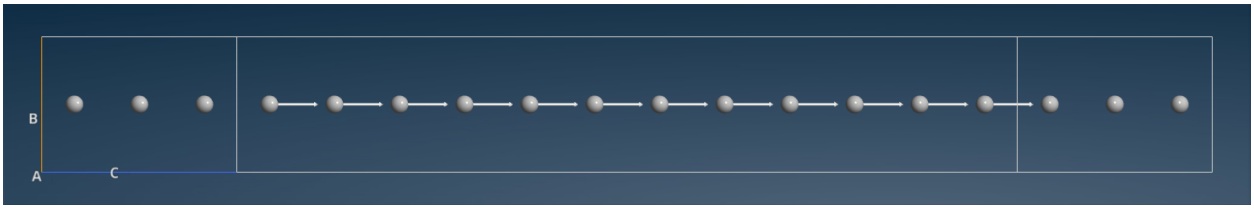
Two key features have therefore been implemented in QuantumATK to improve the SCF convergence rate for non-collinear calculations:

1. use of a collinear spin-polarized calculation as starting point;
2. a special density mixing scheme which diagonalizes the density matrix before mixing it.

Using these techniques, the required number of iterations to reach the selfconsistent noncollinear ground state can be reduced substantially.

Getting started

As mentioned above, the recommended approach for noncollinear calculations is to use a collinear spin-polarized calculation as the initial state. This tutorial therefore takes as starting point the collinear spin-parallel ground state of a simple carbon-chain device obtained in the tutorial *Transmission spectrum of a spin-polarized atomic chain*.



Start by opening **QuantumATK** and create a new project. If you have not already completed the aforementioned tutorial, use a script to calculate the required spin-parallel ground state: `carbon_para.py`. The calculation takes less than 5 minutes and saves the result in the file `carbon_para.nc`.

You will now use the selfconsistent calculation stored in this file as the starting point for a noncollinear calculation of the same linear 1D chain of carbon atoms. However, instead of just considering the parallel and anti-parallel (left electrode *up*, right electrode *down*) spin configurations, you will consider any angle of spin rotation between the two electrodes.

Spin rotation of 120ř

Open the QuantumATK **Editor** (or your own favorite editor) and copy/paste the following lines of *ATK Python* code into it:

```
# Read in the collinear calculation
device_configuration = nlread('carbon_para.nc', DeviceConfiguration)[0]

# Use the special noncollinear mixing scheme
iteration_control_parameters = IterationControlParameters(
    algorithm=PulayMixer(noncollinear_mixing=True)
    )

# Get the calculator and modify it for noncollinear LDA
calculator = device_configuration.calculator()
calculator = calculator(
    exchange_correlation=NCLDA.PZ,
    iteration_control_parameters=iteration_control_parameters
    )

# Define the spin rotation
theta = 120*Degrees
left_spins   = [(i, 1, 0*Degrees, 0*Degrees) for i in range(3)]
center_spins = [(i+3, 1, theta*i/5, 0*Degrees) for i in range(6)]
right_spins  = [(i+9, 1, theta, 0*Degrees) for i in range(3)]
spin_list    = left_spins + center_spins + right_spins
initial_spin = InitialSpin(scaled_spins=spin_list)

# Setup the initial state as a rotated collinear state
device_configuration.setCalculator(
    calculator,
    initial_spin=initial_spin,
    initial_state=device_configuration
    )

# Calculate and save
```

(continues on next page)

(continued from previous page)

```
device_configuration.update()
nlsave('carbon_nc120_ncmix.nc', device_configuration)
```

The spin setup corresponds to the spin polarization of the atoms in the left electrode pointing along the transport axis C, while in the right electrode the polarization is rotated 120 degrees (polar angle in a coordinate system where the XY plane is the equator). In the central region, the angle is interpolated between these two values. Note that this is just the **initial spin configuration** – the actual spin polarization vectors will be computed selfconsistently and may therefore change (you can see the result below).

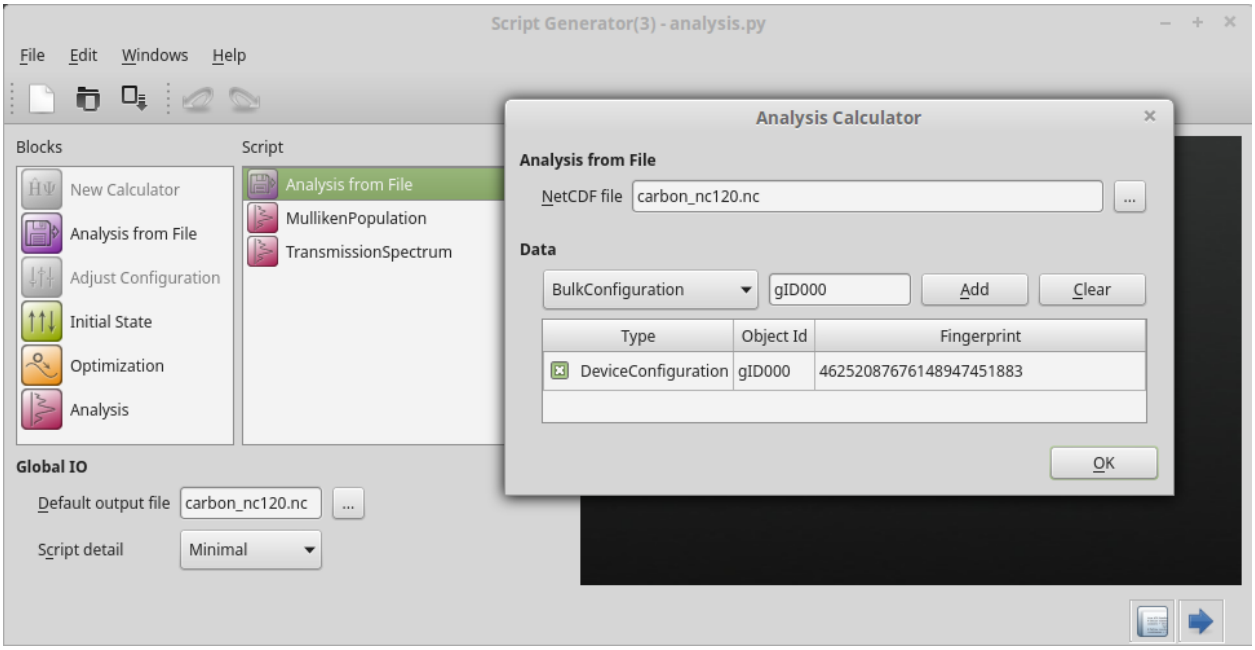
Note: The initial electrode spins are automatically identical to the initial spins on the atoms in the electrode extensions in the central region, in this case the 3 first and last atoms.

Save the script as `carbon_nc120.py`, and then run it – it should take a few minutes only. Remember that you can use the **Job Manager** for this.

Analysis

The NEGF calculation is done, and its time to do some analysis. Use the Script Generator to set up the post-SCF analysis calculations:

1. Open the **Script Generator**.
2. Double-click the **Analysis from File** block to insert it into the Script panel. Then double-click the inserted block and select the file `carbon_nc120.nc`, which was generated in the previous section.
3. Add a **MullikenPopulation** analysis block.
4. Add a **TransmissionSpectrum** analysis block (use default parameters).
5. Set the output file to `carbon_nc120.nc`.
6. Run the script using the **Job Manager**.



The analysis script should look roughly like this:

```
# -*- coding: utf-8 -*-
# ------------------------------------------------------------
# Analysis from File
# ------------------------------------------------------------
path = u'carbon_nc120.nc'
configuration = nlread(path, object_id='gID000')[0]

# ------------------------------------------------------------
# Mulliken Population
# ------------------------------------------------------------
mulliken_population = MullikenPopulation(configuration)
nlsave('carbon_nc120.nc', mulliken_population)
nlprint(mulliken_population)

# ------------------------------------------------------------
# Transmission Spectrum
# ------------------------------------------------------------
kpoint_grid = MonkhorstPackGrid()

transmission_spectrum = TransmissionSpectrum(
    configuration=configuration,
    energies=numpy.linspace(-2,2,101)*eV,
    kpoints=kpoint_grid,
    energy_zero_parameter=AverageFermiLevel,
    infinitesimal=1e-06*eV,
    self_energy_calculator=RecursionSelfEnergy(),
    )
nlsave('carbon_nc120.nc', transmission_spectrum)
nlprint(transmission_spectrum)
```

Mulliken populations

The Mulliken populations is now available as an analysis object on the QuantumATK LabFloor, and can be inspected using the **Text Representation** tool in the right-hand panel bar.

Text Representation - carbon_nc120.nc gID001

```
+-------------------------------------------------------------------------------+
|                                                                               |
| Noncollinear Mulliken Population                                              |
|                                                                               |

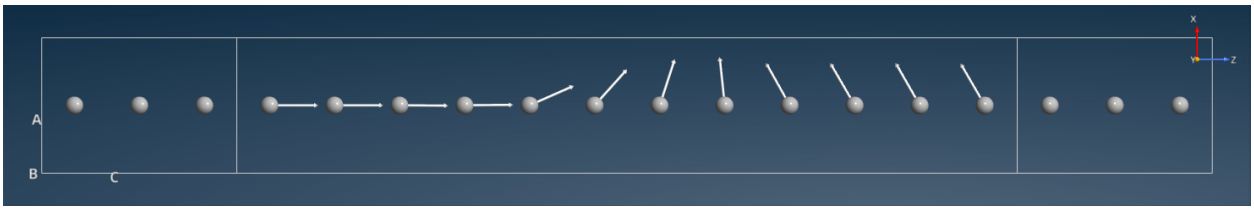
|   8   C     2.9961    1.0039        119.4304           0.0000                 |
|   9   C     2.9996    0.9999        120.3376           0.0000                 |
|  10   C     3.0000    1.0002        119.9731           0.0000                 |
|  11   C     2.9881    1.0117        120.3336           0.0000                 |
|                                                                               |
+-------------------------------------------------------------------------------+
|                                                                               |
| Mulliken Population Report in Local Atomic Spin-Directions                    |
|                                                                               |
| ----------------------------------------------------------------------------- |
```

You immediately notice the difference to the collinear case: Now the Mulliken population on each atom is described by 4 variables; *Up*, *Down*, *Theta* and *Phi*. Note that *Phi=180* is equivalent to *Phi=0*. The sum of the up and down populations corresponds, as usual, to the total Mulliken charge (the number of electrons), and their difference – combined with the two angles – forms a spin polarization vector, which can be visualized in the QuantumATK **Viewer**:

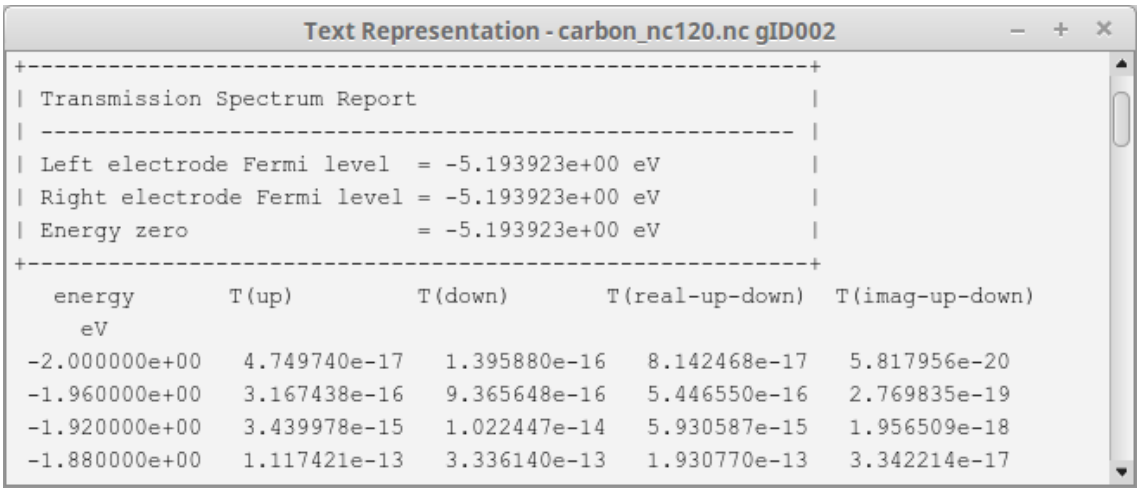


It is clear that the spin polarization direction changes smoothly between the two values in the electrodes.

Tip: The Viewer **view plane** used in the image is ZX. Use the *Camera* settings menu to select a view plane different from the default ZY.

Transmission spectrum

The *TransmissionSpectrum* analysis object is also available on the LabFloor. Use the **Text Representation** tool to inspect it – you again see that it has 4 components; *up*, *down*, *real-up-down* and *imag-up-down*:



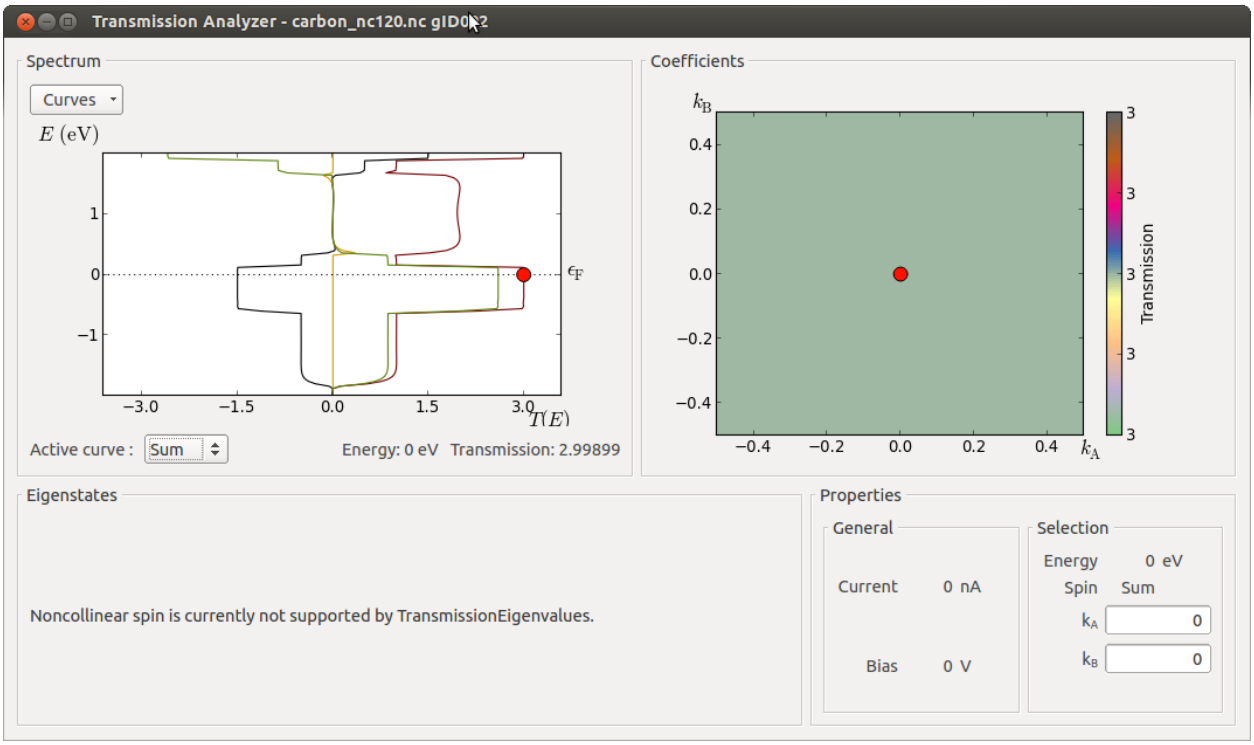
The last spin component (*imag-up-down*) is very small in this simple system, but will in general be important in cases where the spins have other directions.

Note: Any quantitty calculated using noncollinear spin is represented as a 2x2 matrix (a spinor) with different mixing of *up* and *down* components: $\uparrow\uparrow$, $\downarrow\downarrow$, $\uparrow\downarrow$, and $\downarrow\uparrow$.

As explained in the QuantumATK Manual section *Spin*, a range of different **spin projections** may be derived from these 4 basic components, including *Sum*, *X*, *Y*, and *Z*:

$$
\begin{aligned}
T(\text{Spin.Sum}) &= T(\uparrow\uparrow) + T(\downarrow\downarrow) \\
T(\text{Spin.X}) &= 2 \cdot \text{Re}(T(\uparrow\downarrow)) \\
T(\text{Spin.Y}) &= 2 \cdot \text{Im}(T(\uparrow\downarrow)) \\
T(\text{Spin.Z}) &= T(\uparrow\uparrow) - T(\downarrow\downarrow)
\end{aligned}
$$

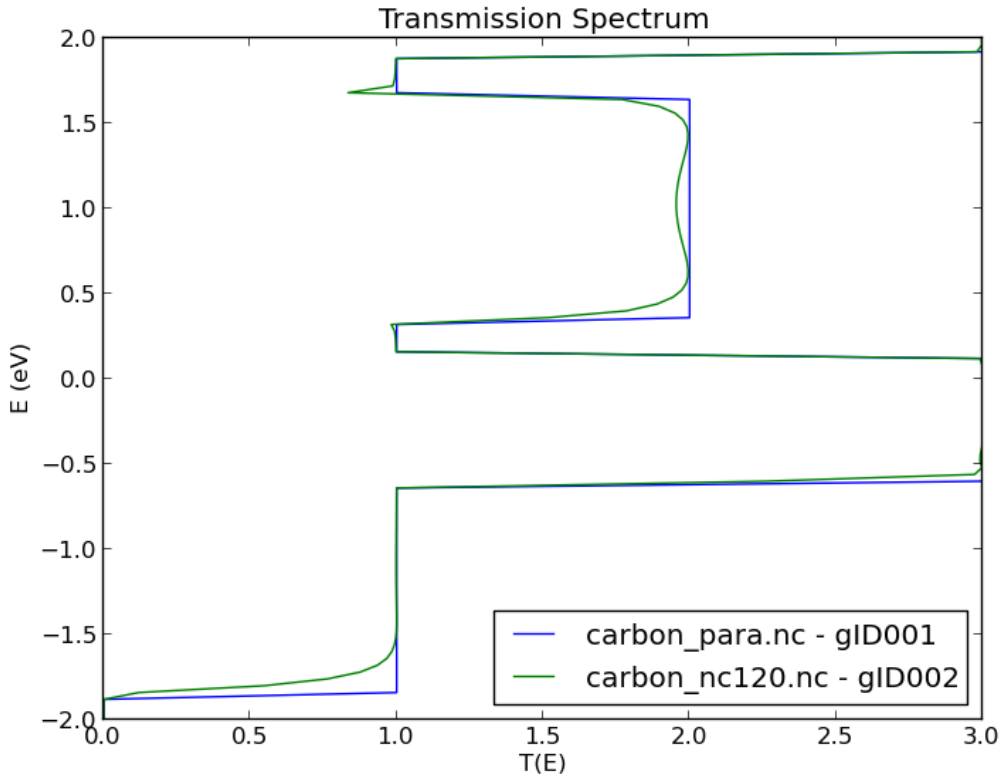
Use the **Transmission Analyzer** plugin to plot the transmission spectrum. The transmission components *Sum*, *X*, *Y*, and *Z* are by default included in the graph:



Tip: The drop-down menu *Curves* at the top-left of the window lets you choose which spin projection to include, while the lower Active curve option is for choosing which k-point resolved spectrum to show in the right-hand Coefficients plot (for this 1D system there is only one transmission coefficient, at (k_A, k_B)=(0,0), so the plot is rather uninteresting). This can also be chosen by clicking the corresponding transmission curve.

The *Spin.Sum* transmission spectrum is very similar to the parallel collinear case, and very different from the anti-parallel collinear case. This may surprise, since the spin configuration in the electrodes are more anti-parallel than parallel. However, due to the noncollinear degrees of freedom, the electron can propagate in a **helical state** when moving from left to right, and this allows for a high transmission. In fact, if you set the rotation angle to 180 degrees, corresponding to anti-parallel alignment of the electrodes, the result will be almost the same.

The figure below compares the transmission spectra for the collinear spin-parallel state and the noncollinear state, using the **Compare Data** plugin.



Spin-orbit interactions

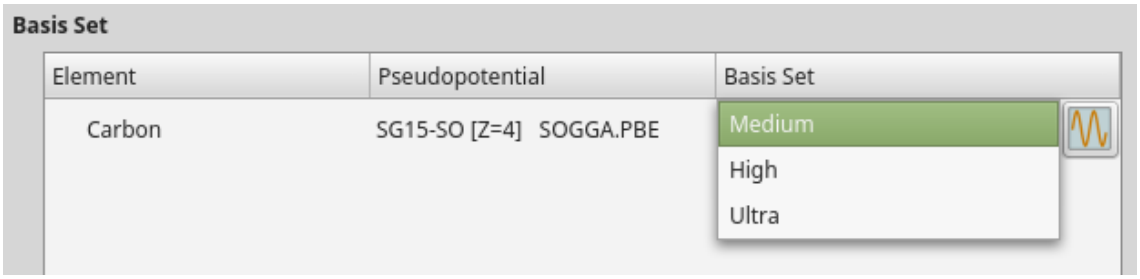
Spin-orbit coupling (SOC) is most often neglected in electronic structure calculations, but it can actually be included in a noncollinear calculation, provided that suitable pseudopotentials are used. You can find more details in the tutorial *Spin-orbit splitting of semiconductor band structures*.

The carbon chain considered here has a very small SOC, so results with spin-orbit interactions included in the electronic structure method will hardly be different from those obtained above. Even so, if you wish to include SOC in calculations similar to the ones outlined in the section *Spin rotation of 120ř*, simply change the exchange–correlation method and pseudopotentials used in the ATK-DFT calculator:

- use spin-orbit GGA (SOGGA) exchange–correlation and SG15-SO pseudopotentials,
- or use spin-orbit LDA (SOLDA) exchange–correlation and OMX pseudopotentials.

Spin-orbit GGA

When setting up the initial collinear calculation, saved as `carbon_para.nc`, choose SGGA exchange-corerlation instead of LSDA, and navigate to the *Basis set/exchange correlation* calculator settings and select the **SG15-SO** type pseudopotential. You will usually have the option to choose between three different basis set sizes:



Note: The density mesh cutoff should not be smaller than 100 Ha when using SG15 pseudopotentials.

Run the spin-polarized GGA calculation, which creates `carbon_para.nc`, and then use `SOGGA.PBE` exchange-correlation when setting up the calculator with spin-orbit coupling:

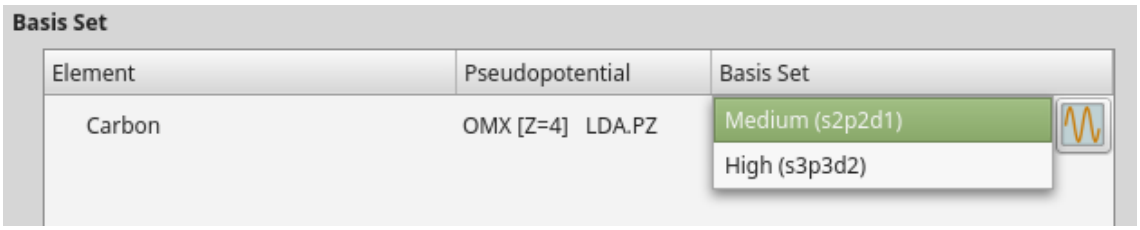
```
# Read in the collinear calculation
device_configuration = nlread('carbon_para.nc', DeviceConfiguration)[0]

# Use the special noncollinear mixing scheme
iteration_control_parameters = IterationControlParameters(
    algorithm=PulayMixer(noncollinear_mixing=True)
    )

# Get the calculator and modify it for spin-orbit GGA:
calculator = device_configuration.calculator()
calculator = calculator(
    exchange_correlation=SOGGA.PBE,
    iteration_control_parameters=iteration_control_parameters
    )
```

Spin-orbit LDA

When setting up the initial collinear calculation, saved as `carbon_para.nc`, navigate to the *Basis set/exchange correlation* calculator settings and select the **OMX** type pseudopotential. You will usually have the option to choose between different basis set sizes:



Note: The OMX potentials are in general fairly hard, so they often require a larger mesh cutoff than e.g. the FHI potentials, usually at least 150 Ha.

Run the spin-polarized LDA calculation, which creates `carbon_para.nc`, and then use `SOLDA.PZ` exchange-correlation when setting up the calculator with spin-orbit coupling:

```
# Read in the collinear calculation
device_configuration = nlread('carbon_para.nc', DeviceConfiguration)[0]

# Use the special noncollinear mixing scheme
iteration_control_parameters = IterationControlParameters(
    algorithm=PulayMixer(noncollinear_mixing=True)
    )

# Get the calculator and modify it for spin-orbit GGA:
calculator = device_configuration.calculator()
calculator = calculator(
    exchange_correlation=SOLDA.PZ,
    iteration_control_parameters=iteration_control_parameters
    )
```

Tip: Whats next? You should consider the tutorial *Noncollinear calculations for metallic nanowires*.

Noncollinear spin is essential when computing the spin transfer torque, see for example the tutorials *Spin Transfer Torque* and *Spin transport in magnetic tunnel junctions*.

The tutorials *Spin-orbit splitting of semiconductor band structures* and *Relativistic effects in bulk gold* give more details of spin-orbit calculations with ATK-DFT.

3.5.4 Carbon Nanotube Junctions

QuantumATK: CNT Junctions Platforms: Links: *3D View*, *Exploring Graphene* *An important feature of the NEGF transport model implemented in QuantumATK is its ability to treat heterogeneous systems, meaning device geometries where the two electrodes are not the same. This makes it possible to study a wide range of important systems, such as the contact resistance between two materials (for instance a semiconductor/metal interface) or the capacitance of junctions between nanotubes of different chirality. In this tutorial you will learn how to set up the geometry of such a junction.*

NEGF

You may find a short introduction to the **Non-Equilibrium Greens Function** method here: arXiv.

The steps involved in the Builder are rather simple, but for this type of geometry it is important to study how the transmission and other properties change depending on how much the two tubes overlap. Therefore, you will also learn how to vary this distance, by adding a few lines of Python code to the script.

Note:

•CNTs: Types and Properties

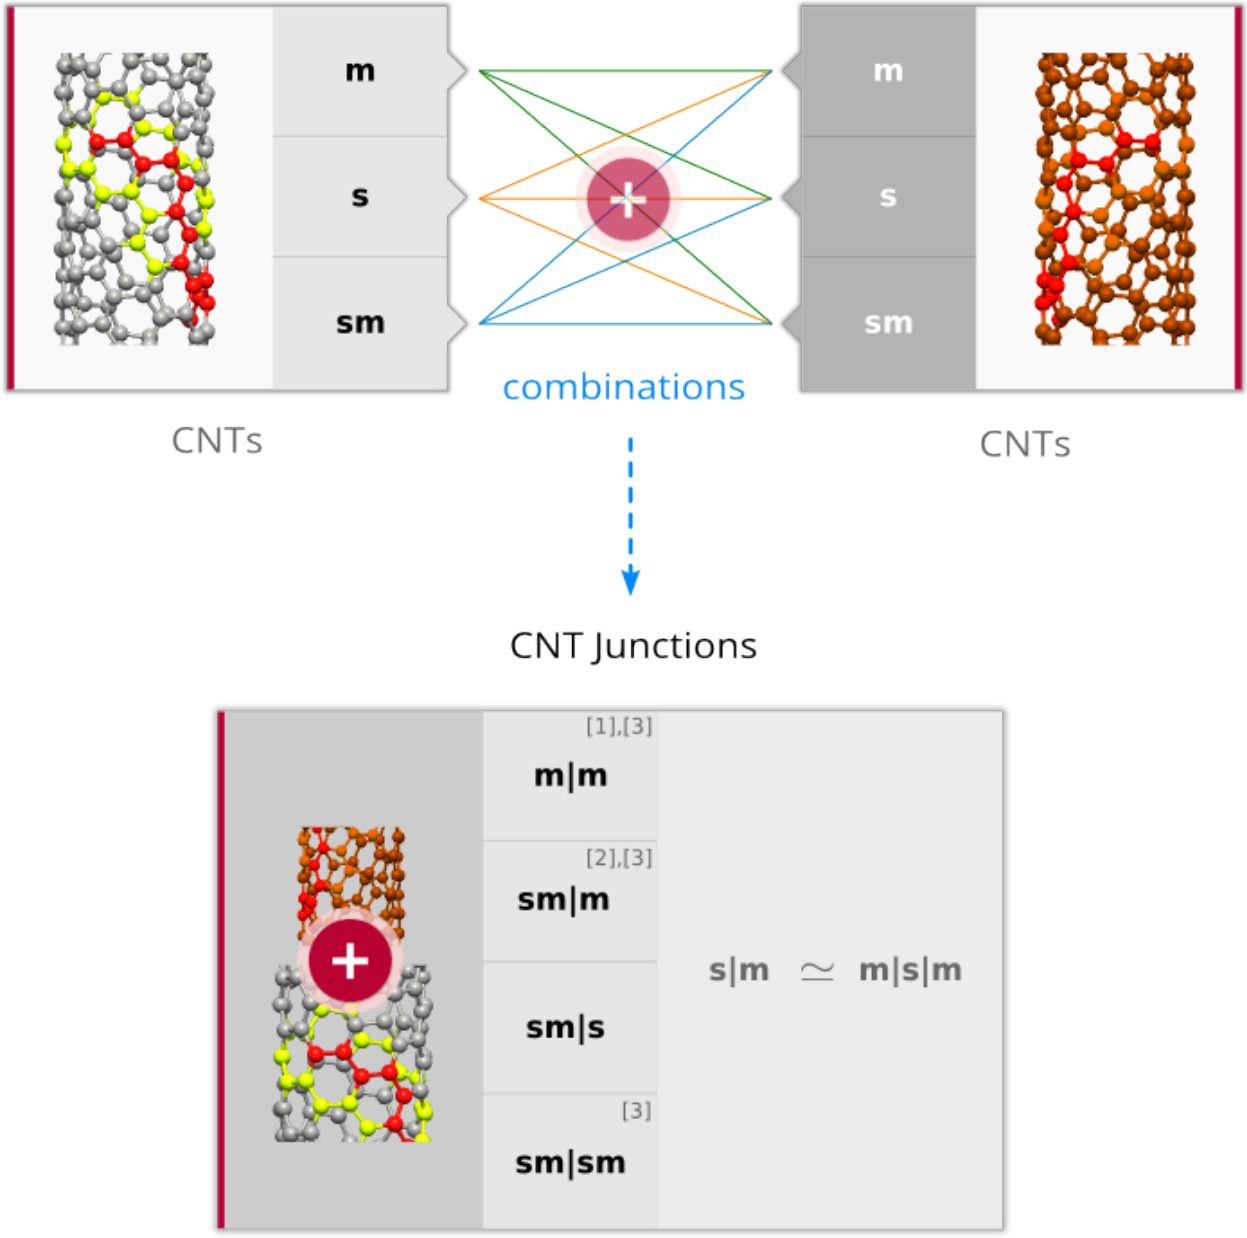
The atomic structure of a CNT is described by a pair of integers called chiral indices $(n, m) \in \mathbf{Z}^2$. If $m = 0$ then the CNT has a zigzag structure. Other special values of these indices describe CNTs with special properties as follows:

1.If $n = m$ then the CNT is **metallic (m)** (armchair structure).

2.If $n \neq m$ then the CNT is **semiconducting (s)** (chiral structure).

3.If $n - m \in 3\mathbf{Z}^*$ then the CNT is **semimetallic (sm)** (chiral structure).

•Possible Combinations for CNT Junctions



Note 1: Here we denote the junction with a vertical bar: |. **Note 2:** Junctions between metallic and semiconducting would be interesting too, although probably in that case the relevant geometry is m|s|m, rather than m|s.

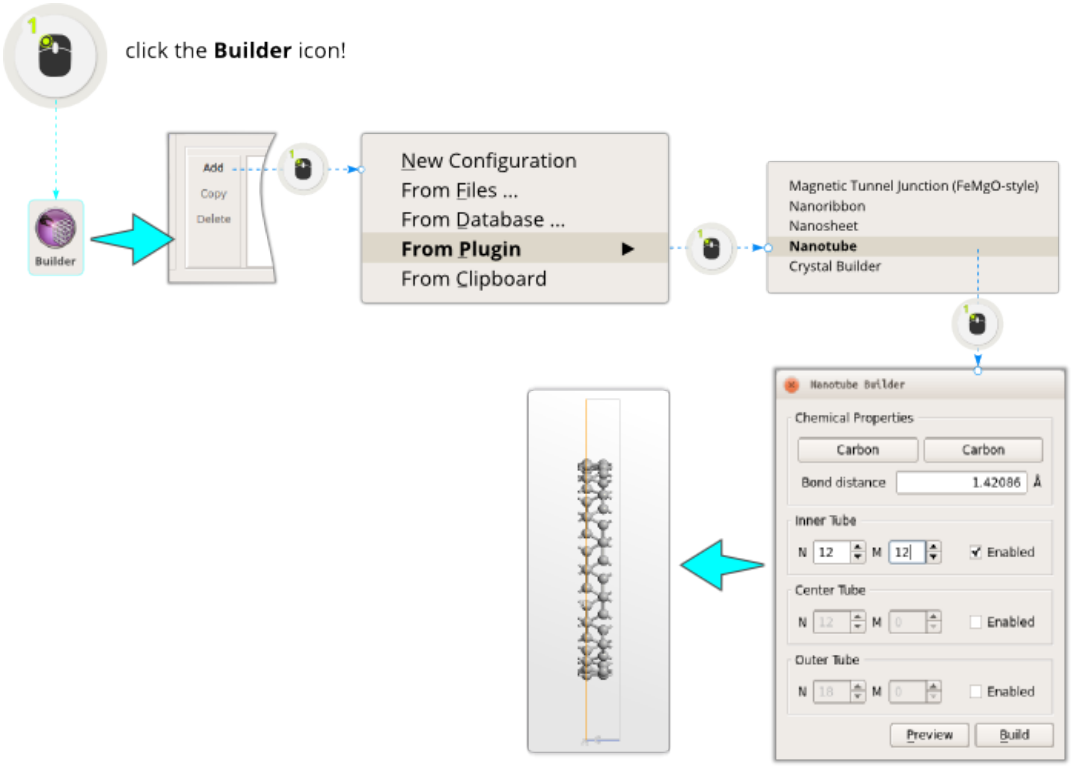
Setting up the geometry

First, you need to set up the reference geometry where the two tubes are just in contact with each other. It is reasonable to define this as the case where the atoms on the edges of the two tubes have the same Z coordinate.

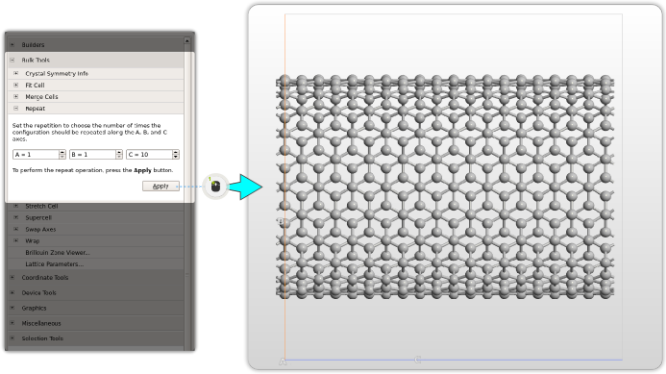
CNT Junction Example: m|m with (12,12)|(5,5)

The instructions below will be using the m|m case of a (12,12)|(5,5) junction, but the steps involved are identical for any combination of chiralities.

•**Step 1:** Create a (12,12) metallic CNT using the **Nanotube** plugin following the steps bellow.



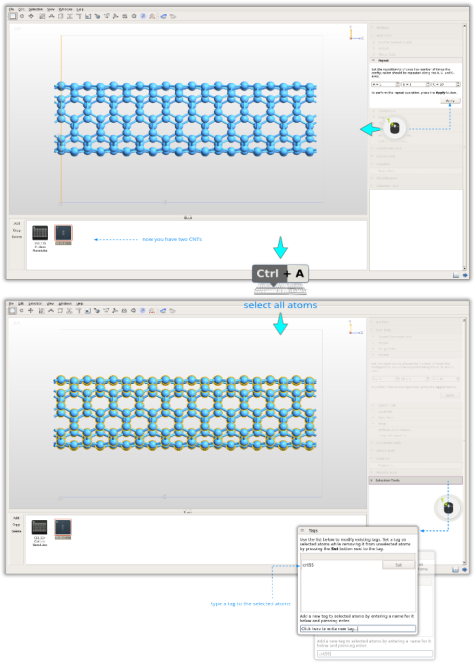
•**Step 2:** The CNT is quite thin and its better to increase its length. Lets repeat the structure 10 times along the C (tube) axis using the *Boolk Tools* → *Repeat* tool and choosing C=10:



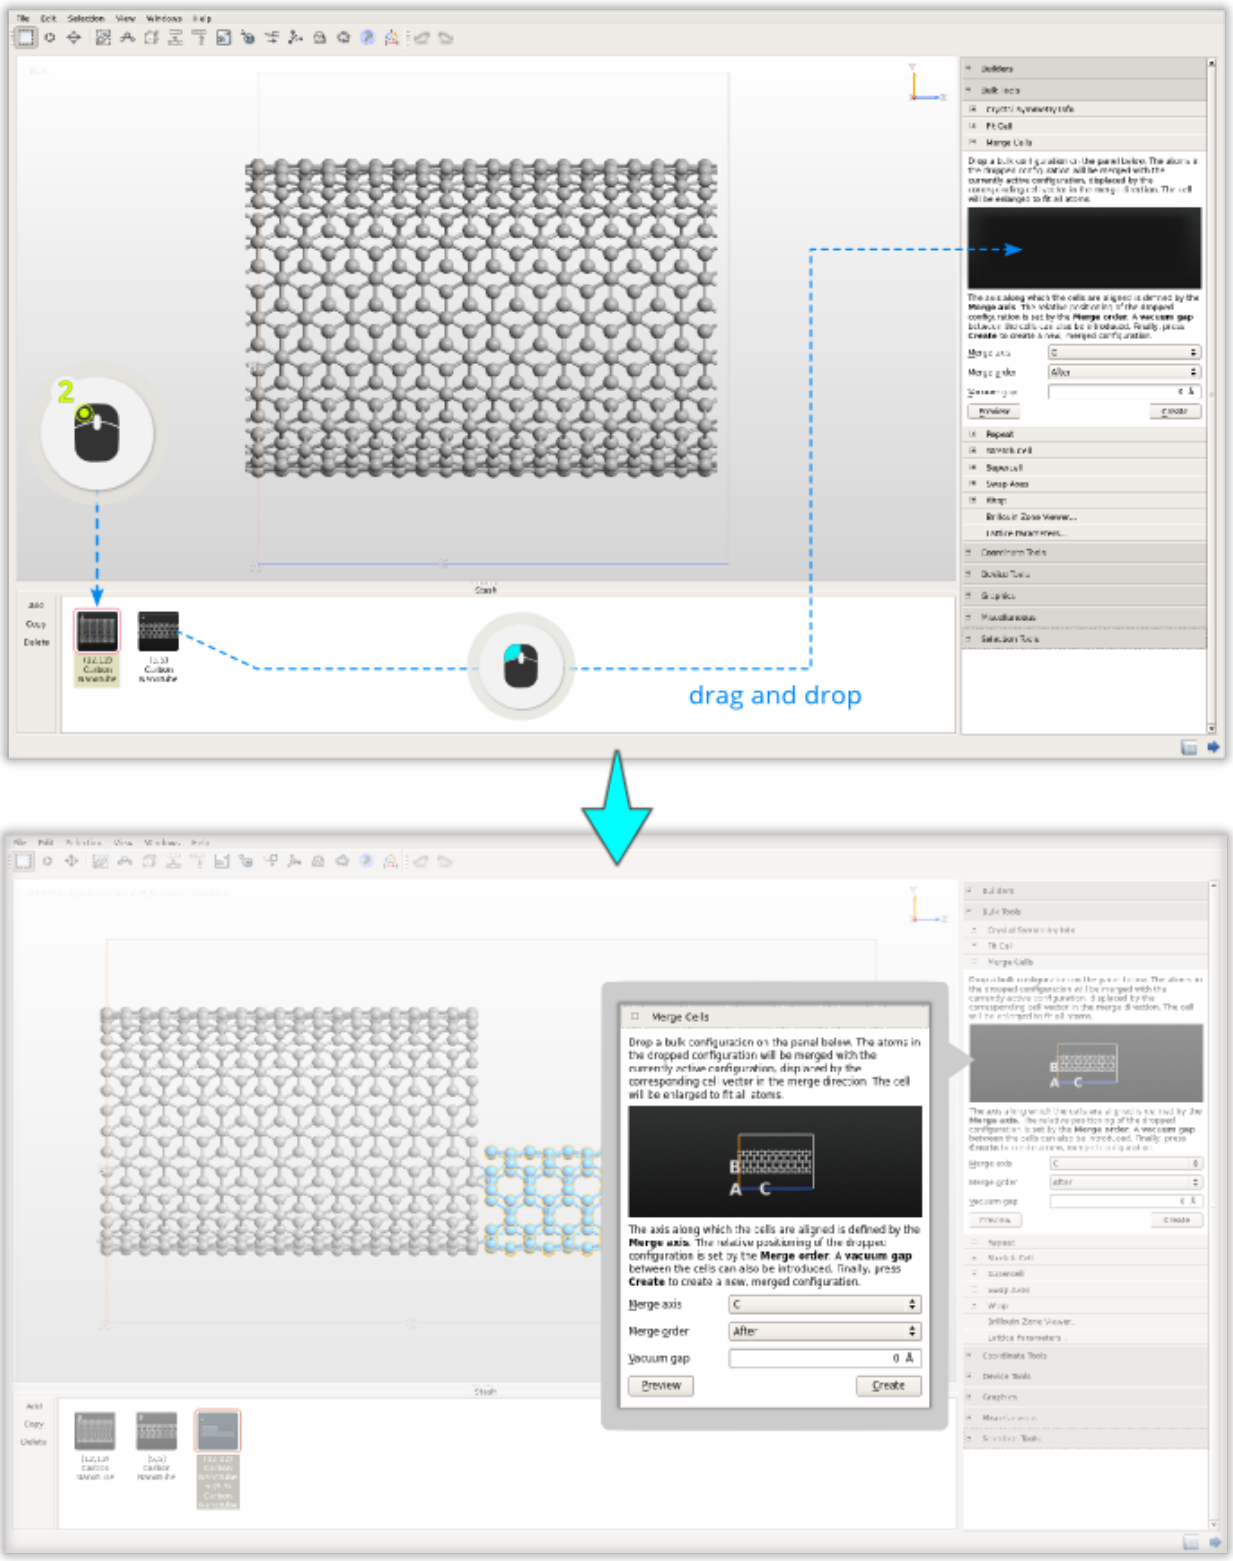
•**Step 3:** In order to create a second CNT with (n,m)=(5,5) just repeat the previous steps and type N=5 and M=5 in the Nanotube plugin. Also we choose to have the same length as the first CNT and thus we repeat the structure ten times.

In the end you will have two CNTs of equal length (one with (12,12) and another one with (5,5) chiral indices) on the Builder **Stash**.

Tip: **Tagging:** In order to later on be able to identify the two tubes, add a tag to all atoms in the (5,5) tube by first selecting all atoms (Ctrl+A) and then open *Select* → *Tags*. Add the tag **cnt55** to all atoms in the (5,5) tube.



- **Step 4:** Double click to the (12,12) structure on the Stash in order to activate it.
- **Step 5:** There is a specific tool in the Builder for *gluing* two bulk cells together: *Bulk Tools* → *Merge Cells*. This plugin takes a bulk configuration and attaches it to the active configuration, on a specified side of the existing unit cell. Drag the (5,5) tube onto the 3D window in the plugin panel. The default options are correct - the (5,5) tube should be added after the (12,12) tube in the C direction. Click **Create**.



•**Step 6:** The (5,5) tube needs to be centered in the z=0 plane (xy-plane), since its original unit cell was smaller than that of the (12,12) tube. Therefore, select all atoms in the (5,5) tube by opening the **Tag Select** tool , select the tag **cnt55**, then OK. Then open *Coordinate Tools* → *Center* and center the tube in the A,B direction - that is, untick C, and

click **Apply**.

•**Step 7:** The system is no longer periodic in any direction, so remove the unit cell by clicking the **Molecule button** .

An interesting quantity to study for a junction like this is how the conductance changes as a function of the amount of overlap - or distance - between the tubes. To have a clear definition of the distance d between the tubes, its important to establish a reference point which we define as d=0. The most convenient definition is the case when the edges of the tubes overlap, and the next steps will align the tubes into this configuration.

•**Step 8:** Activate the **Move tool** and select an atom on the right-most edge of the (12,12) tube (largest Z coordinate).

This selects all atoms in the (12,12) tube - or, more specifically, all atoms connected by bonds to the clicked atom - and the clicked atom becomes an anchor atom, as indicated by the label 0 and the red selection marker.

Set the Z coordinate of this atom to 0 Angstroms. Press Enter. Exit the Move tool by closing the Move widget, and deselect all atoms by clicking the black background (or by pressing Esc). Repeat these steps for the (5,5) tube, but this time select an atom on the left-most edge (smallest Z coordinate).

•**Step 9:** In order to create a device we need a unit cell, so add back the unit cell (it was primarily removed to make it easier to align the two tubes) by clicking the **Bulk icon** . Finally, open *Device Tools* → *Device From Bulk* and click OK.

Changing the distance between the tubes: Manual way

You now have the geometry for the d=0 case, i.e. the geometry where the distance between the tubes is defined as zero. To change the overlap distance d between the tubes, you could now in principle carry out the following steps:

•Make a copy of the geometry on the Stash.

•Convert back to a molecular geometry ( ).

•Select all atoms in the (5,5) tube ( ).

•Open *Coordinate Tools* → *Translate* and move the (5,5) tube the desired distance d.

•Convert back to a bulk configuration ( ) and convert to a device.

Repeat this procedure for all values of d you want to study Now, that becomes rather tiresome, if you want to scan several distances. So instead, you can make a small Python function that performs these tasks automatically. This will be described in the next section.

Using a Python function for changing the overlap distance

Save a copy of the d=0 geometry as a Python script, for safety. Then, send the structure from the Builder to the Editor, by using the **Send To** icon ( ) in the lower right-hand corner of the Builder. Scroll to the bottom of the script, and insert the following lines of code at the bottom of the script:

```
# ------------------------------------------------------------------------------
def moveTube(device_configuration, d=0.0):
    # d is assumed to be in Angstrom
    # Extract the central region from the device configuration
    central_region = device_configuration.centralRegion()

    # Number of atoms
    N = len(central_region.cartesianCoordinates())
    # Which atoms are in the right tube? Those with tag="2"
    right_tube = device_configuration.indicesFromTags("2")

    # Set a Z shift of d for these atoms, and zero for others
    delta = numpy.zeros(N)
    delta.put(indices=right_tube, values=d)
    Delta = numpy.array([numpy.zeros(N),numpy.zeros(N),delta]).transpose()
    # Shift coordinates!
    new_coordinates = central_region.cartesianCoordinates() + Delta*Angstrom
    # Extend (or contract) the unit cell by the same amount
    va, vb, vc = central_region.bravaisLattice().primitiveVectors()
    vc = vc + [0.0, 0.0, d]*Angstrom
    new_cell = UnitCell(va,vb,vc)
    # Rebuild central region (transfer ghost atoms too)
    new_central_region = BulkConfiguration(
        bravais_lattice=new_cell,
        elements=central_region.elements(),
        cartesian_coordinates=new_coordinates,
        ghost_atoms = central_region.ghostAtoms(),
    )

    # Transfer the tags to the new configuration
    for tag in central_region.tags():
        new_central_region.addTags(tag, central_region.indicesFromTags(tag))

    # "Device from bulk" the scripting way
    from NL.CommonConcepts.Configurations.DeviceFromBulk import deviceFromBulk
    left_electrode, right_electrode = device_configuration.electrodes()
    left_electrode_length = left_electrode.bravaisLattice().primitiveVectors()[2,2]
    right_electrode_length = left_electrode.bravaisLattice().primitiveVectors()[2,2]
    new_device = deviceFromBulk(left_electrode_length, right_electrode_length,
                                new_central_region
                )

    return new_device
# ------------------------------------------------------------------------------
d = -5.0
device_configuration = moveTube(device_configuration, d)
```

If you want to understand how this code works, you can study the comments which provide quite detailed explanations. Otherwise, all you really need to know is that by changing the value of d (which is assumed to be given in Angstrom) on the second last line, the right tube is shifted in (negative d) or out (positive d) of the left tube.

Tip: To see the result of the operation, send the script back to the Builder, again using the button. This will add no less than four configurations to the Stash, since the electrodes and central region are also recognized as valid configurations present in the script. If you instead send the script to the **Script Generator**, only the device configuration is transfered.

Comments

•The 10x repetition in the C direction gives a rather large system. This is necessary to be able to set the tube distance d to a large negative value, but also increases the computation time considerably. If you limit the values of d you can reduce the number of repetitions to perhaps 6 or 7, either when building the tubes, or afterwards, by using *Device Tools → Central Region Size*. Just take care so the tubes dont get too close to the opposite edges of the cell, and make sure to inspect visually the geometry of the largest value for d you choose to calculate.

•One can wonder what happens when the tubes are rotated with respect to each other, however the effect is probably small unless perhaps the two tubes have comparable radii such that there is a strong overlap of the pi-orbitals of the two tubes.

•An interesting quantity to compute for systems like this would be the capacitance (see[1] and[2]). This can quite easily be done following a similar procedure as described in the tutorial about a *Atomic-scale capacitance*

References

3.5.5 Capping a carbon nanotube

In this tutorial you will learn how to create a capped nanotube. Specifically you will:

•Create a nanotube.

•Cut a C_{60} fullerene in half - this will be the cap.

•Attach the cap to the nanotube.

•Clean up a bit.

In this tutorial we will build a (5,5) nanotube capped by a C_{60} hemisphere. There are, however, multiple other combinations of nanotubes and fullerenes that match, but such capped tubes can also be constructed using the approach presented here.

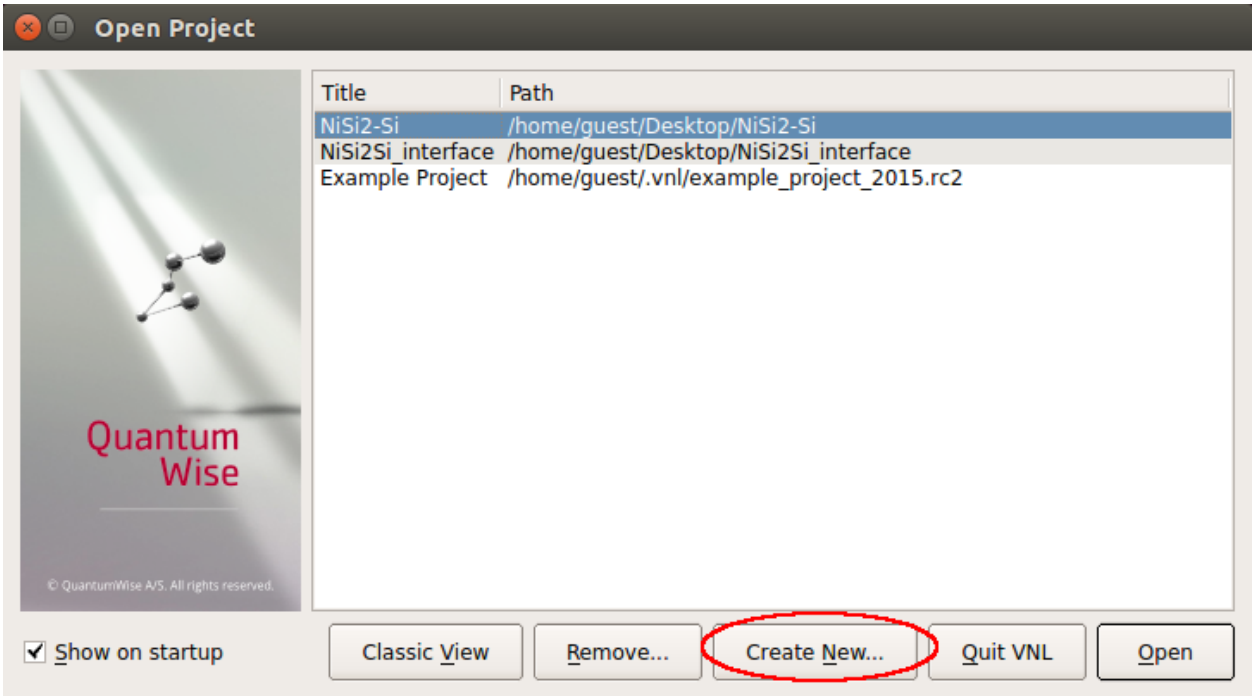
Please see also the video tutorial below. Many more are available on the QuantumATK YouTube channel.

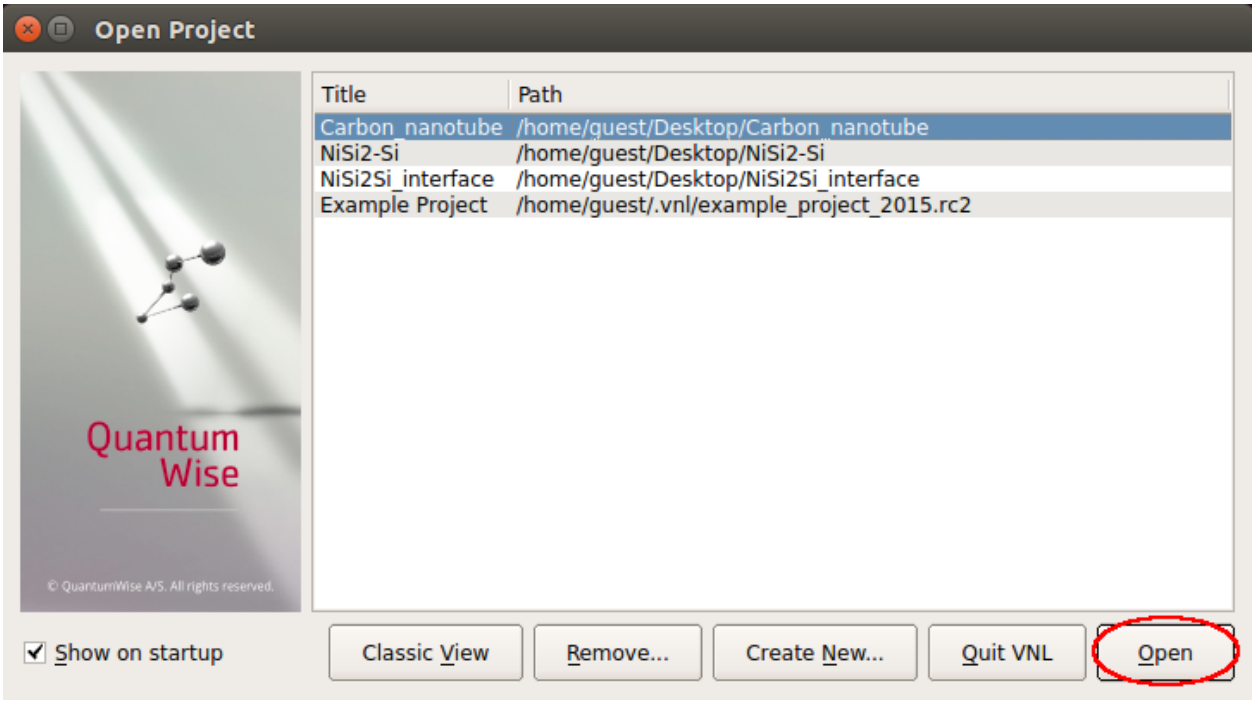
[1] Pawel Pomorski, Christopher Roland, Hong Guo, and Jian Wang. First-principles investigation of carbon nanotube capacitance. *Phys. Rev. B*, 67:161404, Apr 2003. doi:10.1103/PhysRevB.67.161404.

[2] Pawel Pomorski, Lars Pastewka, Christopher Roland, Hong Guo, and Jian Wang. Capacitance, induced charges, and bound states of biased carbon nanotube systems. *Phys. Rev. B*, 69:115418, Mar 2004. doi:10.1103/PhysRevB.69.115418.

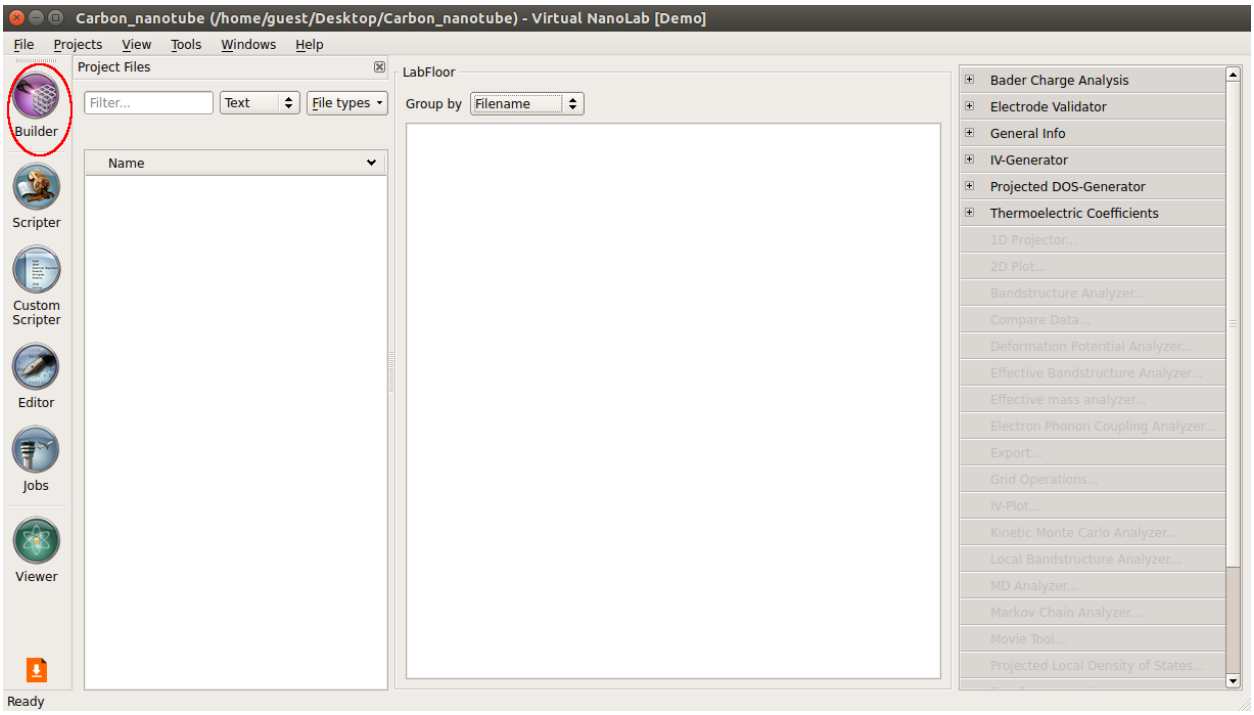
Build an extended (5,5) carbon nanotube

1. Open **QuantumATK** and create a new project by clicking **Create New**. Give the project a *Title* (here: Carbon_nanotube), select the folder where data will be stored, then click **OK** and **Open** to start the project.

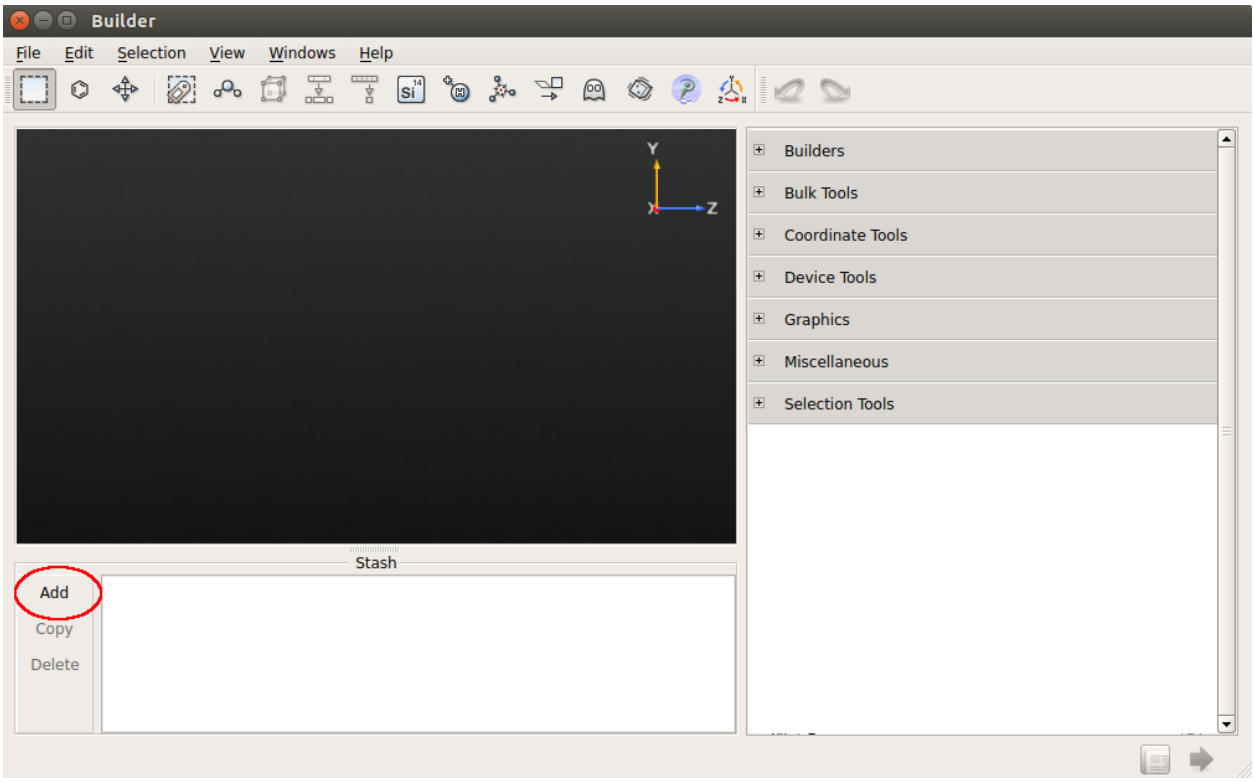


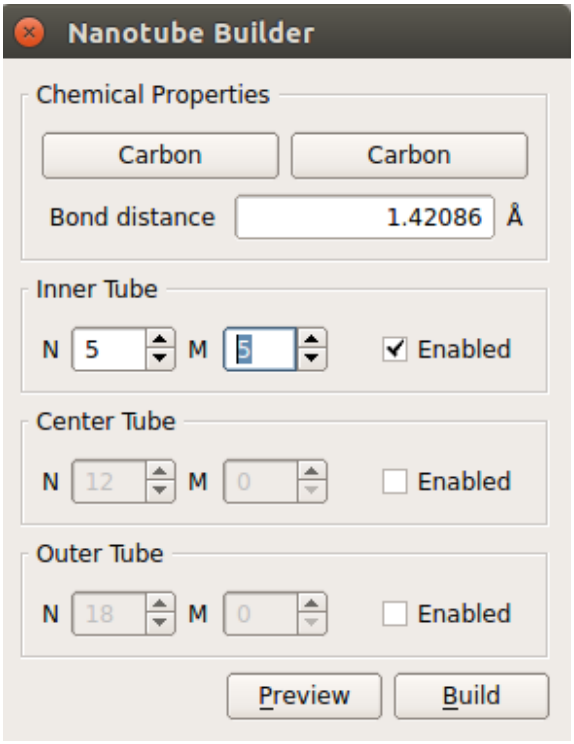


2.In the **QuantumATK** main window, click on the icon to open the **Builder**.

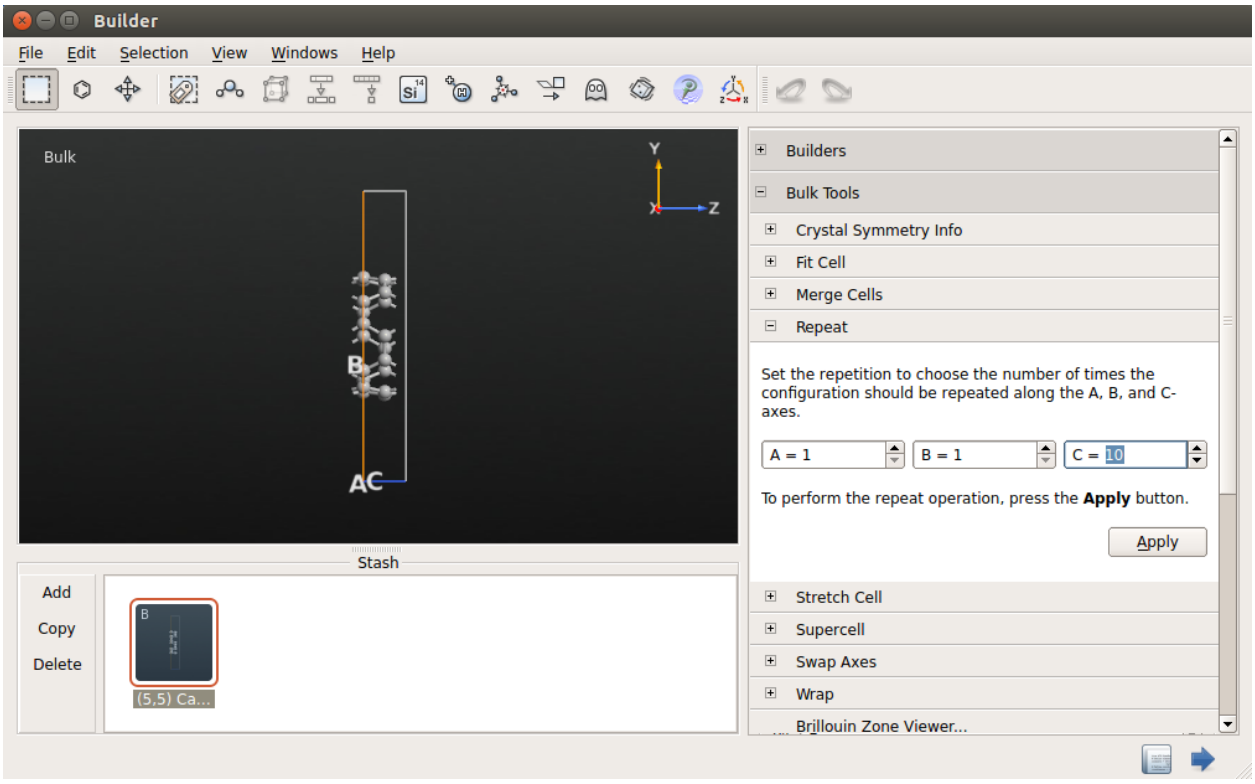


3.Go to the **Stash**, click *Add* → *From Plugin* → *Nanotube*, and the **Nanotube Builder** window will come up. Here, set the parameters as shown in the figure bellow (M = N= 5), and press *Build*.

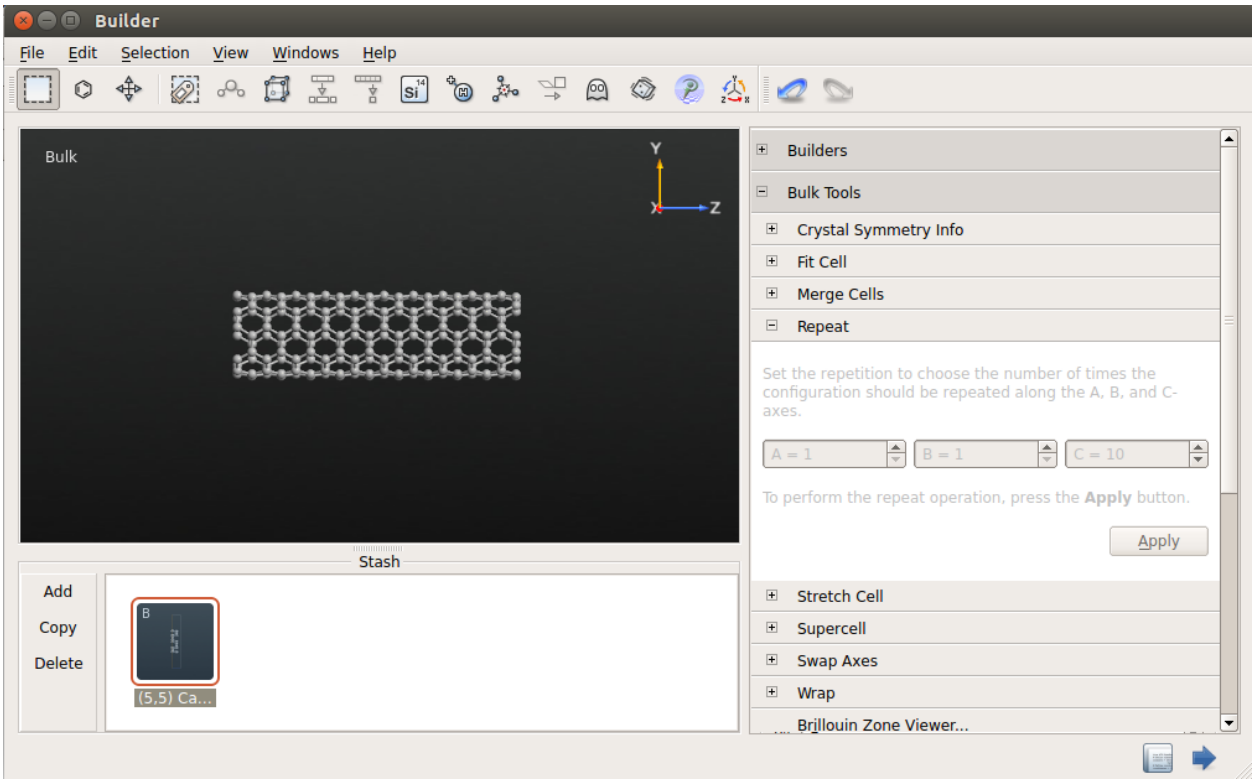




4.In the **Builder**, go to *Bulk Tools* → *Repeat* to extend the structure 10 times in the C-direction, as shown in the figure that follows, and Press *Apply* and after `Crtl` + `R` to see the whole structure properly.



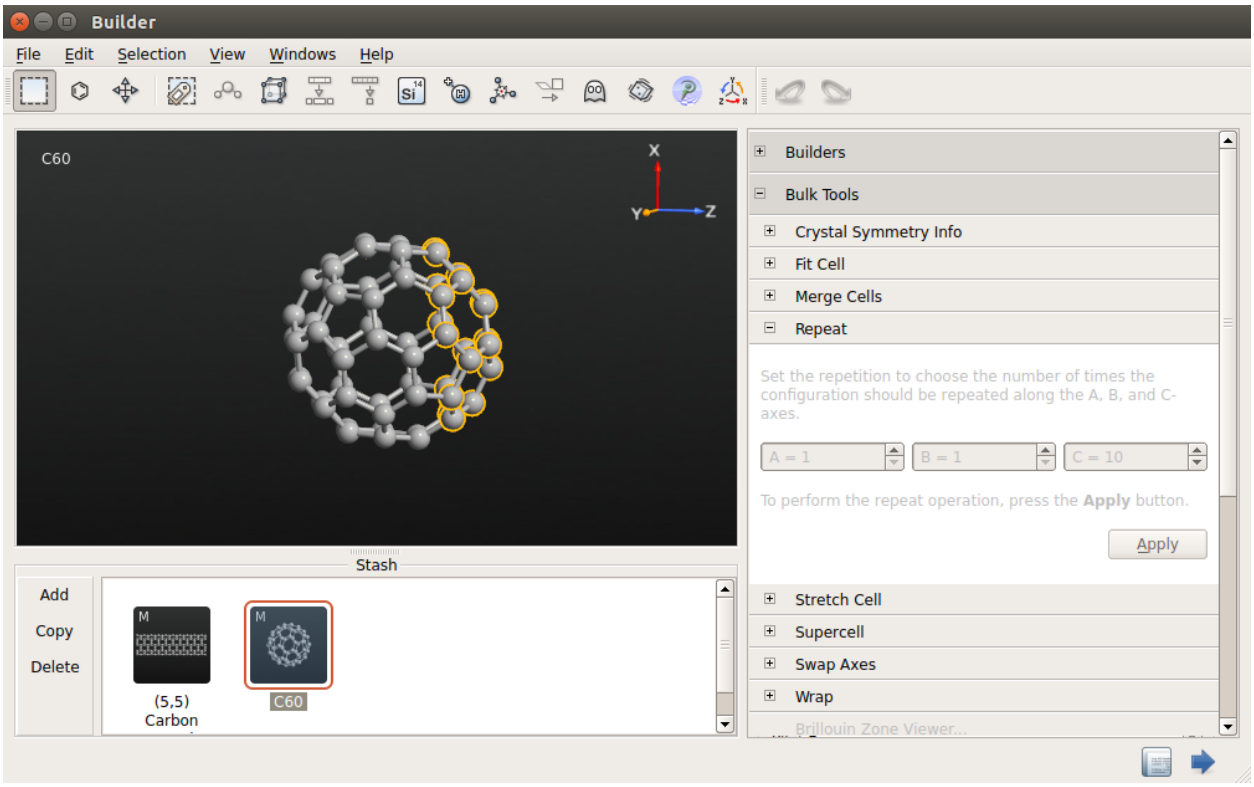
5.Remove the unit cell by clicking the button. The capped tube is anyway not periodic, so we build it as a molecule.



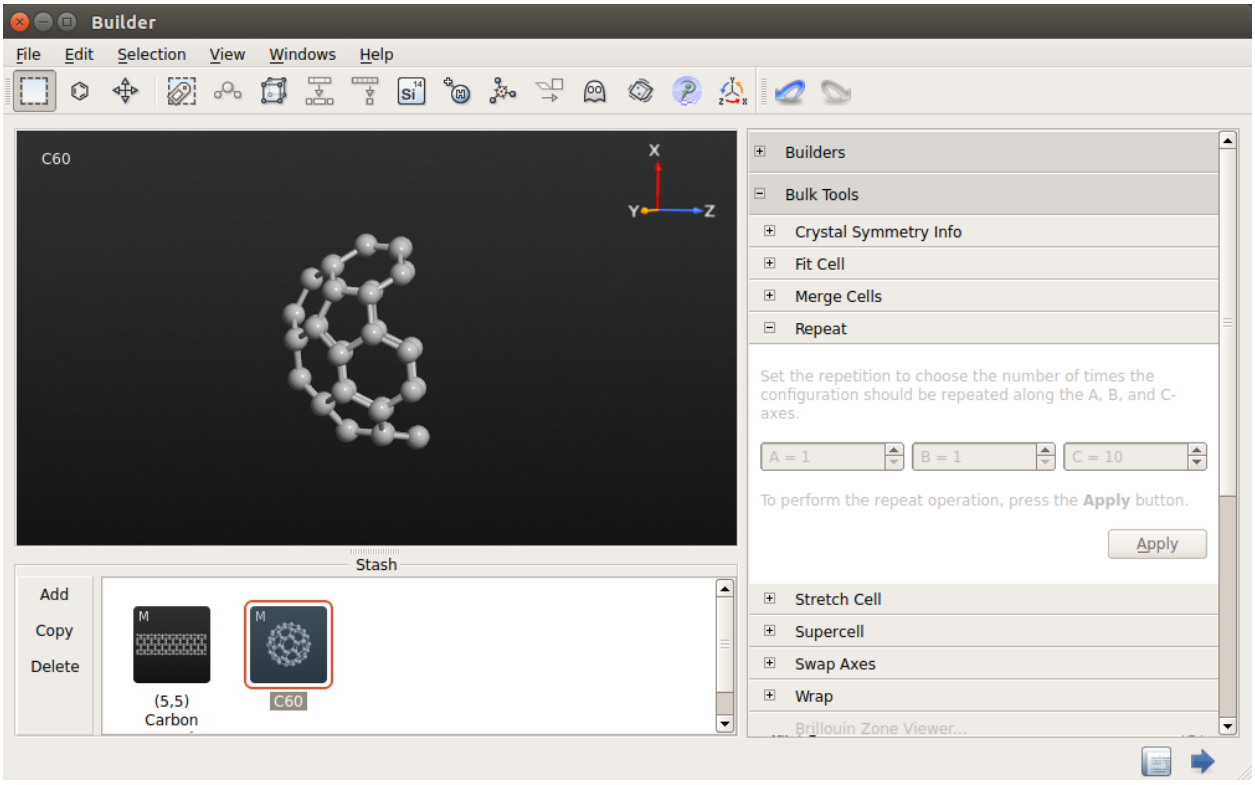
Cut the fullerene in half

1.In order to insert the C_{60} molecule in the **Stash** click on *Add* → *Add From Database*, and choose *Databases* → *Fullerenes* from the menu. Locate C_{60} in the list. Press the icon, or double-click its line in the list, to send it to the **Stash**.

2.In the C_{60}-CNT (5,5) system the tip of the cap is a pentagon. Imagine now a coordinate system in the screen plane where east is right, north up, south down, and west left. Then rotate the fullerene so that the western face of the system is a pentagon, while keeping the Z axis pointing to the east and the X axis roughly to the north.

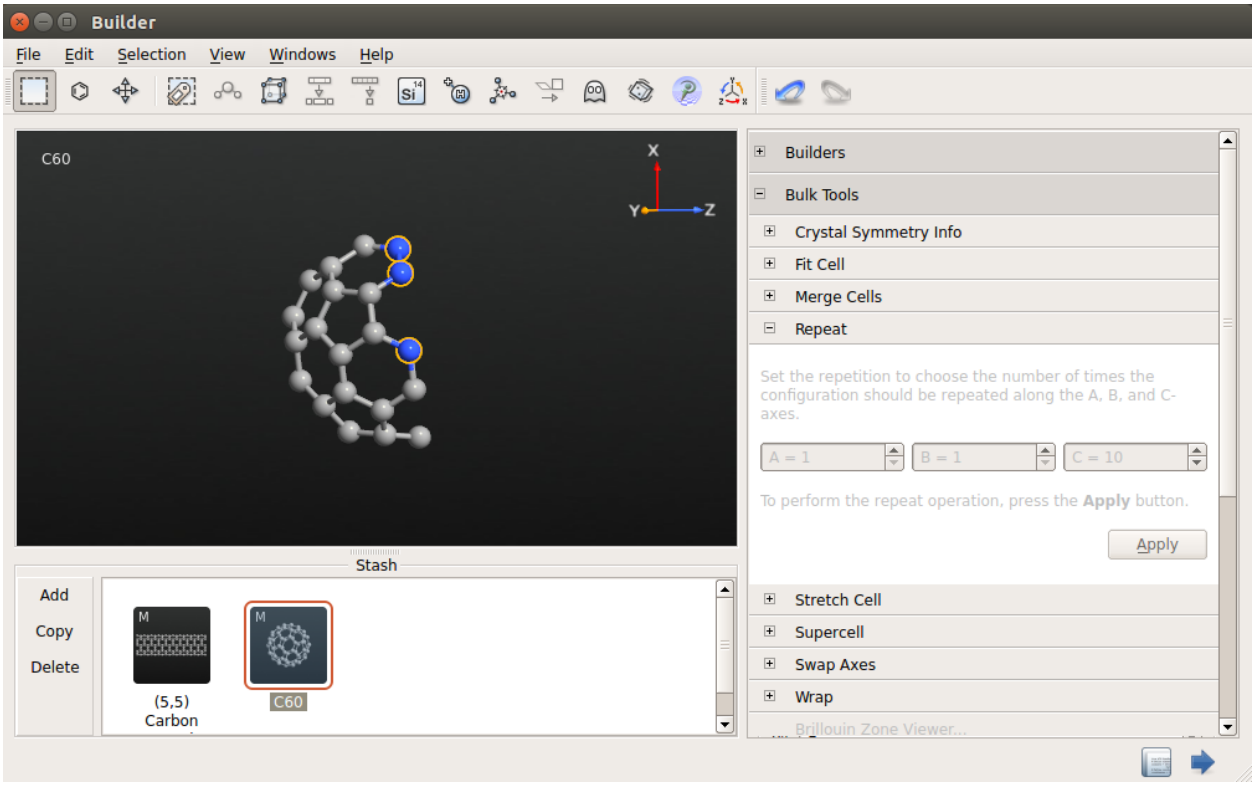


3. The cap is made from 30 carbon atoms, corresponding to half the C_{60}. If, however, you cut the molecule in half, it becomes very difficult to attach it to the nanotube. The trick is instead to leave one extra layer of atoms, which match almost perfectly the edge of the nanotube. Therefore, select the atoms as shown in the picture above, and delete them.



4. The edge of the cap consists of pairs of atoms - just like the edge of the tube. Thus, select 3 atoms as shown in the picture below - two in a pair and one more in the neighboring pair - and change them to nitrogen using the button.

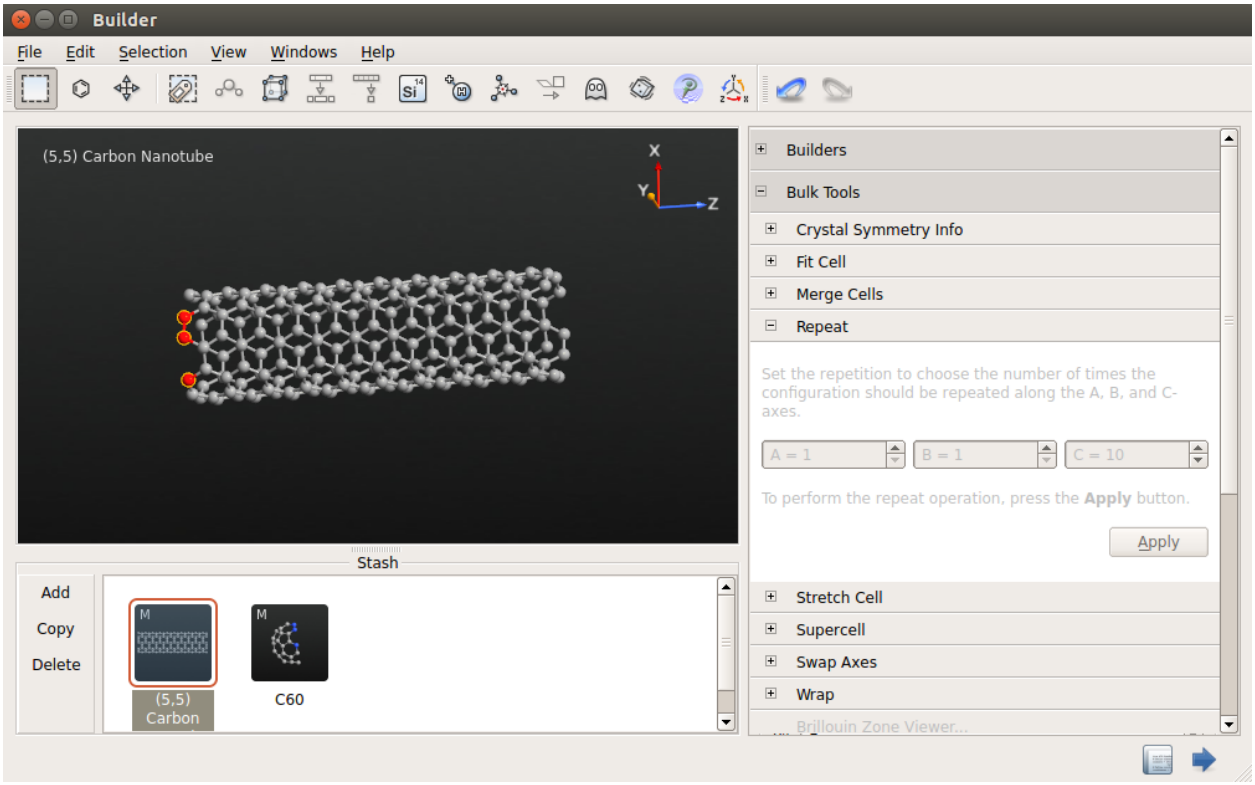
   This is just to make it easier to identify them in the next step.



Capping the tube

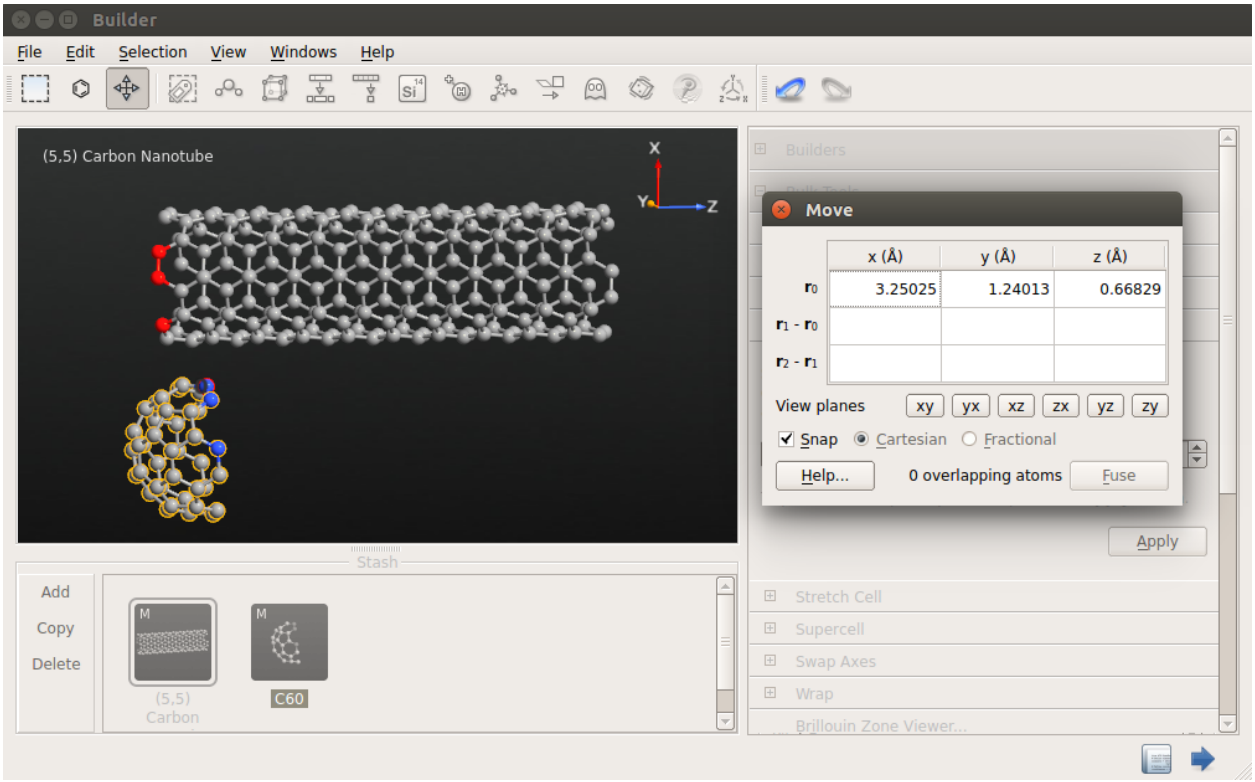
1. In the **Stash**, double-click on the *(5,5) Carbon Nanotube* object.

2. Select three equivalent atoms in the tube, as you did in the cap. By equivalent it means that the edge of the tube looks just like the edge of the cap, with pairs of atoms, and the goal is to match up these pairs. Change these three atoms to oxygen, again to make them easy to identify.



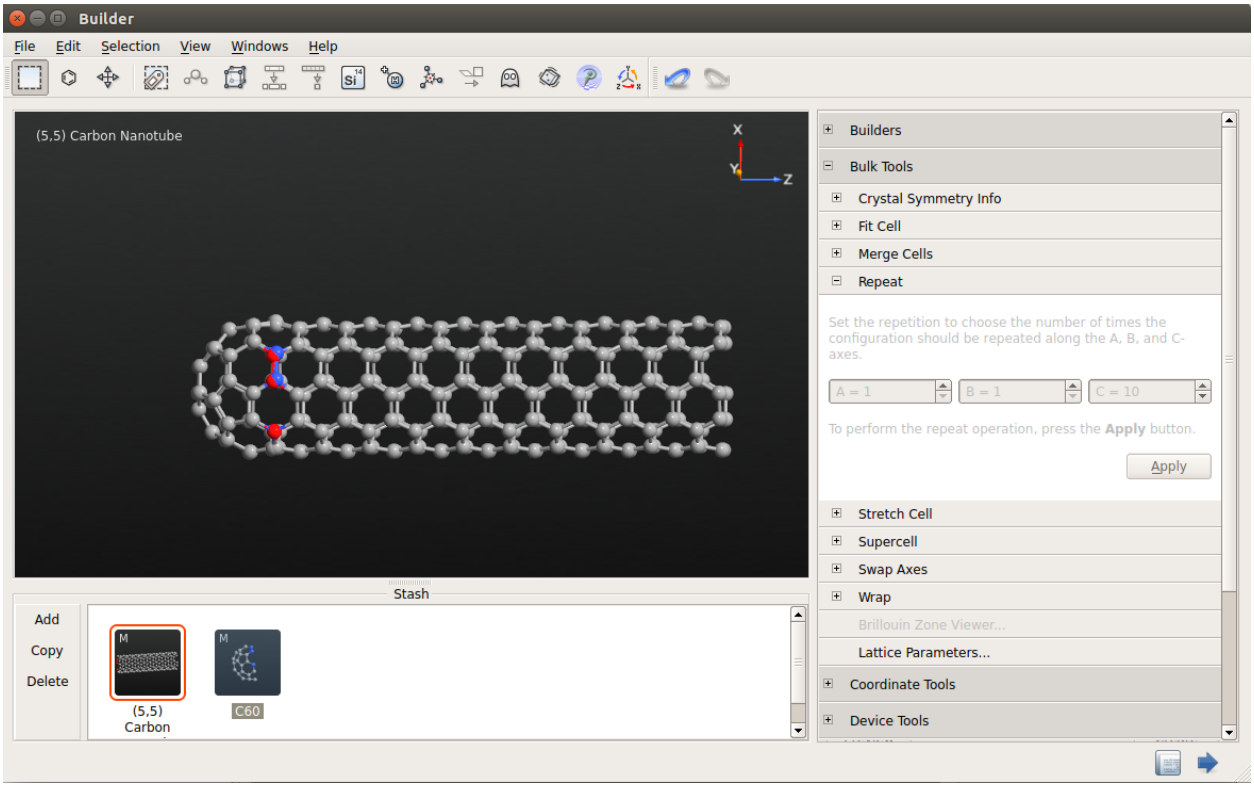
3. Drag and drop the C_{60} object from the **Stash** to the **3D window** to import the cap. The next few steps may differ slightly in precise detail from the images, depending on which precise atoms you changed to nitrogen.

4. When the cap was imported, the **Move** tool was automatically activated. Select one of the nitrogen atoms (as shown in the picture, the first atom in the pair which is not next to the lone nitrogen atom) - its selection marker turns red and the atom is labeled 0. Then drag it so that it ends up on top of the equivalent oxygen atom in the tube.



5. Then select the second nitrogen atom in the pair. When you now drag this atom (red selection marker, and labeled 1), the cap will not move, it will rotate around the bond between atoms 0 and 1. Rotate the cap in place by making atom 1 overlap the next oxygen atom in the pair on the tube edge. You may need to rotate the view to get a clear aim.

6. Finally, select the third nitrogen atom, and move it on top of the third oxygen atom (dihedral rotation). The final structure is shown below.

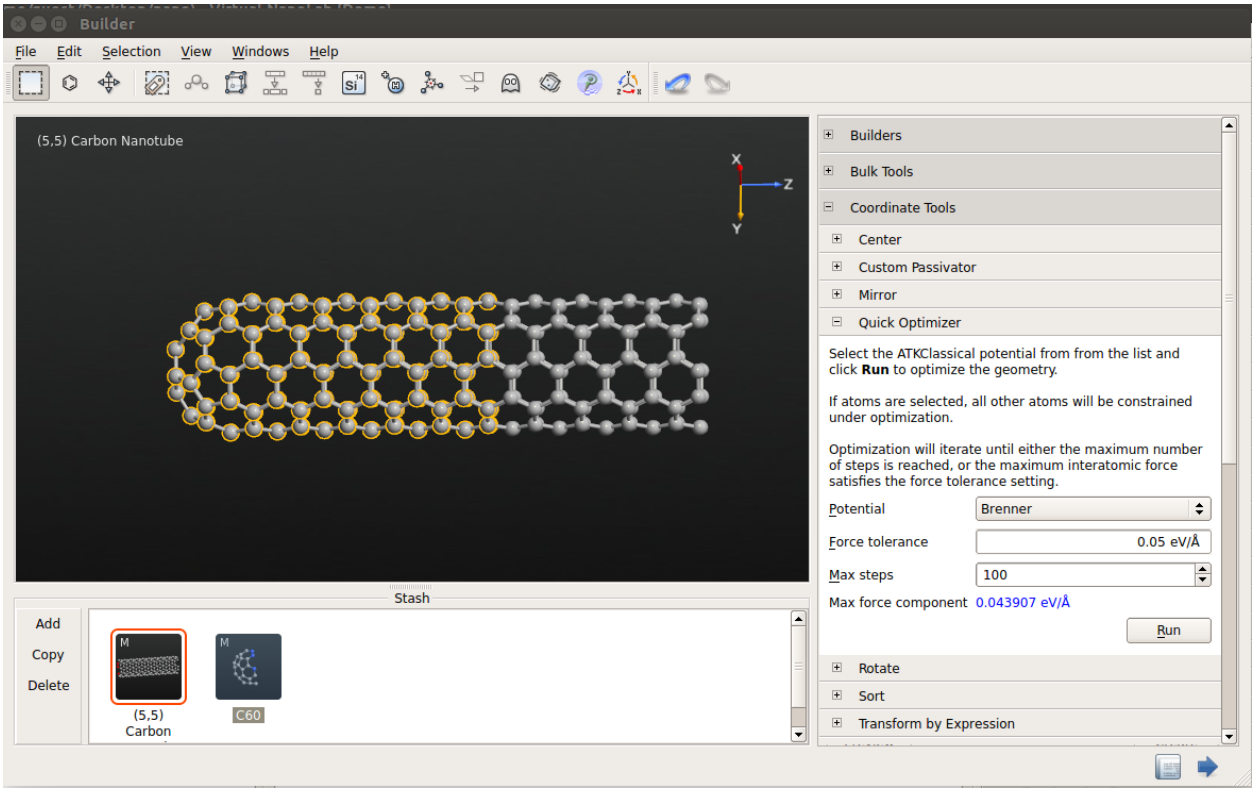


In case you did not succeed (sometimes the cap becomes inverted), undo the last two steps, unselect all anchor atoms by clicking the background, select only one atom and move the cap out a bit from the tube, and try again from 4. It can also be a good idea to pre-align the cap with the tube - see the video above for details!

Finalizing the geometry

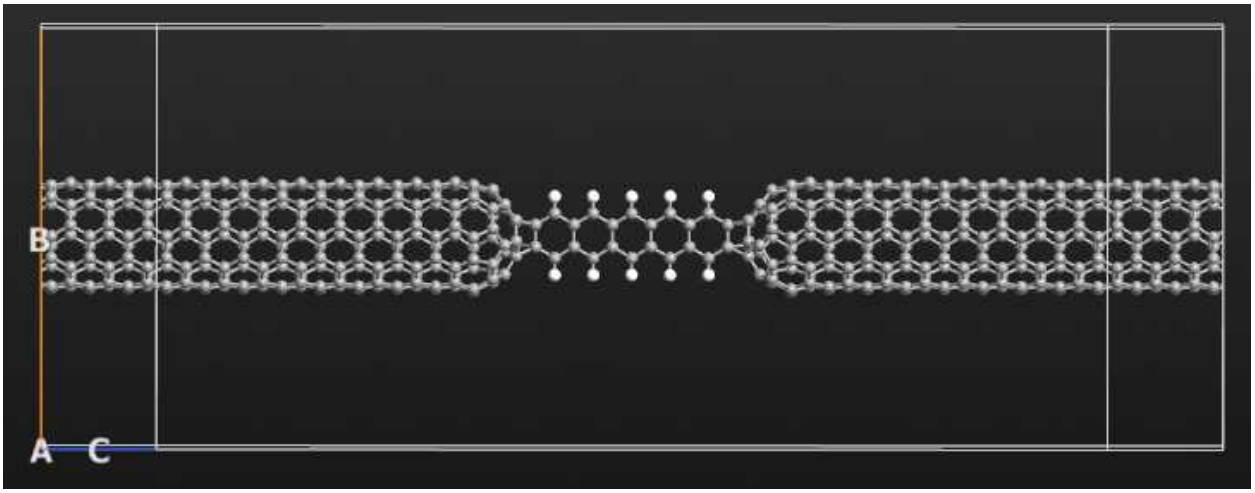
At this point there are overlapping atoms - in fact we utilized this to construct the geometry. You could use Fuse in the **Move** tool, but there are atoms which are only almost overlapping, which are not detected.

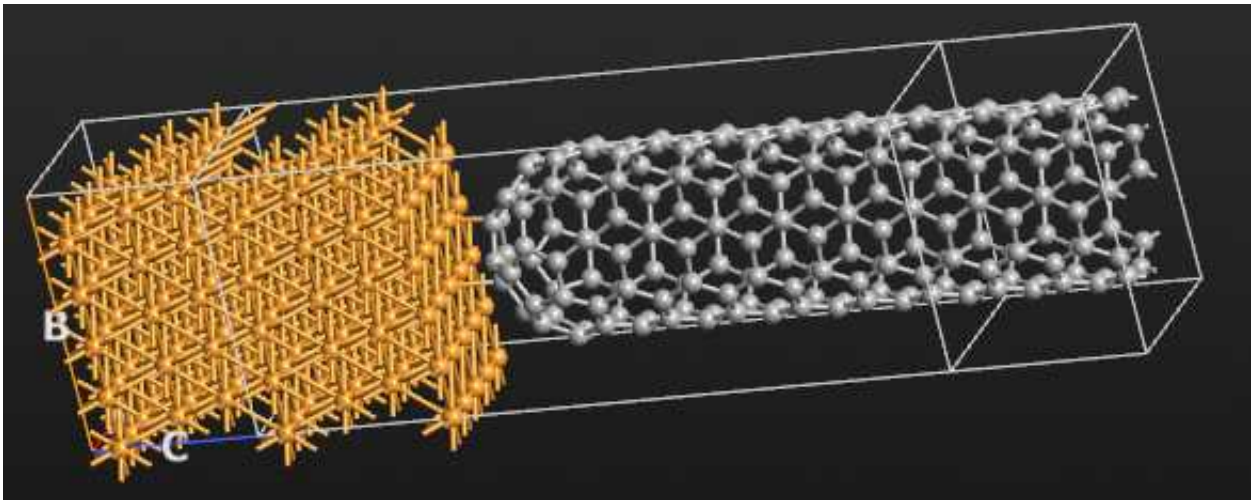
1. Instead, close the **Move** tool, and open *Selection tools* → *Close Neighbors*, enter a distance of 0.7 Å and press *Select* (10 atoms should be selected) and then click `Delete`.
2. Change all atoms back to carbon.
3. You need to optimize the cap, since the radius of the fullerene is slightly different from the naontube. You will however at the same time want to keep the other end of the nanotube as it is (perfectly periodic) so that we can later extend it, if necessary. Therefore, first select the cap and a few more layers of atoms in nanotube (about half of the tube should be fine). Then, open *Coordinate Tools* → *Quick Optimizer*, set the maximum number of iterations to 100, and click *Run*. The tool uses the *ATKClassical* potentials, so the optimization only takes a few seconds.



Connection to other structures

Building this structure just by itself is not very meaningful - you will want to connect it to something, like a surface or molecule. This will be covered by other tutorials, where you will learn how to build structures like those in the pictures below.

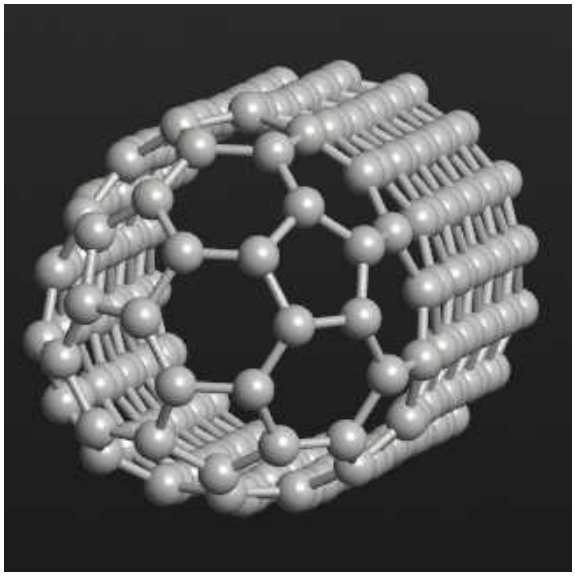




Below is selection of other capped nanotubes that can be built with a very similar approach. These system are slightly more difficult to build, and require some hand tuning.

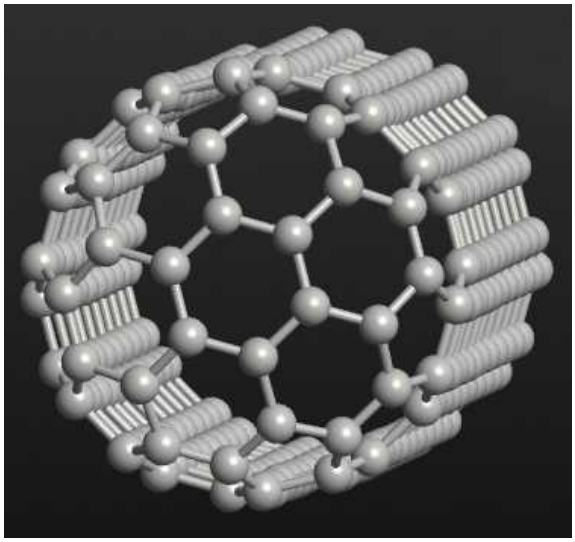
(9,0) CNT + C_{60}

The cap tip is a hexagon and the edge of the tube is zigzag.



(6,6) CNT + fullerene

The cap tip is made from fullerene No. 134 (C_{3v} symmetry) from the QuantumATK database.



3.5.6 Simple carbon nanotube device

In this tutorial you will build a single-wall carbon nanotube (CNT), relax it along the tube length, and then turn it into a device configuration suitable for nanoscale transport studies.

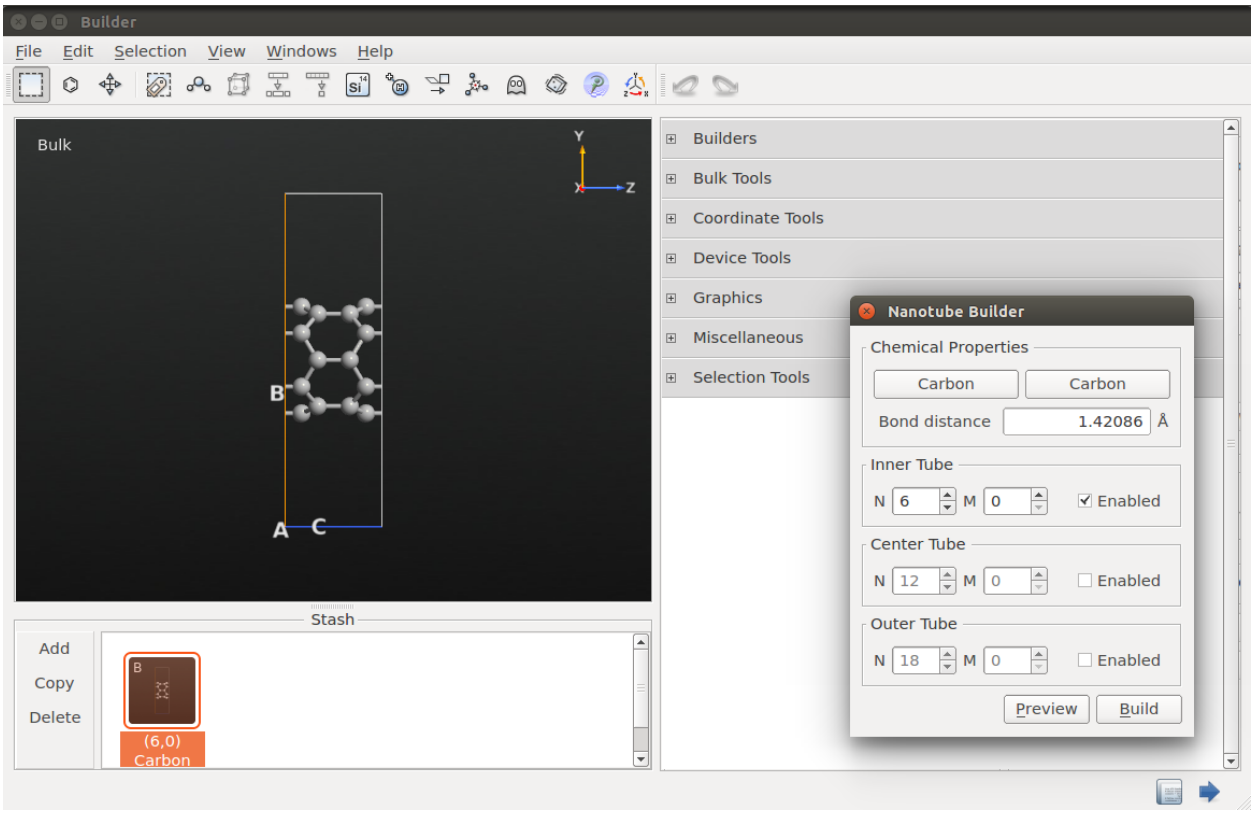
Attention: This is a two-step procedure:

1. Build and geometry optimize a single CNT unit cell.
2. Elongate the relaxed CNT and turn it into a device configuration.

Note: Geometry relaxing the CNT is particularly important for phonon calculations: Negative phonon frequencies will appear in the phonon band structure if the configuration is not properly relaxed.

Build and geometry optimize a short CNT

Open the QuantumATK **Builder** , and use *Add* → *From Plugin* → *Nanotube* to create a (6,0) carbon nanotube.

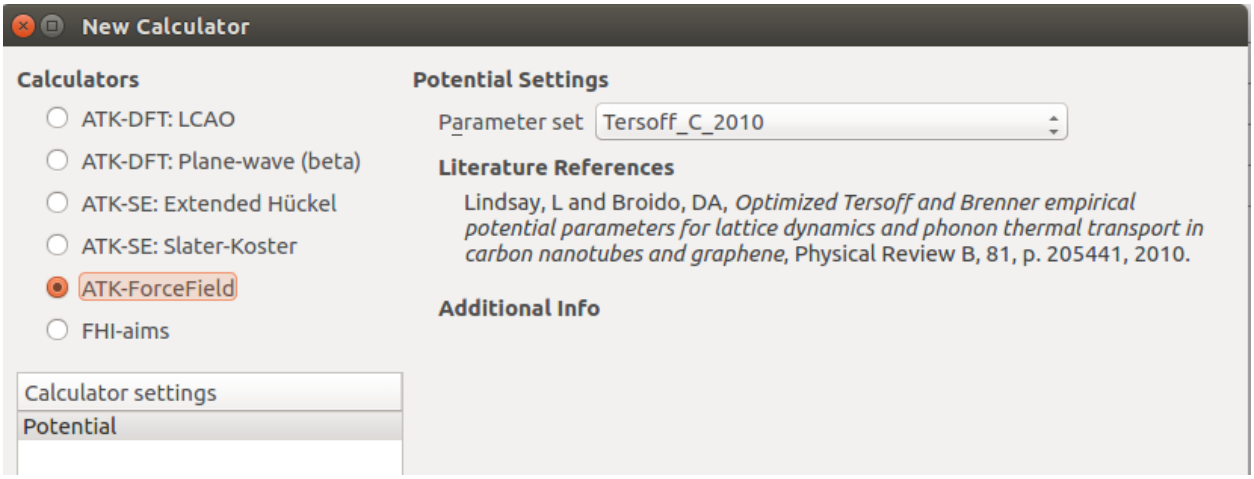


Then send the configuration to the **Script Generator** by using the botton. In the Scripter, add the following blocks:

- New Calculator.
- *Optimization* → *OptimizeGeometry*.

Change the output file to `cnt.hdf5` and double-click the New Calculator block to edit the settings:

•Select the ATK-ForceField calculator and the Tersoff_C_2010 potential.



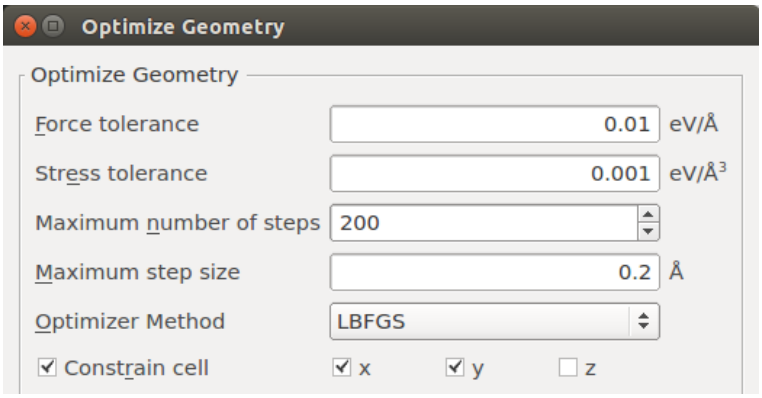
Note: For QuantumATK-versions older than 2017, the **ATK-ForceField** calculator can be found under the name **ATK-Classical**.

Then open the OptimizeGeometry block and edit it:

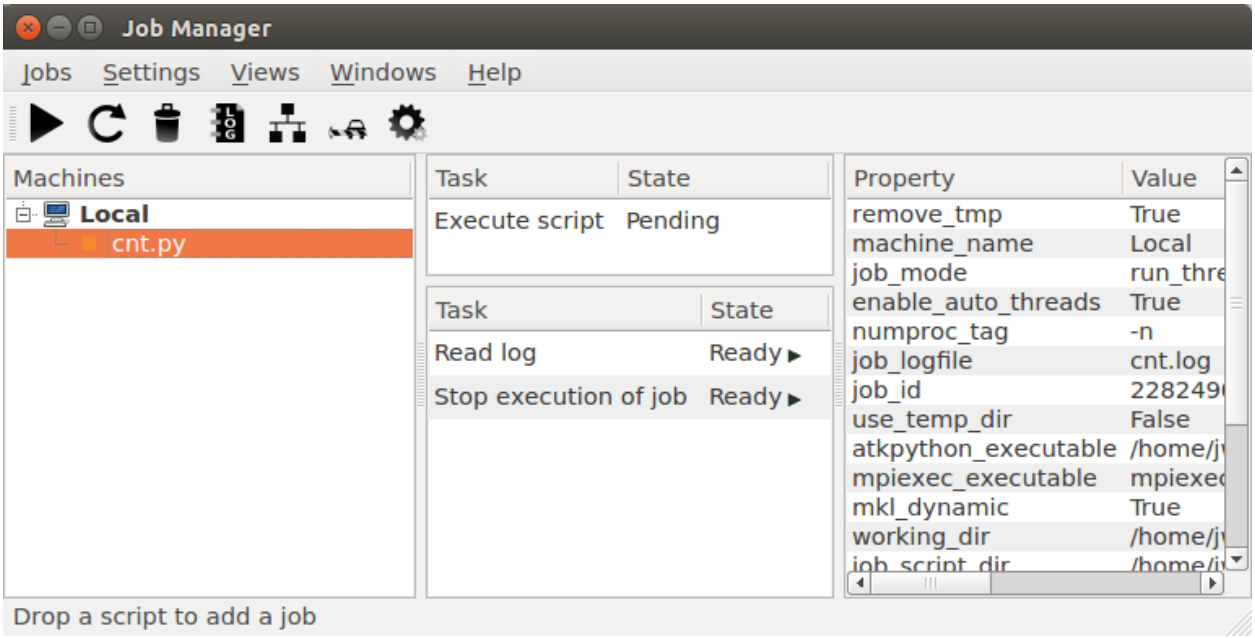
•Set the maximum force to 0.01 eV/Å.

•Set the maximum stress to 0.001 eV/Å^3.

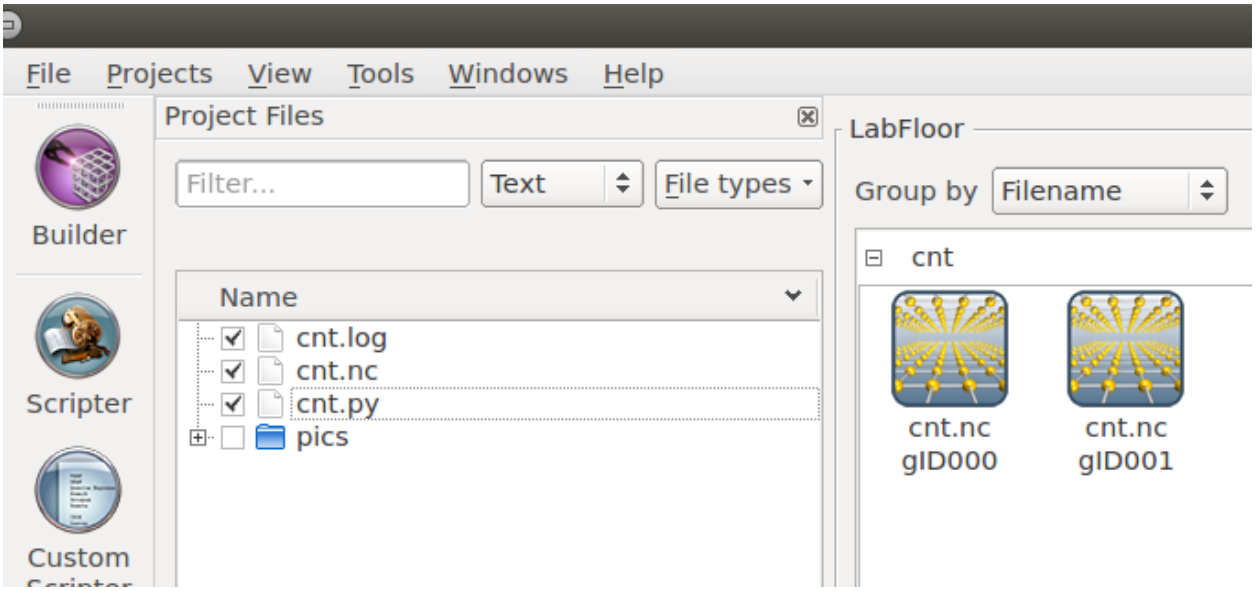
•Remove the checkmark for z under Constrain cell to allow relaxation of the cell along the periodic direction.



Send the script to the **Job Manager**, save the script as `cnt.py`, and run the calculation by clicking. The calculation uses a classical potential, so it should be very fast.



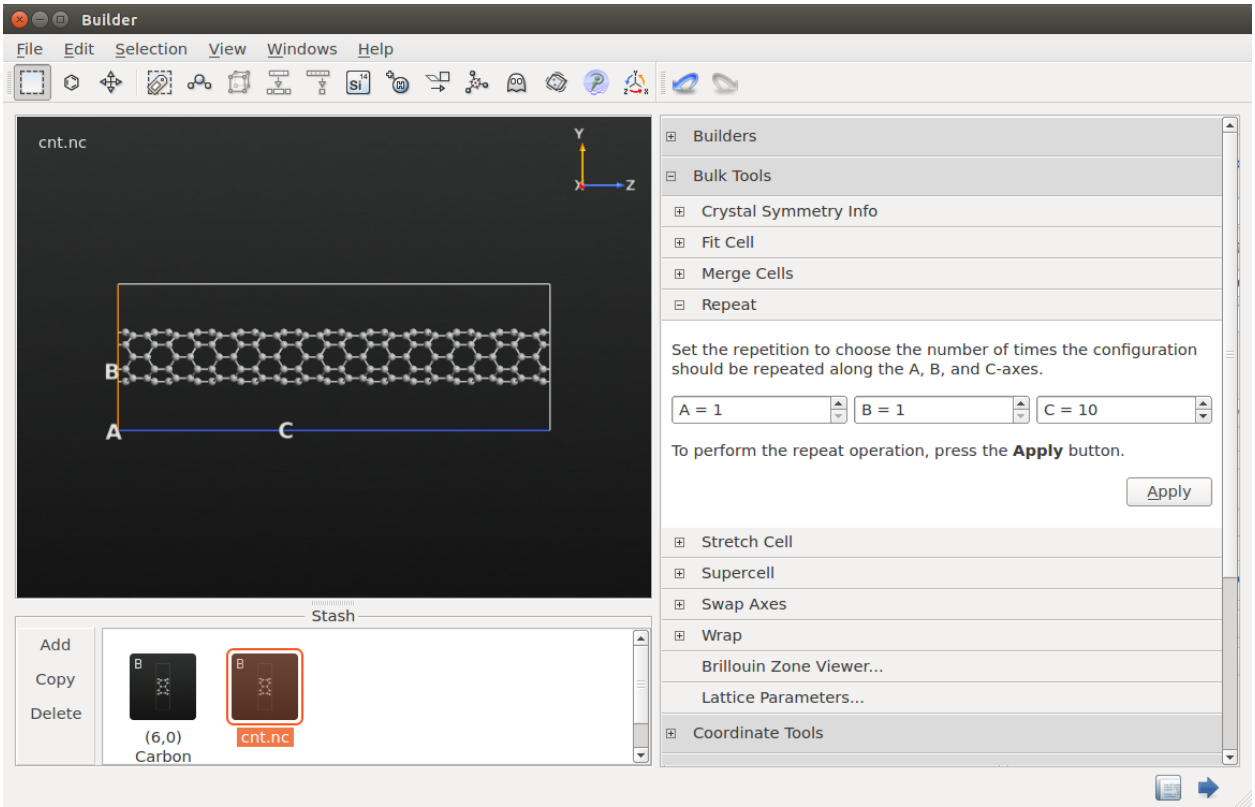
Once finished, you should find the output `cnt.hdf5` on the QuantumATK **LabFloor**. It contains two objects of the type `bulk_configuration` - the initial (`glD000`) and the optimized (`glD001`) CNT structures. You can click an object to highligt it and then use the **Viewer** to visualize it.



CNT device configuration

Drag and drop the optimized CNT onto the **Builder** . Then do the following to make it longer:

- In the right-hand side panel, open the *Bulk Tools* → *Repeat* plugin.
- Enter a repetition of 10 along C (the tube axis) and click **Apply** to create a longer CNT.



You are finally ready to convert the configuration to a device and save it:

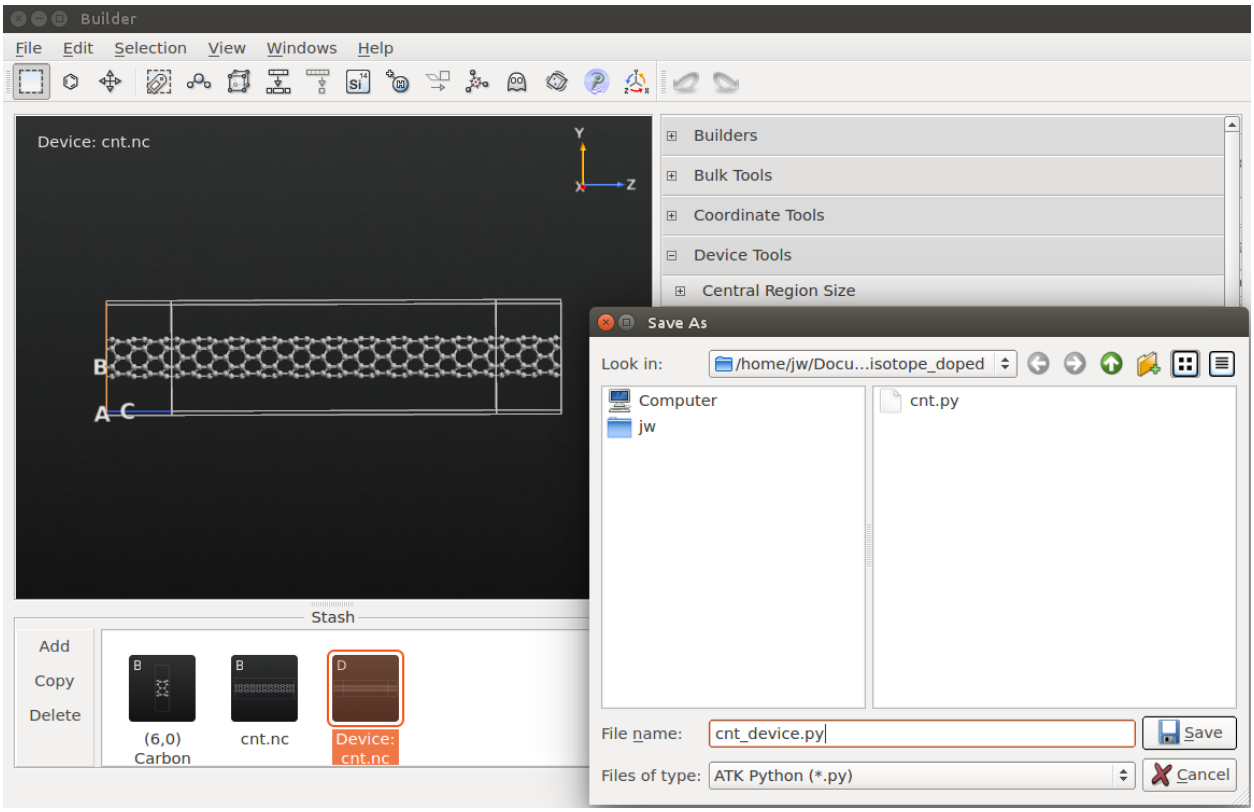
•Open the *Device Tools* → *Device From Bulk* plugin.

•Leave the electrode lengths at default.

•Click **OK** to create the device.

•Highlight the device configuration, right-click it, and choose **Save as** in the drop-down menu. You can now save the configuration in either a HDF5 file (`cnt_device.hdf5`) or as a Python script (`cnt_device.py`).

•Note that the CNT device consists of a **central scattering region** sandwiched between left and right **electrodes**.



Attention: The instructions above result in a CNT device with a central region that is roughly 43 Å long. This is a somewhat arbitrary choice and it may well be that specific applications require a shorter or a longer central region!

The central region and electrode lengths are easily modified:

•Highlight the device Stash item.

•Use the *Device Tools* → *Central Region Size* plugin to change the central region length along the C axis.

•Similarly, the *Device Tools* → *Electrode Size* plugin lets you change the electrode lengths.

Tip: What next? You have created a carbon nanotube device configuration. You can now use it in scientific studies of electron and phonon transport in CNTs.

Thermoelectrics For example, you can check out the tutorial *Thermoelectric effects in a CNT with isotope doping*, where phonon and electron transmission spectra, thermal conductance, and the *ZT* product is calculated for CNTs with and without isotope impurities.

Scripts For your reference, you can download the CNT device configuration created in this tutorial here: `cnt_device.py`.

3.5.7 Thermoelectric effects in a CNT with isotope doping

Although the mass of the nucleus has almost no influence on the electronic properties of an atom (at least in the Born-Oppenheimer approximation), different isotopes will have different thermal properties. The consequences of isotope doping are very important for the case of 1D nanostructures and nanotubes in particular[1],[2],[3]. It is therefore interesting to study how the thermal properties of a CNT (carbon nanotube) change when the isotope distribution in one part of the tube is changed[4].

In this tutorial, you will study the effect of doping a carbon nanotube with a ring of ^{14}C atoms. Specifically, you will calculate the phonon and electron transmission spectra, the thermal conductance, and the *ZT* product. You will use the **ATK-ForceField** engine for phonon calculations, while electronic transmission is calculated using **ATK-SE**.

Attention: This tutorial assumes that you have already finished the tutorial *Simple carbon nanotube device*, where the CNT device configuration used in this tutorial is created. If not, please go through that tutorial first, or simply download the configuration here: `cnt_device.py`.

CNT device with tags for ^{14}C doping

Drag and drop the undoped CNT device configuration (`cnt_device.py`) onto the **Builder** . Then, assign a tag to the ^{12}C atoms that you will convert to ^{14}C:

- Select a ring of C atoms in the middle of the structure as shown below.
- Open the *Selection Tools* → *Tags* plugin, and assign the tag C14 to these atoms.

Phonon transmission

First set up and run the calculation of the phonon transmission spectrum for the undoped CNT. Transfer the configuration to the **Script Generator** and add the following blocks:

- New Calculator
- *Analysis* → *PhononTransmissionSpectrum*

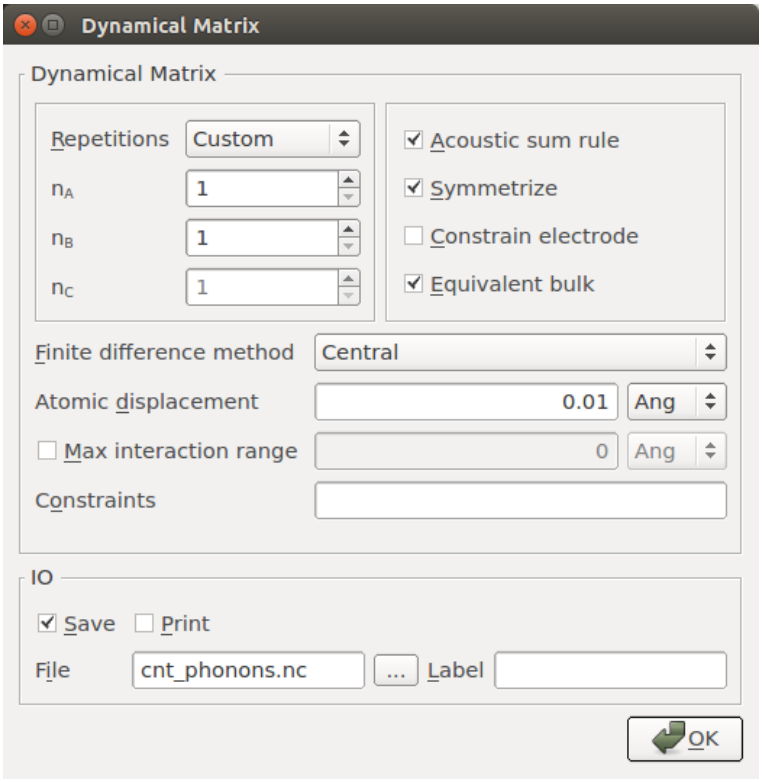
Note that a DynamicalMatrix object was automatically added as well. Change the output file to `cnt_phonons.hdf5` and edit the settings in all three blocks:

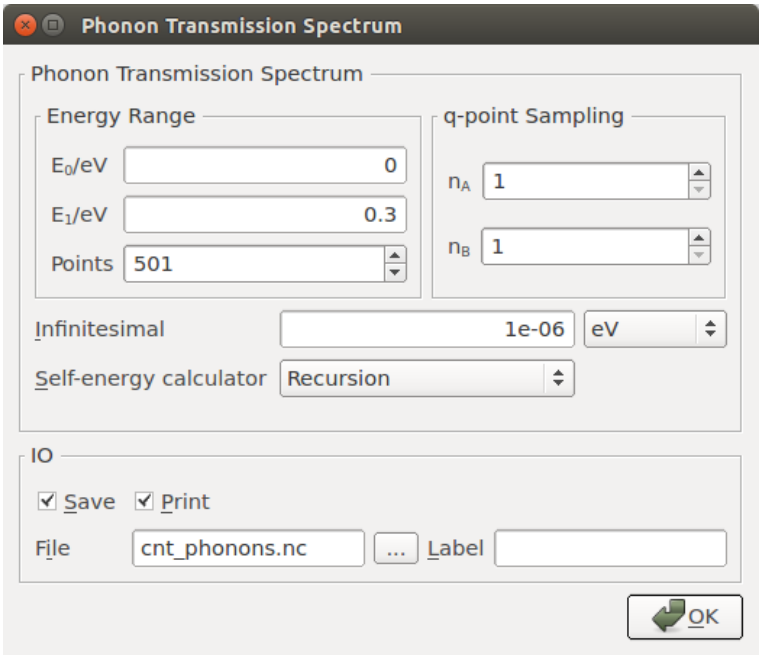
•Calculator: Select the ATK-ForceField calculator and the Tersoff_C_2010 potential.

•DynamicalMatrix: Set Repetition to Custom and leave the repetitions along A, B, and C at the default value 1.

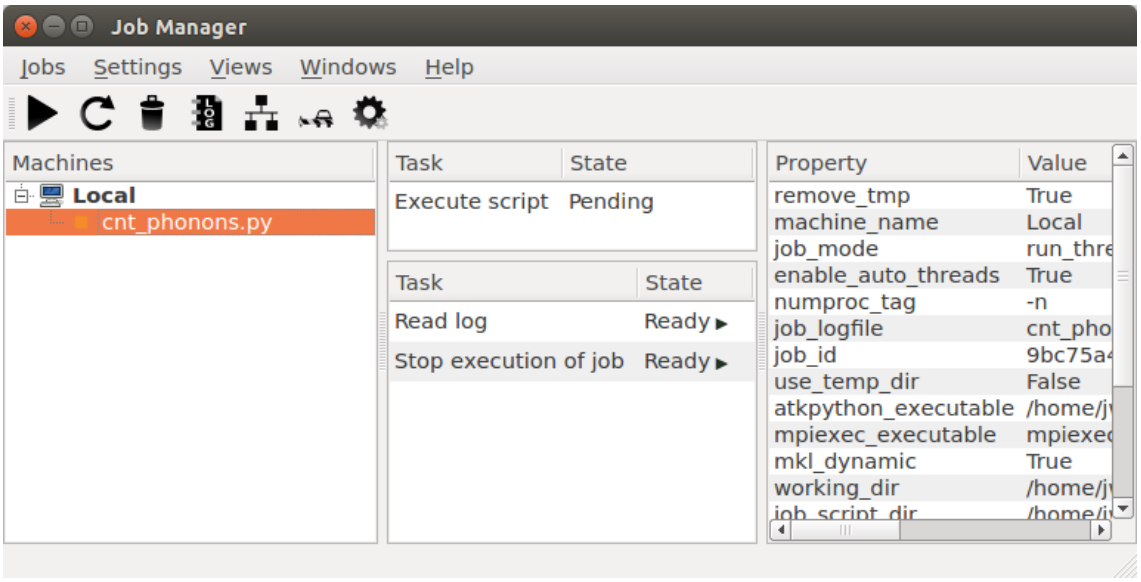
•PhononTransmissionSpectrum: Set the energy range to 0-0.3 eV and the number of points to 501. Leave the q-point sampling at defaults.

Note: For QuantumATK-versions older than 2017, the **ATK-ForceField** calculator can be found under the name **ATK-Classical**.





Run the calculation by sending it to the **Job Manager** . When prompted, save the script as `cnt_phonons.py`, select the default Local machine, and start the script by clicking .



Adding ^{14}C impurity atoms

Once the calculation for the undoped CNT has finished, it is time to introduce the ^{14}C dopants. The predefined elements in QuantumATK are isotope averages, so the mass of carbon in QuantumATK is 12.0107 amu. In order to create ^{14}C, all you need to do is a bit of simple Python scripting: *Implement a new element by writing a derived Python class with a different mass, and add it to the list of available elements*. Do it like this:

- Open your Python script (`cnt_phonons.py`) in the **Editor** , e.g. using drag and drop.
- Find the place where the `device_configuration` is defined (lines 447-450). Insert the following lines of code immediately after:

```
# Define a new class where the C atom has mass 14.00
class C14(Carbon):
    @staticmethod
    def atomicMass():
        return 14.00*Units.atomic_mass_unit

PeriodicTable.ALL_ELEMENTS.append(C14)

# Replace all atoms tagged "C14" with carbon-14
for index in device_configuration.indicesFromTags("C14"):
    device_configuration.elements()[index] = C14
```

- Change the output filename to `cntc14_phonons.hdf5` everywhere in the script (3 places).
- Save the script as `cntc14_phonons.py` and execute it using the **Job Manager**.

Transmission spectra

The QuantumATK **LabFloor** should now contain the calculated results for the doped and undoped CNT:

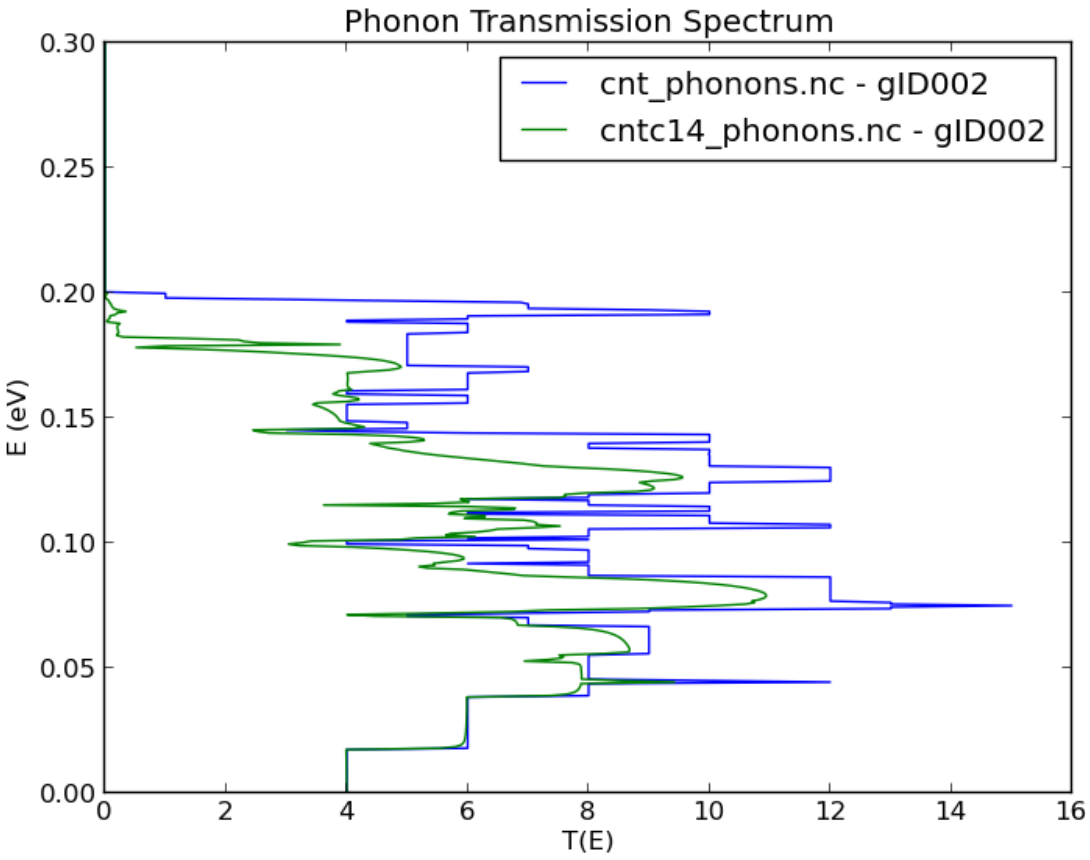
- DynamicalMatrix

$$D_{ij}$$

- PhononTransmissionSpectrum

$$T(\mathbf{q}, \omega)$$

Highlight the transmission spectra and use the **Transmission Analyzer** plugin to display the results. If you select both of them at the same time (holding down Ctrl), you can plot both in the same figure by using the **Compare Data** plugin.



The two phonon transmission spectra in the above figure (blue: undoped CNT, green: isotope doped CNT) are significantly different. The difference is caused by phonon scattering by the ring of ^{14}C impurities. You can see that at low energy (long wavelength) the spectrum is unchanged, while the main difference is at higher energies (shorter wavelength).

Thermal conductance

You can also calculate the thermal conductance of phonons, κ_{ph}, using the **Thermoelectric Coefficients** plugin, situated in the right-hand side of the LabFloor. Select again the PhononTransmissionSpectrum elements and click calculate on the Thermoelectric Coefficients plugin. As expected, κ_{ph} of the isotopically doped CNT is lower than for the CNT with a natural isotope distribution. The difference is small at 300 K, but it increases with temperature. The same effect was reported in[Page 949, 4], where the CNT was also doped by ^{14}C, but in a cluster arrangement.

It is interesting to construct a plot similar to Figure 11(b) in[Page 949, 4]. You can do this by applying a bit of Python scripting. Save the Python code below as `plot_thermal_conductance.py` or simply download the script: `plot_thermal_conductance.py`. If you wish to understand how the script works, try to have a look at the entry about the PhononTransmissionSpectrum object in the *PhononTransmissionSpectrum*.

```
# Read the phonon transmission spectrum from file cnt_phonons.hdf5
phonon_transmission_spectrum = nlread("cnt_phonons.hdf5",PhononTransmissionSpectrum)[0]
# Define a temperature range
temp = numpy.linspace(10,2000,21)
# Calculate the phonon thermal conductance at each temperature
conductances = []
for t in temp:
    conductance = phonon_transmission_spectrum.thermalConductance(
        phonon_temperature=[t]*Kelvin)
    conductance = conductance*10**9
    conductances.append(conductance)

# Now read the phonon transmission spectrum from file cntc14_phonons.hdf5 ...
phonon_transmission_spectrum_c14 = nlread("cntc14_phonons.hdf5",
↪PhononTransmissionSpectrum)[0]
# ... and calculate the relative phonon thermal conductance
conductances_c14 = []
for t in temp:
    conductance_c14 = phonon_transmission_spectrum_c14.thermalConductance(
        phonon_temperature=[t]*Kelvin)
    conductance_c14 = conductance_c14*10**9
    conductances_c14.append(conductance_c14)

# Plot the phonon thermal conductances as function of temperature
import pylab
pylab.figure()
pylab.plot(temp,conductances,label='CNT',linewidth=2.0)
pylab.plot(temp,conductances_c14,label='14C-CNT',linewidth=2.0)
pylab.xlabel("Temperature (K)")
pylab.ylabel("Phonon Thermal Conductance (nW/K)")
pylab.legend(loc="lower right")
pylab.show()
```

Run the script in the directory where your `.hdf5` files are stored:

```
$ atkpython plot_thermal_conductance.py
```

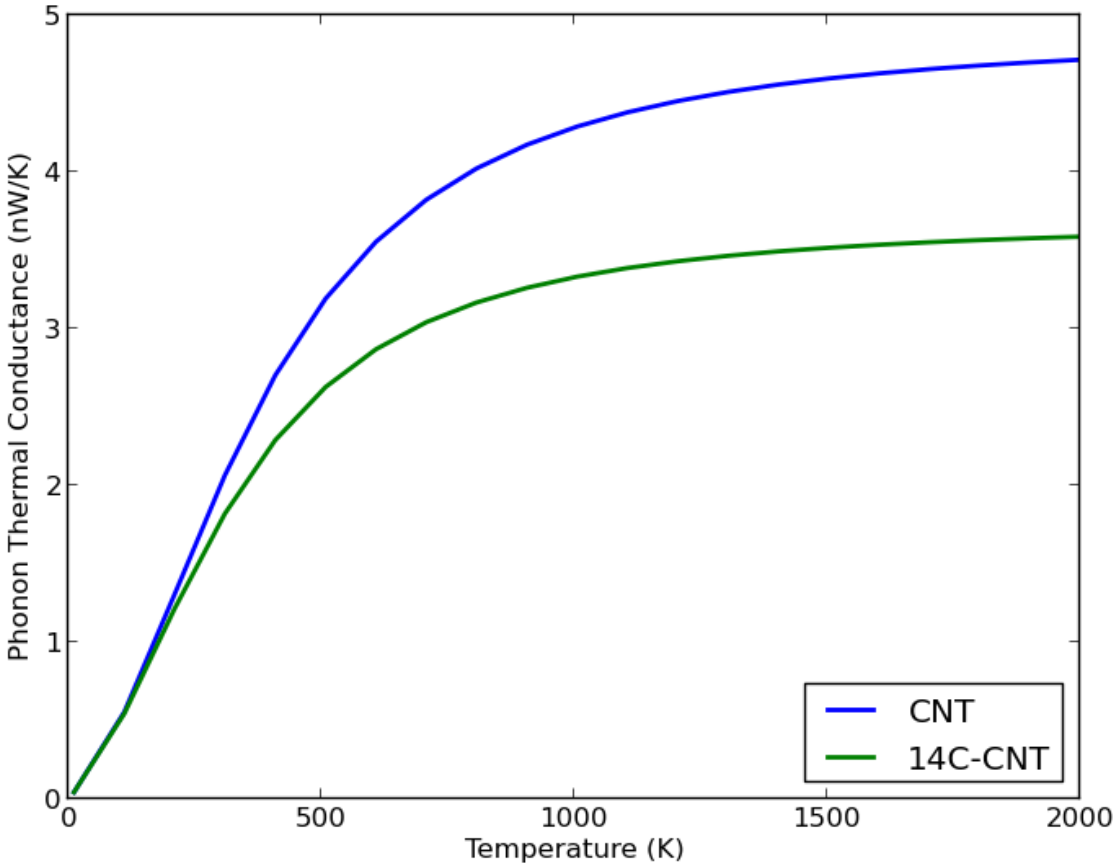


Fig. 3.75: Phonon thermal conductance of a pure CNT and of an ^{14}C isotope doped CNT. The thermal conductance levels out with increasing temperature. The ^{14}C doping clearly inhibits the CNT thermal conductance.

Electron transmission

The thermoelectric figure of merit, *ZT*, has both phononic and electronic contributions. Therefore, even though isotopic doping does not affect the electron transport properties, it is still relevant to calculate the electronic transmission spectrum for the CNT.

From the **Builder** send again your CNT device configuration to the **Script Generator** and add two blocks:

- New Calculator
- *Analysis* → *TransmissionSpectrum*

Change the output file to `cnt_electrons.hdf5` and edit the calculation parameters:

•Calculator: Select the ATK-SE: Slater-Koster calculator and choose the Hancock.C ppPi basis set.

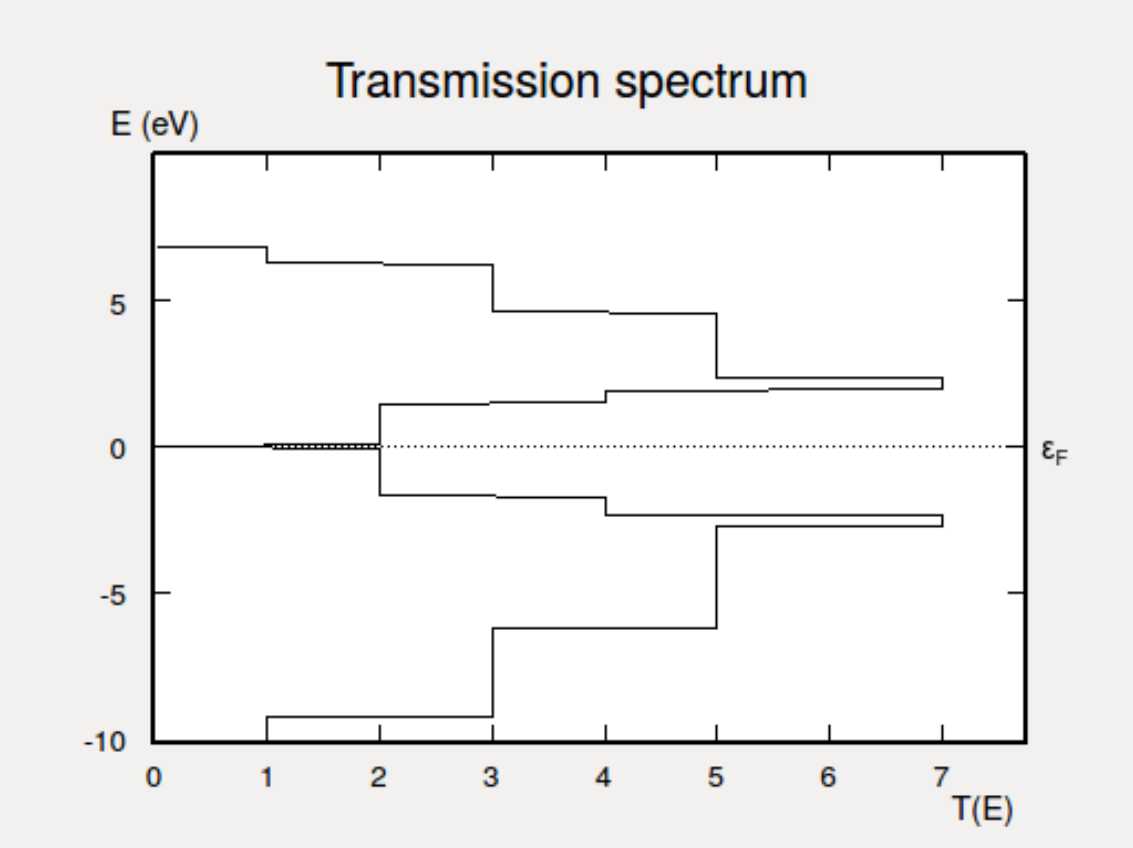
•TransmissionSpectrum: Set the energy range to -10 to 10 eV and the number of points to 501.

Run the script using the **Job Manager** .

In the LabFloor you will now find the **TransmissionSpectrum** object, which you can plot using the **2D Plot** plugin.

- TransmissionSpectrum

$T(\mathbf{k}, \epsilon)$

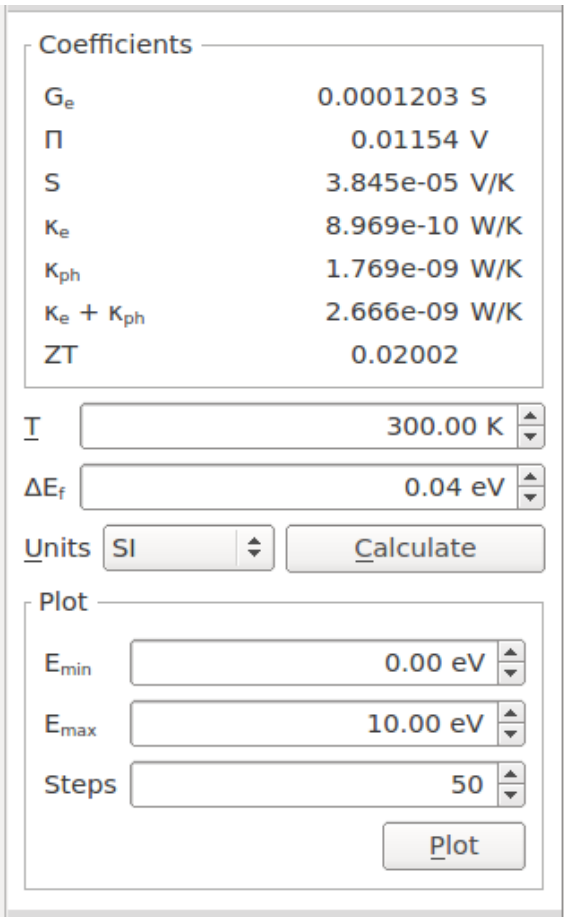


The electronic transmission is clearly non-zero in the vicinity of the Fermi level. However, if you zoom in, you will see that the transmission is zero exactly at the Fermi level. This is also clear if you study the transmission data using the **Text Representation** plugin.

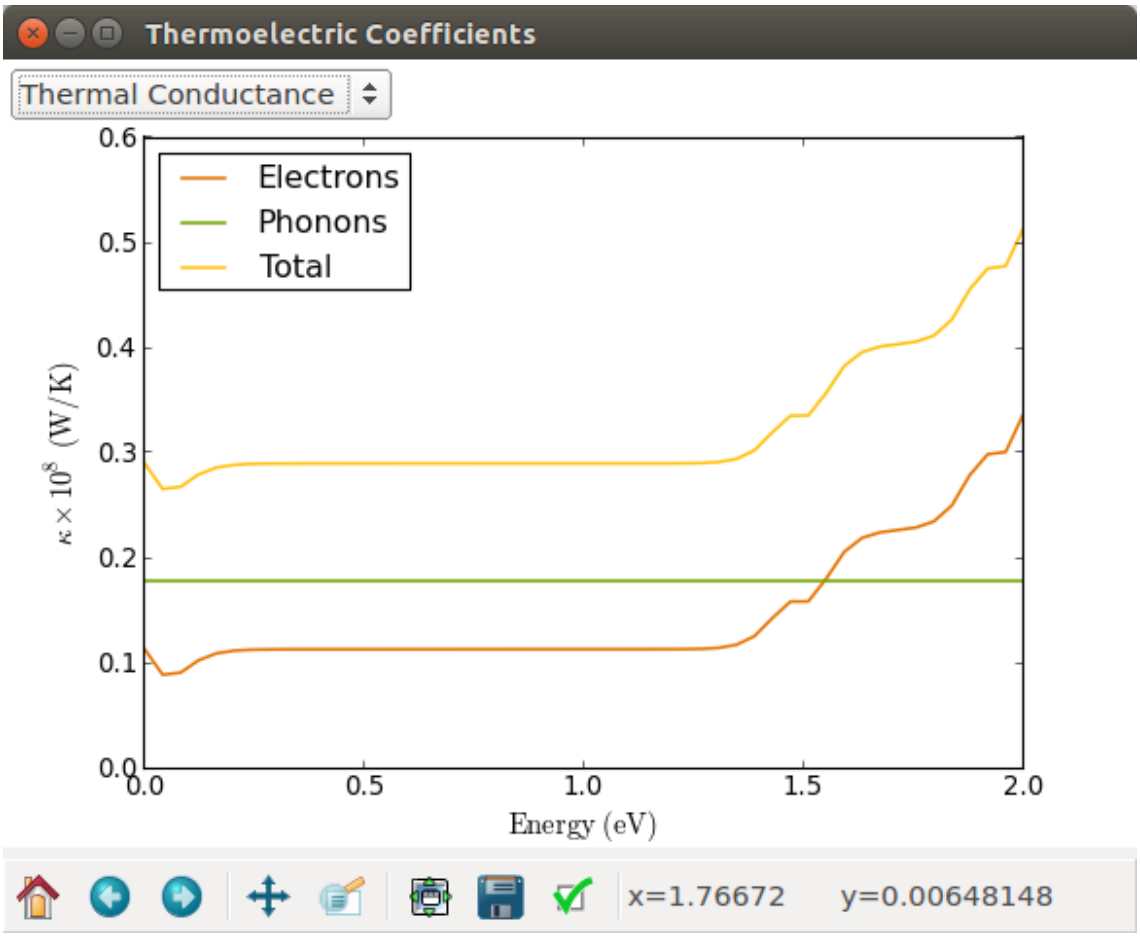
Thermoelectric transport properties

Now you have all the ingredients for calculating thermoelectric transport properties such as conductance, Peltier coefficient, Seebeck coefficient, and heat transport coefficients of electrons and phonons, all of which are ingredients in the thermoelectric figure of merit, *ZT*.

Select from the LabFloor both the **PhononTransmissionSpectrum** AND the **TransmissionSpectrum** objects (by holding down Ctrl while clicking them). Open the **Transmission Coefficient** plugin and set the Fermi level shift to 0.04 eV, corresponding to the band edge. Finally, click **Calculate** to compute all the transport coefficients, and in particular the value of *ZT* at room temperature.



By clicking **Plot**, you can also get an interactive window with plots of the different transport quantities as a function og energy.



Compare *ZT* for doped and undoped CNTs

If you compare the two values of *ZT* for the two devices with and without ^{14}C doping, you will find that the effect of isotopic doping is to slightly increase *ZT*. The effect is indeed very small.

One way to illustrate this result is by plotting *ZT* as a function of the energy for both CNTs in one figure. Once again, a bit of Python scripting will do the job. Use the following piece of Python code, or simply download the script: `plot_zt.py`.

```
from AddOns.TransportCoefficients.Utilities import evaluateMoments
from NL.CommonConcepts import PhysicalQuantity as Units

# Set input parameters
e_min = 0.0
e_max = 2.0
n_steps = 400
temperature = 300.00*Kelvin
energies = numpy.linspace(e_min, e_max, n_steps) * eV

# Read phonon transmission spectrum from file cnt_phonons.nc
# and get the phonon conductance at the specified temperature
phonon_transmission_spectrum = nlread('cnt_phonons.nc', PhononTransmissionSpectrum)[0]
conductance_phonons = phonon_transmission_spectrum.thermalConductance(phonon_
```

(continues on next page)

(continued from previous page)

```
↪temperature=temperature)

# Read phonon transmission spectrum from file cntc14_phonons.nc
# and get the phonon conductance at the specified temperature
phonon_transmission_spectrum_c14 = nlread('cntc14_phonons.nc',␣
↪PhononTransmissionSpectrum)[0]
conductance_phonons_c14 = phonon_transmission_spectrum_c14.thermalConductance(phonon_
↪temperature=temperature)

# Read electron transmission spectrum from file cnt_electrons.nc
electron_transmission_spectrum = nlread("cnt_electrons.nc",TransmissionSpectrum)[0]

# define lists for ZT data
zzt = []
zzt_c14 = []

# Calculate the ZTs at each energy
for energy in energies:
    # Calculate moments of the electron transmission spectrum
    k0, k1, k2 = evaluateMoments(electron_transmission_spectrum, temperature, energy)
    # Calculate transport properties.
    conductance       = k0*Units.e**2
    peltier           = k1/(k0*Units.e)
    seebeck           = k1/(k0*Units.e*temperature)
    thermal_electrons = (k2*k0-k1*k1)/(temperature*k0)
    total_thermal     = thermal_electrons + conductance_phonons
    total_thermal_c14 = thermal_electrons + conductance_phonons_c14
    zt                = conductance*seebeck**2*temperature/total_thermal
    zt_c14            = conductance*seebeck**2*temperature/total_thermal_c14
    zzt.append(zt)
    zzt_c14.append(zt_c14)

# Plot the ZT as function of energy
zzt = numpy.asarray(zzt)*1e3
zzt_c14 = numpy.asarray(zzt_c14)*1e3
import pylab
pylab.plot(energies,zzt,'-',label='CNT',linewidth=1.0,color='b')
pylab.plot(energies,zzt_c14,'--',label='14C-CNT',linewidth=1.0,color='r')
pylab.xlabel('Energy (eV)')
pylab.ylabel('ZT x 1000')
pylab.legend(loc='upper center')
pylab.show()
```

The script produces the figure shown above. It is clear that isotopic doping increases the value of *ZT*, though only marginably.

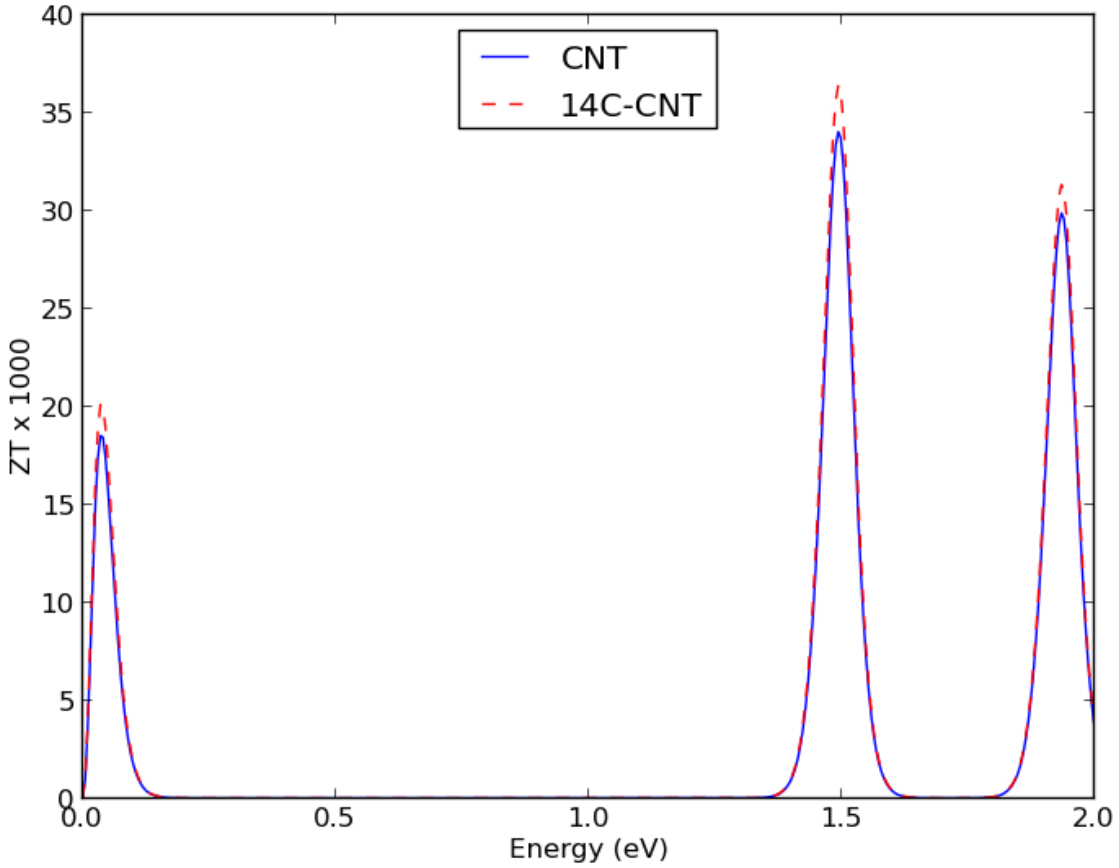


Fig. 3.76: *ZT* at 300 K for a CNT with a natural isotopic distribution (blue line) and for a CNT with a full ring of ^{14}C impurities (red broken line).

3.5.8 Graphene nanoribbon device: Electric properties

The purpose of this tutorial is to show you how the **ATK-SE** package can be used to calculate the electric properties of a **nano-scale transistor device**. You will compute quantities like the electron transmission spectrum, conductance, I–V curve, and electron thermal transport.

Attention: Graphene nanoribbon device with a gate and a dielectric spacer

The device system considered in this tutorial consists of a z-shaped graphene nanoribbon on top of a dielectric and controlled by a metallic gate, as illustrated below. It forms a metal–semiconductor–metal junction. By applying a gate potential across the central region, the system can function as a field effect transistor (FET).

Attention: This tutorial assumes that you have already built the small nanoribbon transistor as described here: *Small nanoribbon transistor*. If you have not, please do so before continuing with this tutorial.

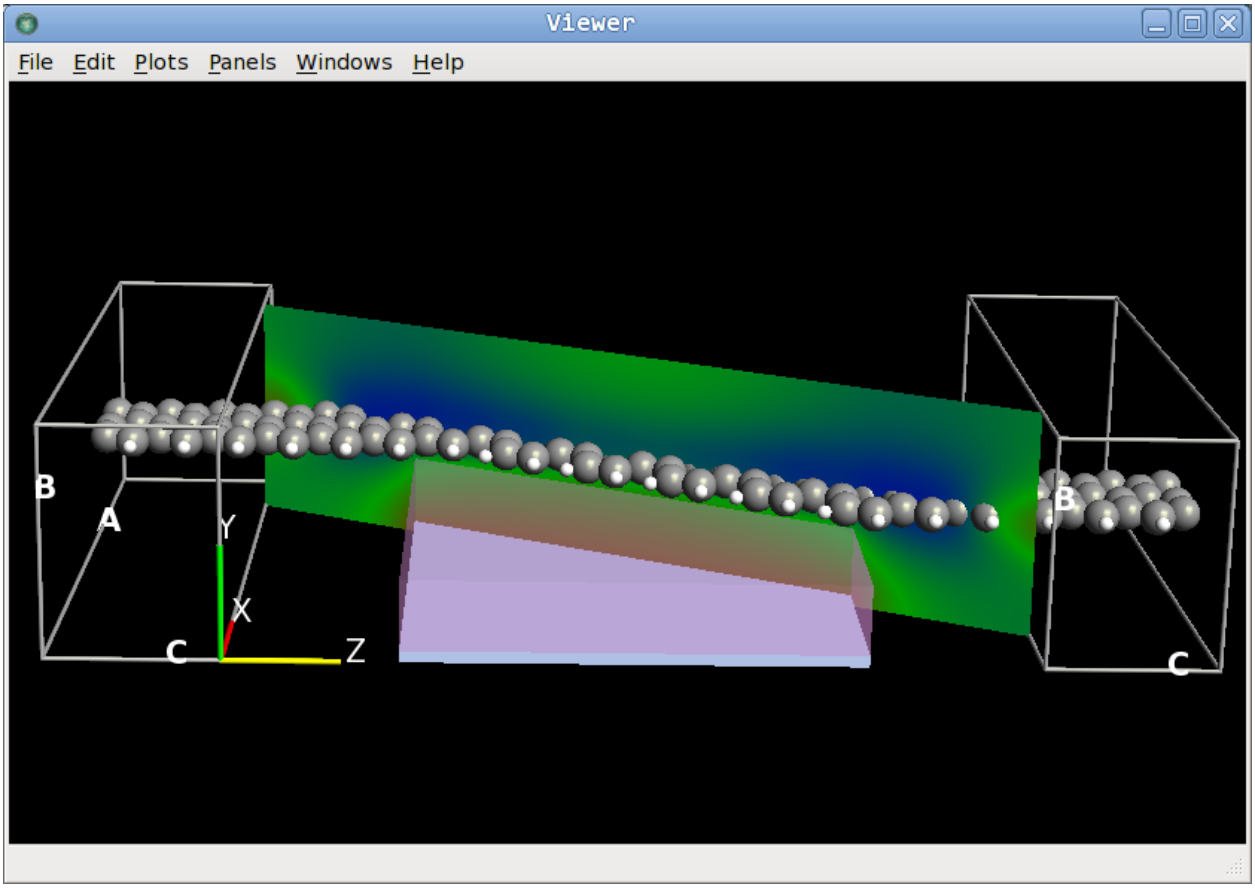

Fig. 3.77: The device system considered in this tutorial consists of a z-shaped graphene nano-ribbon, on top of a dielectric and controlled by a metallic gate. The contour plot illustrates the electrostatic potential through the system.

The device is illustrated in the figure above. It consists of three regions; a central region and two electrodes. You will calculate the following properties of the system.

•Transmission spectrum

•Temperature dependent conductance

•Temperature induced current

•Conductance as function of gate potential and temperature

•Current as function of bias, gate potential and temperature

Get started

Create a new QuantumATK project and add the already built nanoribbon device to the project:

•Open the Builder and use *Add* → *From Files* to find the saved `device_configuration` (in QuantumATK Python or HDF5 format) and add it to the Stash.

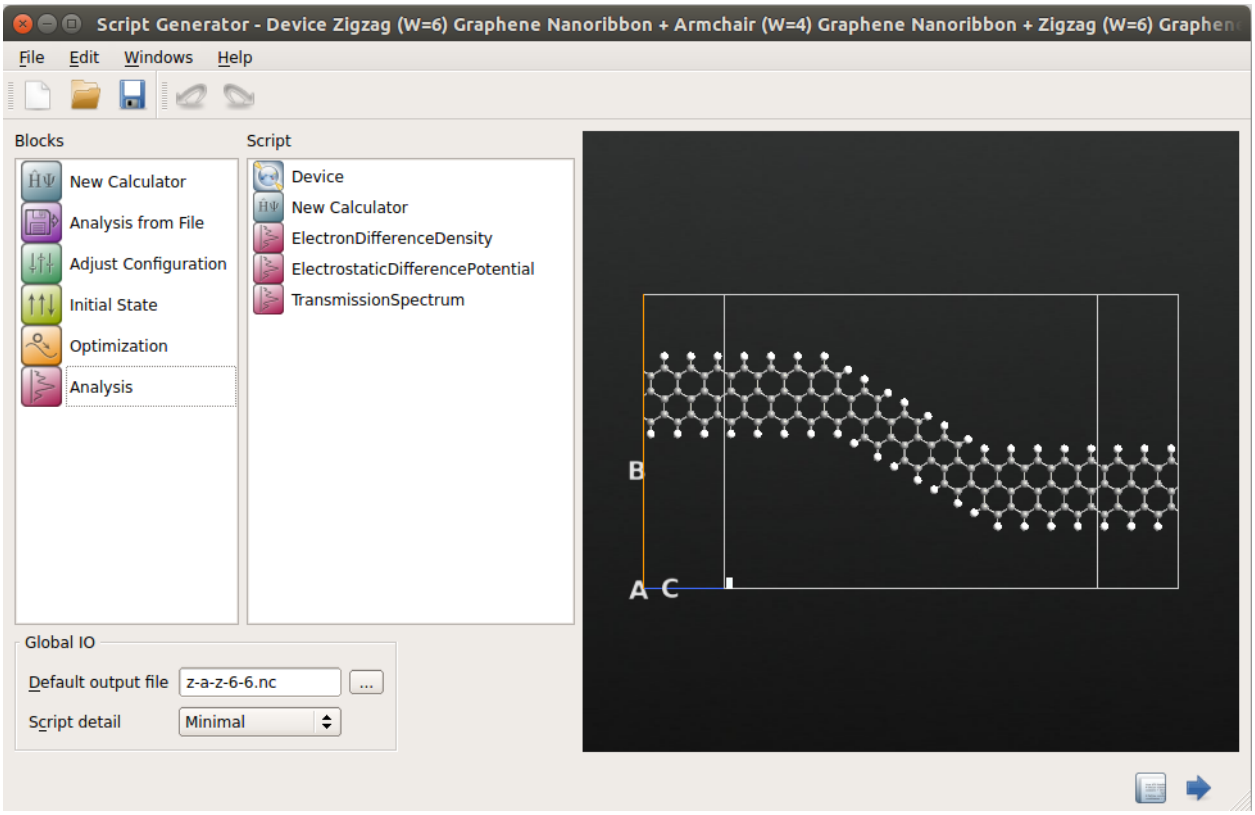
Electron transmission spectrum

Send the configuration from the Builder to the **Scripter** by using the icon in the lower right-hand corner of the Builder window.

Then set up the semi-empirical electron transmission calculation. Add the following blocks to the script:

- **New Calculator**
- *Analysis* → **ElectronDifferenceDensity**
- *Analysis* → **ElectrostaticDifferencePotential**
- *Analysis* → **TransmissionSpectrum**

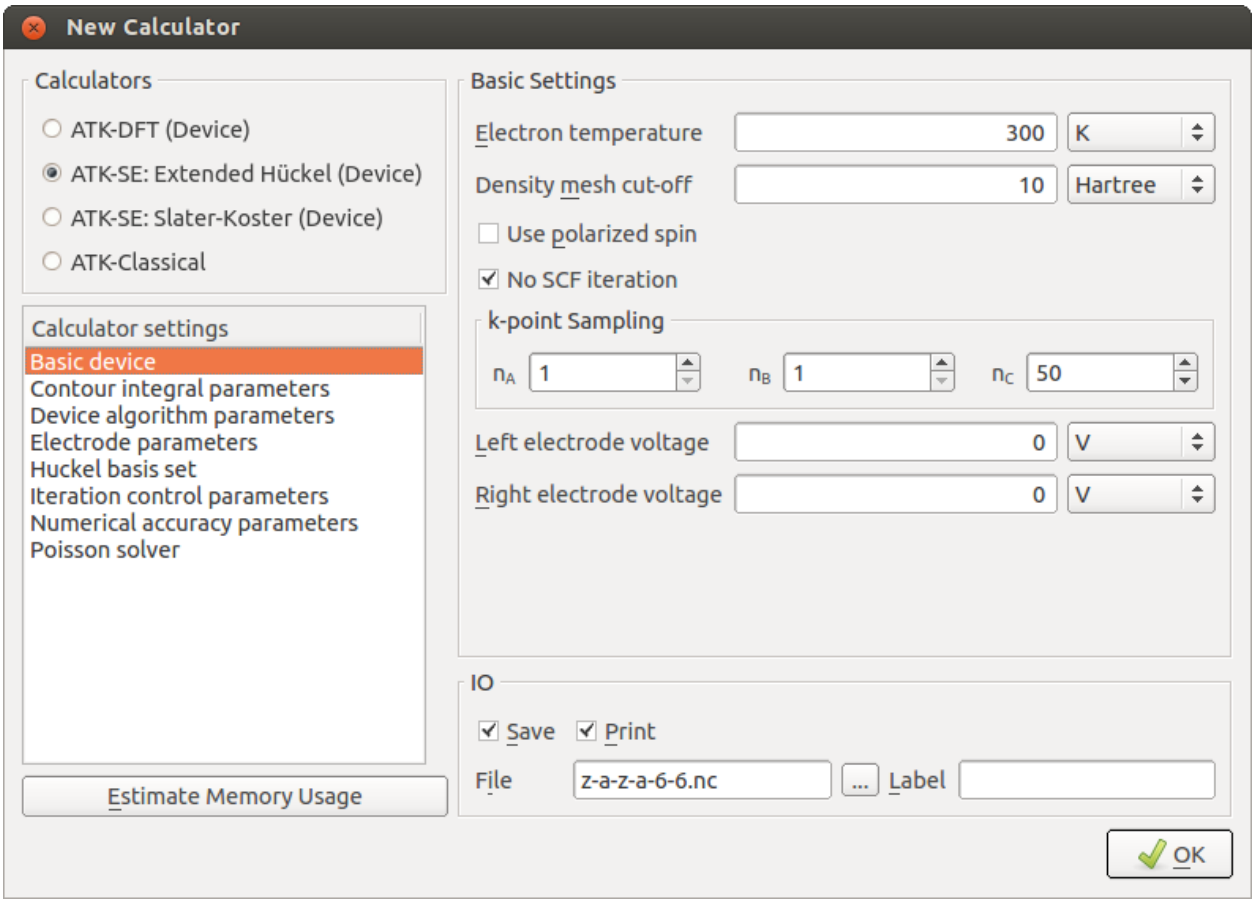
Then change the output filename to `z-a-z-6-6.hdf5`.



Calculator settings

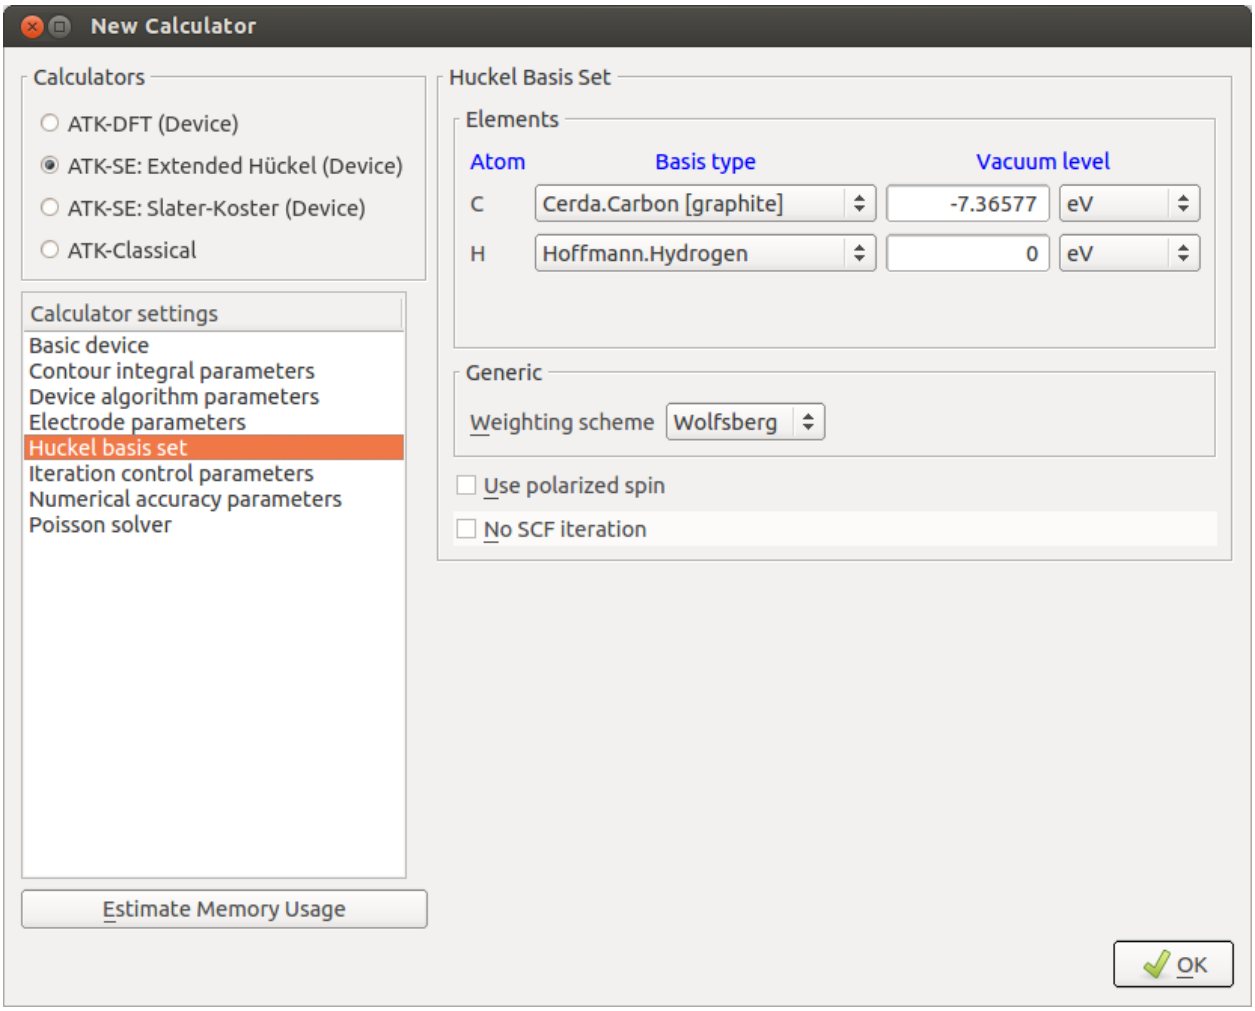
Open the calculator block and edit the settings:

- Select the *ATK-SE: Extended Hückel (Device) calculator*, and lower the number of k-points in the C direction to 50, which should be sufficient for this calculation.
- Uncheck the No SCF iteration box, to perform a self consistent calculation.



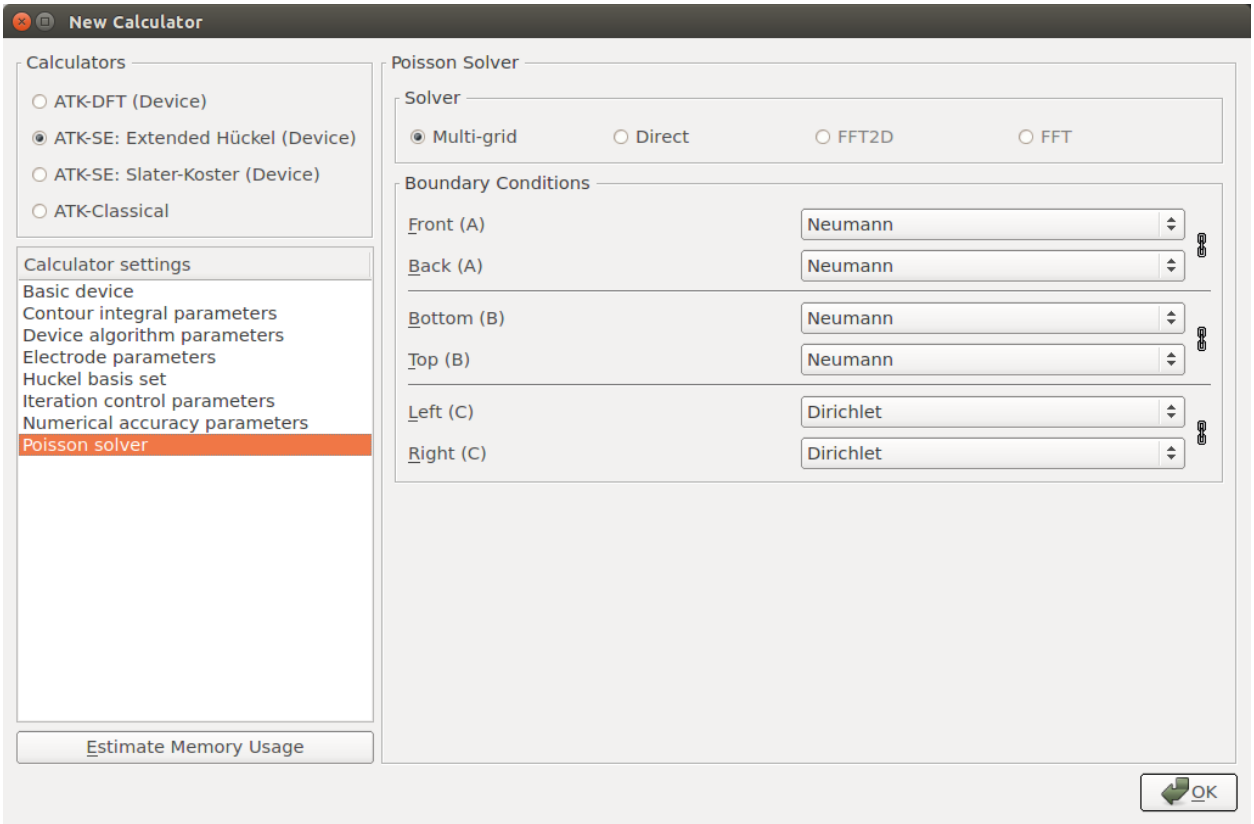
•The next step is to change the basis set for the calculation to use parameters specifically optimized for describing carbon structures[1]. To this end, enter the Huckel basis set menu and select the *Cerda.Carbon [Graphite]* and *Hoffmann.Hydrogen* basis sets.

[1] J.ăCerda and F.ăSoria. Accurate and transferable extended Hückel-type tight-binding parameters. *Phys. Rev. B*, 61:7965–7971, Mar 2000. doi:10.1103/PhysRevB.61.7965.



Note: The default vacuum level for each basis set is chosen such that the carbon and hydrogen parameters they can be used together, even though they are fitted to different reference systems.

•Make sure to use the Multigrid Poisson solver and Neumann boundary conditions along the A and B directions, which are perpendicular to the transport direction. See the image below.



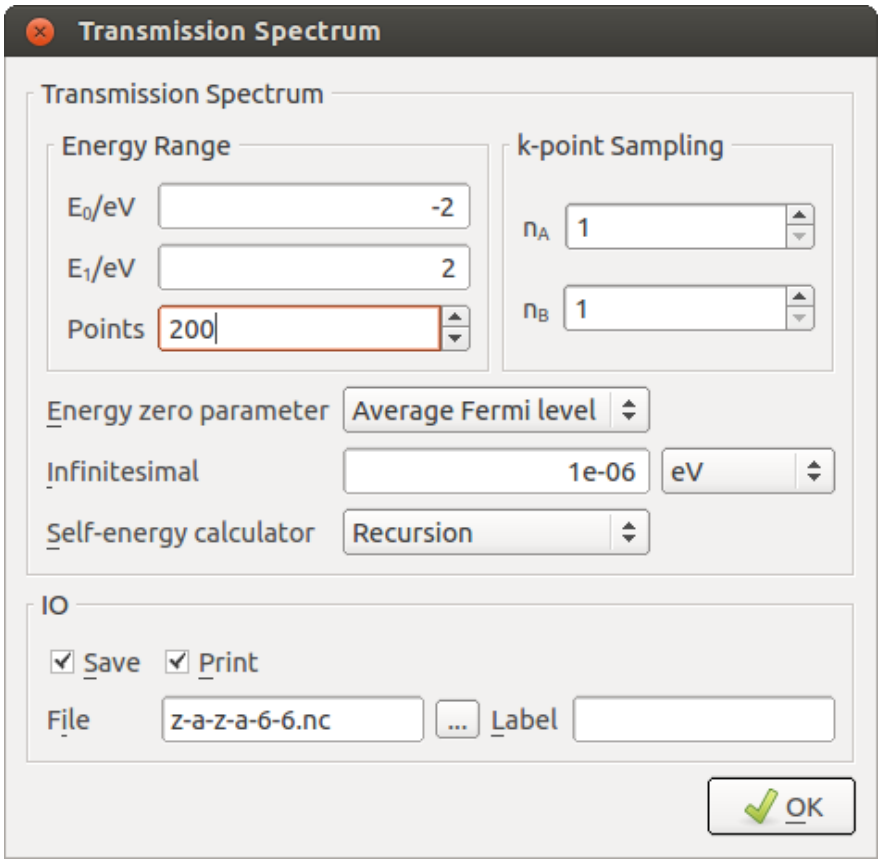
Attention: It is import to use **Neumann boundary conditions** along **non-periodic** directions perpendicular to C, when your device has a metallic gate. Why is this?

The Neumann boundary condition imposes the constraint that the derivative of the electrostatic potential should be zero on that boundary. Put diffferently; the electrostatic potential should be constant at the boundary (but make take on any value). This is the appropriate boundary condition when the device has a metallic gate!

Setup the analysis blocks

•Keep the default settings in the **ElectronDifferenceDensity** and **ElectroStaticDifferencePotential** blocks.

•In **TransmissionSpectrum**, increase the number of sampling points to 200.



You have now completed setting up the calculation. Save the script in the project directory as `z-a-z-6-6.py`.

Run the calculation

Execute the calculation by sending the script to the **Job Manager**, again using the botton. You may be asked to save the script again. Click the botton to start the job. It will take 5 to 15 minutes, depending on your computer.

Note: What is actually happening during the calculation?

The job will first perform a self-consistent calculation for each of the electrodes. The self-consistent electrode Hartree potential is then used as a boundary condition in a self-consistent calculation for the central region of the device. Finally, the transmission spectrum and other analysis objects of the structure are calculated.

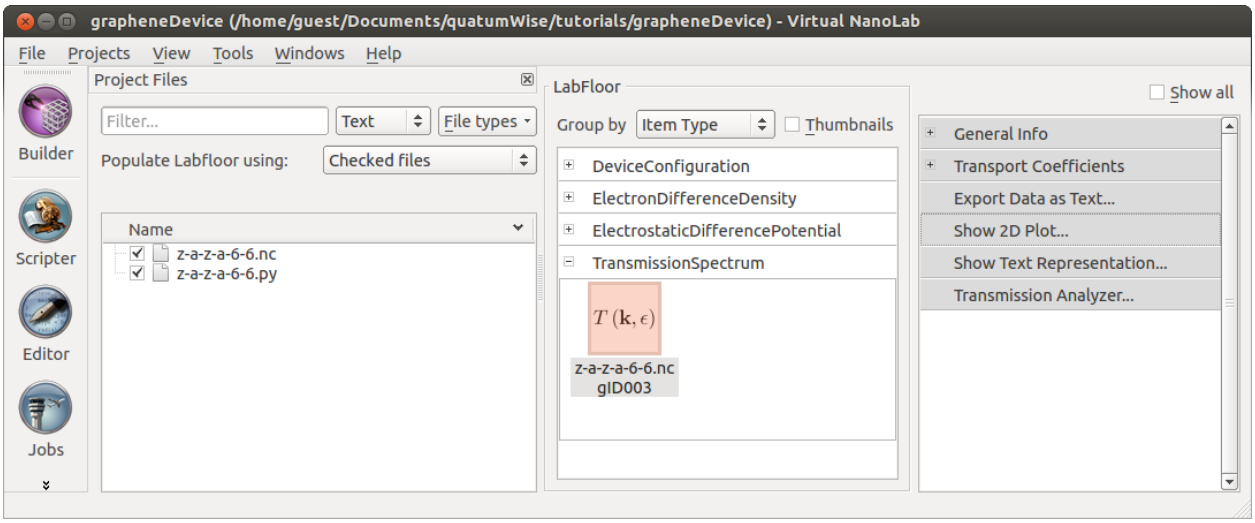
Tip: If you accidentally closed down the Scripter window, or even the QuantumATK main window, your work is not lost! You can simply drag-and-drop the saved Python scipt onto the Scripter to open it for editing. Similarly, you can directly send any saved script to the Job Manager.

Examine the results

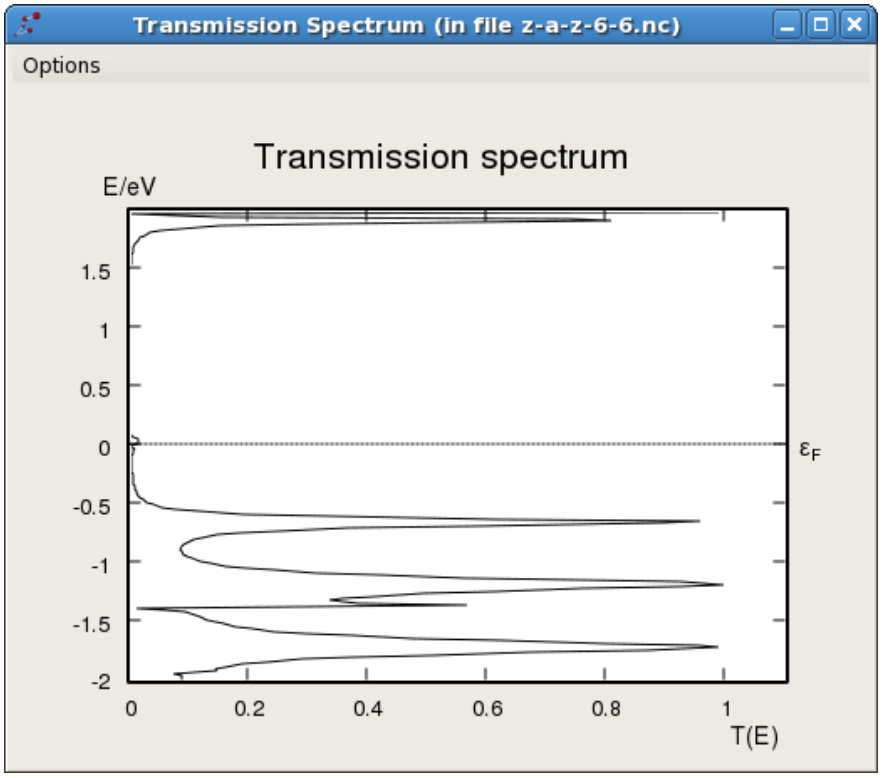
Transmission Spectrum

Switch to the QuantumATK main window, where you will note that the HDF5 file `z-a-z-6-6.hdf5` has been generated. The contents of the file should already be displayed on the **LabFloor**. It contains the **DeviceConfiguration** and the requested analysis objects:

- **ElectronDifferenceDensity** $\delta n(\mathbf{r})$
- **ElectrostaticDifferencePotential** $\delta V_{\mathbf{E}}(\mathbf{r})$
- **TransmissionSpectrum** $T(\mathbf{k}, \epsilon)$



Select the TransmissionSpectrum object and use the **2D Plot** plugin to visualize the calculated transmission spectrum.



Note: The transmission spectrum has a low value in the energy range [-0.5, 1.5] eV, corresponding to the energy window within the band gap of the central semi-conducting armchair-edge ribbon. The asymmetric position of the electrode Fermi levels relative to the band edges, i.e. the shift of the valence band edge of the central region towards the electrode Fermi levels, is due to the applied gate potential of -1V.

Electrostatic potential

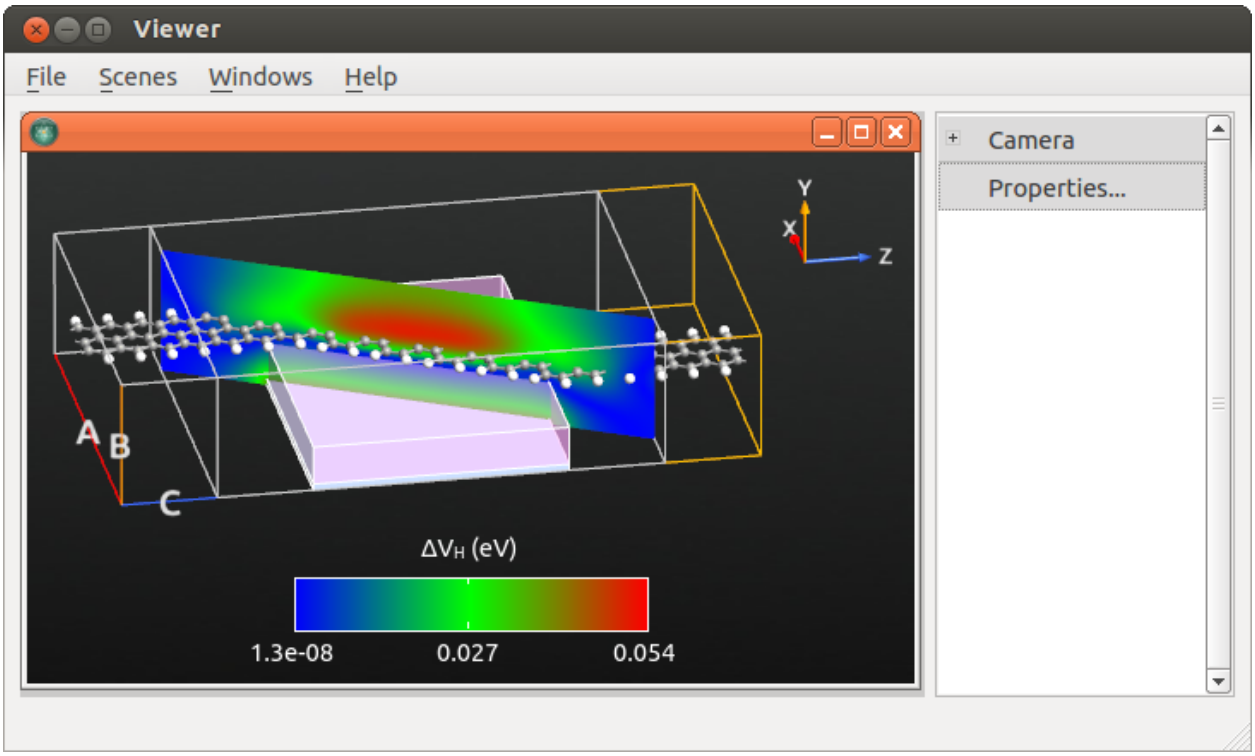
To visualize the effect of the gate potential, select the **ElectrostaticDifferencePotential** object and click the **Viewer** plugin. Select Contour Plot from the dialogue that pops up.

To make the plot more interesting, add a 3D rendering of the graphene junction by dropping the **DeviceConfiguration** from the LabFloor onto the open scene in the Viewer. Then rotate the contour plot:

•Click **Properties** and select CutPlanes from the top.

•Change the rotation angle, θ_y, to 151ř and set the color map to RGB.

•Finally, rotate the camera of the 3D view with the mouse to obtain a plot similar to the image shown below.



If you wish to **export** a copy of the contour plot, right-click in the Viewer window, and choose Export (or use Ctrl+E). You can choose to export as PNG og JPG graphics. The image is now stored on disk and can be used for further processing in any other third party application of your choice.

Effect of the Gate Potential

You will now investigate the effect of changing the gate potential. In the previous section, the gate potential was fixed at -1 V. You will now vary the potential in the range of [-2,2] V and calculate the transmission spectrum at each gate potential.

Gate potential loop

For each value of the gate potential you should perform a new self-consistent calculation to obtain the corresponding transmission spectrum. Such a loop is conveniently done by the following QuantumATK script. You can download it here: `gate_loop.py`

```
#read in the old configuration
device_configuration = nlread("z-a-z-6-6.nc",DeviceConfiguration)[0]
calculator = device_configuration.calculator()
metallic_region0 = device_configuration.metallicRegions()[0]
# Define gate_voltages
gate_voltage_list=numpy.linspace(-2.0,2.0,17)*Volt
for gate_voltage in gate_voltage_list:
    # set the gate potential
    device_configuration.setMetallicRegions(
        [metallic_region0(value = gate_voltage)] )
    # make a copy of the calculator and attach it to the configuration
    # restart from the previous scf state
```

(continues on next page)

(continued from previous page)

```
    device_configuration.setCalculator(calculator(),
        initial_state=device_configuration)
    #Analysis
    filename= 'gatescan-6-6.nc'
    electron_density = ElectronDifferenceDensity(device_configuration)
    nlsave(filename, electron_density,object_id='dens'+str(gate_voltage))
    electrostatic_potential = ElectrostaticDifferencePotential(device_configuration)
    nlsave(filename, electrostatic_potential, object_id='pot'+str(gate_voltage))
    transmission_spectrum = TransmissionSpectrum(
        configuration=device_configuration,
        energies=numpy.linspace(-2,2,200)*eV,
        )
    nlsave(filename, transmission_spectrum,object_id='trans'+str(gate_voltage))
    nlprint(transmission_spectrum)
```

The script implements the following workflow:

1. Read the self-consistent calculation obtained in the previous chapter and use this as the starting point for the calculations:

```
#read in the old configuration
device_configuration = nlread("z-a-z-6-6.nc",DeviceConfiguration)[0]
calculator = device_configuration.calculator()
metallic_region0 = device_configuration.metallicRegions()[0]
```

2.Set up a list of gate voltage values [-2.0, -1.75, , 2.0]*Volt:

```
# Define gate_voltages
gate_voltage_list=numpy.linspace(-2.0,2.0,17)*Volt
```

3. Loop through the gate voltage list, and for each value modify the value of the gate voltage in the metallic region:

```
for gate_voltage in gate_voltage_list:
    # set the gate potential
    device_configuration.setMetallicRegions(
        [metallic_region0(value = gate_voltage)] )
```

4.Initialize the self-consistent state of the device configuration by calling the `calculator()` method.

```
    # make a copy of the calculator and attach it to the configuration
    # restart from the previous scf state
    device_configuration.setCalculator(calculator(),
        initial_state=device_configuration)
```

This method will make a copy of the previous Huckel calculator using the same settings. Since a new calculator is attached, a self-consistent calculation will automatically be performed the next time a property of the system is required:

5.Finally, the same analysis objects as in the previous chapter are calculated and save them into a HDF5 file. Note that for each analysis object a specific **object_id** is specified. This will make it easier to retrieve the correct entries from the HDF5 file:

```
    #Analysis
    filename= 'gatescan-6-6.nc'
```

(continues on next page)

(continued from previous page)

```
    electron_density = ElectronDifferenceDensity(device_configuration)
    nlsave(filename, electron_density,object_id='dens'+str(gate_voltage))
    electrostatic_potential = ElectrostaticDifferencePotential(device_configuration)
    nlsave(filename, electrostatic_potential, object_id='pot'+str(gate_voltage))
    transmission_spectrum = TransmissionSpectrum(
        configuration=device_configuration,
        energies=numpy.linspace(-2,2,200)*eV,
        )
    nlsave(filename, transmission_spectrum,object_id='trans'+str(gate_voltage))
    nlprint(transmission_spectrum)
```

Run the script using the **Job Manager** or execute it from a terminal:

```
$ atkpython gatescan-6-6.py > gatescan-6-6.out
```

The script will take a while to complete, since 17 self-consistent calculations are needed. The total execution time may be between 2 and 8 hours, depending on your hardware.

Conductance as a function of gate potential

The script in the previous section produced the data file `gatescan-6-6.hdf5`. It should contain all the calculated transmission spectra. Try to inspect them using the **Transmission Analyzer** to see how the transmission spectrum changes with the gate potential.

Note: You will find that all the spectra look rather similar and that the main difference between the different spectra is a shift of the valence and conduction band edges relative to the Fermi level.

This is the main function of the metallic gate: It can be used to tune the band edge positions relative to the Fermi level, and thereby control the electric properties of the device!

You will now use the data to calculate the conductance of the junction as a function of the gate potential for different electrode temperatures. Use the following script, which is a slight modification of the script used in the previous chapter. You can also download it here: `conductance_diff_gate.py`.

```
#make list of relevant temperatures
temperature_list=numpy.linspace(0,2000,21)*Kelvin
#make list of relevant gate voltages
gate_voltage_list=numpy.linspace(-2.0,2.0,17)*Volt
#make list to hold the conductance calculations
conductance_list=numpy.zeros(len(gate_voltage_list)*len(temperature_list))
conductance_list=conductance_list.reshape(len(gate_voltage_list),
                                          len(temperature_list))
#specify the filename for the netcdf data file
filename="gatescan-6-6.nc"
#loop through the gate voltages
for n in range(len(gate_voltage_list)):
    transmission_spectrum=nlread(filename,
        object_id="trans"+str(gate_voltage_list[n]))[0]
    #loop through the temperature list
    for i in range(len(temperature_list)):
```

(continues on next page)

(continued from previous page)

```
        conductance_list[n,i]=transmission_spectrum.conductance(
            electrode_temperatures=(temperature_list[i],temperature_list[i]))
#plot the conductance as function of gatevoltage
import pylab
pylab.figure()
# make curve for each temperature
for i in range(len(temperature_list)):
    pylab.semilogy(gate_voltage_list,conductance_list[:,i])
pylab.xlabel("Gate Voltage (V)")
pylab.ylabel("Conductance (S)")
pylab.show()
```

The script produces the following figure:

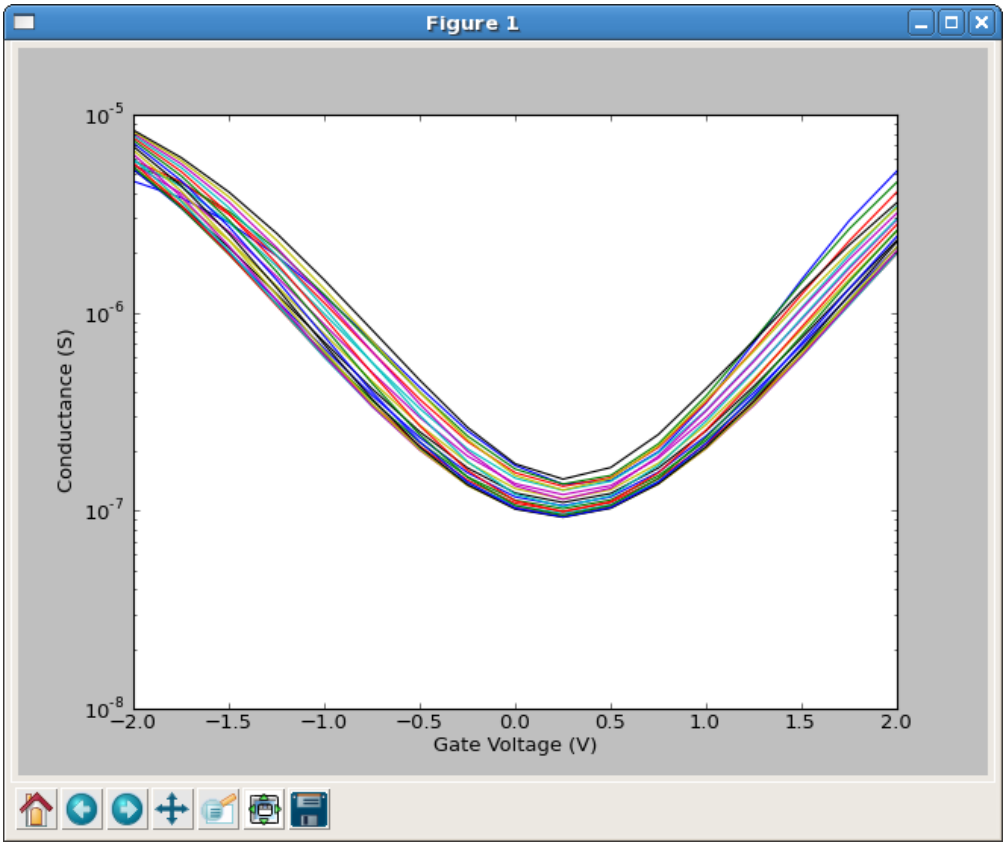


Fig. 3.78: Conductance as a function of the gate potential. Different curves are for different electron temperatures, namely 0, 100, 200, , 2000 Kelvin.

The conductance has a minimum for a gate potential of about 0.25 Volt. At this point, the Fermi level is positioned in the mid gap between the valence and conductance band of the central ribbon. Note that there is only a weak dependence of the conductance on the electron temperature, which illustrates that the transmission is dominated by electron tunnelling.

Tip: This tutorial relies heavily on scripting access to inputs and outputs of the **TransmissionSpectrum** object. For further information on all the options and methods available, see the ATK Reference Manual.

Also note that we use the pylab package to generate plots. This is readily available with `atkpython` and is very handy

for making plots with Python scripts.

Linear response calculations

You just saw that the transmission spectra for different gate potentials are rather similar and that the main difference is a shift of the band edges relative to the Fermi level. This suggests that you may avoid the self-consistent loop and simply shift the Fermi level rigidly and calculate all the transmission spectra using linear response theory.

The following script implements a linear response calculation of the conductance as function of the gate potential, assuming that the effect of the gate potential is a simple shift of the relative positions of the electrode Fermi levels within the transmission spectra. You can download it here: `linear_response.py`.

```
#make list of relevant temperatures
temperature_list=numpy.linspace(0,2000,21)*Kelvin
#make list of relevant gate voltages
gate_voltage_list=numpy.linspace(-2.0,2.0,17)*Volt
#make list to hold the conductance calculations
conductance_list=numpy.zeros(len(gate_voltage_list)*len(temperature_list))
conductance_list=conductance_list.reshape(len(gate_voltage_list),
                                          len(temperature_list))
#read the reference transmission spectrum from the netcdf data file
gate_potential_ref = 0.*Volt
transmission_spectrum = nlread("gatescan-6-6.nc",
    object_id="trans"+str(gate_potential_ref))[0]
#loop through the gate voltages
for n in range(len(gate_voltage_list)):
    #loop through the temperature list
    for i in range(len(temperature_list)):
        conductance_list[n,i]=transmission_spectrum.conductance(
            electrode_temperatures=(temperature_list[i],temperature_list[i]),
            electrode_voltages=(gate_voltage_list[n]-gate_potential_ref,
                                gate_voltage_list[n]-gate_potential_ref))
#plot the conductance as function of gatevoltage
import pylab
pylab.figure()
# make curve for each temperature
for i in range(len(temperature_list)):
    pylab.semilogy(gate_voltage_list,conductance_list[:,i])
pylab.xlabel("Gate Voltage (V)")
pylab.ylabel("Conductance (S)")
pylab.show()

```

The script implements a quite simple workflow:

1. It reads in the transmission spectrum from the calculation with 0 V gate potential:

```
#read the reference transmission spectrum from the netcdf data file
gate_potential_ref = 0.*Volt
transmission_spectrum = nlread("gatescan-6-6.nc",
    object_id="trans"+str(gate_potential_ref))[0]
```

2. Instead of setting the gate potential, the electrode voltages are varied such that the electrode Fermi levels are shifted

relative to each other:

```
            electrode_voltages=(gate_voltage_list[n]-gate_potential_ref,
                                gate_voltage_list[n]-gate_potential_ref))
```

The script produces the figure below. We see that the main main trends of the fully self-consistent calculations are reproduced by the linear response procedure.

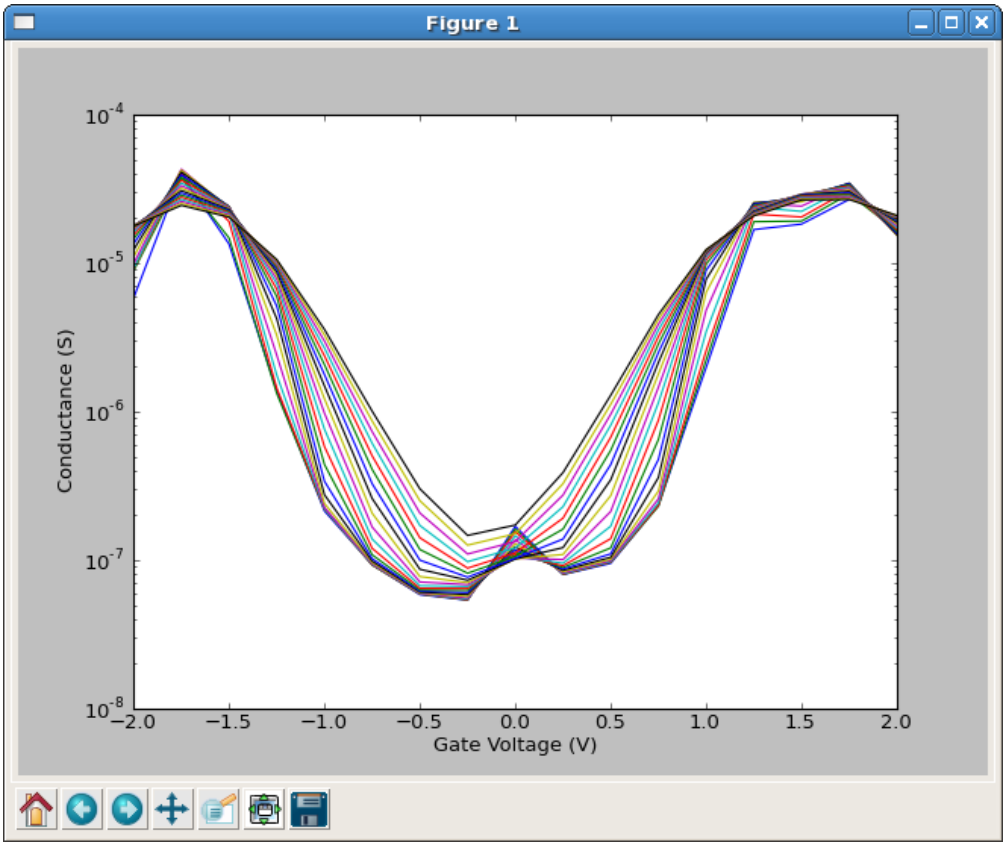

Fig. 3.79: Conductance as function of the gate potential calculated using linear response. Different curves are for electron temperatures 0, 100, 200, , 2000 Kelvin.

I–V characteristics

You will now investigate the effect of changing the external bias across the electrodes in the range 0-2 Volt. The calculations follow a similar procedure as the gate potential scan in the previous section.

Electrode bias loop

Use the script displayed below. You can download it here: `electrode_loop.py`.

```
# Read in the old configuration
device_configuration = nlread("z-a-z-6-6.nc",DeviceConfiguration)[0]
calculator = device_configuration.calculator()
# Output filename
filename = 'ivscan-6-6.nc'
# Define bias voltages
voltage_list=numpy.linspace(0.0,2.0,9)*Volt
for voltage in voltage_list:
    # Set new calculator with modified electrode voltages on the configuration
    # use the self consistent state of the old calculation as starting input.
    device_configuration.setCalculator(
    calculator(electrode_voltages=(-0.5*voltage,0.5*voltage)),
               initial_state=device_configuration)
    #Analysis
    electron_density = ElectronDifferenceDensity(device_configuration)
    nlsave(filename, electron_density, object_id='dens'+str(voltage))
    electrostatic_potential = ElectrostaticDifferencePotential(device_configuration)
    nlsave(filename, electrostatic_potential, object_id='pot'+str(voltage))
    transmission_spectrum = TransmissionSpectrum(
        configuration=device_configuration,
        energies=numpy.linspace(-2,2,200)*eV)
    nlsave(filename, transmission_spectrum, object_id='trans'+str(voltage))
    nlprint(transmission_spectrum)
```

The calculation uses the calculation for the junction with an applied gate potential of -1 V as a starting point. This value for the gate potential is fixed through the entire calculation. The electrode voltages are modified through the `electrode_voltages` variable of the `DeviceHuckelCalculator`.

The entire calculation will take more than 10 times longer than the single zero bias calculation. During the loop, the results will be saved in the file `ivscan-6-6.hdf5`. The file may be inspected during the calculation to follow how the calculation is progressing.

The plot below shows the electrostatic potential for a bias of 1 Volt, i.e. -0.5 V on the left electrode and +0.5 V on the right electrode. Notice how the electrostatic potential in the left electrode is closer to the electro-static potential of the gate.

Self-consistent I–V characteristics

You can now use all the **TransmissionSpectrum** objects in `ivscan-6-6.hdf5` to calculate the I–V curve for a gate potential of -1 V. Use the script shown below, which combines the methods presented in the previous sections. You can also download it here: `IV_curve.py`.

```
#make list of relevant temperatures
temperature_list=numpy.linspace(0,2000,21)*Kelvin
#make list of relevant gate voltages
voltage_list=numpy.linspace(0.0,2.0,9)*Volt
#make list to hold the current calculations
current_list=numpy.zeros(len(voltage_list)*len(temperature_list))
current_list=current_list.reshape(len(voltage_list),len(temperature_list))
```

(continues on next page)

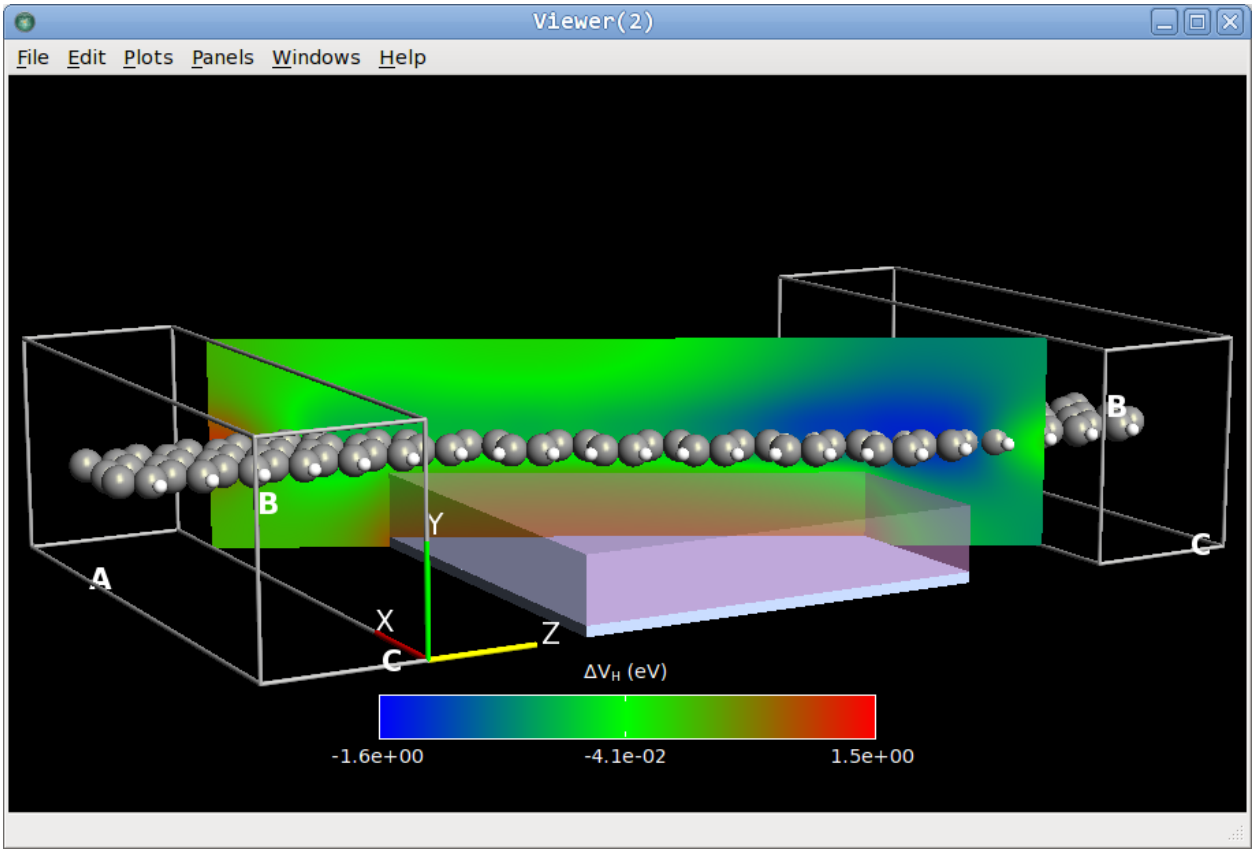

Fig. 3.80: Electrostatic potential of the junction with a symmetrically applied bias of 1 Volt and a gate potential of -1 Volt.

(continued from previous page)

```
#specify the filename for the netcdf data file
filename="ivscan-6-6.nc"
#loop through the gate voltages
for n in range(len(voltage_list)):
    transmission_spectrum=nlread(filename, object_id="trans"+str(voltage_list[n]))[0]
    #loop through the temperature list
    for i in range(len(temperature_list)):
        current_list[n,i]=transmission_spectrum.current(
            electrode_temperatures=(temperature_list[i],temperature_list[i]))
#plot the current as function of voltage
import pylab
pylab.figure()
# make curve for each temperature
for i in range(len(temperature_list)):
    pylab.plot(voltage_list,current_list[:,i])
pylab.xlabel("Bias (V)")
pylab.ylabel("Current (A)")
pylab.show()
```

The result of the calculation is illustrated below.

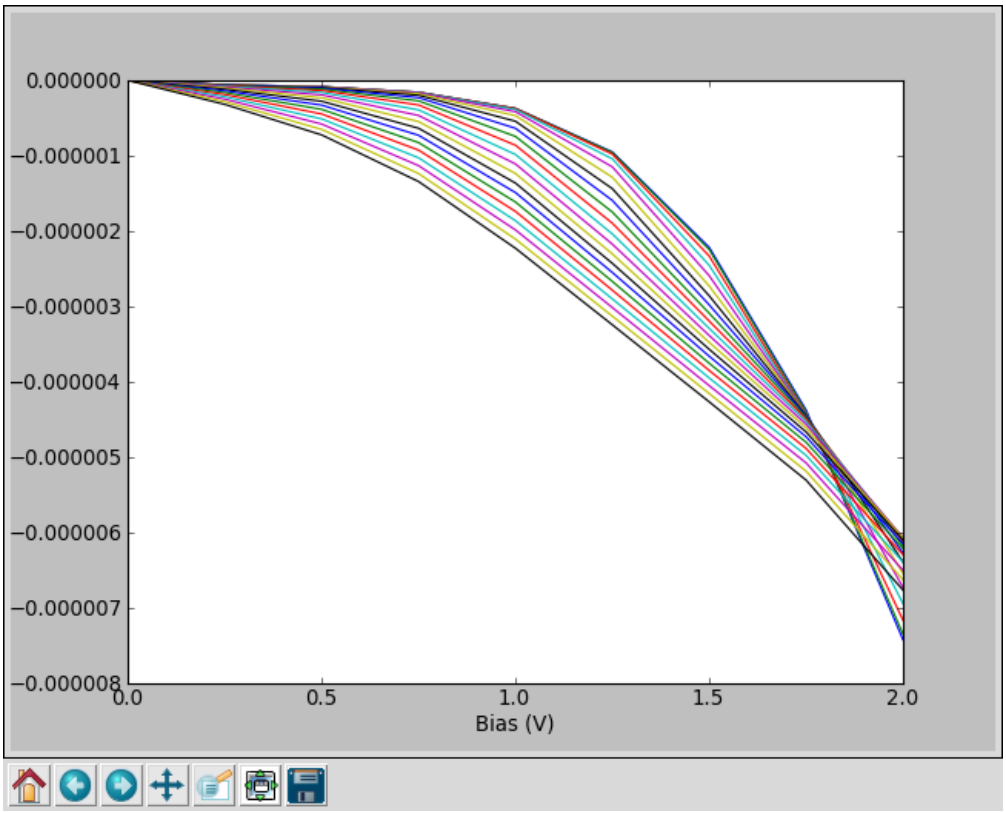

Fig. 3.81: Self-consistent current-voltage characteristics of the nanoribbon junction with -1 V gate potential. Curves are for electrode temperatures 0, 100, 200, .. 2000 Kelvin. The electric current increases with temperature.

Linear response I–V characteristics

Similar to the linear response approximation for the gate potential presented in the previous section, you may use a linear response approximation to calculate the finite-bias transmission spectra from the zero-bias spectrum. The following script performs a calculation of the linear response current for an electrode temperature of 300 Kelvin:

```
#make list of relevant temperatures
temperature=300*Kelvin
#make list of relevant gate voltages
voltage_list=numpy.linspace(0.0,2.0,9)*Volt
#make list to hold the current calculations
current_list=numpy.zeros(len(voltage_list))
current_list_lin=numpy.zeros(len(voltage_list))
#read the reference transmission spectrum from the netcdf data file
potential_ref = 0.*Volt
filename="ivscan-6-6.nc"
transmission_spectrum0 = nlread(filename, object_id="trans"+str(potential_ref))[0]
for n in range(len(voltage_list)):
    transmission_spectrum=nlread(filename, object_id="trans"+str(voltage_list[n]))[0]
    current_list[n]=transmission_spectrum.current(
        electrode_temperatures=(temperature,temperature))
    current_list_lin[n]=transmission_spectrum0.current(
        electrode_temperatures=(temperature,temperature),
        electrode_voltages=(-0.5*(voltage_list[n]-potential_ref),
        0.5*(voltage_list[n]-potential_ref) ) )
#plot the current as function of bias
import pylab
pylab.figure()
pylab.plot(voltage_list,current_list,label="self consistent")
pylab.plot(voltage_list,current_list_lin,label="linear response")
pylab.xlabel("Bias (V)")
pylab.ylabel("Current (A)")
pylab.legend(loc="lower left")
pylab.grid(True)
pylab.show()
```

The figure below compres the linear response results to the self-consistent ones. The agreement is quite good for low bias, but at large bias the linear response current does start to deviate from the self-consistently calculated current.

When is the linear response approximation valid?

The previous sections illustrate how to perform calculations of the current as function of the electrode bias or the gate potential. Even though the methodology is based on the extended Huckel formalism, such calculations can be quite time consuming, and an alternative is to invoke the linear response approximation in and use non-self-consistent calculations, which are much faster than self-consistent ones.

However, an important question emerges: **When is it OK to use linear response instead of fully self-consistent calculations?** You have already seen that linear response works well for a relatively small electrode bias, but how about the influence of the gate potential?

The scripts presented in the previous sections can be easily modified to vary the gate potential and the electrode bias simultaneously. Below is a comparison between the self-consistent current and the linear response current. For a small bias and gate potential the two are in good agreement, illustrating that the linear response current is a good first approximation.

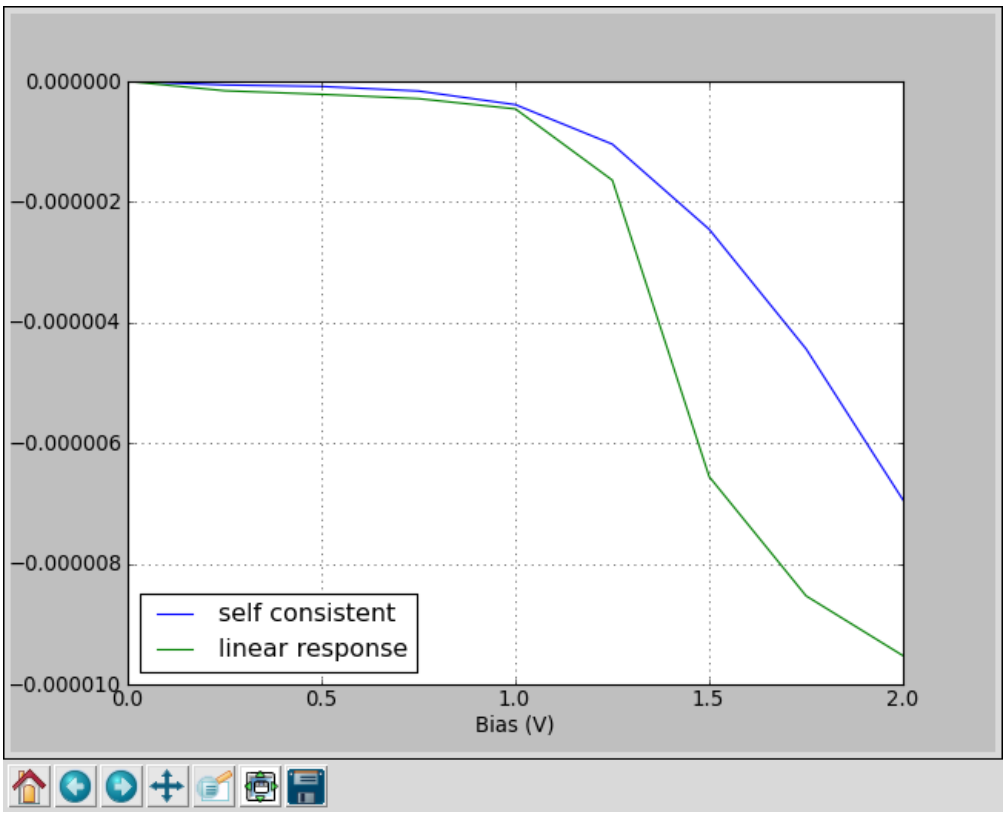

Fig. 3.82: Comparison of the self-consistent (blue) and linear response (green) current-voltage characteristics of the junction with a -1 V gate potential and an electrode temperature of 300 Kelvin.

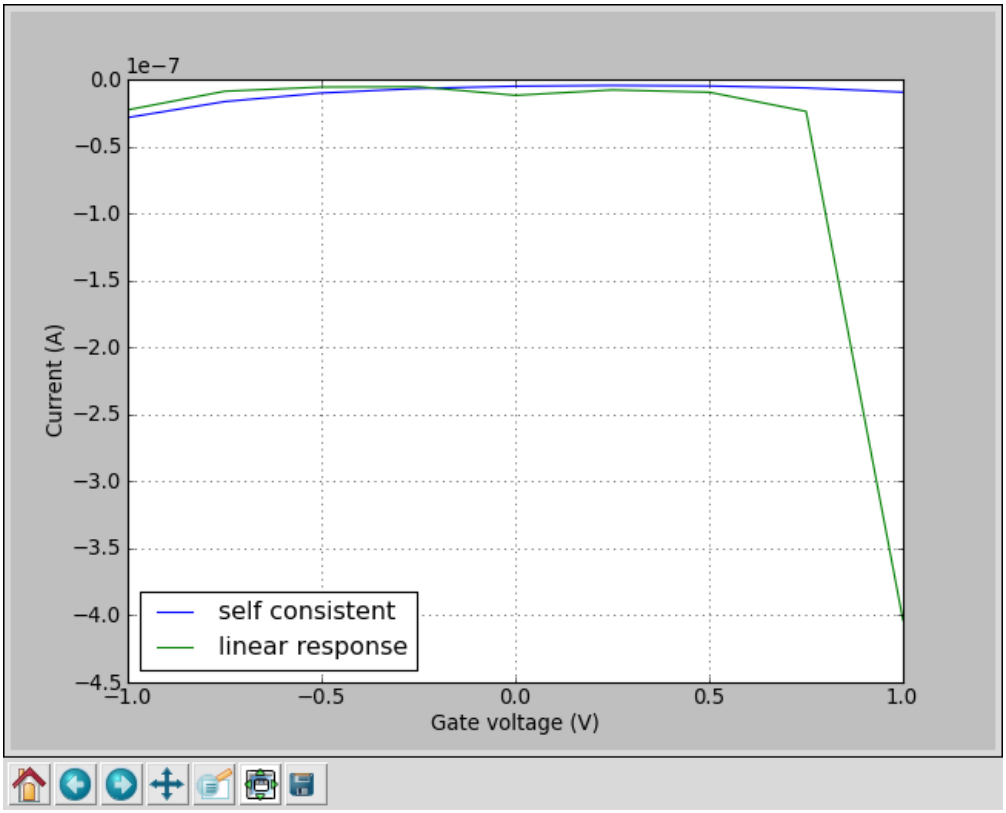

Fig. 3.83: Current for an applied bias of 0.2 Volt as a function of the gate potential. The blue curve was obtained from a fully self-consistent calculation, while the green curve was obtained from a linear response calculation using the transmission spectrum of a system with zero gate potential and bias.

The scripts that generated the self-consistent data at the plot can be downloaded here: `potentials_vary.py`, `electrode_0.2V_gate_varies.py`.

Further analysis with ATK-SE

Some of the other analyses that can be performed with **QuantumATK** are

- 3D visualization of scattering states.
- 3D visualization of transmission pathways.
- Projected density of states.

The main part of the analysis in this tutorial are performed using QuantumATK scripts. However, analysis can in most cases also be performed directly from the QuantumATK GUI. For further information, see the *Transport calculations with QuantumATK*.

Temperature dependent conductance

In this section you will learn how the transmission spectrum can be used to calculate the conductance of the device as a function of the left and right electrode temperatures, T_L and T_R. At $T_L = T_R = 0$, the conductance is determined by the transmission coefficient at the Fermi Level, while for finite electrode temperatures, the conductance depends on the value of the transmission coefficient in an energy window around the Fermi level. The zero-bias conductance is given by

$$\sigma(T_L) = \frac{2e^2}{h} \int T(E)\ f'(\eta(E)) \frac{dE}{k_b T_R},$$

where $f'(\eta(E)) = f'\left(\frac{E-E_F^L}{k_b T_R}\right)$ is the derivative of the Fermi function[2].

In semiconductors the conductance is often determined by hot electrons or holes propagating within the conduction or valence band, so-called thermionic emission. The hot electrons are located in the energy range of the tails of the Fermi function. Thus, for an accurate calculation of the conductance from thermionic emission, it is important that the energy range of the transmission spectrum is such that the tails of the Fermi functions are properly sampled. The transmission spectrum figure in the previous chapter shows that both the valence and conduction band edges of the central region are within the energy range of the transmission spectrum. From that data you will therefore be able to accurately determine the temperature dependent conductance.

Use the following QuantumATK script to calculate and plot the temperature dependent conductance. It can be downloaded here: `temperature_dependent.py`.

```
# Read first transmission spectrum from file z-a-z-6-6.hdf5
transmission_spectrum = nlread("z-a-z-6-6.hdf5",TransmissionSpectrum)[0]
#make list of temperatures
temperature_list=numpy.linspace(0,2000,21)*Kelvin
#make list for holding conductance
conductance_list=numpy.zeros(len(temperature_list))
#calculate the conductance for each temperature in the temperature list
for i in range(len(temperature_list)):
    conductance_list[i]=transmission_spectrum.conductance(
        electrode_temperatures=(temperature_list[i], temperature_list[i]))
#plot the conductance as function of temperature
import pylab
```

(continues on next page)

[2] H.ăH.ăB. Sorensen, P.ăC. Hansen, D.ăE. Petersen, S.ăSkelboe, and K.ăStokbro. Efficient wave-function matching approach for quantum transport calculations. *Phys. Rev. B*, 79:205322, May 2009. doi:10.1103/PhysRevB.79.205322.

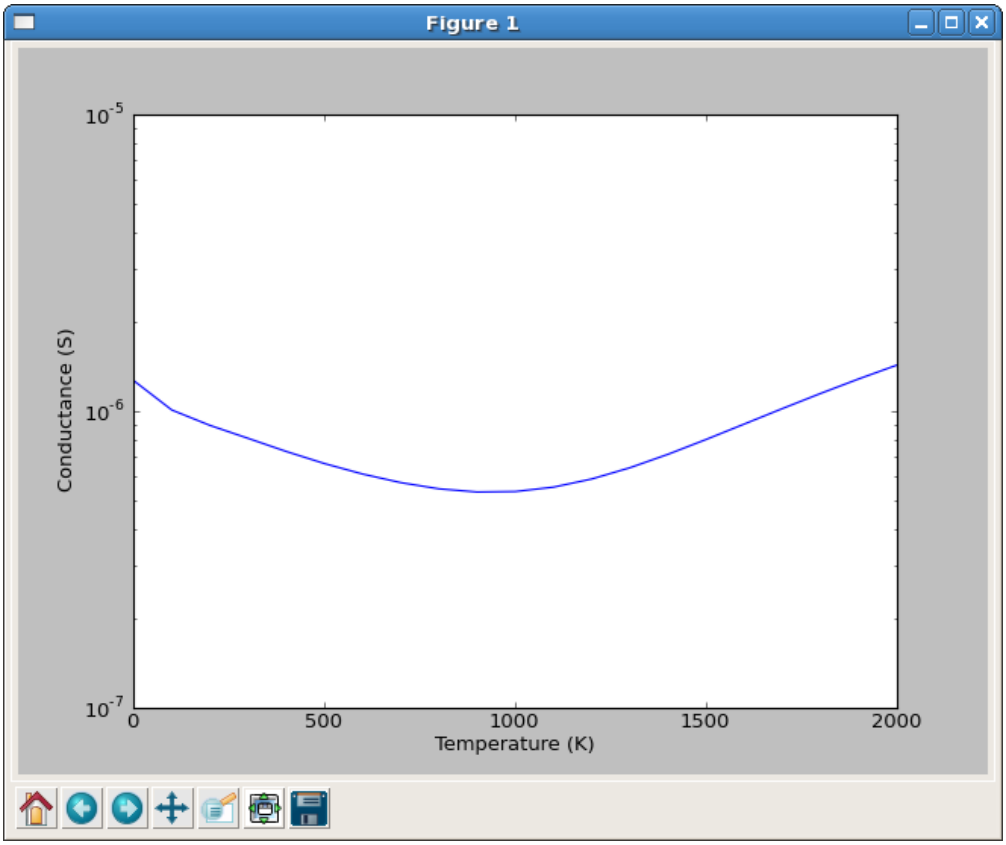
(continued from previous page)

```
pylab.figure()
pylab.semilogy(temperature_list,conductance_list)
pylab.xlabel("Temperature (K)")
pylab.ylabel("Conductance (S)")
pylab.show()
```

The script reads the previously calculated transmission spectrum and then uses the `conductance()` method for calculating the conductance for a number of electrode temperatures. Save the script and run it using the Job Manager or run it from a terminal:

```
$ atkpython temperature_dependent.py
```

You will obtain the figure below.



The temperature dependent conductance for this device is typical for a field effect transistor: The initial decrease in conductance as a function of temperature is related to a large conductance at the Fermi level caused by electron tunneling. At larger temperatures, the usual increase of conductance with temperature starts dominating. The tunneling effect will be suppressed in a longer device, as you will see in the next section.

Comparison to results for a longer device

Attention: This section employs a device with a longer nanoribbon. Build the device as described here: *A longer nanoribbon transistor*.

You will now calculate the transmission spectrum of the nanoribbon transistor with a longer channel, and compare its temperature dependent conductance with the shorter system investigated earlier.

Electron conductance

Open the large transistor configuration in the Builder, and confirm that it looks as expected. Next step is to set up the calculations needed for analyis of the electronic conductance in exactly the same way as outlined in the previous section for the shorter device. There are two ways to do this:

1. Send the device to the **Scripter** and repeat all the steps that were needed to prepare the script `z-a-z-6-6.py`, and save the new script as `z-a-z-20-6.py`.
2. Alternatively, you may use the **Editor** to generate the new script:

- Save the new geometry into the file `z-a-z-20-6.py`.
- Copy the lines specifying the calculation from `z-a-z-6-6.py`, and insert them into `z-a-z-20-6.py`.

Note: Remember to change the HDF5 output filename to `z-a-z-20-6.hdf5`.

- The part of the script specifying the calculation is found below the lines indicating Calculator:

```
#########################################################
# Calculator
#########################################################
```

- Run the script using the Job Manager or from a terminal. The calculation will take approximately twice as much time as the previous calculation for the shorter junction.
- When the calculation is done, use the script below to plot and compare the temperature dependent conductance of the two junctions. You can download it here: `temperature_dependent_compare.py`.

```
# Read first transmission spectra from fil z-a-z-6-6.hdf5 and z-a-z-20-6.hdf5
transmission_spectrum6 = nlread("z-a-z-6-6.hdf5",TransmissionSpectrum)[0]
transmission_spectrum20 = nlread("z-a-z-20-6.hdf5",TransmissionSpectrum)[0]
#make list of temperatures
temperature_list=numpy.linspace(0,2000,21)*Kelvin
#make list for holding conductance
conductance_list6=numpy.zeros(len(temperature_list))
conductance_list20=numpy.zeros(len(temperature_list))
for i in range(len(temperature_list)):
    conductance_list6[i]=transmission_spectrum6.conductance(
        electrode_temperatures=(temperature_list[i],temperature_list[i]) )
    conductance_list20[i]=transmission_spectrum20.conductance(
        electrode_temperatures=(temperature_list[i],temperature_list[i]) )
#plot the conductance as function of temperature
```

(continues on next page)

(continued from previous page)

```
import pylab
pylab.figure()
pylab.semilogy(temperature_list,conductance_list6,label="short junction")
pylab.semilogy(temperature_list,conductance_list20,label="long junction")
pylab.xlabel("Temperature (K)")
pylab.ylabel("Conductance (S)")
pylab.legend(loc="lower left")
pylab.grid(True)
pylab.show()
```

Below is the result of the calculation. The green curve shows the result for the longer junction. Note that in this case the conductance increases strongly with temperature, indicating that the dominating transport mechanism is thermionic emission rather than electron tunneling.

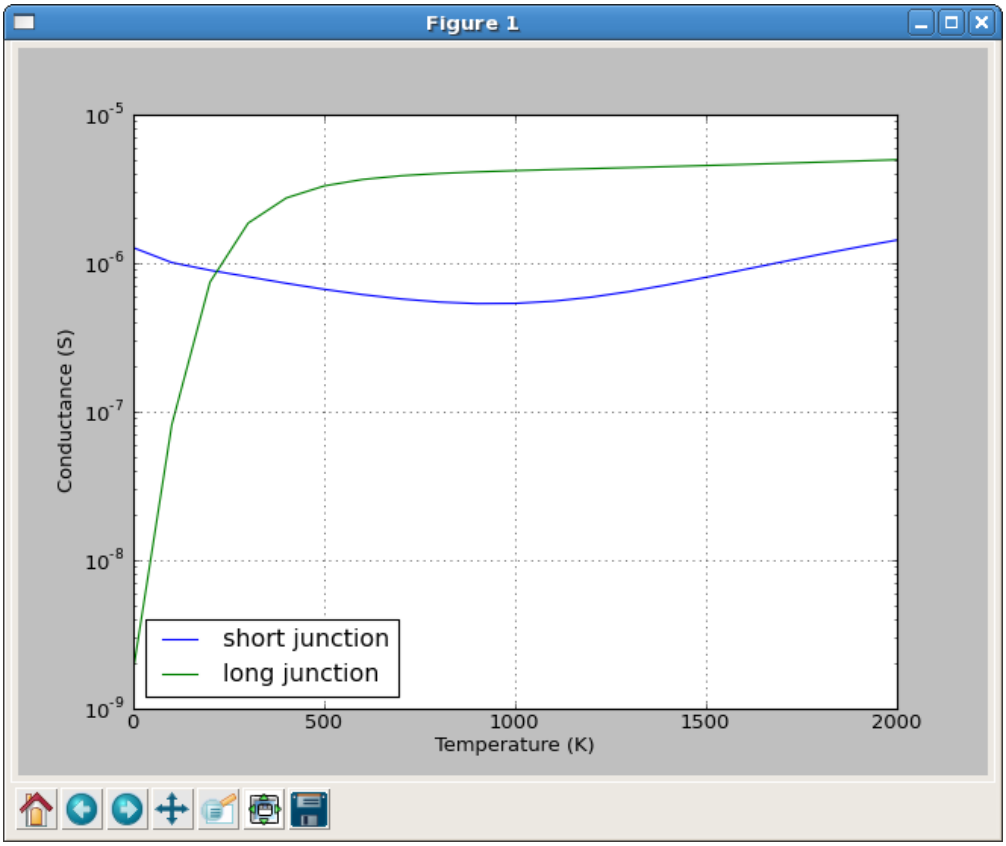


Fig. 3.84: Conductance as a function of the electron temperature for the short (blue) and 20 unit long (green) graphene nanoribbon transistor.

Electron thermal transport

In the previous section you calculated the conductance of the junction. To obtain an electrical current it is usually necessary to apply an external bias. This section shows how it is also possible to drive a current through the junction by having the two electrodes at different temperatures. The QuantumATK script for the calculation is displayed below. You can download the script here: `electrodes_diff_temperature.py`.

```
# Read first transmission spectra from file z-a-z-6-6.hdf5 and z-a-z-20-6.hdf5
transmission_spectrum6 = nlread("z-a-z-6-6.hdf5",TransmissionSpectrum)[0]
transmission_spectrum20 = nlread("z-a-z-20-6.hdf5",TransmissionSpectrum)[0]
#make list of temperatures
temperature_list=numpy.linspace(0,2000,21)*Kelvin
#make list for holding current
current_list6=numpy.zeros(len(temperature_list))
current_list20=numpy.zeros(len(temperature_list))
#fix the temperature in the left electrode
temperature_left=300*Kelvin
for i in range(len(temperature_list)):
    current_list6[i]=transmission_spectrum6.current(
        electrode_temperatures=(temperature_left,temperature_list[i]) )
    current_list20[i]=transmission_spectrum20.current(
        electrode_temperatures=(temperature_left,temperature_list[i]) )
#plot the current as function of temperature in right electrode
import pylab
pylab.figure()
pylab.plot(temperature_list,current_list6,label="short junction")
pylab.plot(temperature_list,current_list20,label="long junction")
pylab.xlabel("Right Electrode Temperature (K)")
pylab.ylabel("Current (A)")
pylab.legend(loc="lower left")
pylab.grid(True)
pylab.show()
```

The electron temperature of the left electrode is now fixed at 300 Kelvin, while the temperature of the right electrode is varied from 0 to 2000 Kelvin. The figure below shows the output of the calculation. The change in temperature has the strongest effect on the longer junction (the green curve). The positive direction of the current is from left to right, thus, the electrical current goes from the high temperature to the low temperature.

If you use the **Transmission Analyzer** to plot the transmission spectrum for the long junction, you will see that the valence band of the central region is closest to the Fermi Level. The charge transport is therefore dominated by hole transport. The electrode with the highest temperature will have most holes, which will propagate to the other electrode, giving rise to a current in this direction.

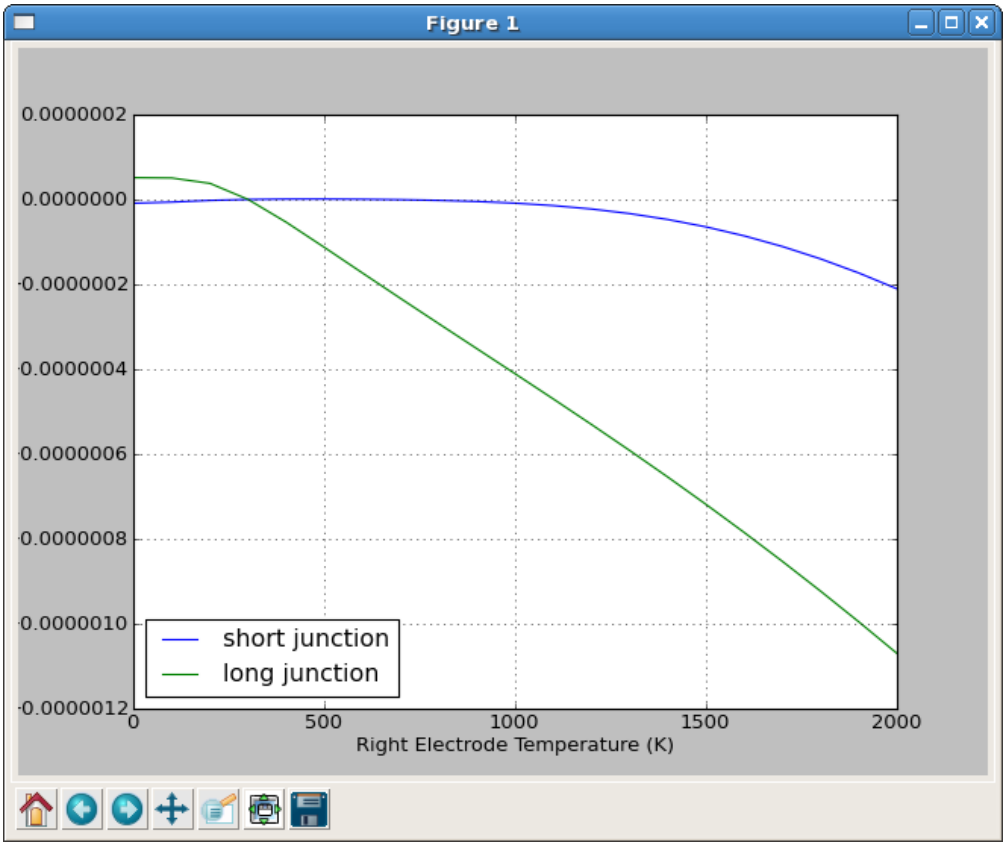

Fig. 3.85: Current as a function of the electron temperature of the right electrode for the short (blue) and 20 unit long (green) graphene junction. The electron temperature of the left electrode is fixed at 300 Kelvin.

Introduction

This tutorial shows you how to set up and perform calculations for a device based on a silicon nanowire. You will define the structure of a hydrogen passivated Si(100) nanowire, and set up a field-effect transistor (FET) structure with a cylindrical wrap-around gate. The tutorial ends with calculations of the device conductance as a function of gate bias.

Note: You will primarily use the graphical user interface QuantumATK for setting up and analyzing the results. The underlying calculation engines for this tutorial are ATK-DFT and ATK-SE. A complete description of all the parameters, and in many cases a longer discussion about their physical relevance, can be found in the ATK Reference Manual.

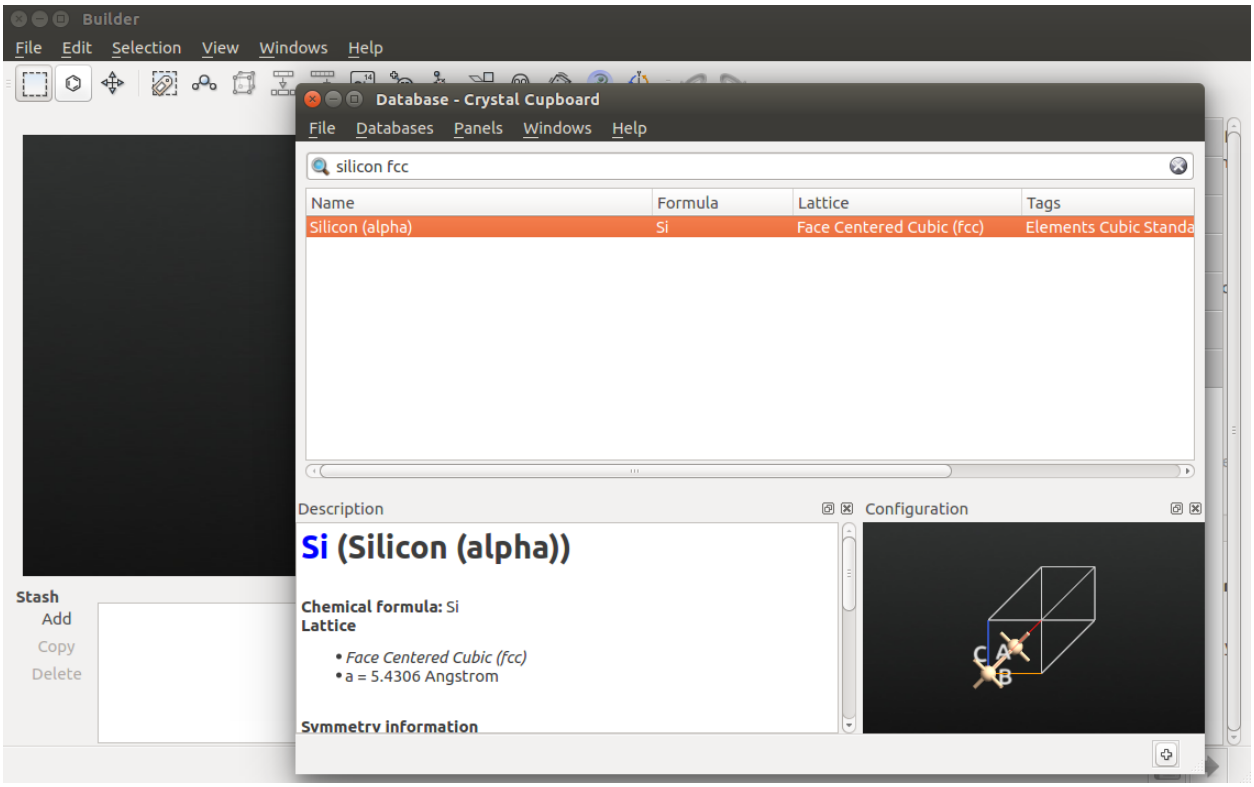
Band structure of a Si(100) nanowire

First step is to set up the Si(100) nanowire and optimize the geometry. You should use the ATK-DFT calculator for this. We then compute the band structure of the nanowire using 3 different computational models; DFT-GGA, DFT-MGGA, and the Extended Hückel method.

Building the nanowire

Open QuantumATK and create a new empty project called silicon_nanowire. Then launch the **Builder**.

- Go to *Add* → *From Database* and type silicon fcc to locate the diamond phase of silicon.
- Add the *Silicon (alpha)* bulk configuration to the **Stash** (double-click or use the icon).



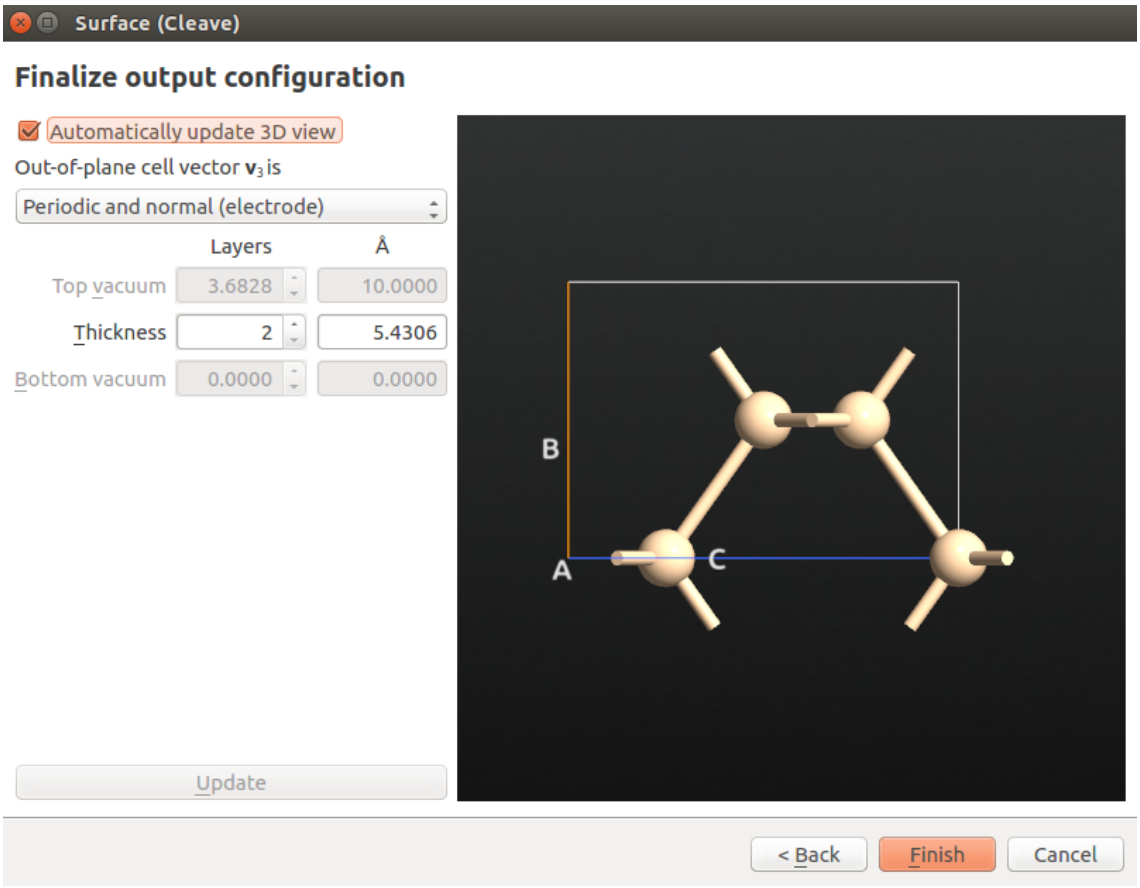
In the Builder, use the *Builders* → *Surface (Cleave)* tool to create the Si(100) facet:

•keep the default (100) cleave direction, and click *Next*;

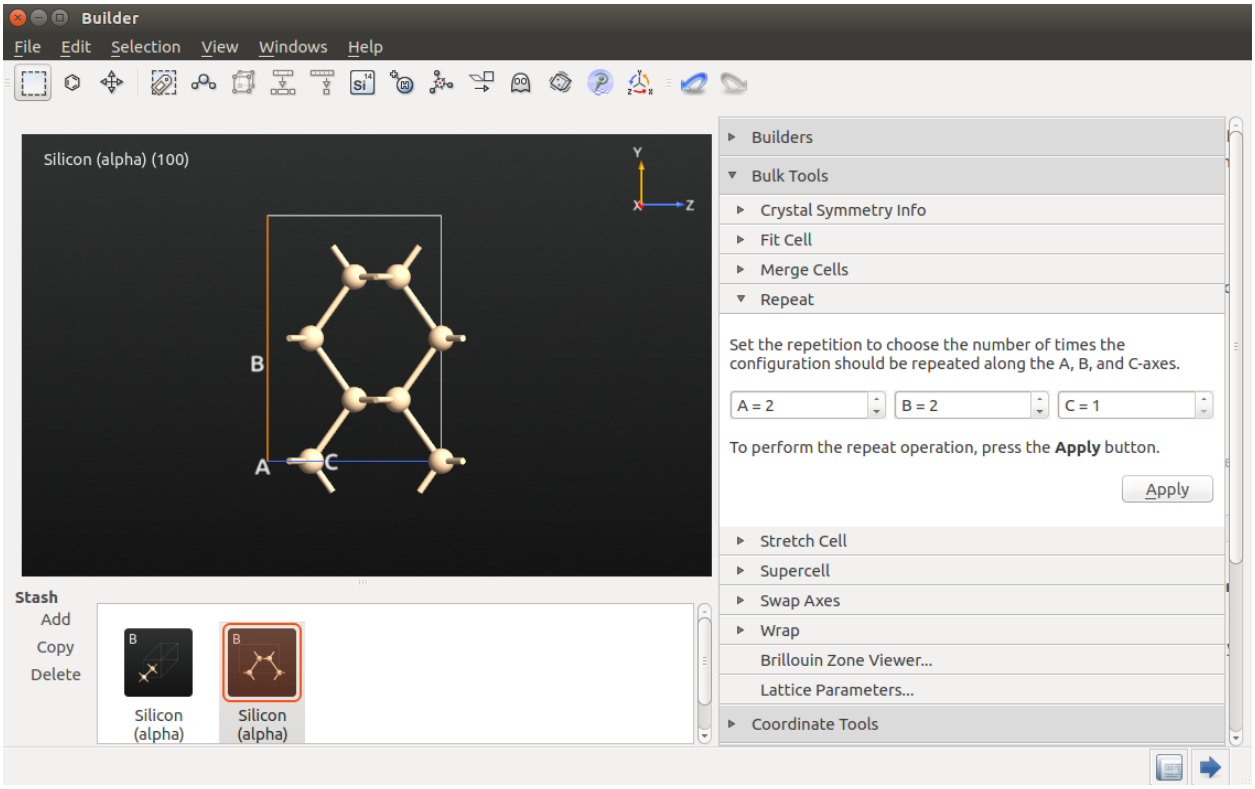
•keep the default surface lattice, and click *Next*;

•keep the default supercell, which will ensure that the wire direction is perpendicular to the surface, and click *Next*.

•Click *Fiish* to add the cleaved structure to the Stash.



Next, use the *Bulk Tools* → *Repeat* tool to repeat the structure twice along the A and B directions:

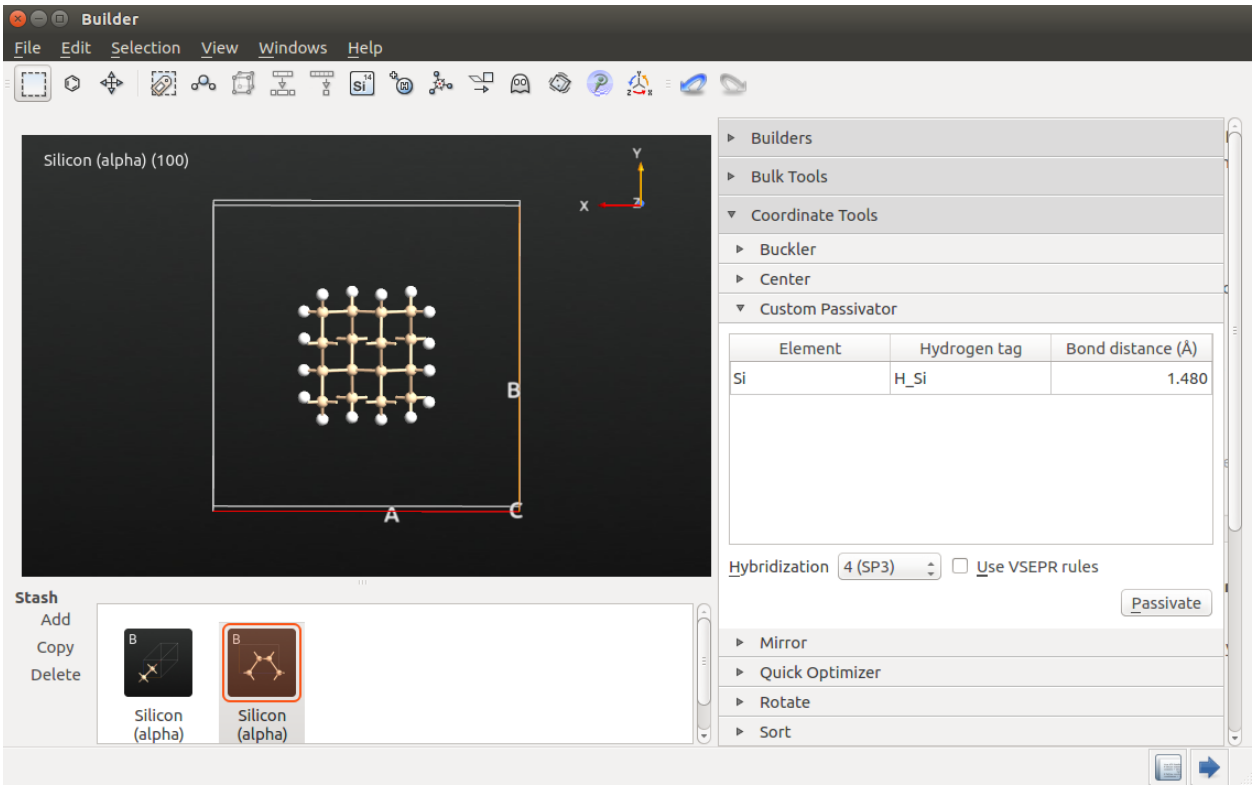


Finalize the nanowire by following these steps:

•use the *Bulk Tools* → *Lattice Parameters* tool to set the A and B lattice vector lengths to 20 Å;

•use the *Coordinate Tools* → *Center* tool to center the structure along all directions;

•go to *Coordinate Tools* → *Custom Passivator* and apply the 4(SP3) type hydrogen passivation to the nanowire.



Send the H-passivated Si(100) nanowire to the **Script Generator** by using the in the lower right-hand corner of the Builder window.

Setting up and running the calculations

You should now relax the nanowire and compute the band structure. The DFT-GGA method is used for geometry optimization, while the band structure is computed using DFT-GGA, DFT-MGGA, and the Extended Hückel model.

Important: The TB09 meta-GGA and Extended Hückel models can not be used for relaxation.

In the Script Generator, change the default output file name to `si_100_nanowire.hdf5`, and add the following blocks to the script:

- New Calculator
- OptimizeGeometry
- Bandstructure
- New Calculator
- Bandstructure

- New Calculator
- Bandstructure

Open the first **New Calculator** block, and make the following changes to the calculator settings:

•set the k-point sampling to 1x1x11;

•change the exchange-correlation potential to GGA.

Open the second **New Calculator** block, and make the following changes:

•set the k-point sampling to 1x1x11;

•change the exchange-correlation potential to MGGA.

Open the third **New Calculator** block, and make the following changes:

•select the **ATK-SE: Extended Hückel** calculator;

•uncheck No SCF iteration to make the calculation selfconsistent;

•set the k-point sampling to 1x1x11;

•increase the density mesh cut-off to 20 Hartree;

•go to the **Hückel basis set** tab, and select the Hoffmann.Hydrogen and Cerda.Silicon [GW diamond] basis sets. The latter has been fitted to GW calculations, and gives an excellent description of the silicon bandstructure, including the value of the band gap.

Finally, open each **Bandstructure** script block and set the number of points per segment to 100.

Tip: The default value for the density mesh cut-off is often sufficient, but by increasing it you may sometimes obtain a slightly higher accuracy at a small additional computational cost.

TB09 meta-GGA c-parameter

You should also adjust the value of the c-parameter used in the TB09 meta-GGA method. This is essentially a fitting parameter that can be used to adjust the calculated band gap of the material. If the c-parameter is not defined by the user, a value is automatically calculated from the electronic structure of the material. However, this will not work for a system with vacuum regions, like a nanowire.

You will therefore use a fixed value, c=1.0364, which has been fitted to yield an accurate prediction of the fundamental band gap in silicon (1.13 eV).

Transfer the QuantumATK Python script to the **Editor** using the icon. Then locate the script line defining the variable `exchange_correlation` for the MGGA exchange-correlation, and set the fixed value of c to 1.0364, as illustrated below.

```
#-----------------------------------------
# Exchange-Correlation
#-----------------------------------------
exchange_correlation = MGGA.TB09LDA(c=1.0364)
```

Running the calculations

Save the QuantumATK Python script as `si_100_nanowire.py` and execute it using the **Job Manager**. It will take just a few minutes to complete the calculations.

Analyzing the results

Once the calculations have finished, the HDF5 data file `si_100_nanowire.hdf5` should appear on the QuantumATK **LabFloor**. Locate the Bandstructure items inside this file. The order of the item IDs corresponds to the order in which the band structures were computed and saved, i.e. GGA, MGGA, and Hückel.

Select one of the band structures and open the **Bandstructure Analyzer** in the right-hand Panel Bar to inspect the computed band structure. You can do this for all three band structures, or use the **Compare Data** plugin to plot a direct comparison of the three band structures.

Detailed band structure analysis

In order to compare the band gaps obtained with the three computational models, it is convenient to use `bandstructure_analyzer.py`, which uses QuantumATK Python for detailed analysis of the gaps in a band structure. The script is shown below:

```
from QuantumATK import *
import pylab
# Custom analyzer for calculating the band gap of a bandstructure

#helper function to find minima
def fitEnergyMinimum (i_min, energies, k_points, nfit=3):
    """
    Function for fitting the energy minimum located around i_min.

    @param i_min   : approximate position of the energy minimum.
    @param energies: list of energies.
    @param k_points: list of k_points which correspond to the energies.
    @param nfit    : order of the polynomium.
    @return d2_e, e_min, k_min : second derivative of energy,
                                 minimum energy, minimum k_point.
    """
    #list of energies
    n = len(energies)
    efit = numpy.array([energies[(n+i_min-nfit/2+i)%n] for i in range(nfit)])
    kfit = numpy.array([i-nfit/2 for i in range(nfit)])
    #special cases
    if i_min == 0: #assume bandstructure symmetric around zero
        for i in range(nfit/2):
            efit[i] = energies[nfit/2-i]

    if i_min == n-1: #assume bandstructure symmetric around end point
        for i in range(nfit/2+1, nfit):
            efit[i] = energies[n-1+nfit/2-i]

    #make fit
```

(continues on next page)

(continued from previous page)

```
    p = numpy.polyfit(kfit,efit,2)
    i_fit_min = -p[1]/2./p[0]
    pf = numpy.poly1d(p)
    e_min = pf(i_fit_min)
    i0 = int(i_fit_min+i_min+n)
    w = i_fit_min+i_min+n-i0
    k_min = (1-w)*k_points[i0%n]+w*k_points[(i0+1)%n]

    return p[0], e_min, k_min

def analyseBandstructure(bandstructure, spin):
    """
    Function for analysing a band structure and calculating bandgaps.

    @param bandstructure :  The bandstructure to analyze
    @param spin          :  Which spin to select from the bandstructure.
    @return  e_val, e_con, e_gap :  maximum valence band energy,
                                    minimum conduction band energy,
                                    and direct band gap.
    """
    energies = bandstructure.evaluate(spin=spin).inUnitsOf(eV)

    #some placeholder variable to help finding the extrema
    e_valence_max = -1.e10
    e_conduction_min = 1.e10
    e_gap_min = 1.e10
    i_valence_max = 0
    i_conduction_min = 0
    i_gap_min = 0
    n_valence_max = 0
    n_conduction_min = 0
    n_gap_min = 0

    # Locate extrema
    for i in range(energies.shape[0]):
        # find first state below Fermi level
        n = 0
        while n < energies.shape[1] and energies[i][n] < 0.0:
            n += 1

        # find maximum of valence band
        if (energies[i][n-1] > e_valence_max):
            e_valence_max = energies[i][n-1]
            i_valence_max = i
            n_valence_max = n-1
        # find minimum of conduction band
        if (energies[i][n] < e_conduction_min):
            e_conduction_min=energies[i][n]
            i_conduction_min=i
            n_conduction_min=n
        # find minimum band gap
        if (energies[i][n]-energies[i][n-1] < e_gap_min):
```

(continues on next page)

(continued from previous page)

```
            e_gap_min = energies[i][n]-energies[i][n-1]
            i_gap_min = i
            n_gap_min = n-1

    # Print out results
    a_val, e_val, k_val = fitEnergyMinimum(i_valence_max,
                                           energies[:,n_valence_max],
                                           bandstructure.kpoints())
    print('Valence band maximum    %7.4f eV at [%6.4f, %6.4f,%6.4f]   ' \
                         %(e_val, k_val[0], k_val[1], k_val[2]))

    a_con, e_con, k_con = fitEnergyMinimum(i_conduction_min,
                                           energies[:,n_conduction_min],
                                           bandstructure.kpoints())
    print('Conduction band minimum %7.4f eV at [%6.4f, %6.4f,%6.4f]   ' \
                         %(e_con, k_con[0], k_con[1], k_con[2]))

    print('Fundamental band gap    %7.4f eV ' % (e_con-e_val))

    a_gap, e_gap, k_gap = fitEnergyMinimum(i_gap_min,
                            energies[:,n_gap_min+1]- energies[:,n_gap_min],
                            bandstructure.kpoints())

    print('Direct band gap         %7.4f eV at [%6.4f, %6.4f,%6.4f]   ' \
                         %(e_gap, k_gap[0], k_gap[1], k_gap[2]))
    return e_val, e_con, e_gap

def analyzer(filename, **args):
    """
    Find band gaps of band structures in netcdf file.
    """

    if filename == None:
        return

    #read in the bandstructure you would like to analyze
    bandstructure_list = nlread(filename, Bandstructure)
    if len(bandstructure_list) == 0 :
        print('No Bandstructures in file ', filename)
        return

    for s in [Spin.All]:
        b_list = []
        n = 0
        for b in bandstructure_list:
            print('Analyzing bandstructure number ', n)
            b_list = b_list + [analyseBandstructure(b,s)]
            print()
            print()
            n += 1

        x = numpy.arange(len(b_list))
```

(continues on next page)

(continued from previous page)

```
        e_val =  numpy.array([b[0] for b in b_list])
        e_con =  numpy.array([b[1] for b in b_list])
        e_indirect = e_con-e_val
        e_direct = numpy.array([b[2] for b in b_list])

analyzer("si_100_nanowire.hdf5")
```

Download the script (link: `bandstructure_analyzer.py`), and execute it using the **Job Manager**. You should get the following output:

```
Analyzing bandstructure number  0
Valence band maximum    -1.6395 eV at [0.0000, 0.0000,0.0121]
Conduction band minimum  1.6400 eV at [0.0000, 0.0000,0.0000]
Fundamental band gap     3.2795 eV
Direct band gap          3.2799 eV at [0.0000, 0.0000,0.0000]

Analyzing bandstructure number  1
Valence band maximum    -1.8434 eV at [0.0000, 0.0000,0.1501]
Conduction band minimum  1.8450 eV at [0.0000, 0.0000,0.0000]
Fundamental band gap     3.6884 eV
Direct band gap          3.6914 eV at [0.0000, 0.0000,0.0026]

Analyzing bandstructure number  2
Valence band maximum    -1.7737 eV at [0.0000, 0.0000,0.0000]
Conduction band minimum  1.7735 eV at [0.0000, 0.0000,0.0000]
Fundamental band gap     3.5472 eV
Direct band gap          3.5472 eV at [0.0000, 0.0000,0.0000]
```

The output shown above gives the band structure analysis for the DFT-GGA, DFT-MGGA, and Extended Hückel models. The script gives the valence band maximum, conduction band minimum, fundamental band gap, and direct band gap from the valence band maximum. The fundamental band gap for the Si(100) nanowire is significantly larger than that of bulk silicon, and all three computational models place it at the Gamma point or close to it.

Furthermore, the TB09-MGGA model gives a gap which is about 0.5 eV larger than the GGA model, which is in accordance with the difference in the band gaps of bulk Si calculated with the GGA and TB09-MGGA methods. The Extended Hückel model is in agreement with the TB09-MGGA method.

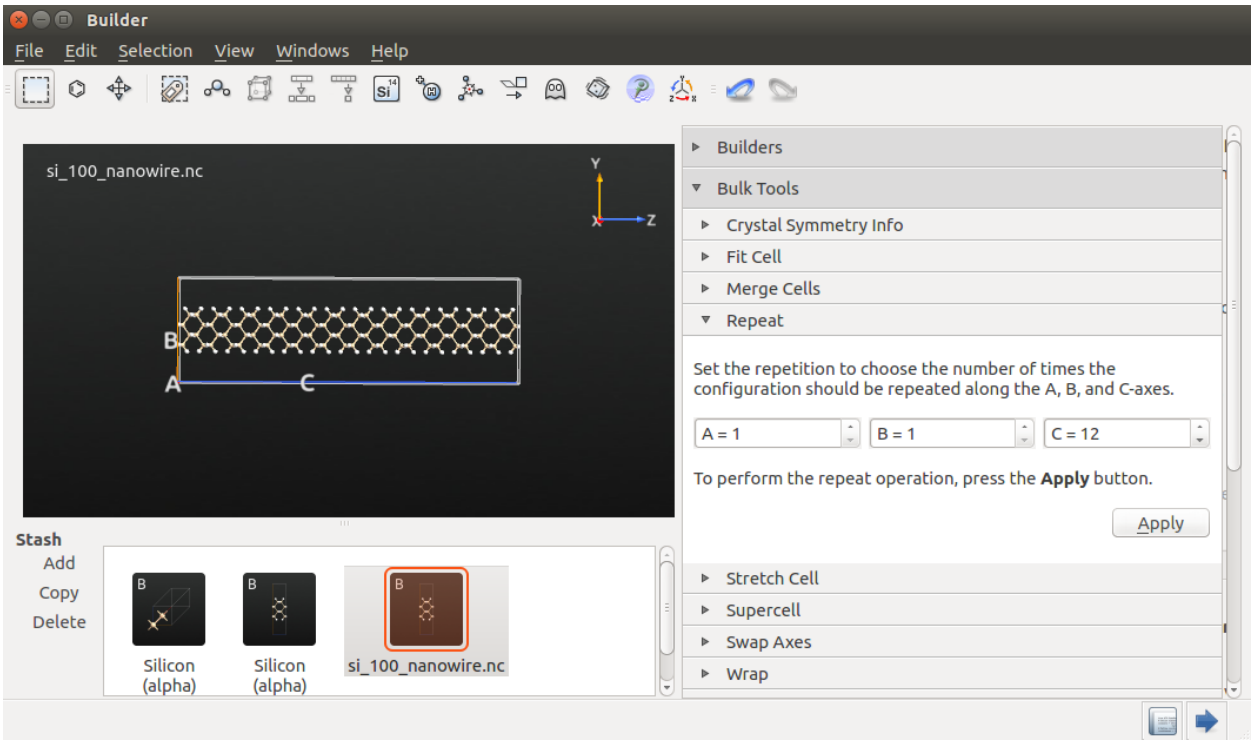
Si(100) nanowire FET device

You will now consider a Si(100) nanowire field-effect transistor with a cylindrical wrap-around gate. You should first build the device configuration, including the gate and doping of the silicon nanowire, and then use the Extended Hückel model to compute device properties such as zero-bias transmission and conductance vs. gate voltage.

FET device configuration

You should use the relaxed nanowire configuration as a starting point for building the device. The contents of the file `si_100_nanowire.hdf5` should be available on the QuantumATK **LabFloor**. It contains four bulk configurations: The first one *(gID000)* is the unrelaxed structure, while the remaining ones correspond to the relaxed structure, calculated with different methods (DFT-GGA, DFT-MGGA and Extended Hückel).

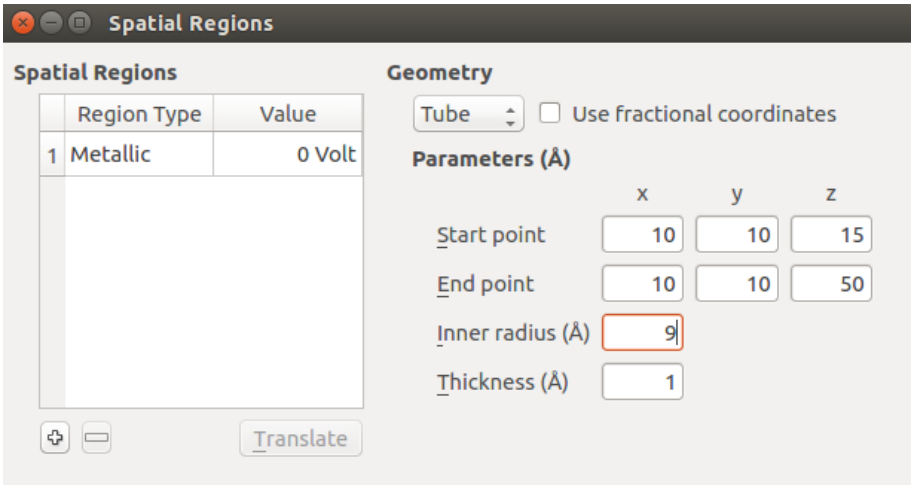
Send the configuration with ID *gID001* to the **Builder**. It will appear in the Builder Stash. Then use the *Bulk Tools* → *Repeat* tool to repeat the configuration 12 times along C.



Setting up the gate

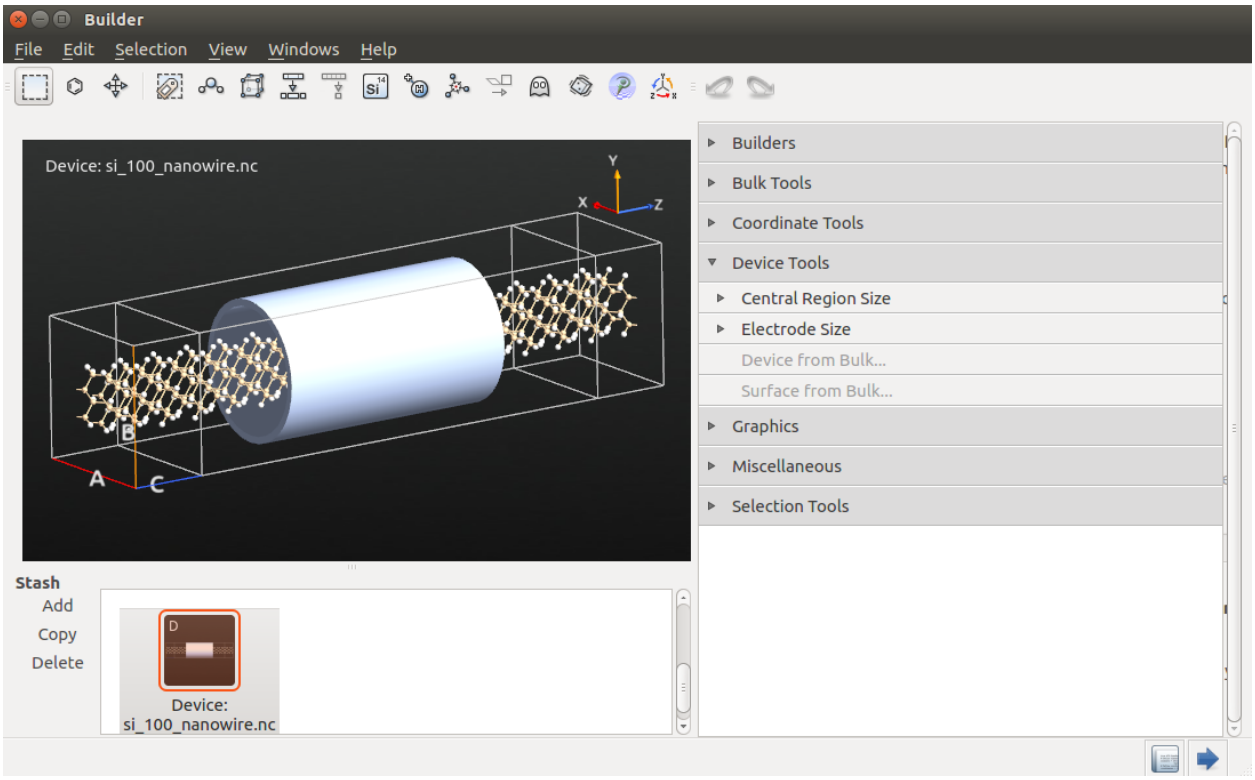
Next, use the *Miscellaneus* → *Spatial regions* tool to define the metallic wrap-around gate:

- First, add a new metallic region with a value of 0 Volt.
- Under *Geometry*, select **Tube** to create a cylindrical region.
- Define the geometry of the tube by entering the parameters shown in the image below. The cylinder will extend to the edge of the simulation cell along A and B, and will cover most of the central part of the nanowire along C.



Build the device

Use the *Device Tools* → *Device From Bulk* tool to build the Si(100) nanowire FET device from the bulk nanowire configuration. Use the default suggestion for the electrode lengths.



Then send the device configuration to the **Script Generator**.

Doping the Si(100) wire

You will now introduce doping in the nanowire. Instead of explicitly adding dopant atoms, which would result in a very high doping concentration for this relatively small device, you will set up the system as a **p-i-n junction**, by adding certain amounts of charge to the electrodes. This will lead to shifts in the Fermi levels of the two electrodes, resulting in a built-in potential in the device.

Use the mouse to select all atoms in the left electrode and open the *Miscellaneus* → *Doping* tool. In the window that shows up, choose the following settings:

•**Doping Type**: p-type

•**Value**: $4e^{+19}$

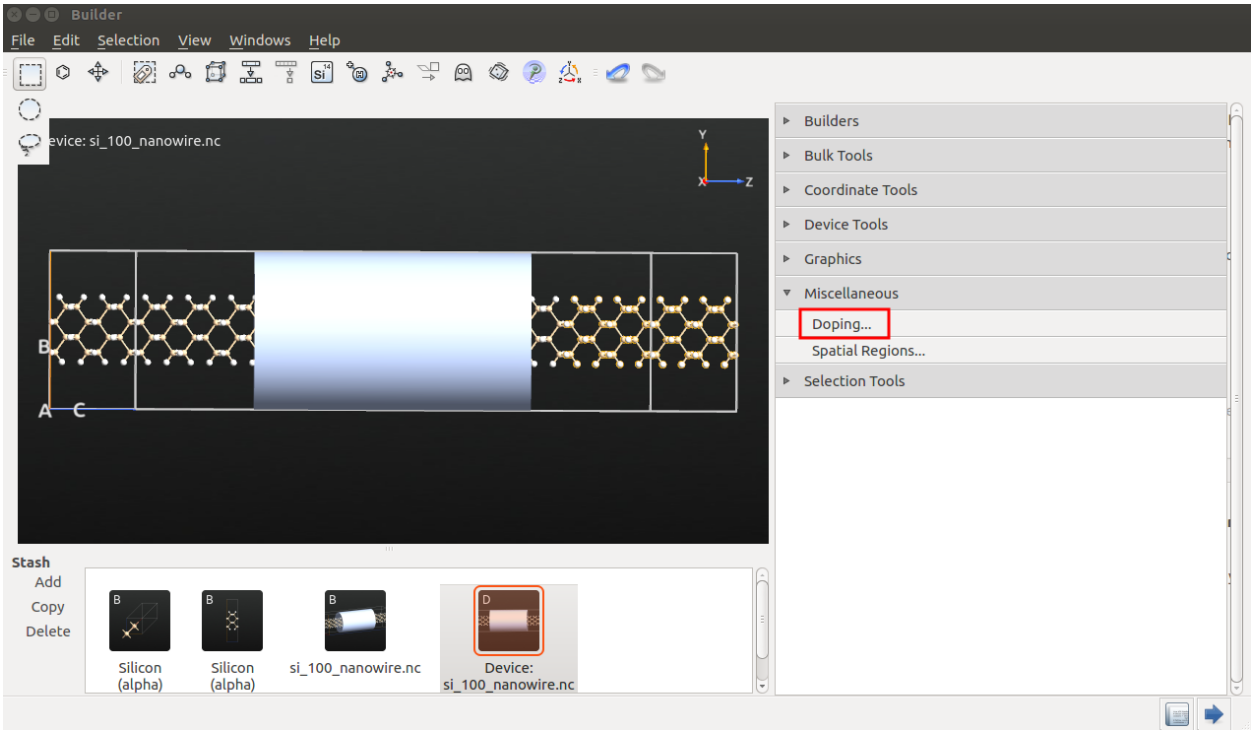
•**Unit**: e/cm^3 (left electrode)

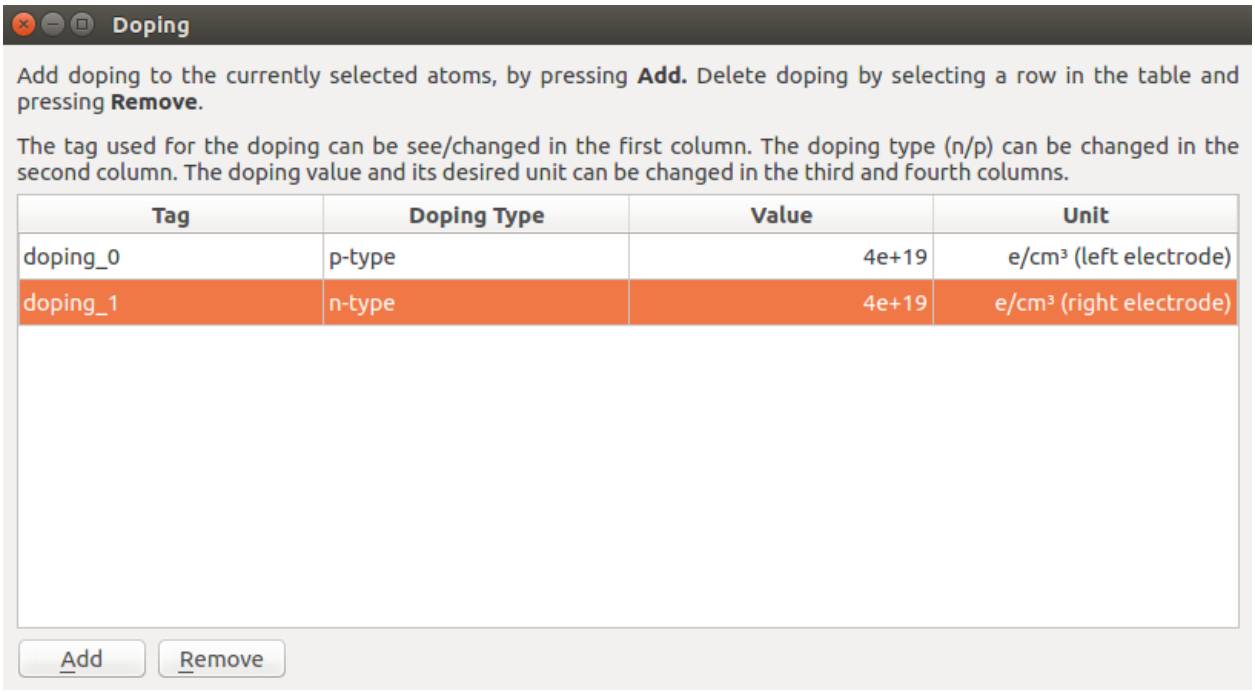
Next, close the Doping window and select all atoms in the right electrode. Open again the Doping tool, and choose the following settings:

•**Doping Type**: n-type

•**Value**: $4e^{+19}$

•**Unit**: e/cm^3 (right electrode)





Zero gate voltage calculation

You will now calculate the transmission spectrum of the p-i-n doped Si(100) nanowire FET device at zero gate potential using the Extended Hückel model. In the **Script Generator**, change the default output file name to `si_100_nanowire_fet_pin.hdf5` and add the following blocks to the script:

- New Calculator
- TransmissionSpectrum
- ElectronDifferenceDensity
- ElectrostaticDifferencePotential

Open the **New Calculator** block, select the Extended Hückel device calculator, and set up the calculator parameters similarly to what you did above for the bulk nanowire calculations:

- Uncheck No SCF iteration to make the calculation selfconsistent.
- Increase the density mesh cut-off to 20 Hartree.
- Go to the *Hückel basis set* tab and select the Hoffmann.Hydrogen and Cerda.Silicon [GW diamond] basis sets.
- Under *Poisson solver*, use Neumann boundary conditions in the A and B directions.

In the **TransmissionSpectrum** block, set the energy range to -4 to +4 eV with 301 points.

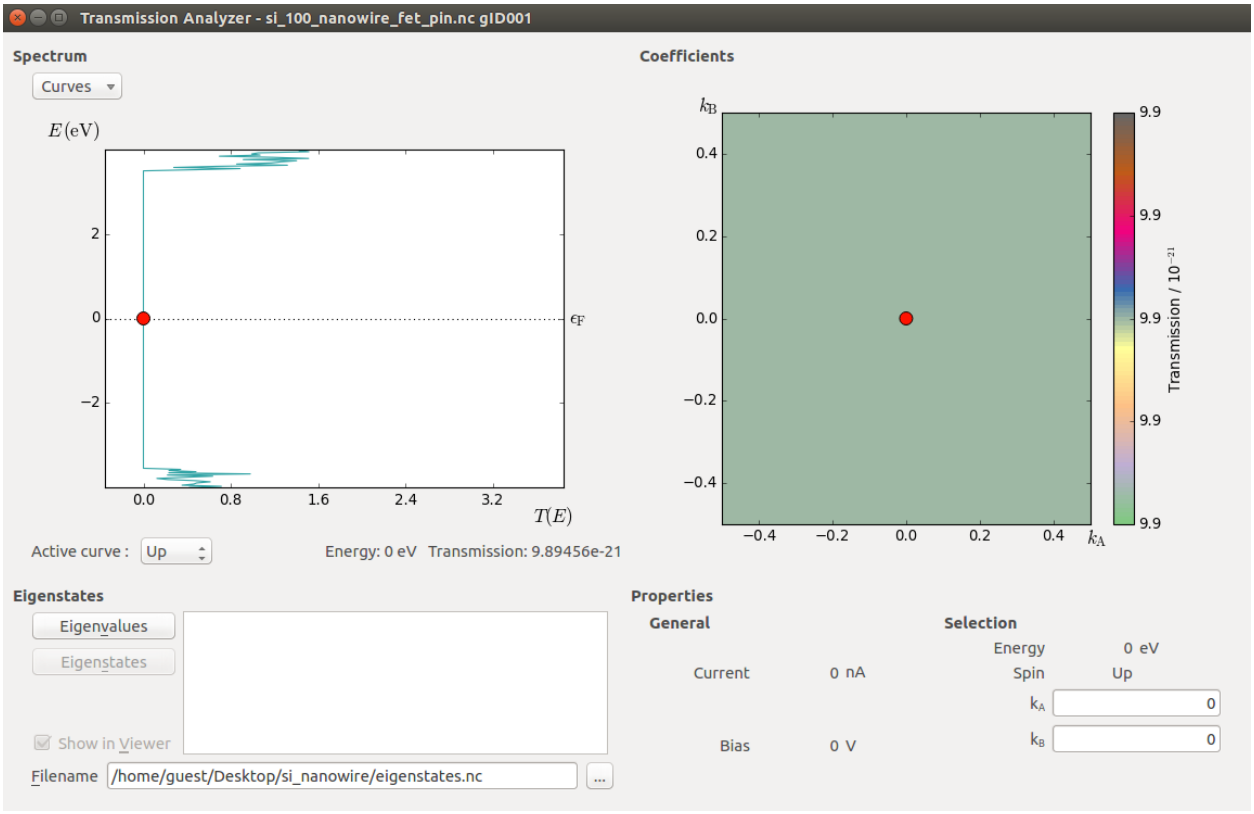
Save the QuantumATK Python script as `si_100_nanowire_fet_pin.py` and execute it using the **Job Manager**.

The calculation will take about 30 minutes if executed in parallel with 4 MPI processes.

Note: It would be physically incorrect to use periodic boundary conditions along the A and B directions when there are gates present in the system. We therefore choose Neumann boundary conditions along A and B instead.

Analyzing the results

Once the calculation is completed, locate the `file si_100_nanowire_fet_pin.hdf5` HDF5 file on the **Labfloor** and unfold it. Select the TransmissionSpectrum item and use the **Transmission Analyzer** to plot the transmission spectrum.



The transmission spectrum is shown above. The transmission is zero inside the nanowire band gap, which appears to be roughly 7 eV, significantly larger than computed earlier. This is due to the p- and n-doping, which has moved the valence and conduction band edges with respect to the Fermi level.

Performing a gate scan

Finally, you will calculate the transmission spectrum for different values of the gate bias. You can then plot the device conductance as function of gate bias.

The calculations are most conveniently done using QuantumATK Python scripting. Use the script `nanodevice_gatescan.py` for this. Download it to the active QuantumATK project folder, which also contains the file `si_100_nanowire_fet_pin.hdf5`. The script is reproduced below.

```
# Read in the old configuration
device_configuration = nlread("si_100_nanowire_fet_pin.nc",DeviceConfiguration)[0]
```

(continues on next page)

(continued from previous page)

```
calculator = device_configuration.calculator()
metallic_regions = device_configuration.metallicRegions()

# Define gate_voltages
gate_voltage_list=[-1, 0, 1.0, 2.0, 3.0, 4.0, 5.0, 6, 7, 8,]*Volt
# Define output file name
filename= "nanodevice_huckel.nc"

# Perform loop over gate voltages
for gate_voltage in gate_voltage_list:
    # Set the gate voltages to the new values
    new_regions = [m(value = gate_voltage) for m in metallic_regions]
    device_configuration.setMetallicRegions(new_regions)

    # Make a copy of the calculator and attach it to the configuration
    # Restart from the previous scf state
    device_configuration.setCalculator(calculator(),
         initial_state=device_configuration)
    device_configuration.update()
    nlsave(filename, device_configuration)

    # Calculate analysis objects
    electron_density = ElectronDifferenceDensity(device_configuration)
    nlsave(filename, electron_density)

    electrostatic_potential = ElectrostaticDifferencePotential(device_configuration)
    nlsave(filename, electrostatic_potential)

    transmission_spectrum = TransmissionSpectrum(
        configuration=device_configuration,
        energies=numpy.linspace(-4,4,301)*eV,
        kpoints=MonkhorstPackGrid(1,1),
        energy_zero_parameter=AverageFermiLevel,
        infinitesimal=1e-06*eV,
        )
    nlsave(filename, transmission_spectrum)
    nlprint(transmission_spectrum)
```

Execute the script using the **Job Manager** or from a command line. The script consists of 8 different calculations and it will take about 5 hours running in parallel with 4 MPI processes. You can, however, decide to reduce this time by reducing the number of gate voltages that the transmission spectrum is computed for – simply edit the variable `gate_voltage_list`.

Analyzing the gate scan

Download and execute the script `conductance_plot.py`, which reads the computed transmission spectra, calculates the conductance for each, and plots the conductance against gate bias.

```
# Read the data
transmission_spectrum_list = nlread("nanodevice_huckel.hdf5", TransmissionSpectrum)
configuration_list = nlread("nanodevice_huckel.hdf5", DeviceConfiguration)

conductance = numpy.zeros(len(configuration_list))
gate_bias = numpy.zeros(len(configuration_list))
for i, configuration in enumerate(configuration_list):
    transmission_spectrum = transmission_spectrum_list[i]
    energies = transmission_spectrum.energies().inUnitsOf(eV)
    spectrum = transmission_spectrum.evaluate()
    gate_bias[i] = configuration.metallicRegions()[0].value().inUnitsOf(Volt)
    conductance[i] = transmission_spectrum.conductance()

# Sort the data according to the gate bias
index_list = numpy.argsort(gate_bias)

# Plot the spectra
import pylab
pylab.figure()
ax = pylab.subplot(111)
ax.semilogy(gate_bias[index_list],  conductance[index_list])
ax.set_ylabel("Conductance (S)", size=16)
ax.set_xlabel("Gate Bias (Volt)", size=16)
ax.set_ybound(lower=1e-26)

for g,c in zip(gate_bias[index_list],  conductance[index_list]):
    print(g,c)
pylab.show()
```

3.5.10 Exploring Graphene

In this tutorial you will build a range of graphene structures and study some of their properties. With QuantumATK you can easily twist and stretch the structures using plug-in modules. You can then use QuantumATK to calculate their electronic and vibrational properties. You will also learn to automate calculations on large structures using Python scripting.

Hint: In many QuantumATK projects (depending on the study of course) you will need the appropriate plugins/AddOns, which can be installed via the **AddOn Manager**.

In this particular tutorial, you will need the `TubeWrapper.zip` and **CNTBuilder** plugins. Please check that these are available, and install them if they are not. You can install addons following the instructions in the *AddOns* page.

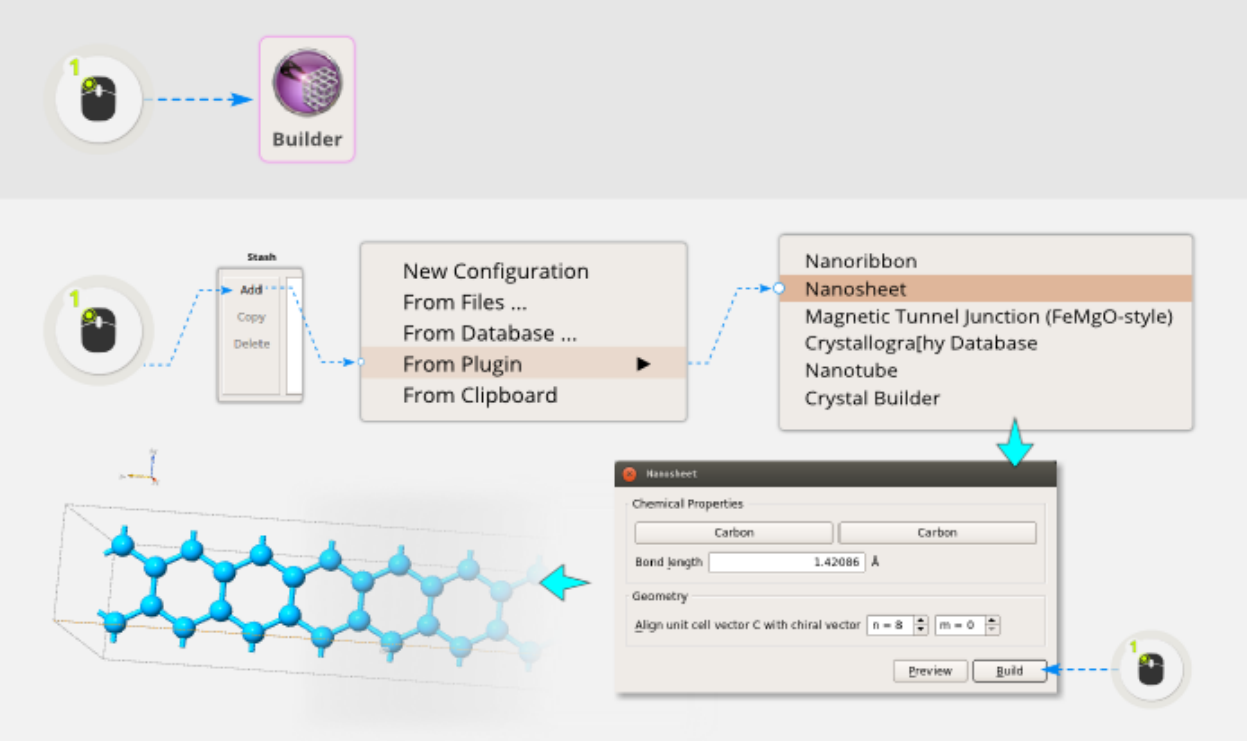
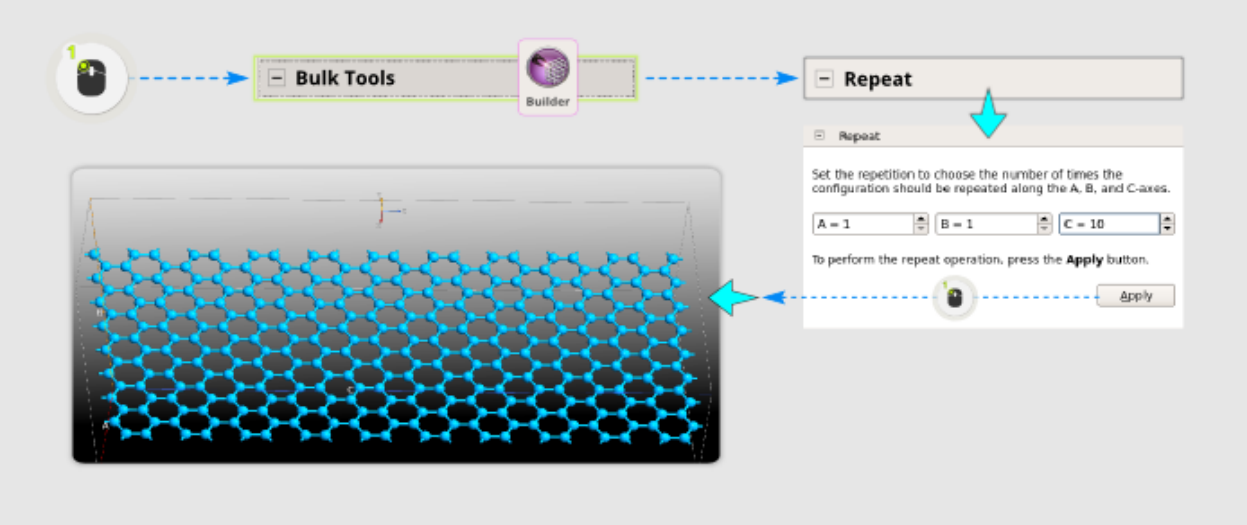
Build a graphene sheet

Open the QuantumATK Builder . It is then easy to create a graphene sheet using a plugin; simply click *Add* → *From Plugin* → *Nanosheet*. Leave the option for Chemical Properties at defaults. In the Geometry options, choose a chiral vector of (n,m)=(8,0), and click *Build*.

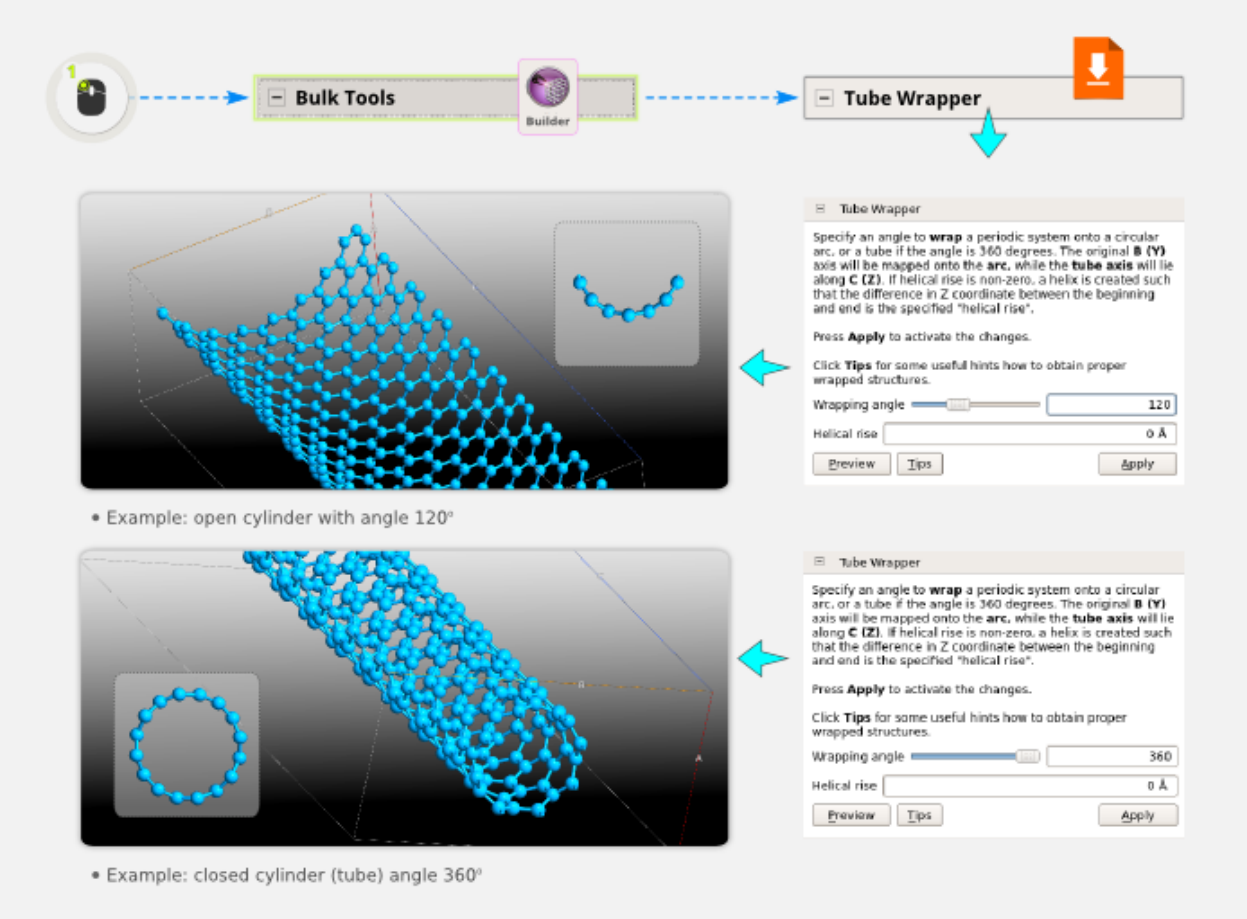


You now have a basic building block for the structure. Use the *Bulk Tools* → *Repeat* plugin to repeat it 10 times along the C-direction:



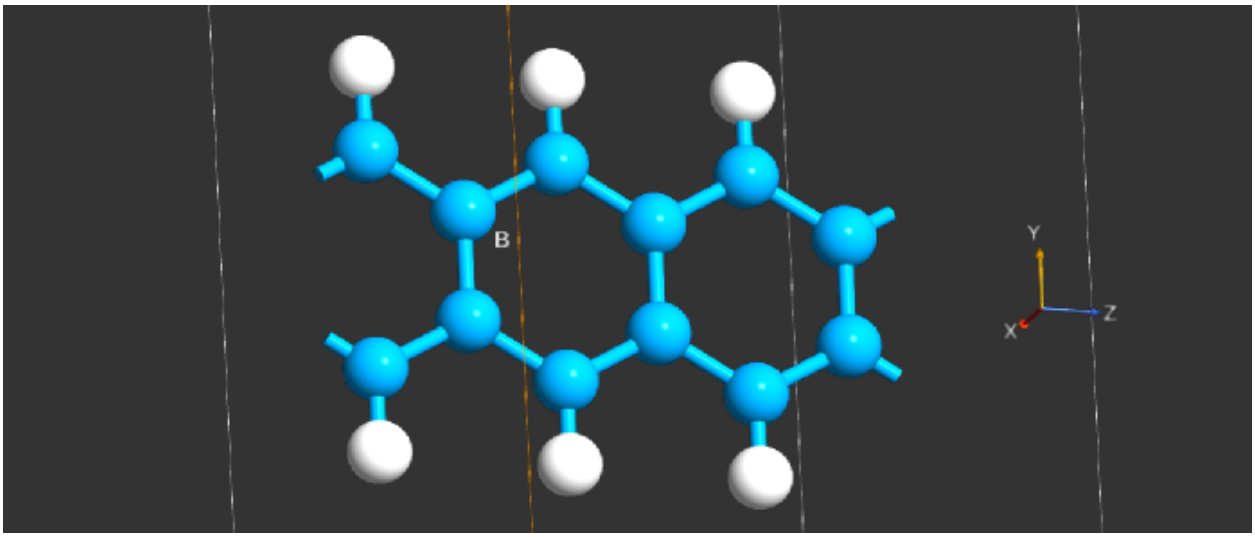
Build a CNT

You can now use the TubeWrapper plugin to wrap the nanosheet into a carbon nanotube (CNT). It is possible to turn the nanosheet into an open or a closed cylinder:



Transmission spectrum of a GNR

Let us calculate the electronic transmission spectrun of a graphene nanoribbon (GNR). First, build the ribbon using the *Add* → *From Plugin* → *Nanoribbon* plugin. Choose chiral indices (n,m)=(1,1) and repeat the structure 3 times the C-direction:



Note: In order to correctly calculate the transmission spectrum for a bulk system, the bulk must qualify as a valid device electrode. This requires that the C-axis is perpendicular to the A,B plane, and that it is sufficiently long that the atoms in the unit cell only have Hamiltonian matrix elements with atoms in the nearest neighbour cells along C. This condition is usually fullfilled if the C-vector is longer than 7 Å.

Next, transfer the structure to the Script Generator using the botton, and double-click the **New Calculator** icon to add a calculator block to the script.

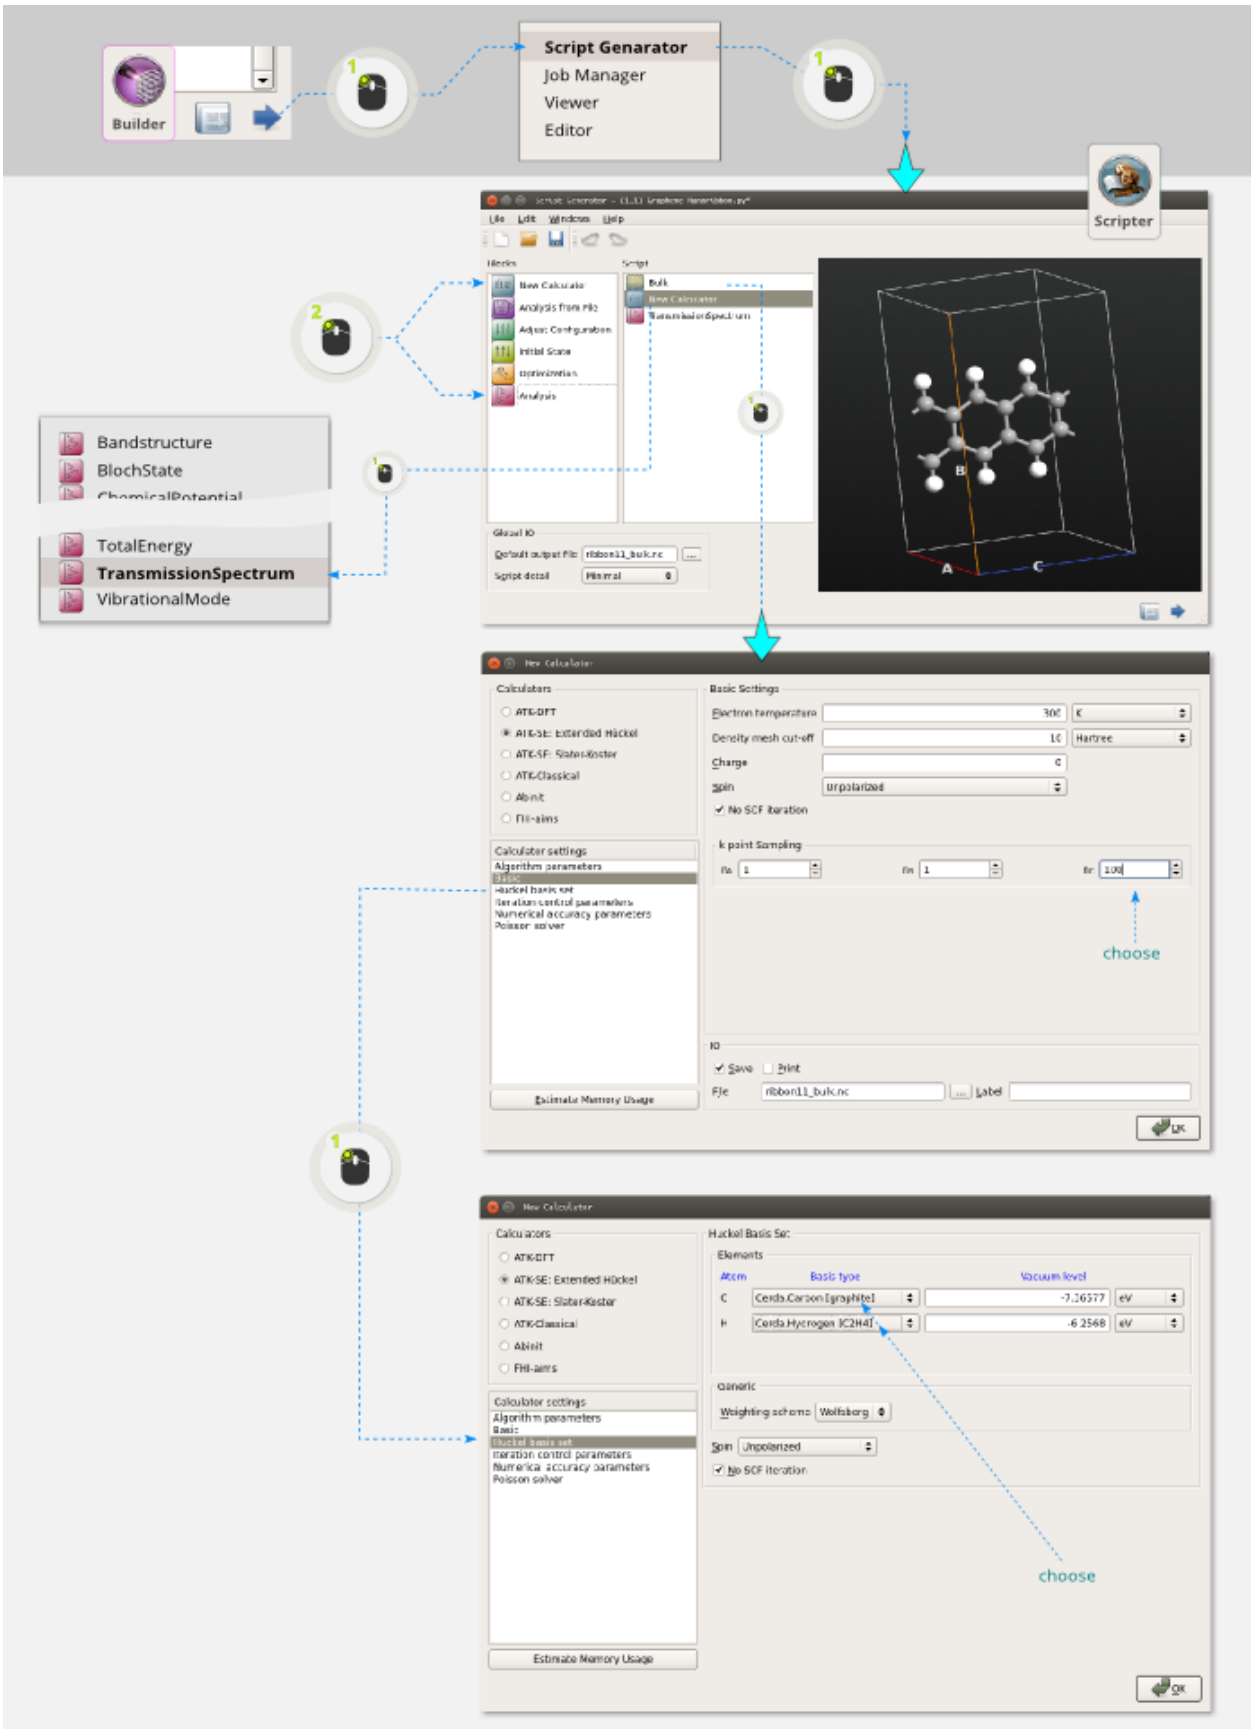
•First, change the default output file to `ribbon11_bulk.hdf5`.

•Then open the added calculator block to start editing the settings.

•Select the **Extended Huckel** calculator, and make sure the number of k-points is 1 for the A and B directions, and high for the C-direction, e.g. 100 k-points along C.

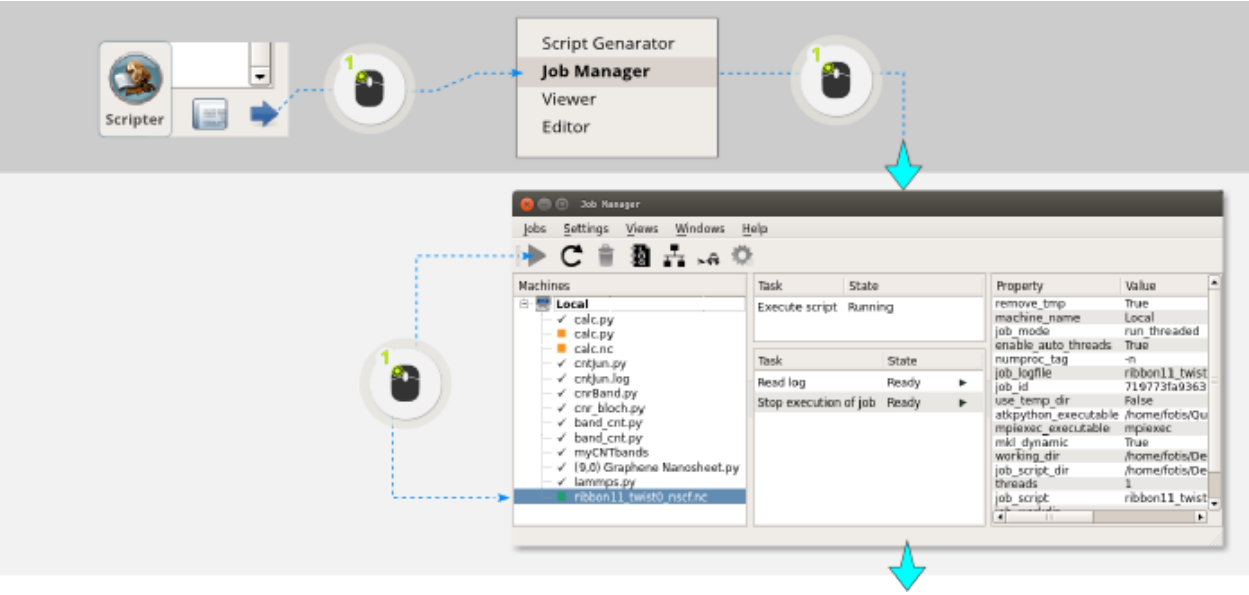
•In the **Huckel basis set** options, select *Cerda.Carbon [graphite]* for carbon and *Cerda.Hydrogen [C2H4]* for hydrogen.

•Finally, add a **TransmissionSpectrum** block to the script, and save the Python script as `ribbon11_bulk.py`.

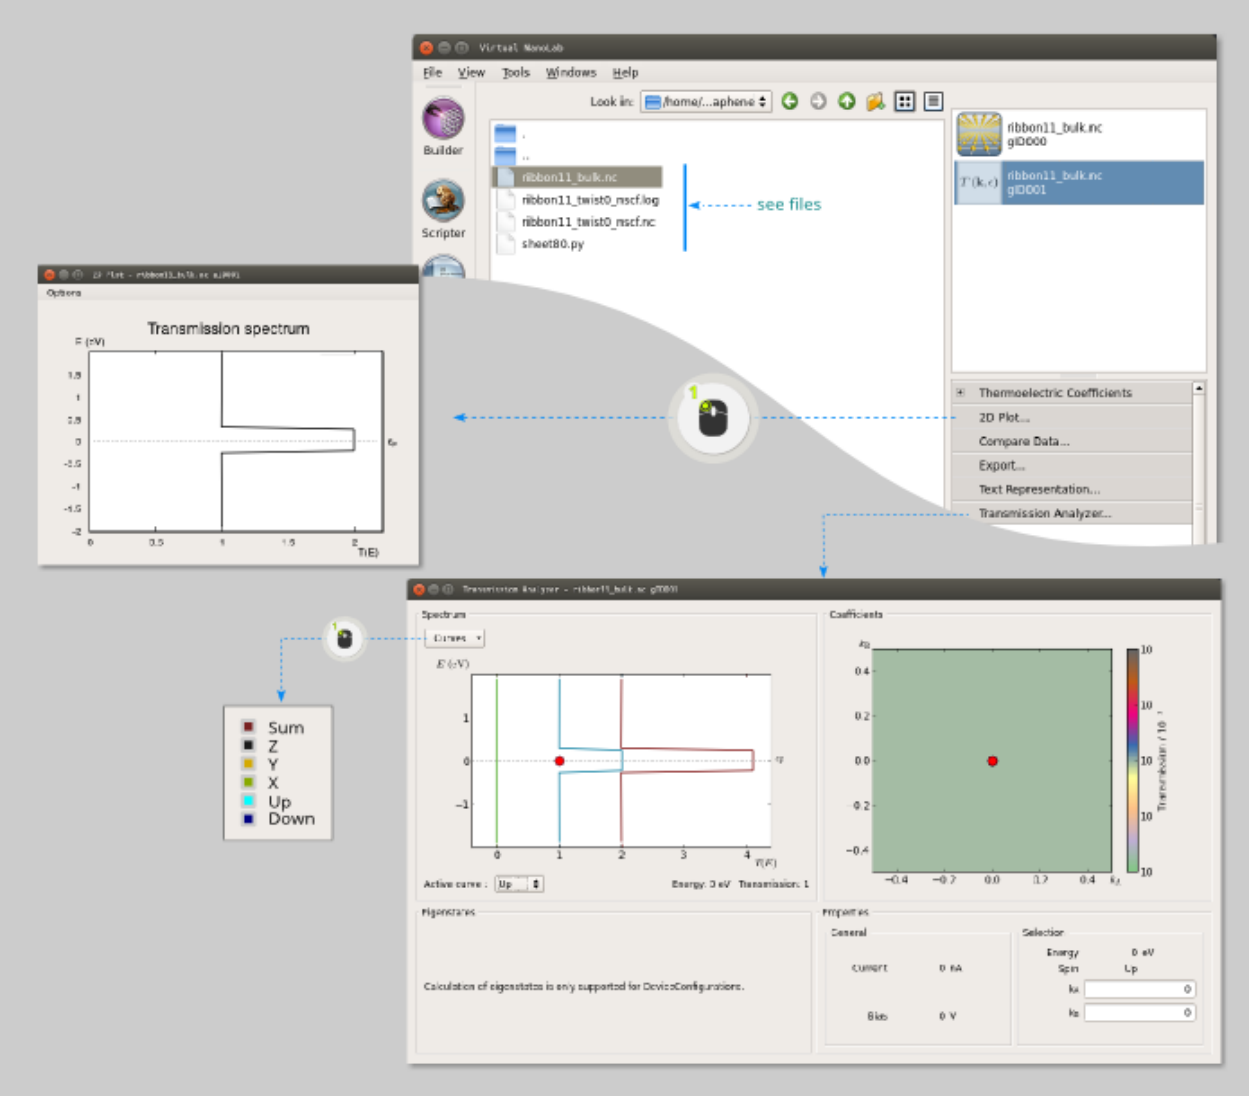


Builder
Script Genarator
Job Manager
Viewer
Editor
Scripter
Bandstructure
BlochState
TotalEnergy
TransmissionSpectrum
VibrationalMode
choose
choose

Send the script to the **Job Manager** in order to execute it. The job starts when you click the icon.



When the calculation is finished (it will run extremely fast), locate the output file **ribbon11_twist0_nscf.hdf5** in the QuantumATK file browser window. Select the file and notice that the contents of the file are displayed in the QuantumATK panel:

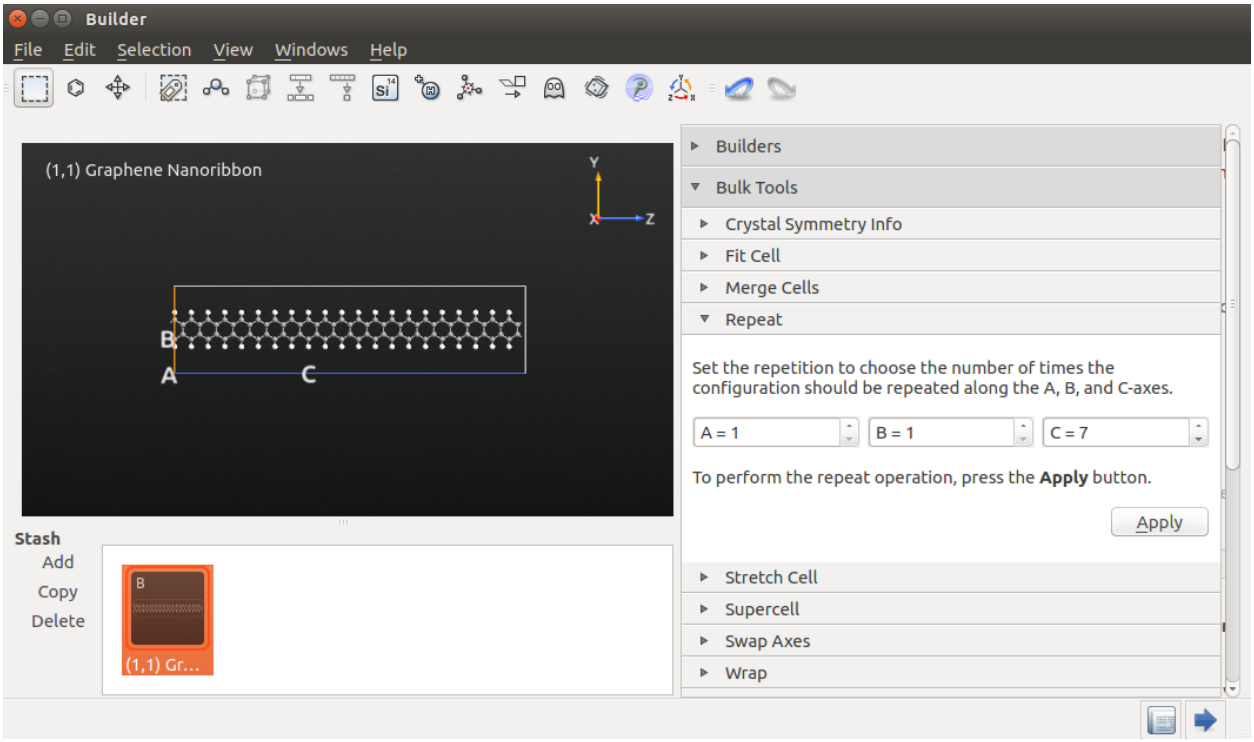


You can now select the TransmissionSpectrum object, which has this icon: $T(\mathbf{k}, \epsilon)$ and use the **2D Plot** or **Transmission Analyzer** plugins to plot the electronic transmission spectrum.

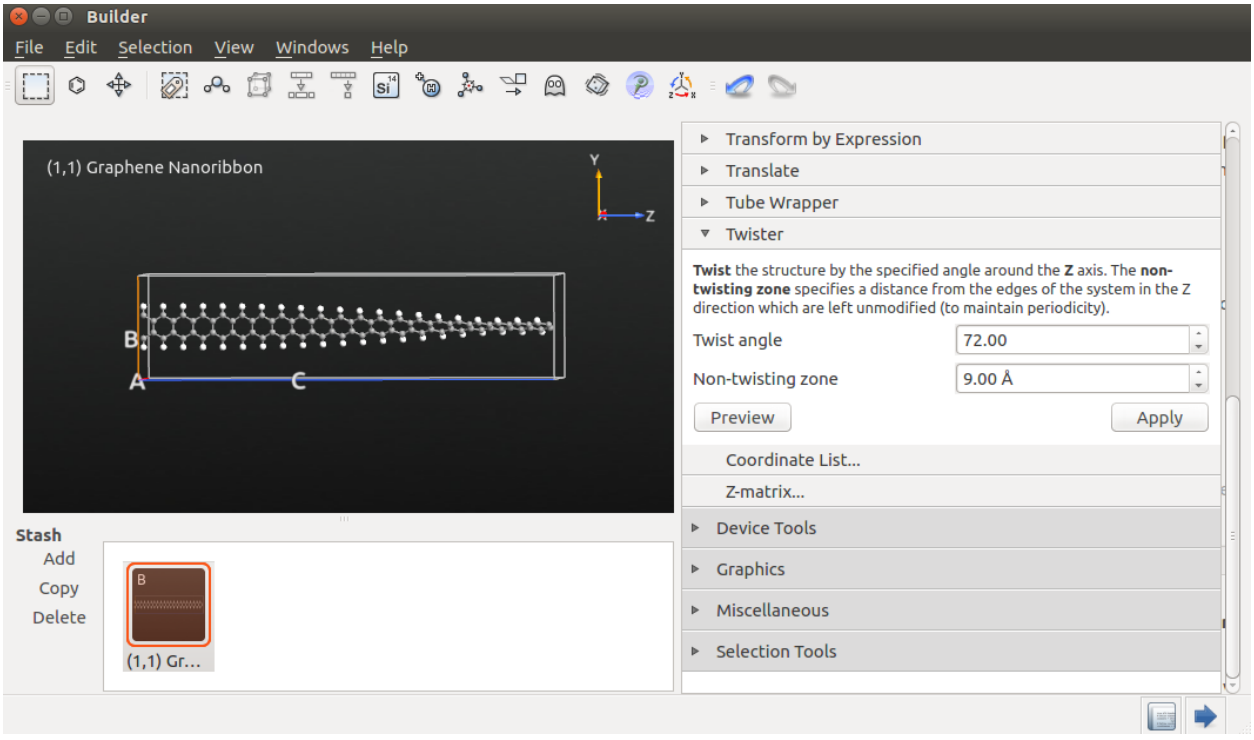
Twisted nanoribbon

In this section you will learn how to twist a graphene nanoribbon using the QuantumATK **Twister** plugin, and then compute the transmission spectrum.

Open the Builder, and select the nanoribbon created in the previous section. Then use the *Bulk Tools* → *Repeat* tool to repeat the configuration 7 times in the C direction:



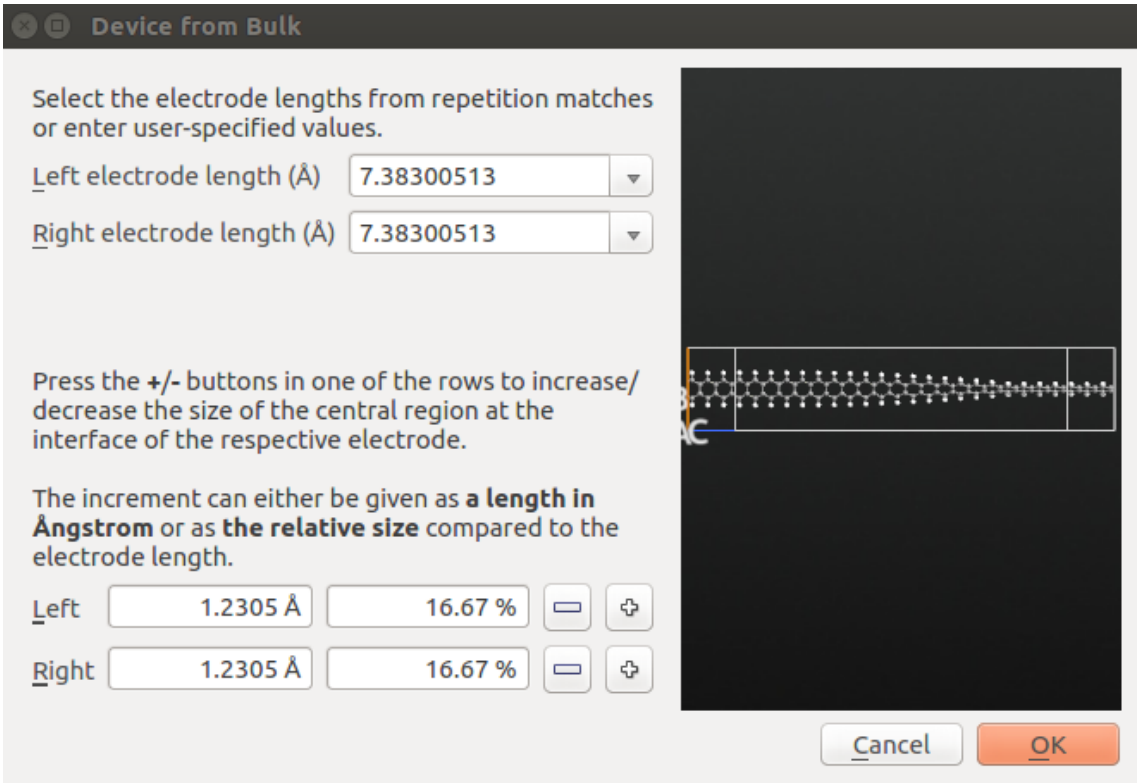
Then open the *Coordinate Tools* → *Twister* plugin, and set a Twist angle of 72 degrees and a Non-twisting zone of 9 Å. Click **Apply** to perform the twisting operation.



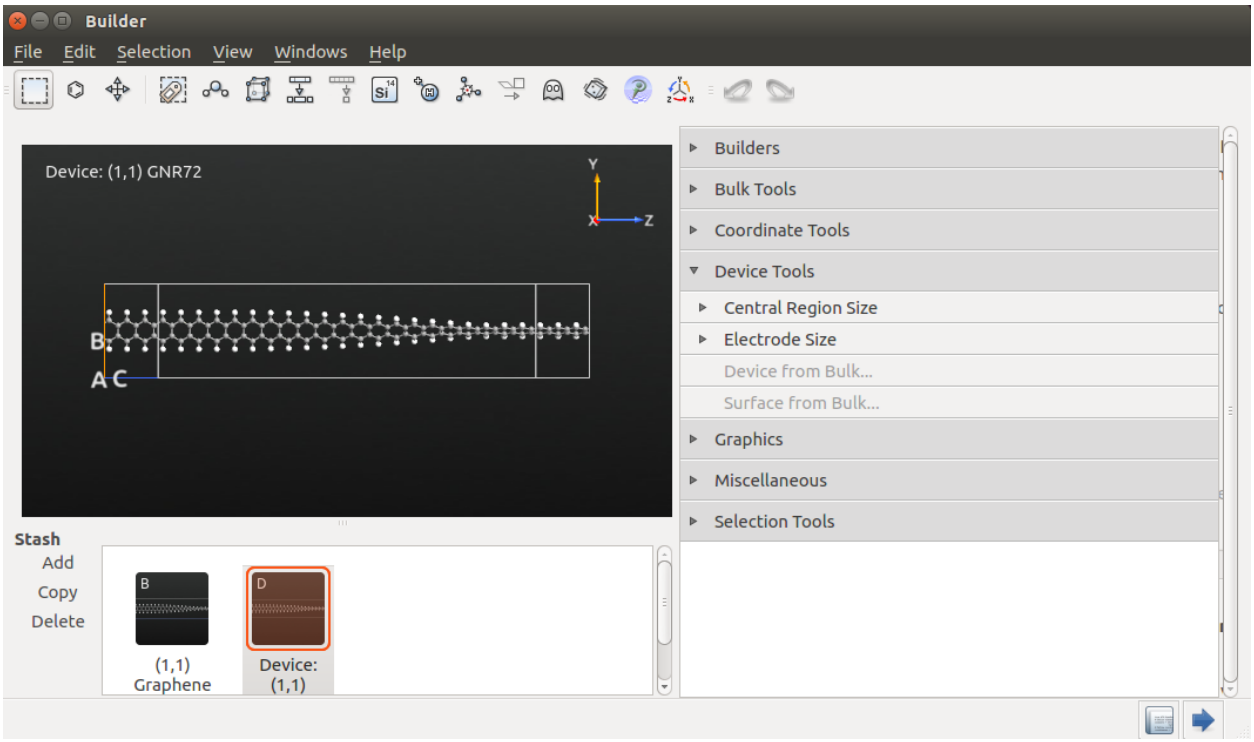
Certain parts of the system to the left and right of the structure are not twisted; the length of the non-twisted part is specified by the value of Non-twisting zone. The rest of the structure is twisted by the sepcified angle.

Transmission spectrum

You will now calculate the transmission spectrum of the twisted graphene nanoribbon. First, you need to convert the twisteds ribbon into a device – use the *Device Tools* → *Device from Bulk* tool for this.



Then rename the device configuration as `GNR_twist` and send it to the **Script Generator** to create the required ATK Python script.



In the Scripter, add the following script blocks:

- New Calculator
- Transmission Spectrum

Open the **New Calculator** block and use the following settings:

•ATK-SE: Extended Hückel (Device) calculator;

•1x1x100 k-point grid;

•Cerda.Carbon [graphite] basis set for C and Cerda.Hydrogen[C2H4] basis set for H.

Select the following settings in **TransmissionSpectrum** block:

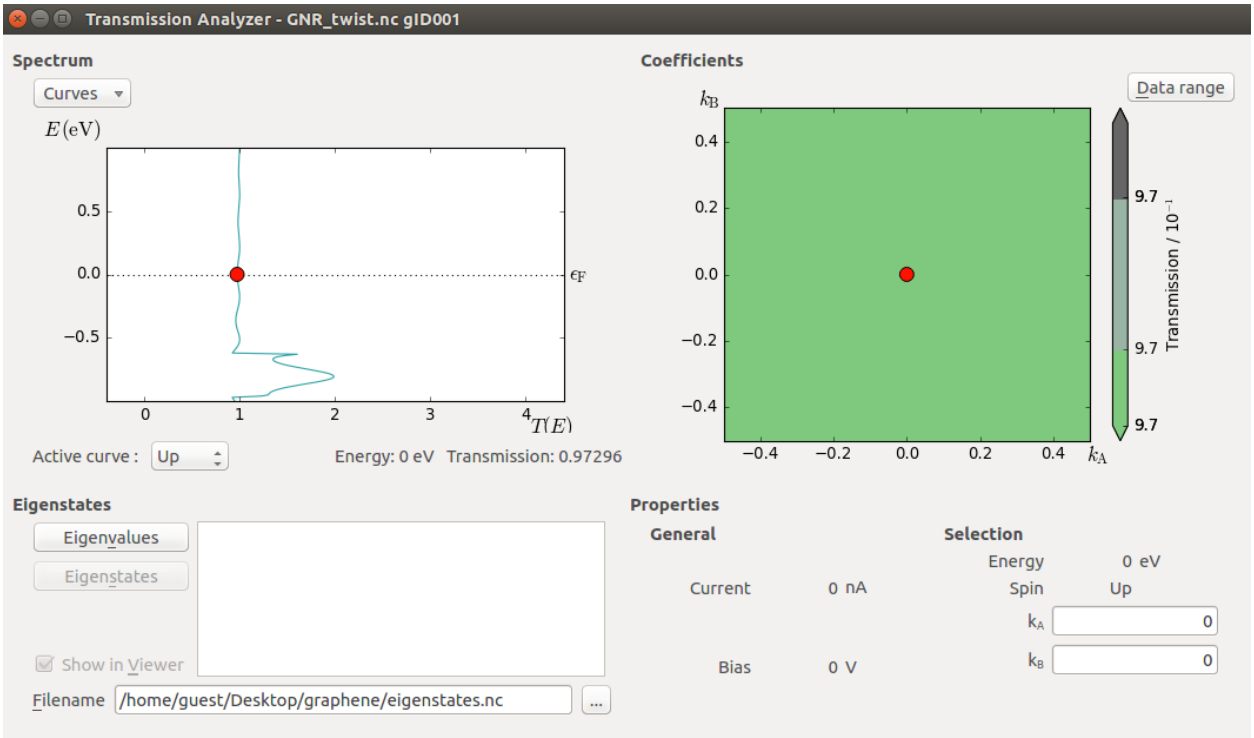
•energy range of [-1,1] eV and 201 energy points;

•Krylov self-energy calculator;

•1x1 k-point grid.

Then save the script as `GNR_twist.py` and execute it using the **Job Manager**. This calculation will take just a few minutes.

The HDF5 data file `GNR_twist.hdf5` should now have appeared on the QuantumATK **LabFloor**. Select the *TransmissionSpectrum* item and use the **Transmission Analyzer** plugin to visualize the computed transmission spectrum.



Note that the transmission peak has shifted down in energy as compared to the non-twisted ribbon. The twist represents a source of electron scattering, since it breaks the translational symmetry of the non-twisted ribbon electrodes along the transport direction.

Möbius nanoribbon

Next, we are going to create a Möbius nanoribbon. Download the script `Moebius.py`, which is also reproduced below. The script loads a basic nanoribbon from the file `nanoribbon.hdf5`, then performs the required operations of repeating, twisting, and wrapping the ribbon, and finally saves the Möbius ribbon in `moebius.hdf5`.

```
from NL.Math.Utilities import rotationMatrix
import math
from QuantumATK import *

def twister_displacement(x, rotation_angle_per_z, rotation_axis,
                         rotation_axis_center, z_start, z_end):
    """
       Function for twisting a 1-d structure
       @param x : Coordinates of 1-d structure
       @param rotation_angle_per_z : size of twist in angle/length
       @param rotation_axis : axis to apply twist along
       @param rotation_axis_center : center of the rotation axis
       @param z_start : z value for starting the twist
       @param z_end : z value for ending the twist
    """

    # do not twist for z > z_end
    z = x[2]
    z = min(z,z_end)
```

(continues on next page)

(continued from previous page)

```
    # do not twist for z < z_start
    z = z - z_start
    z = max (z,0.0)
    # find twist angle
    theta = z*rotation_angle_per_z
    # calculate the rotation matrix
    rotation_matrix = rotationMatrix(theta, *rotation_axis)
    # apply rotation
    return rotation_axis_center+numpy.dot(rotation_matrix, x-rotation_axis_center)

def wrapping_displacement(x, width, wrapping_angle):
    """
       Function for converting a nanosheet coordinate into a partly wrapped nanotube
       @param x : Coordinates of nanosheet atom
       @param width : Width of the nano-sheet
       @param wrapping_angle : maximum wrapping angle of the nanotube in radians
    """
    # calculate the average radius of the incomplete wrapped tube
    radius = width/wrapping_angle
    # find the angle of the current atom
    angle = (x[2]-width/2.)/radius
    # calculate the radius of the current atom
    atom_radius = radius+x[1]

    # return atom position of the wrapped atom
    return numpy.array([x[0], atom_radius*math.cos(angle),atom_radius*math.sin(angle)])

def Moebius(ribbon, n, m, repetition):
    """
       Function for generating a moebius molecule
       @param n : Chiral vector index
       @param m : Chiral vector index
       @param repetition : Repetition along z
    """

    # build n,m ribbon
    #ribbon = NanoRibbon(n,m)
    ribbon = ribbon.repeat(1,1,repetition)

    # get properties of the ribbon
    lattice = ribbon.bravaisLattice()
    elements = ribbon.elements()
    cartesian_coordinates=ribbon.cartesianCoordinates().inUnitsOf(Angstrom)

    # calculate the length of the 1-d structure
    z_length = numpy.linalg.norm(lattice.primitiveVectors()[2].inUnitsOf(Angstrom))

    # calculate twist parameters
    rotation_angle_per_z =  math.pi /z_length
    rotation_axis = numpy.array([0,0,1])
    rotation_axis_center = numpy.sum(cartesian_coordinates,axis=0)/len(cartesian_
↪coordinates)
```

(continues on next page)

(continued from previous page)

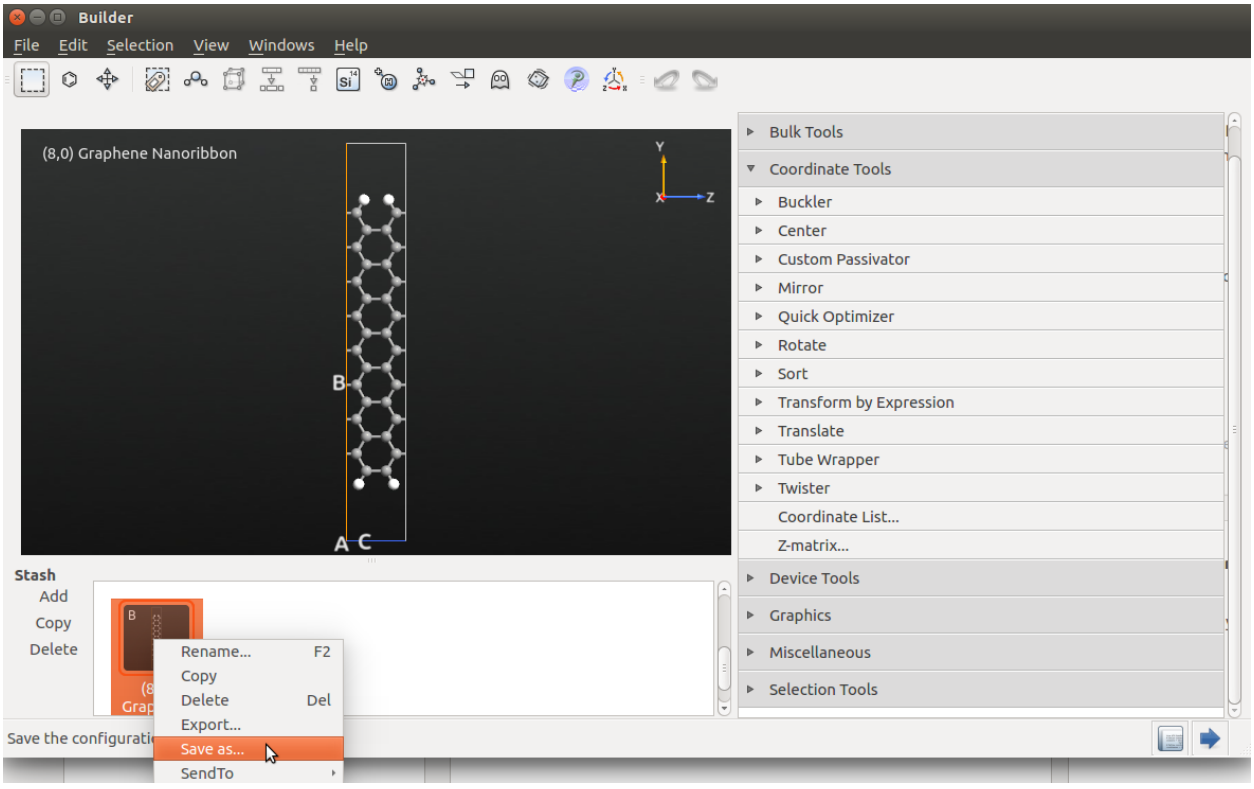
```
    # define a function of one variable, f(c),  for displacing the atoms
    f = lambda c : twister_displacement(c, rotation_angle_per_z, rotation_axis,
                                rotation_axis_center, 0.,z_length)
    # apply the function to find new displaced coordinates
    cartesian_coordinates = numpy.apply_along_axis(f, 1, cartesian_coordinates)
    cartesian_center = numpy.sum(cartesian_coordinates,axis=0)/len(cartesian_coordinates)
    cartesian_coordinates = cartesian_coordinates - cartesian_center

    # define a function of one variable, f(c),  for displacing the atoms
    f = lambda c : wrapping_displacement(c, z_length,2.0*math.pi)
    # apply the function to find new displaced coordinates
    cartesian_coordinates = numpy.apply_along_axis(f, 1, cartesian_coordinates)

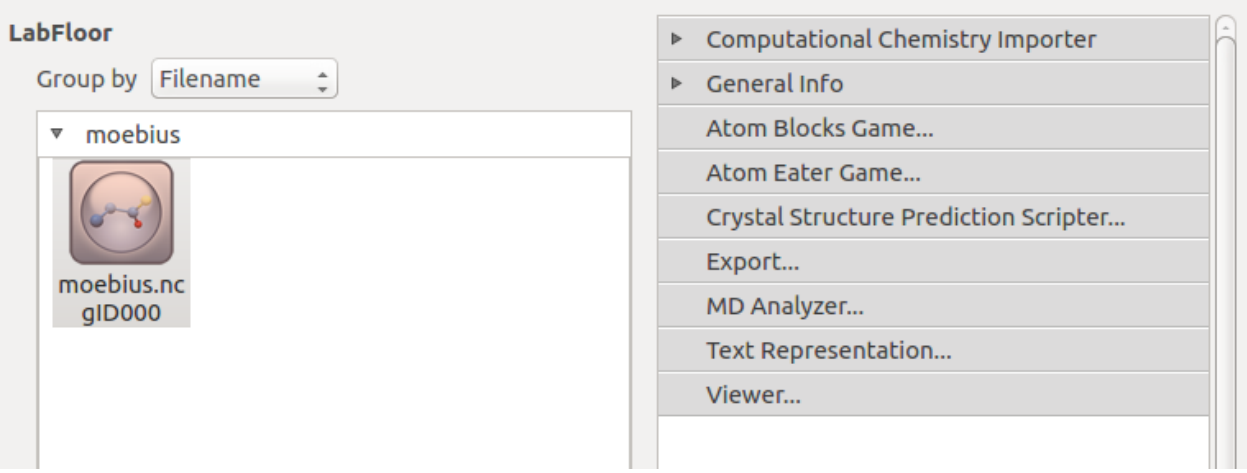
    return MoleculeConfiguration(
            elements=elements,
            cartesian_coordinates=cartesian_coordinates * Angstrom
            )

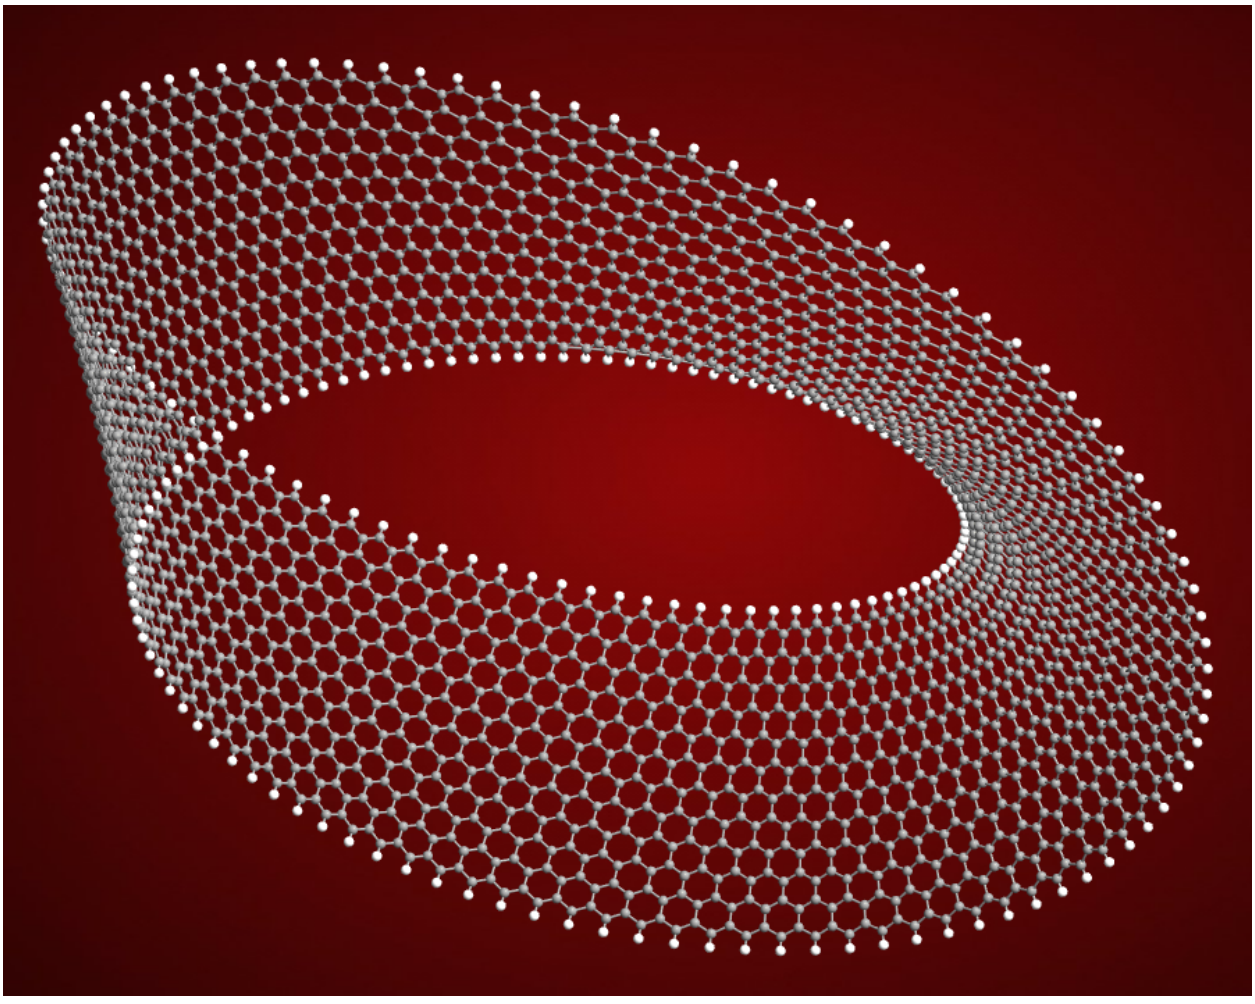
ribbon = nlread('ribbon.nc', BulkConfiguration)[-1]
moebius = Moebius(ribbon,1,1,100)
nlsave('moebius.nc', moebius)
```

You first need to build a basic nanoribbon. Use the *Add* → *From Plugin* → *Nanoribbon* plugin and select, for example, the chiral vector (n,m)=(6,6). Save the created ribbon in the Project Folder as `ribbon.hdf5`.



Then make sure `Moebius.py` is also located in the Prpject Folder, and execute it using the Job Manager or from the command line. The output file `moebious.hdf5` should appear in the Project Files list and the Möbius configuration should appear on the LabFloor. Use the **Viewer** to visualize the structure.





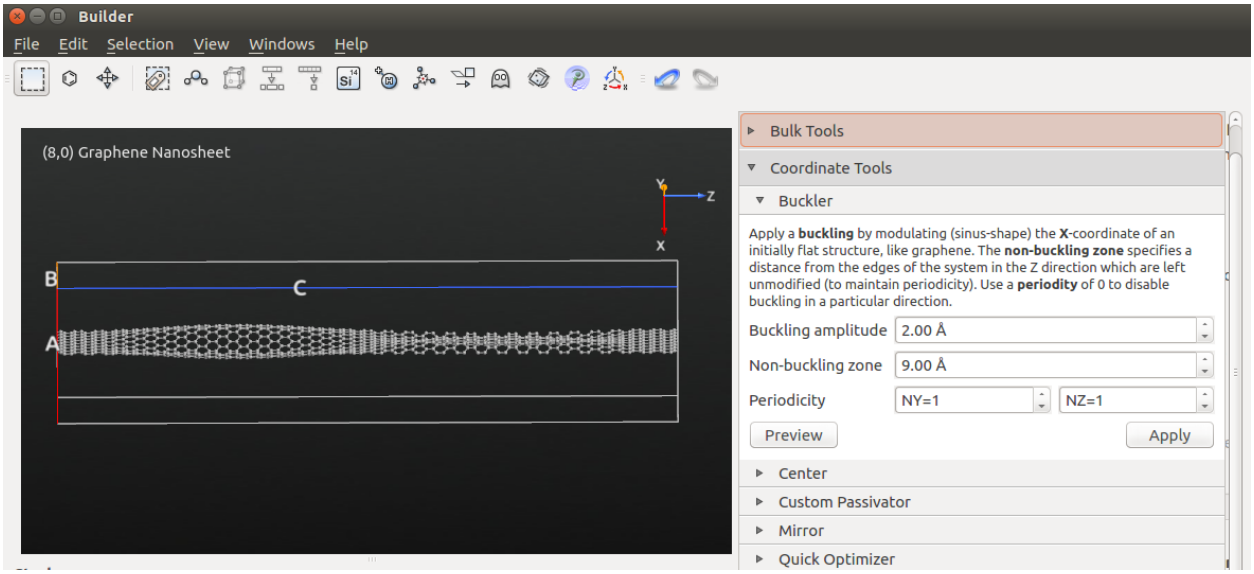
Buckling a graphene sheet

In this final section you will learn how to buckle a graphene sheet using the QuantumATK **Buckler** plugin.

First, create a nanosheet as shown above in section *Build a graphene sheet*. This time, repeat the nanosheet 30 times in the C direction.

Then open the *Coordinate Tools* → *Buckler* plugin, and set the Buckling amplitude to 2 Å and the Non-buckling zone to 9 Å. Select NY = 1 and NZ = 1 to enable buckling along the Y and Z axes.

Click **Apply** to perform the buckling operation.



3.6 2D Materials

3.6.1 Meta-GGA and 2D confined InAs

Version: 2017

In this tutorial you will learn about two topics: (i) bandstructure calculations by density functional theory (DFT) with the meta-generalized- gradient approximation (meta-GGA) exchange-correlation (XC) functional of Tran & Blaha (TB09) and (ii) calculations of confined structures with focusing on how to passivate dangling bonds on the surface. After completing the tutorial, you will be able to:

- Perform calculations with the TB09 meta-GGA XC functional to obtain accurate band gaps of semiconductors;
- Set up and passivate confined III-V systems (InAs, GaAs, InP,);
- Use special pseudopotentials with non-integer charges for the passivating hydrogens, that is, artificial hydrogen atoms or pseudo-hydrogens, which are needed in order to passivate III-V and II-VI surfaces since normal hydrogen passivation leads to metallic surface states;
- Use compensation charges on the passivating (normal) hydrogen atoms as an alternative to using pseudo-hydrogens.

Note: If you are not yet familiar with QuantumATK, go through the basic tutorials first. The underlying calculation engines for this tutorial is ATK-DFT, about which one can find the details in QuantumATK Reference Manual.

TB09 meta-GGA

Short introduction to TB09 meta-GGA

DFT is infamous for predicting too small band gaps, when calculated from the Kohn-Sham energy eigenvalues. However, recent advances of meta-GGA functionals have enabled us to compute accurate band gaps.

Meta-GGA functionals belong to the third rung of the so-called Jacobs ladder of XC functionals, as they not only include the local density $\rho(\mathbf{r})$ (as in LDA; the first rung) and the gradient of the density $\nabla\rho(\mathbf{r})$ (as in GGA; the second rung), but also the kinetic-energy density $\tau(\mathbf{r})$. In 2009, Tran and Blaha[1] showed that accurate band gaps could be obtained for a broad range of materials. In their formulation, the exchange potential is given by

$$v_x^{TB}(\mathbf{r}) = cv_x^{BR}(\mathbf{r}) + \frac{3c-2}{\pi}\sqrt{\frac{4\tau(\mathbf{r})}{6\rho(\mathbf{r})}},$$

where $\tau(\mathbf{r}) = 1/2\sum_{i=1}^{N}|\nabla\psi_i(\mathbf{r})|^2$ is the kinetic-energy density, $\psi_i(\mathbf{r})$ is the ith Kohn-Sham orbital, and $v_x^{BR}(\mathbf{r})$ is the Becke-Roussel exchange potential[2]. The parameter c is calculated as

$$c = \alpha + \beta\left[\frac{1}{\Omega}\int_\Omega \frac{|\nabla\rho(\mathbf{r})|}{\rho(\mathbf{r})}d\mathbf{r}\right]^{1/2},$$

where $\alpha = -0.012$ and $\beta = 1.023\ \mathrm{Bohr}^{1/2}$ were determined by fitting to reproduce the experimental band gaps of a large number of semiconductors and insulators and Ω is the volume of the cell. The correlation potential used by Tran and Blaha is an ordinary LDA correlation.

TB09 meta-GGA in QuantumATK

In **ATK** you can use the XC functional by Tran and Blaha in two ways. You can specify the XC functional as

```
exchange_correlation = MGGA.TB09LDA
```

in which case the c-parameter is determined self-consistently based on the expression above. This is the default, and the way the script is set up by **Script Generator** in **QuantumATK**.

You can also set the value of the c-parameter manually:

```
exchange_correlation = MGGA.TB09LDA(c=1.0)
```

The electron and kinetic-energy densities are still calculated fully self-consistently, but using the fixed value of c.

If the c-parameter is calculated self-consistently, the value will be printed in the log file. It can also be extracted in a script as

[1] F.Tran, and P. Blaha, Phys. Rev. Lett., **102**, 226401, (2009)

[2] A.D. Becke, and M.R. Roussel, Phys. Rev. A., **39**, 3761, 1989

```
c = calculateTB09C(bulk_configuration)
```

after the self-consistent calculation.

Note: Using a self-consistent determination of the c-parameter should only be done for a **bulk configuration** that is periodic in all directions. A confined system such as a slab or a nanowire will include large regions of vacuum. Since the c-parameter is calculated as an integral over the whole unit cell volume, the contributions from the vacuum region will lead to incorrect, even diverging results. You will most likely see warning messages in the log file if you attempt this .

For confined systems one must first determine an appropriate value for c for the corresponding bulk system. This can be done either self-consistently or by fitting the c-parameter to, e.g., the experimental band gap (see *Fitting the TB09 meta-GGA c-parameter*). The so-determined c-parameter can then be used for the confined structure.

Bulk InAs band structure with TB09 meta-GGA

Setting up bulk InAs

You should now setup an InAs bulk crystal. In **Builder**, click **Add** → **Database**, type *InAs* in the search field, and add the structure to the Stash.

The next step is to change the lattice constant to the experimental room temperature lattice constant, $a = 6.0583$[3]

- In the panel to the right, open **Bulk tools** → **Lattice Parameters**
- Importantly, you must select to keep **fractional** coordinates constant (see the figure below), else the symmetry of the crystal will be broken when the lattice constant is changed.
- Set $a = 6.0583$ Å.

Next, send the structure to **Script Generator**.

Setting up the script

In the following you will calculate the band structure of bulk InAs using the TB09 meta-GGA functional with the c-parameter calculated self-consistently and non-self-consistently.

For this purpose:

- Add **New Calculator** and **Bandstructure** blocks.

Open the **New Calculator** block, and make the following changes:

- Set Exchange correlation to meta-GGA
- Set the k-point sampling to 7, 7, 7.
- Under **Basis set/exchange correlation**, change the pseudopotentials to HGH[Z=5], LDA.PZ for Arsenic and HGH[Z=13], LDA.PZ for Indium. Choose the Tier 3 basis set for both elements.
- Finally set the output filename to *InAs_hgh.nc*.

Save the script, then send it to **Job Manager**, by using the Send To icon, and run the job. The calculation will take just a minute or two.

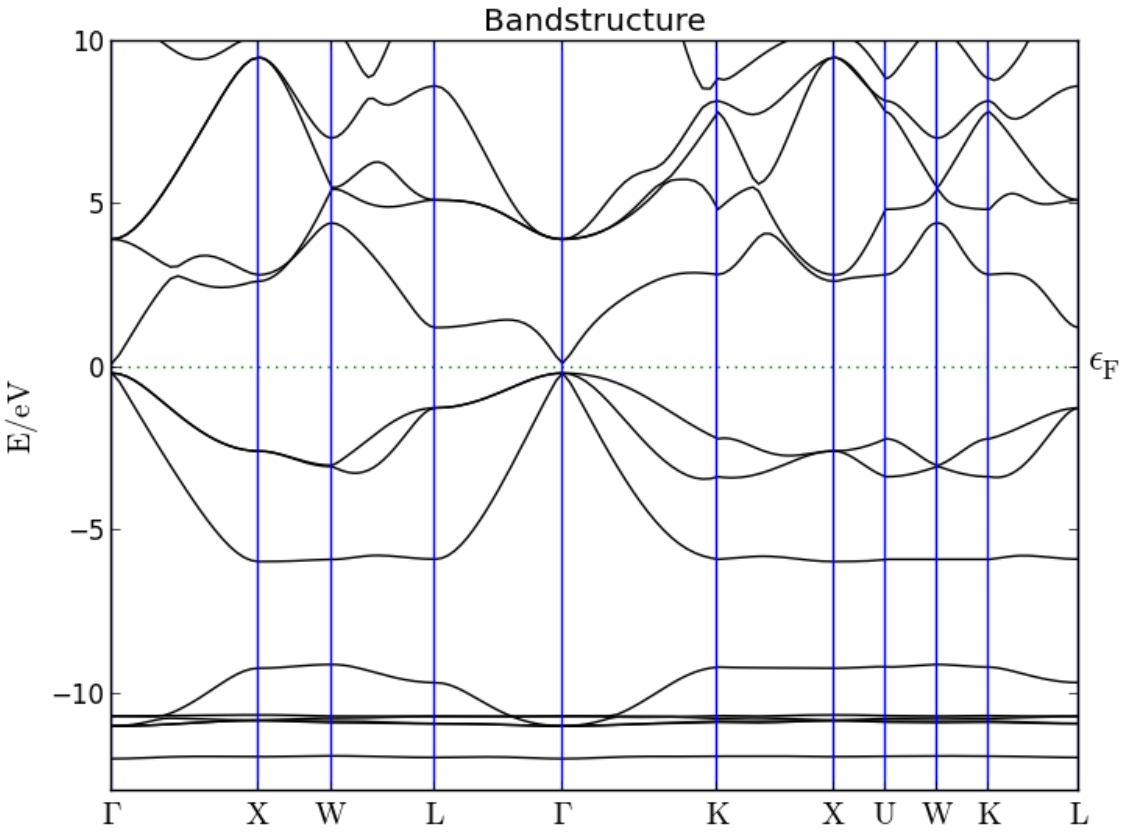
Note: For self-consistent calculations of the c-parameter, more accurate band structures are usually obtained using the HGH pseudopotentials which include semi-core states. This is the case for HGH[Z=13] above for Indium, which include the ten 4d electrons, in contrast to HGH[Z=3] which only includes the 3 valence electrons (5s and 5p states). Semi-core pseudopotentials are however only provided in **ATK** for some elements; for Arsenic there is only a HGH[Z=5] pseudopotential, without pseudocore states.

Band structure for self-consistently determined c

When the calculation finishes, locate the band structure object on the LabFloor and click **Bandstructure Analyzer** to plot the band structure like below.



You will find that the calculated band gap is very close to the experimental value 0.354 eV. This is actually a quite general trend, when using the HGH pseudopotentials. The figure below shows the calculated vs. experimental band gaps for a range of semiconductors and insulators. Results are shown for both LDA and TB09 meta-GGA calculations (additional examples are provided in Ref.[Page 1020, 1]) and show that while LDA always underestimates the band gaps (the famous band gap problem in DFT), the TB09 meta-GGA results are generally quite close to the experimental values, and typically as accurate as the results of much more expensive hybrid functional or even GW calculations.

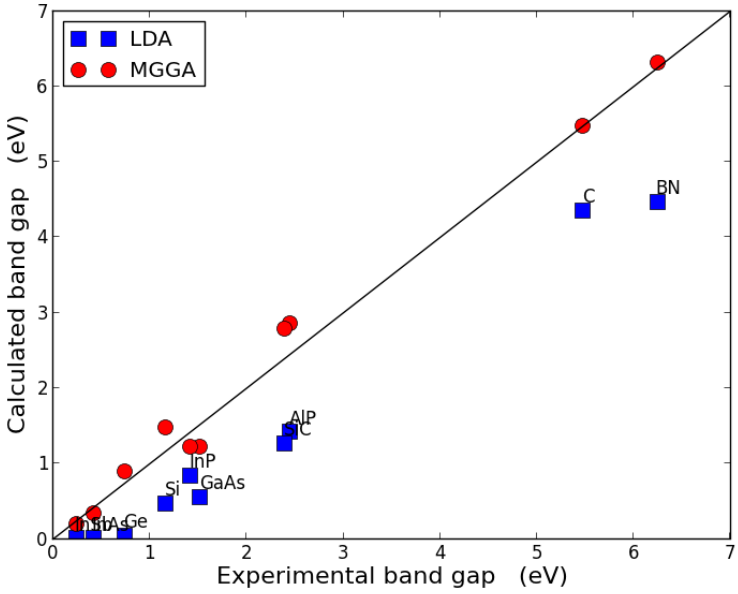


Fig. 3.86: Calculated vs. experimental band gaps. The calculations are performed with LDA (blue squares) and TB09 meta-GGA (red circles) XC functionals. For the TB09 meta-GGA calculations, the HGH pseudopotential have been used with a Tier 4 basis set, and the c-parameter is calculated self-consistently.

Fitting the TB09 meta-GGA c-parameter

While HGH pseudopotentials in general gives rather accurate band gaps by computing the c-parameter self-consistently, it might be desirable to get an even closer agreement with experimental values. In order to achieve that, it is possible to manually set the TB09 meta-GGA c-parameter such that the calculated band gap coincides with the experimental one. This can also be used as a way to compensate for a slightly less accurate pseudopotential or basis set, as will be illustrated in this section.

Setting up the script

Go back to **Script Generator** and open the **New Calculator** block, and make the following settings:

•Under :menuselection:**Basis set** → **exchange correlation**, change the pseudopotentials to FHI[Z=5], LDA.PZ for Arsenic and FHI[Z=3], LDA.PZ for Indium. That is, choose pseudopotentials without semicore states.

•Set the basis set to DoubleZetaPolarized for both elements.

•Change the output filename to InAs_c_fit.nc

Send the script to **Editor**, by using the Send To icon.

In **Editor**, go to the line where the XC function is specified and add the c-parameter argument to the MGGA.TB09LDA functional.

```
#-----------------------------------------
# Exchange-Correlation
#-----------------------------------------
exchange_correlation = MGGA.TB09LDA(c=1.0)
```

Then send the script to **Job Manager** (again use the Send To icon) and run the calculation. This time it will only take a few seconds.

When the calculation is done, plot the band structure and measure the band gap. If the the gap is larger than the experimental value (0.354 eV), then go back to **Editor** and decrease the c-value a bit and run again. If the band gap is smaller, you must increase the c-value. Try a few iterations to see if you can get a close agreement with the experimental value.

The figures below show the calculated band gap (left panel) for four different c-values (0.9, 0.95, 1.0, 1.05). Due to the very linear behavior, we can safely find the optimal c-parameter at the intersect between the interpolated line of the calculated band gaps and the experimental gap. This yields an optimal c-value of 0.936, which we will use in the following.

The right panel shows the calculated conduction band effective mass for the same four c-values. Also indicated is the experimental conduction band mass (0.023 m_e). The lines cross at c=0.935, so - very importantly - approximately the same c-value optimizes both the band gap and the effective mass, thus giving a very good description at least of the lowest Γ valley of InAs.

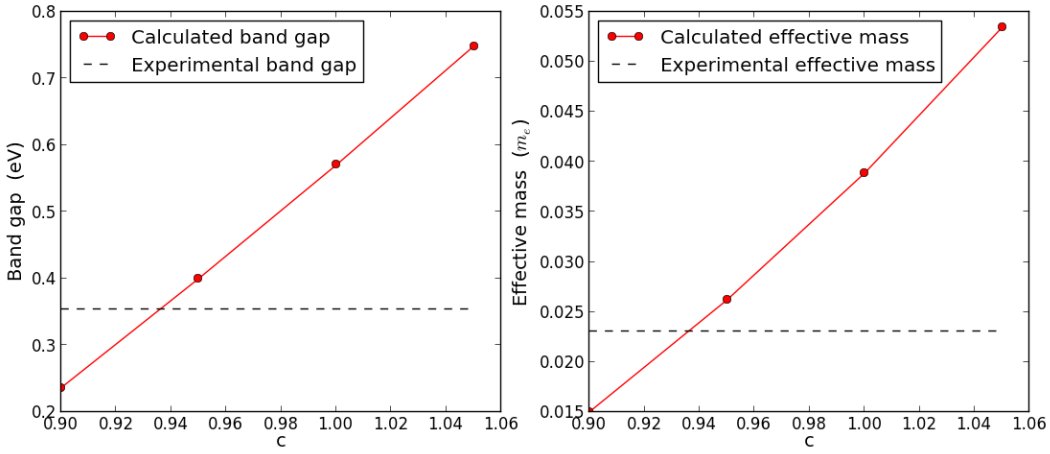

Fig. 3.87: Calculated band gap (left) and conduction band effective mass (right) vs. the TB09 meta-GGA c-parameter. Increasing c will always lead to a larger band gap. Both the band gap and the effective mass are optimized by approximately the same c-parameter (0.936).

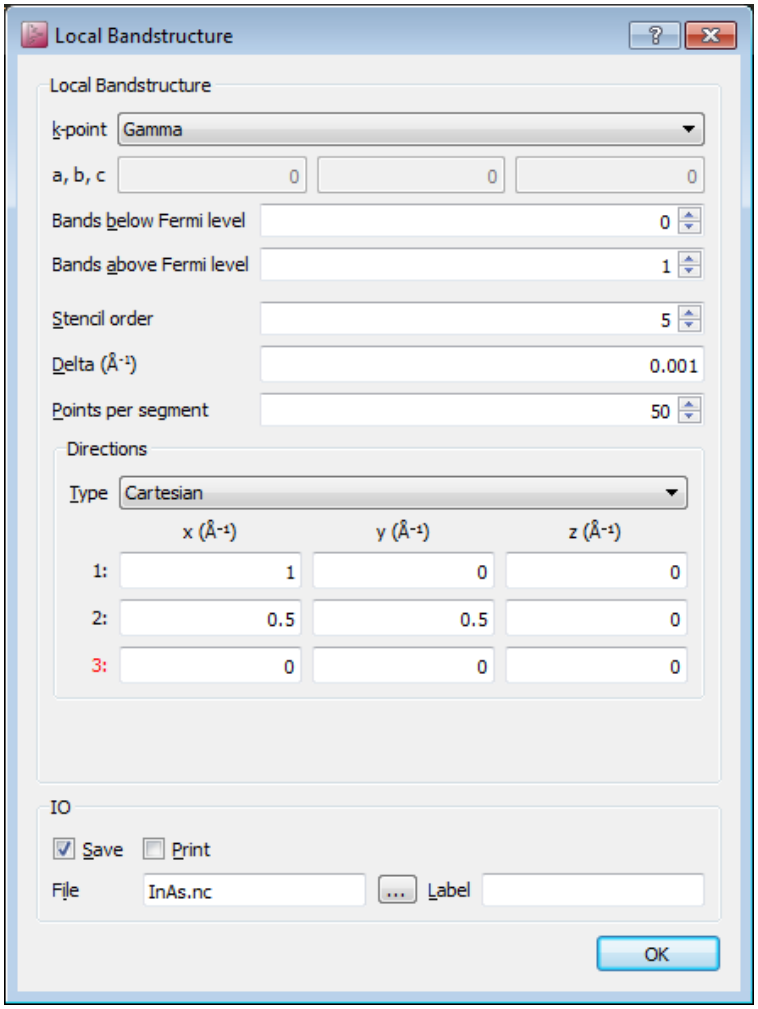
Band structure with optimized c-parameter

Before continuing to study confined InAs structures, you will first calculate and analyze the bulk band structure with the optimized c-parameter in some more detail.

Go back to **Script Generator** and make the following adjustments:

- Delete **Bandstructure** object.
- Insert an **LocalBandstructure** block and open it (see figure below).
  - Set Bands below Fermi level to 0.
  - Set Points per segment to 50.
  - Add a second direction: 0.5, 0.5, 0
  - Otherwise keep the default.

•Change the output file name to InAs_bulk_c_optimized.nc.



Transfer the script to **Editor** and insert the optimized c-parameter value:

```
#----------------------------------------
# Exchange-Correlation
#----------------------------------------
exchange_correlation = MGGA.TB09LDA(c=0.936)
```

Finally, send the script to **Job Manager** and run the calculation.

To analyze the results, use **Local Bandstructure Analyzer**.

LocalBandstructure object calculates the effective mass m^* and further fits the band structure to the function $E(1+\alpha E) = \frac{\hbar^2 k^2}{2m^*}$, where α is the parameter to fit. You can control the range of the fit with the number of **Fit points**. This non-parabolic dispersion relation provides a much better fit to the TB09 meta-GGA band structure than the usual parabolic model $E = \frac{\hbar^2 k^2}{2m^*}$, as shown in the figure below. The red dots indicate the range used for fitting α.

From the LocalBandstructure Analyzer, we see that the InAs conduction band in the [1,0,0] direction is very accurately described by $m^* = 0.028\, m_e$ and $\alpha = 2.869\, eV^{-1}$, while the parabolic model only describes the band well in the vicinity of the conduction band minimum.

Try to change the **Direction** to $(0.5, 0.5, 0)^{-1}$ to calculate the local band structure for this direction. Note that the effective mass is the same as before, i.e. it is isotropic, while the non-parabolicity parameter α is not isotropic.

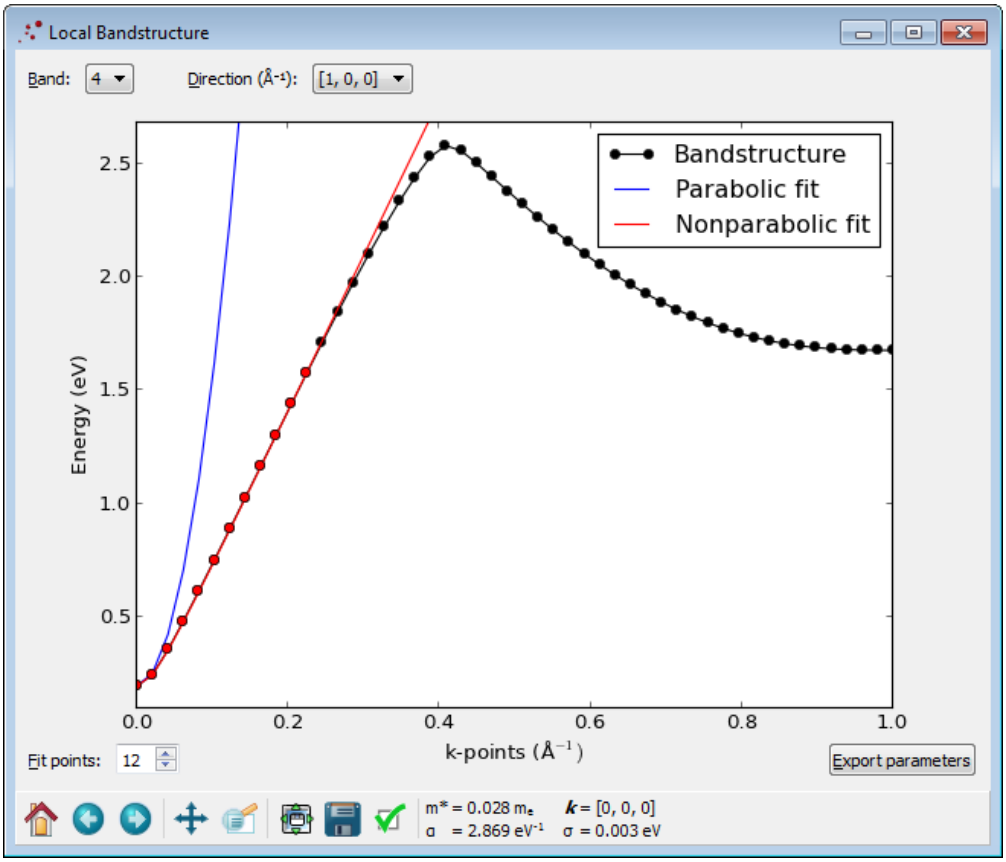


Fig. 3.88: Local bandstructure analyzer. The black dots show the calculated band structure data, while the blue and red curves show the results of a parabolic and non-parabolic model, respectively. The fitted α value is shown below the plot together with the effective mass.

Setting up and passivating an InAs slab

Slab structure

You will now setup an InAs slab which is confined in the [100] direction.

Go back to the **Builder** window, where it will be assumed that you still have the bulk InAs crystal from previous.

Next, **Builders** → **Surface (Cleave)** to cleave the crystal along the (100) direction.

•Keep the default (100) Miller indices, and press Next.

•Keep the default surface lattice vectors, and press Next.

•Keep the default supercell - this will ensure that the wire direction is perpendicular to the surface.

•Finalize your configuration by choosing Non-periodic and normal (Slab) configuration with a thickness of 8 layers and a top and bottom vacuum of 5 Å.

•Press Finish to add the cleaved structure to the Stash.

Adding hydrogens

The surfaces of the so-created bare InAs slab have dangling bonds due to unpaired In and As atoms. This will lead to metallic surface states with energies in the band gap. In order to passivate the surfaces you will now add hydrogen atoms.

•Open **Coordinate Tools** → **Custom Passivator**.

•Set Hybridization to 4 (SP3).

•Change the bond distances to 1.3 Å (otherwise neighboring hydrogen atoms will be too close).

•Press the Passivate button.

Note: The **Custom Passivator** adds tags to the added hydrogen atoms - this is essential for this tutorial, so dont change or remove them. You can inspect the tags by opening **Select** → **Tags**. You will later use these tags to identify H atoms bonded to In and As, respectively, when specifying compensation charges and using specialized pseudopotentials.

The structure should now resemble the figure below.

Send the structure to **Script Generator**.

Band structure with default hydrogen atoms

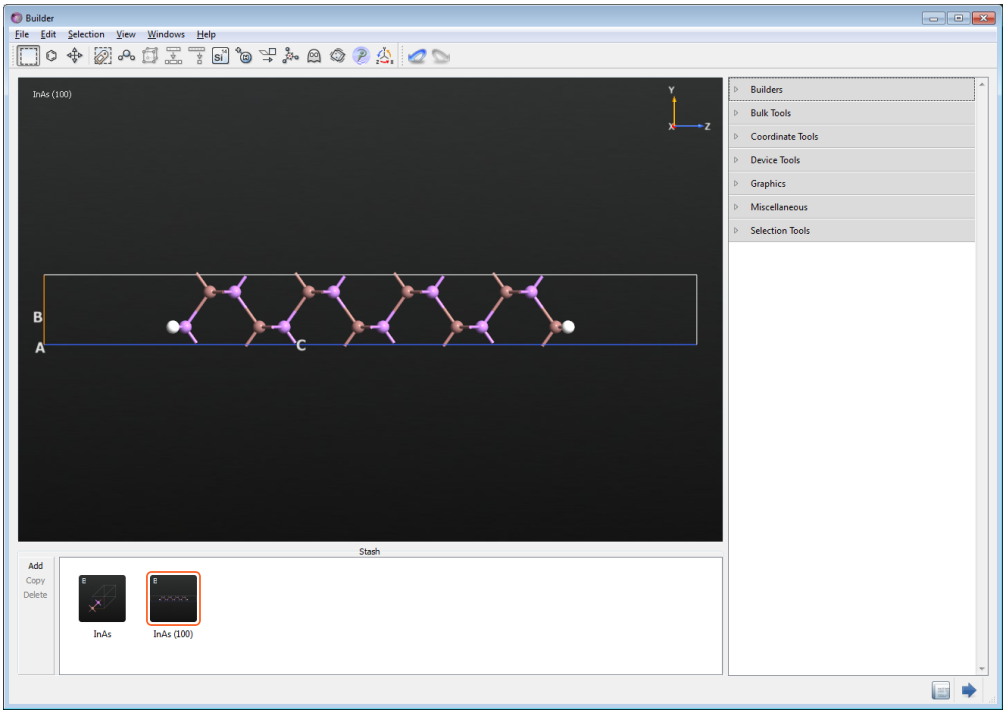
In the following you will calculate the band structure using default settings for the passivating hydrogen atoms. For this purpose:

•Add a New Calculator.

•Add Analysis/Bandstructure.

Open the **New Calculator** block, and set exchange correlation to meta-GGA and the k-point sampling to 7, 7, 1. Note that the FHI pseudopotentials are selected by default.

Finally, open the **Bandstructure** block and set the Brillouin zone route to Y,G,X, and increase the points per segment to 100.



As discussed in *Short introduction to TB09 meta-GGA*, the self-consistent calculation of the c-parameter only works for bulk systems without vacuum regions, whereas for a slab calculation one should use a fixed value. Therefore, send the script to **Editor** and specify the c-parameter you found in *Band structure with optimized c-parameter* to reproduce the experimental band gap for the FHI pseudopotentials:

```
#-----------------------------------------
# Exchange-Correlation
#-----------------------------------------
exchange_correlation = MGGA.TB09LDA(c=0.936)
```

Save the script, then send it to **Job Manager** (again use the Send To icon) and run the calculation. This time it will take a bit longer, around 5 minutes.

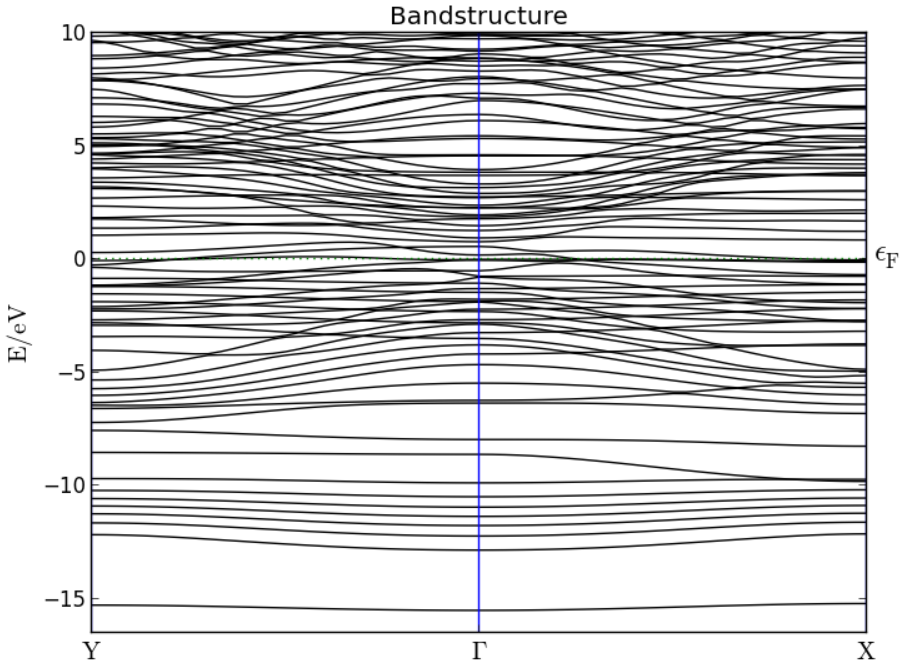
Note: When running the script, you may observe a warning in the log file:

```
################################################################################
# WARNING                                                                      #
#                                                                              #
# The computed TB09 meta-GGA XC potential                        #
# diverged in   0.01 % of the simulation volume, and was                       #
# truncated to be in the range [-10.0000,  10.0000] Hartree                    #
#                                                                              #
################################################################################
```

You do not need to worry about this because you have set the c-parameter to a fixed value. If, on the other hand, you were trying to calculate it self-consistently, the warning would be relevant. However, as explained in *Short introduction to TB09 meta-GGA*, the self-consistent evaluation of the c-parameter involves an integral over the entire calculation unit cell, including the vacuum regions, where the TB09 meta-GGA XC potential can diverge. For confined systems like slabs and nanowires, you therefore always need to specify the c-parameter manually.

Analyzing the results

If you now plot the result of this calculation with the Bandstructure Analyzer you will find that there is no band gap, but instead a lot of more or less flat bands in the region around the Fermi energy. These are due to surface states, which arise due to inadequate passivation of the surface.



In order to get rid of the surface states (or rather to push them away from the Fermi level) the hydrogen atoms need to be treated differently. The following two sections illustrate two possible ways to eliminate the surface states, to produce a proper band structure for your InAs slab.

Passivation using pseudo-hydrogen

In the following you will calculate the band structure and effective mass using so-called pseudo-hydrogen atoms containing fractional charges. The use of pseudo-hydrogen is a well-known procedure in the literature to passivate III-V and II-VI surfaces[4].

Return to the **Script Generator** window and open the **New Calculator** block. Make the following settings to set different basis sets for the hydrogen atoms bonded to Indium and Arsenic, respectively:

•Under **Basis set/exchange correlation** click the **Activate tags** button and check both H_As and H_In for hydrogen.

This technique, i.e. using tags, allows you to assign a different basis sets to atoms of the same element, which can be a useful trick in other situations too.

•Change the pseudopotential for the H_As atoms to FHI Fractional LDA.PZ, and set the basis set to DoubleZetaPolarized, Z=0.75

•Change the H_In pseudopotential to FHI Fractional LDA.PZ, and the basis set to DoubleZetaPolarized, Z=1.25

Note the following important points.

•Two separate hydrogen basis sets are defined: one for hydrogens bonded to Indium atoms, and one for those bonded to Arsenic atoms. The basis sets use different pseudopotentials with charge 1.25 and 0.75 electrons, respectively. (From the widget it may appear that they use the same, but the fractional pseudopotentials are automatically selected to match the basis set charge.)

•The use of these pseudopotential charges can be understood as follows[Page 1031, 4]. The surface of an unpassivated nanocrystal consists of dangling bonds which will introduce band gap states. The purpose of a good passivation is to remove these band gap states. One way to do so is to pair the unbonded dangling bond electron with other electrons. If a surface atom has m valence electrons, this atom will provide m/4 electrons to each of its four bonds in a tetrahedral (sp3) crystal. To pair these m/4 electrons in each dangling bond, a passivating agent should provide (8 m) / 4 additional electrons. Since As has m=5, it should be passivated with pseudo-hydrogen containing (8-5)/4=0.75 electrons. Likewise, In has m=3 valence electrons, and should be passivated with pseudo-hydrogen with (8-3)/4=1.25 electrons.

•Both types of hydrogen atoms are still charge neutral, i.e. there are 1.25 electrons and a core with charge 1.25, and similarly for the 0.75 case.

Add a LocalBandstructure object **Analysis** → **LocalBandstructure** and adjust the following parameters:

•Set bands below Fermi level to 0.

•Increase Points per segment to 50.

Set the output file name to InAs_slab_pseudohydrogen.nc, and send the script to **Editor** and make the usual adjustment of the c-parameter.

```
#----------------------------------------
# Exchange-Correlation
#----------------------------------------
exchange_correlation = MGGA.TB09LDA(c=0.936)
```

Finally, save the script and send it to **Job Manager** to run the calculation.

Results

Plotting the calculated band structure with the Bandstructure Analyzer you can observe that a band gap has opened up. The pseudo-hydrogen atoms have thus indeed moved the surface states away from the Fermi energy, as intended.

By inspecting the band structure, you can see that the band gap has increased to a value of 0.1 eV, compared to the bulk value 0.354 eV, as a result of quantum confinement.

Next you may inspect the calculated effective mass and non-parabolicity parameter using the **Local Bandstructure Analyzer**.

Notice that the effective mass is increased to $0.1\,m_e$ compared to the bulk value (0.028), while the non-parabolicity parameter α has decreased to 1.739 (bulk value was 2.869). In other words, an effective mass description is better for the slab than for the bulk InAs.

In the section *Analytical band structure of a 2D slab* you will analyze the effect of quantum confinement on both the band gap and the effective mass in more detail.

Passivation using compensation charges

An alternative to using pseudo-hydrogen atoms is to use compensation charges on the hydrogen atoms. This adds external potentials corresponding to +0.25 electron charge for hydrogens binding to Indium and -0.25 electron charge for hydrogens binding to Arsenic, resembling the extra +/-0.25 electrons in the pseudo-hydrogen pseudopotentials used in *Passivation using pseudo-hydrogen* above.

•Go to **Script Generator** and open **New Calculator** block.

•Go to **Basis set/exchange correlation** and remove the check marks for H_As and H_In. This sets the basis set to the usual (uncharged) DoubleZetaPolarized for all hydrogen atoms.

•Set the output file name to InAs_slab_compensation_charge.nc.

The compensation charges will be defined in a script. Therefore, transfer the script to **Editor** (again use the Send To icon) and insert the Python code listed below before the specification of the calculator.

```
#------------------------------------------------------------
# Add compensation charges to the hydrogen atoms
#------------------------------------------------------------

# Compensation charge for H_As and H_In
charge_H_As = -0.25
charge_H_In =  0.25

# Set compensation charge
compensation_As = [('H_As',charge_H_As)]
compensation_In = [('H_In',charge_H_In)]

compensation = compensation_As + compensation_In
bulk_configuration.setExternalPotential(AtomicCompensationCharge(compensation))

# ------------------------------------------------------------
# Calculator
# ------------------------------------------------------------
```

Note: The tags on the hydrogen atoms are used to find their indices. Tags can be used for many purposes!

ATK will automatically use a free charge corresponding to the total sum of all compensation charges, in order to keep the entire system neutral still.

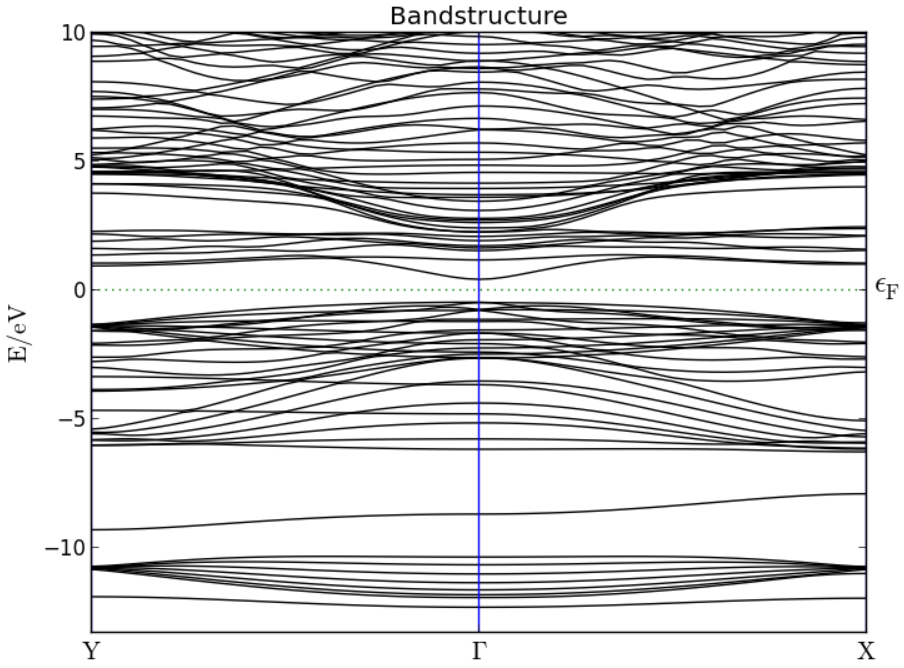
Again, add the c-parameter argument to the MGGA.TB09LDA functional:

```
#---------------------------------------
# Exchange-Correlation
#---------------------------------------
exchange_correlation = MGGA.TB09LDA(c=0.936)
```

Save the modified script and transfer it to **Job Manager** and run the calculation.

Results

Plotting the results, you should obtain an image like below.



Again there is a clear band gap around the Fermi energy, and the band structure is generally very similar to the one obtained with the pseudo-hydrogens.

Non-parabolicity in confined structures

In the section *Band structure with optimized c-parameter* you learned that the bulk conduction band structure in InAs is very well described with a non-parabolic model:

$$E(1+\alpha E) = \frac{\hbar^2 k^2}{2m^*}$$

where $m^* = 0.028\, m_e$ and $\alpha = 2.87\, eV^{-1}$. In this section, you will use this expression to develop an analytical expression for the conduction band dispersion of both the 2D slab and an InAs nanowire. In particular, you will find that the values of m^* and α determined for bulk InAs give an accurate description also of the confined non-parabolic band structures, when treated the correct way.

Analytical band structure of a 2D slab

The equation above only gives the energy as an implicit function of k. A solution to the quadratic equation lead to the explicit dispersion relations

$$E(k_x, k_y, k_z) = \frac{-1 + \sqrt{1 + \frac{2\alpha\hbar^2}{m^*}(k_x^2 + k_y^2 + k_z^2)}}{2\alpha},$$

where it has been assumed that m^* and α are independent of the crystal orientation. This is an excellent approximation for the electron mass m^*, whereas α does vary, as seen above.

In a confined system, i.e. a 2D slab or a 1D nanowire, the allowed wavelengths become quantized in the confined directions. In the case of a slab confined in the z-direction, one may assume that the effective potential can be approximated by a one-dimensional infinite potential well of width W. The allowed wavelengths in this directions are then $\lambda_n = \frac{2W}{n}$, $n = 1, 2, 3, ...$ Only the lowest band with $n = 1$ is relevant here, and the corresponding wavenumber is $k_z = \frac{2\pi}{\lambda_1} = \frac{\pi}{W}$. Inserting this in the equation above yields:

$$E_{2\mathrm{D}}(k_x, k_y) = \frac{-1 + \sqrt{1 + \frac{2\alpha\hbar^2}{m^*}(k_x^2 + k_y^2 + \frac{\pi^2}{W^2})}}{2\alpha},$$

From this expression you can readily calculate the shift in band gap due to quantization:

$$\Delta E_{\mathrm{gap}} = E^{2D}(0, 0) = \frac{-1 + \sqrt{1 + \frac{2\alpha\hbar^2\pi^2}{m^* W^2}}}{2\alpha}.$$

It is also possible to obtain an expression for the Γ-point effective mass $m^* = \hbar^2(\partial^2 E(k)/\partial k^2|_{k=0})^{-1}$. Try yourself to derive the expression

$$m^*_{2\mathrm{D}} = m^* \sqrt{1 + \frac{2\alpha\hbar^2\pi^2}{m^* W^2}}.$$

In order to evaluate the above expressions you only need to know the slab width W. The width might be defined in various ways, but if you consider the confinement of the conduction band Bloch state calculated at the Γ-point, you will find that it extends over a width of approximately $W = 30$ Å in the slab you have defined. Using this number, you get the following values for the band gap increase and effective mass:

$$\Delta E_{\mathrm{gap}} = 0.62eV$$

$$m^*_{2\mathrm{D}} = 0.11 m_e,$$

which compare quite well with the values you found in *Results*, namely $\Delta E_{\mathrm{gap}} = (0.96 - 0.354)$ eV $= 0.61$ eV, and $m^*_{2\mathrm{D}} = 0.1\, m_e$.

Thus, knowing the effective mass and α for bulk InAs is enough to get a very reasonable description of the band structure in a 2D confined InAs slab. A similar approach can be applied to a nanowire, as will be shown in *Nanowire band structure* below.

Note that the very significant increase in effective mass by more than a factor of three cannot be accounted for by a parabolic model $E(k) = \frac{\hbar^2 k^2}{2m^*}$ in which the effective mass remains constant, and only the band gap is affected by quantum confinement.

In order to visually check the quality of the non-parabolic model you can run the script `analyze_nanowire.py` shown below.

```

Nanowire band structure

As a final task, you will investigate if the analytical model can also be used to estimate the band structure of a nanowire. Since the nanowire calculations are rather time-consuming we will just show the results, and leave the actual calculations as an exercise.

You can create an InAs nanowire by going back to the **Builder** window and follow these steps:

•Repeat the InAs slab 6 times along the A-axis.

•Change the lattice parameters so that the A-vector is 40 Å in the x-direction.

•Passivate the nanowire in the same way as the slab, using the **Custom Passivator**.

•Center the coordinates.

Send the structure to **Script Generator** and use exactly the same procedure as for the slab calculations with pseudo-hydrogen atoms. Additionally,

•Set the k-point sampling to (1,9,1)

•Add **Bandstructure** and change the Brillouin zone route to G, Y.

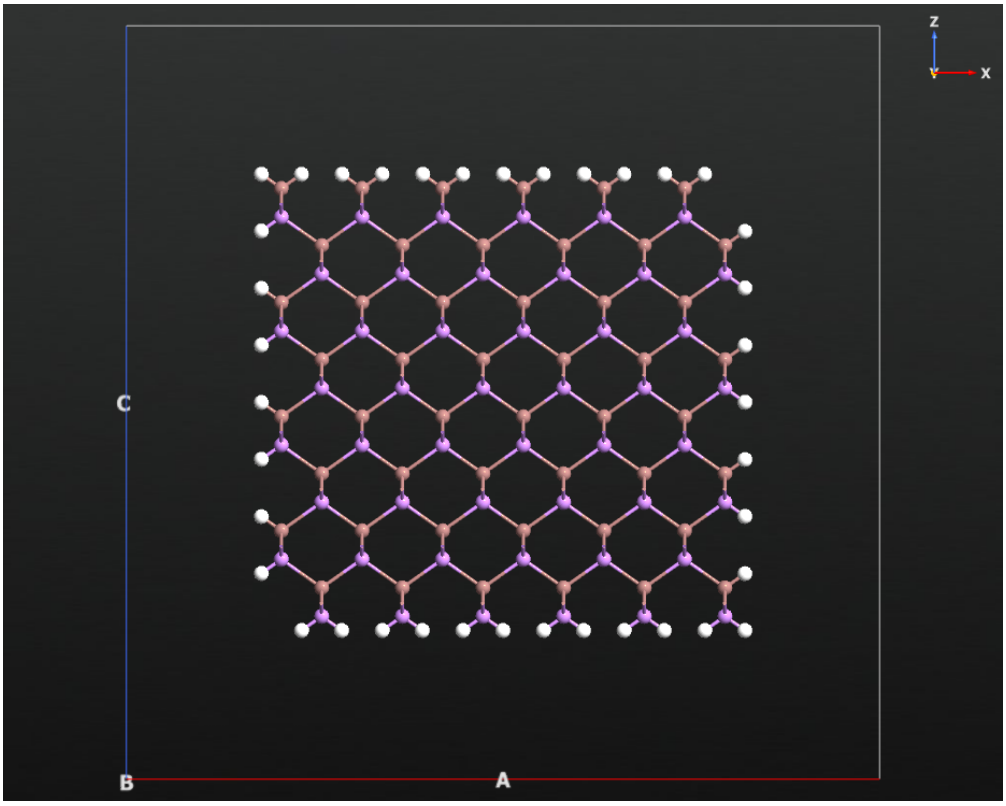
•Add Analysis/EffectiveMass and set Direction to Cartesian, and set (x,y,z)=(0,1,0).

•Set the output file name to InAs_nanowire.nc.

•Send the script to **Editor** and set the TB09 meta-GGA c-parameter to 0.936.

•Finally send the script to **Job Manager** and run it. Note that this calculation might take about an hour to finish.

When the calculation is finished you can run the Python script `analyze_nanowire.py` shown below in order to analyze the quality of the non-parabolic model .



```
import pylab as pl
from NL.CommonConcepts.Configurations.Utilities import fractional2cartesian

#-------------------------------------------------------------------------
# Model data

```

As for the InAs slab, the lowest conduction band in the nanowire is much better described by the the non-parabolic

model than by the parabolic/effective mass model. Although the agreement between the non-parabolic model and the DFT band structure is not quite as good as for the slab, it still provides a very reasonable estimate.

3.6.2 Opening a band gap in silicene and bilayer graphene with an electric field

Version: 2017

In this tutorial you will learn how to insert metallic gate electrodes in an QuantumATK bulk calculation and use them to apply electric fields. You will use these features to study the opening of a band gap in bilayer graphene and in silicene under the presence of an electric field. It is assumed that you are familiar with the basic functionalities of **QuantumATK**.

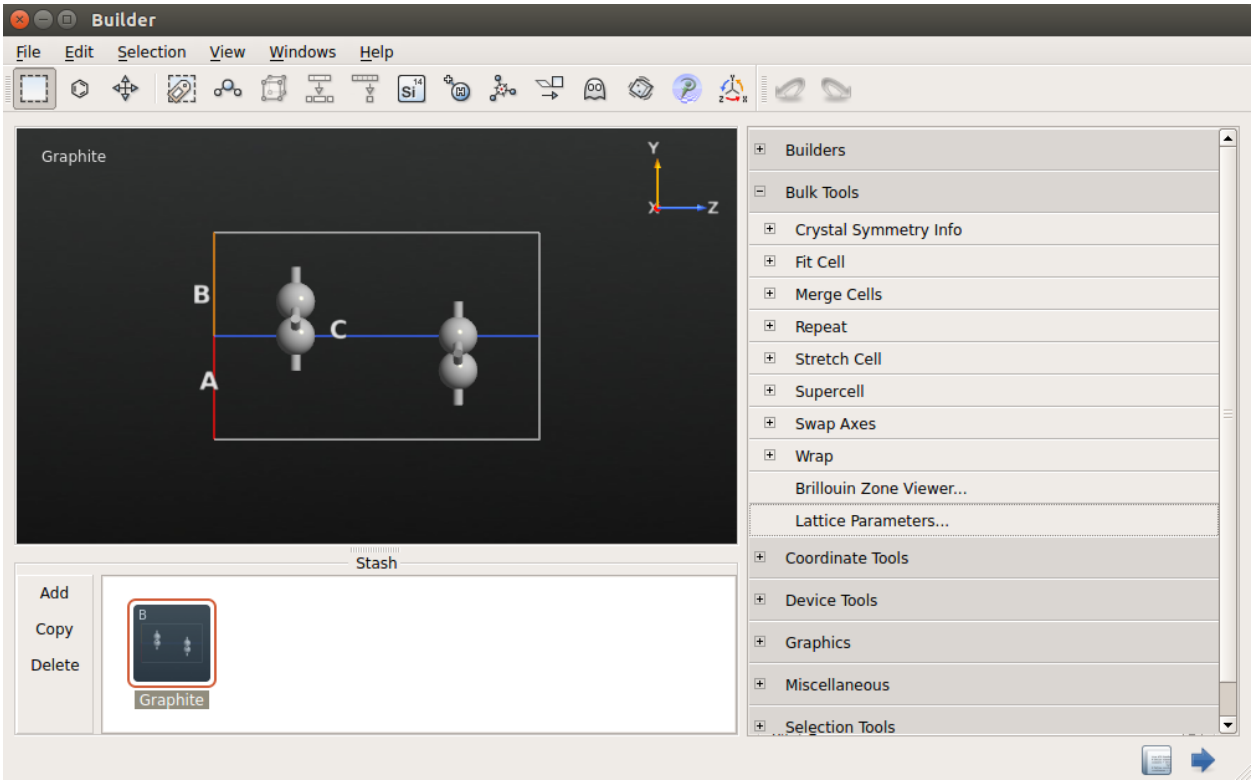
Bilayer graphene

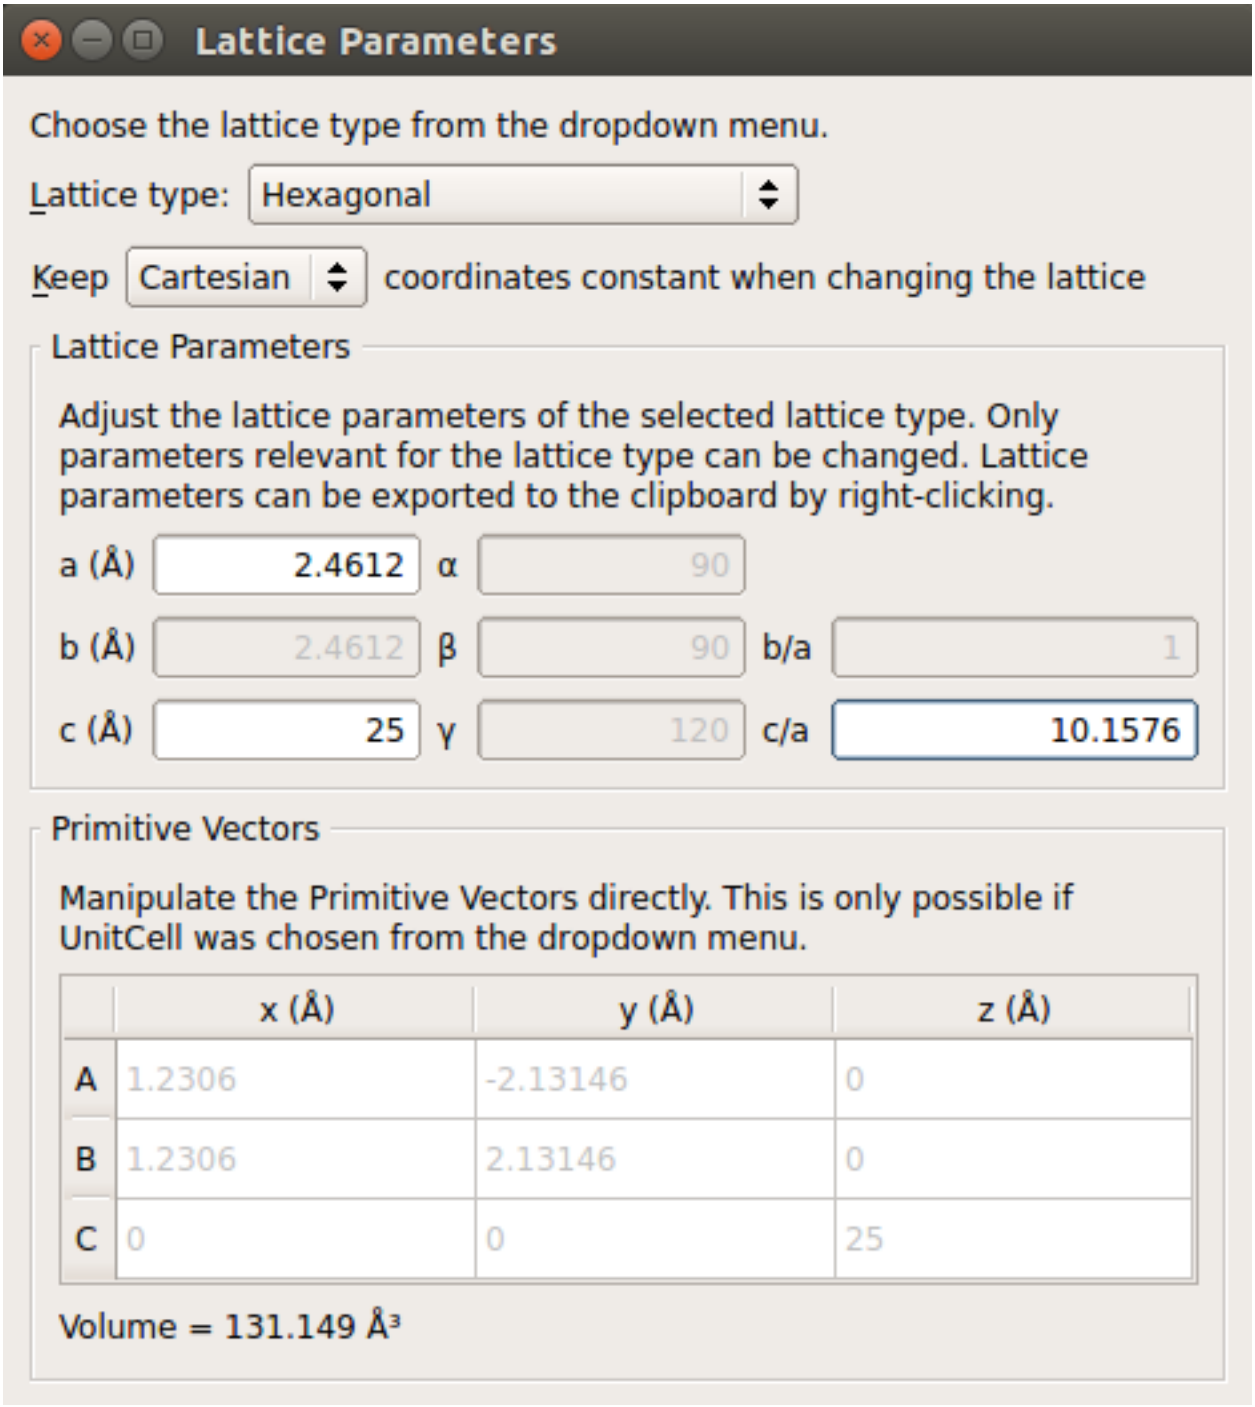
Building a bilayer graphene structure

1. Create a new empty project and open **Builder** (icon).

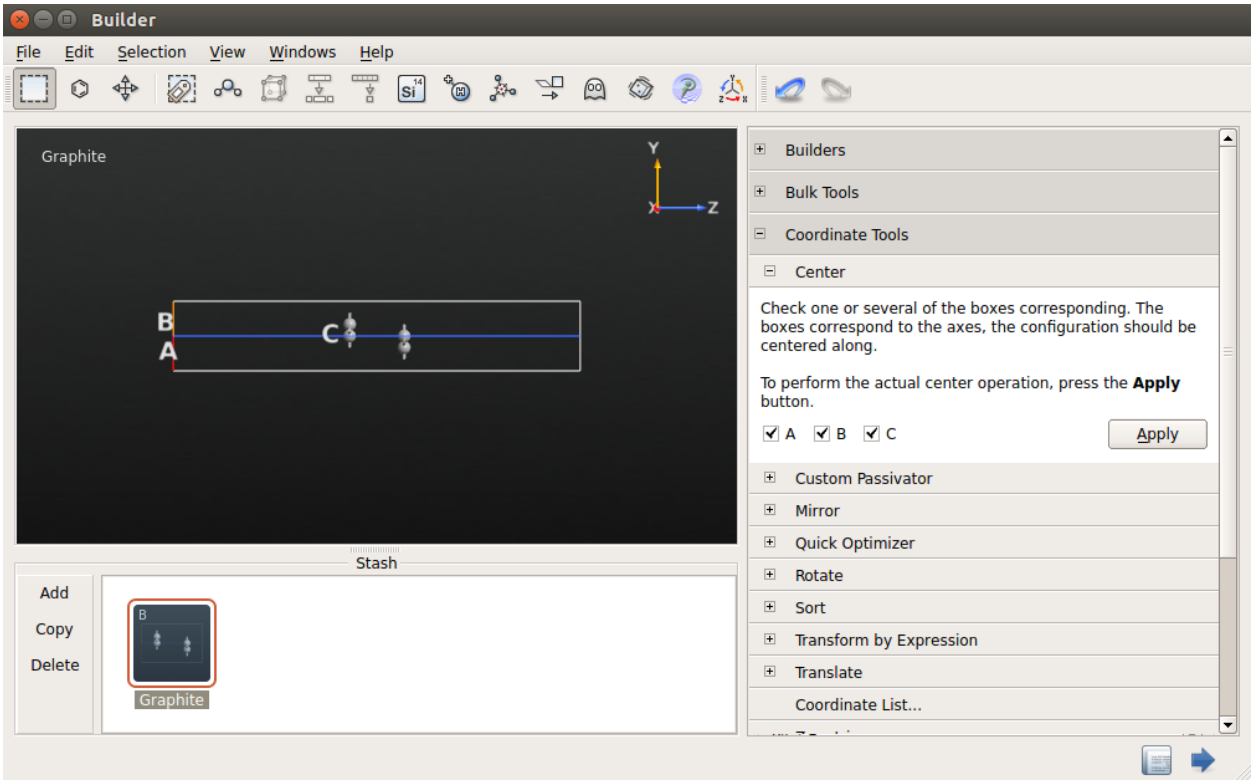
2. Insert graphite (not graphene!) from **Database**.

3. Open *Bulk Tools* → *Lattice Parameters*. Select Cartesian coordinates and set the value of *c* lattice constant to be 25 Å.



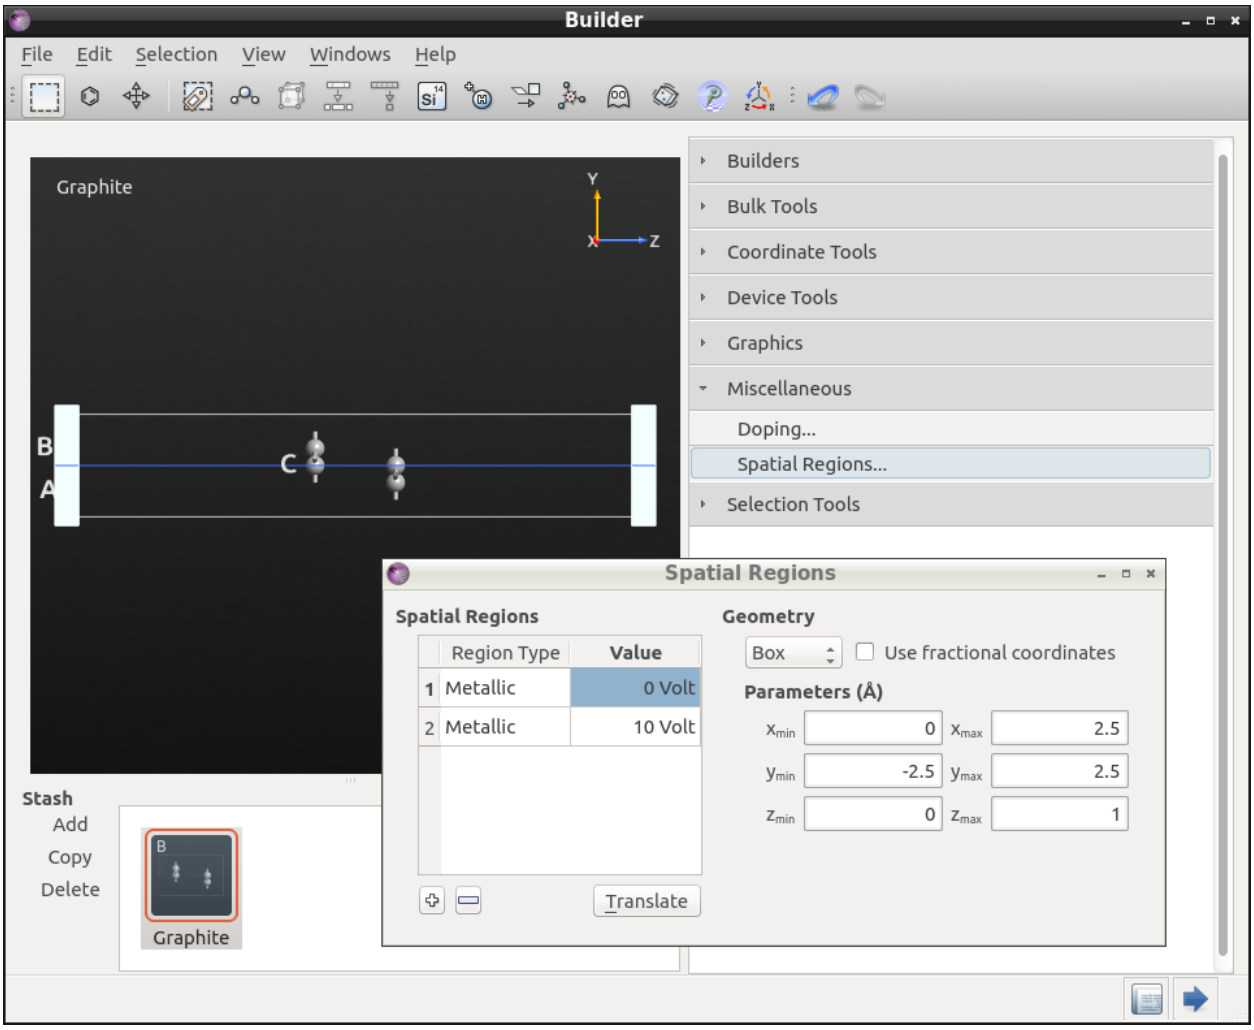


4.Go to *Coordinate Tools* → *Center* and click *Appy* to center the system.



5. To insert the metal electrodes, open *Miscellaneous* → *Spatial Regions*, right-click the table (the area under the headers Region Type/Value) and click *Insert region* twice.

6. Set the voltage to 0 V for the first metallic region, and 10 V for the second. Change their size so that they cover the entire hexagonal unit cell (see the figure below). It does not matter if the regions stick outside the cell, those parts will be ignored in the calculation anyway.

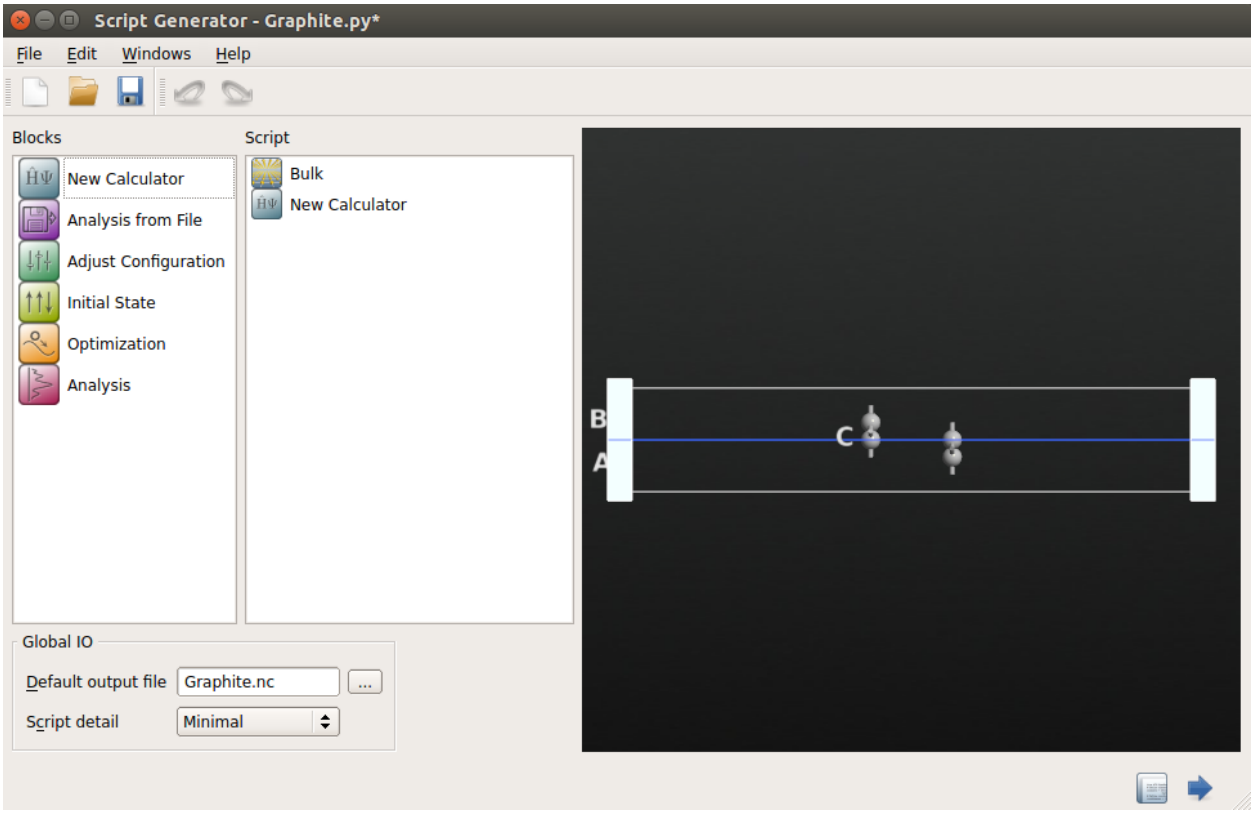


The applied voltage results in 4 V/nm in the z direction, just above the field that has been found in experiments to open a band gap.

Calculation and analysis

We will then analyze the band structure of the graphene bilayer under the static electric field.

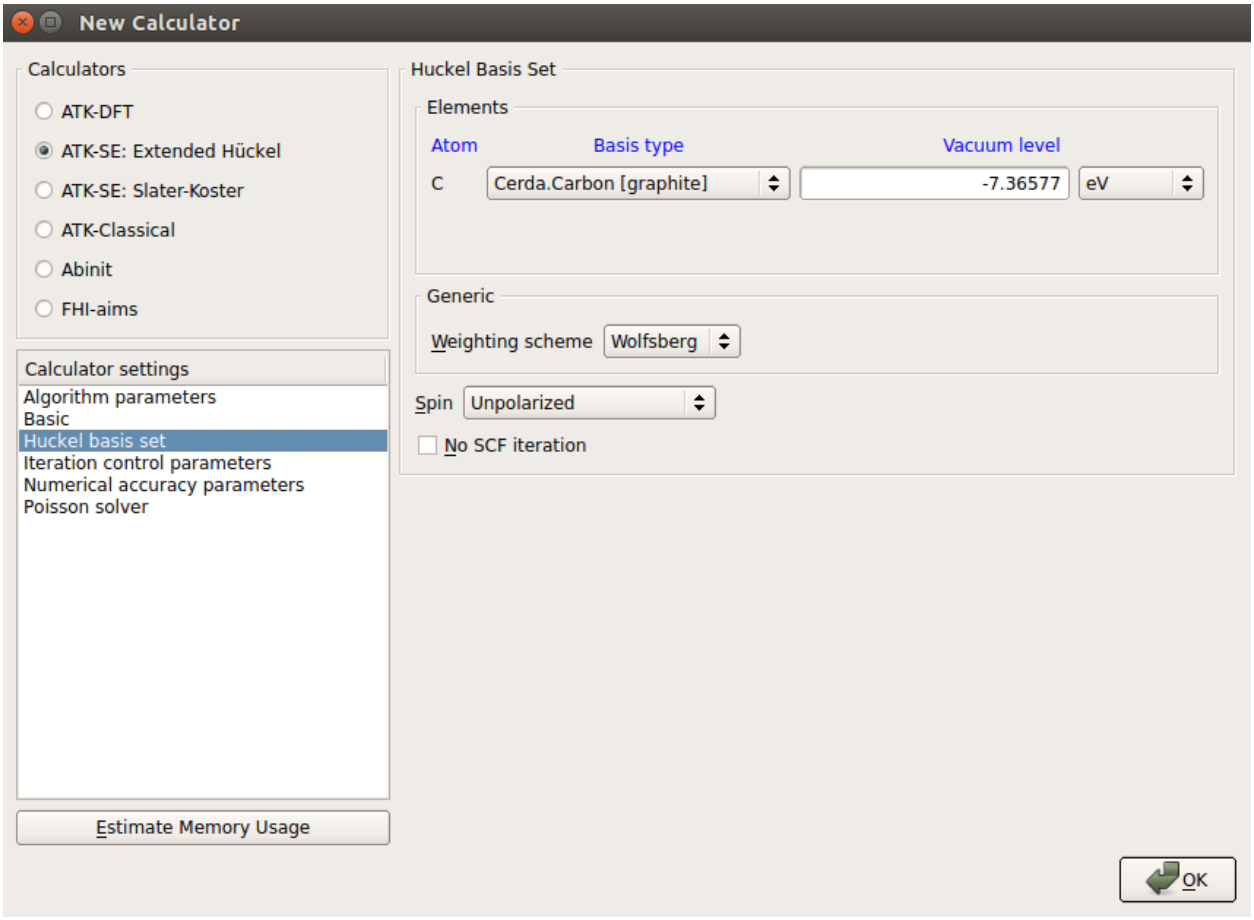
1. Send the graphene bilayer structure to **Script Generator**.
2. Insert a **New Calculator** block



3. Open the **New Calculator** block, and choose the *ATK-SE: Extended Hückel* method. For good accuracy, set the k-points to be 9x9x1.

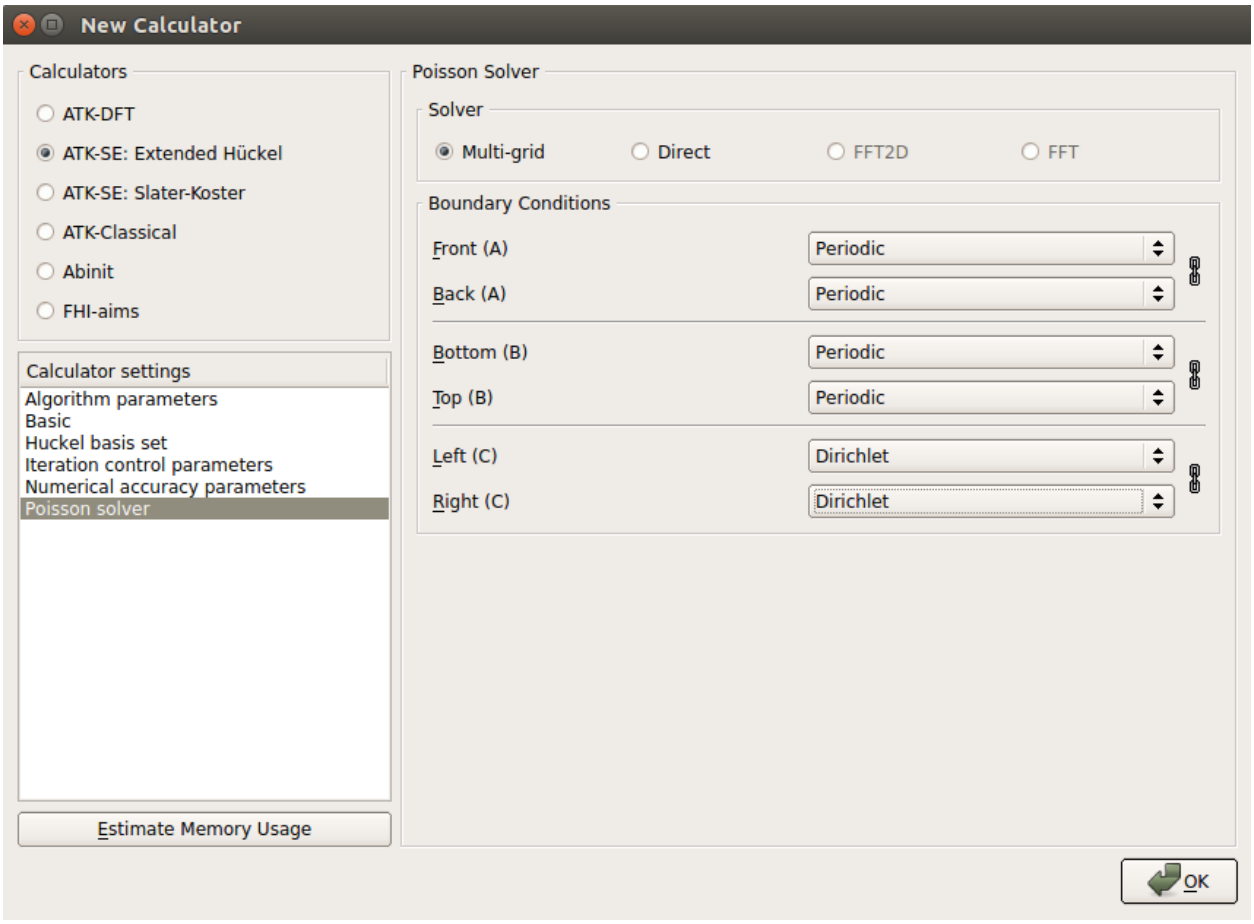
4. Under *Huckel basis set* select the *Cerda. Carbon [graphite]* basis set, which describes the sp2 bonding of graphene very well.

5. Untick the *No SCF iteration* option to carry out the computation self-consistently.



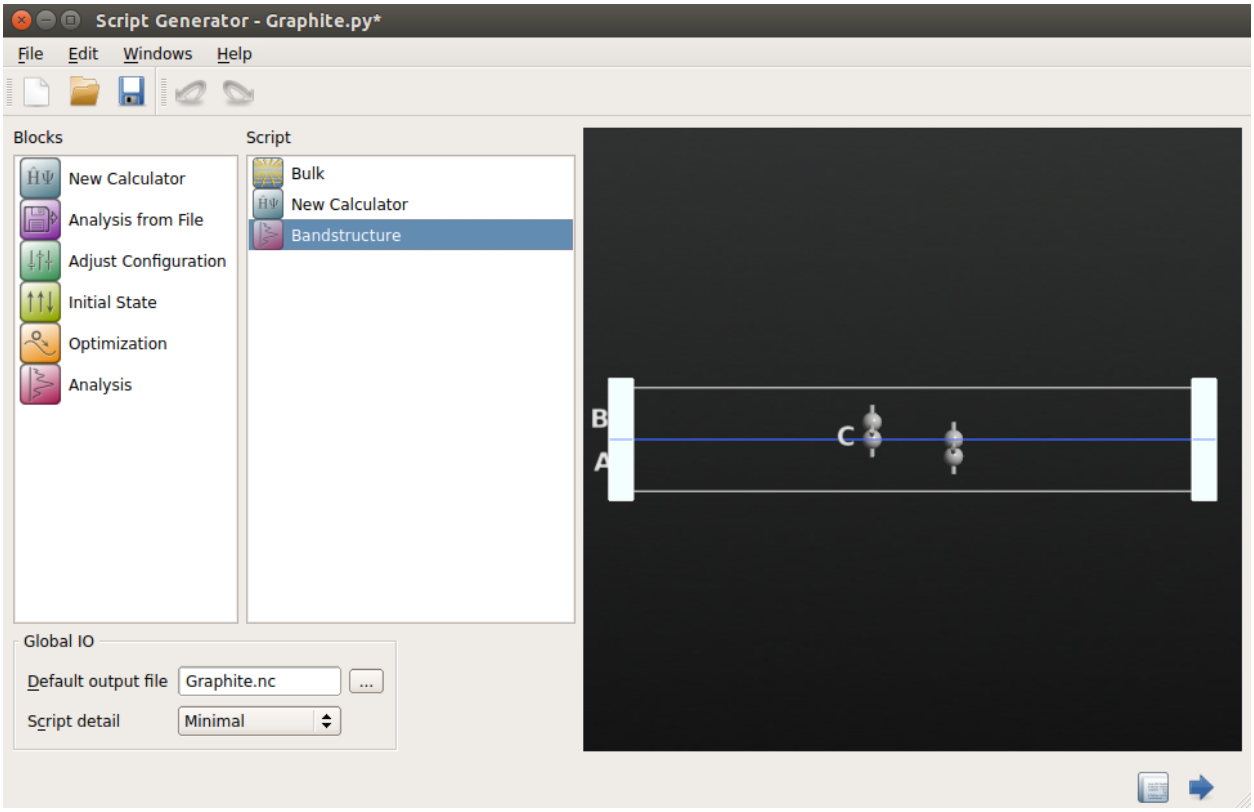
Warning: It is extremely important to include self-selconsistency; otherwise the field will not have any effect at all!

6. Go to *Poisson solver*, set *Multi-grid* in **Solver**, and choose *Dirichlet* in **Boundary Conditioins** on both sides in the C direction.

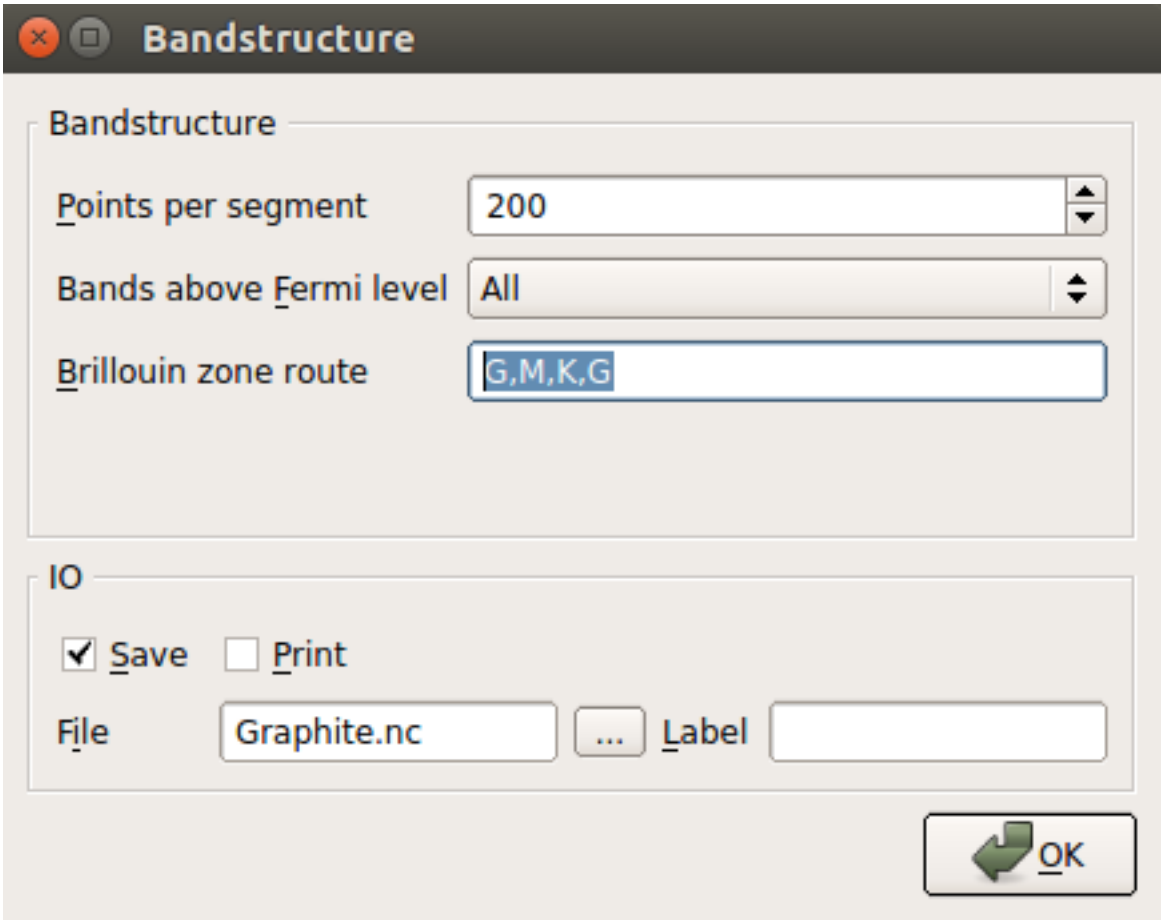


Note: For this particular calculation, you can choose any boundary condition in the C direction since the metal gates will fix the potential at the boundaries anyway, but *Dirichlet* is the physically correct condition when a constant value of the potential is desired at the boundary.

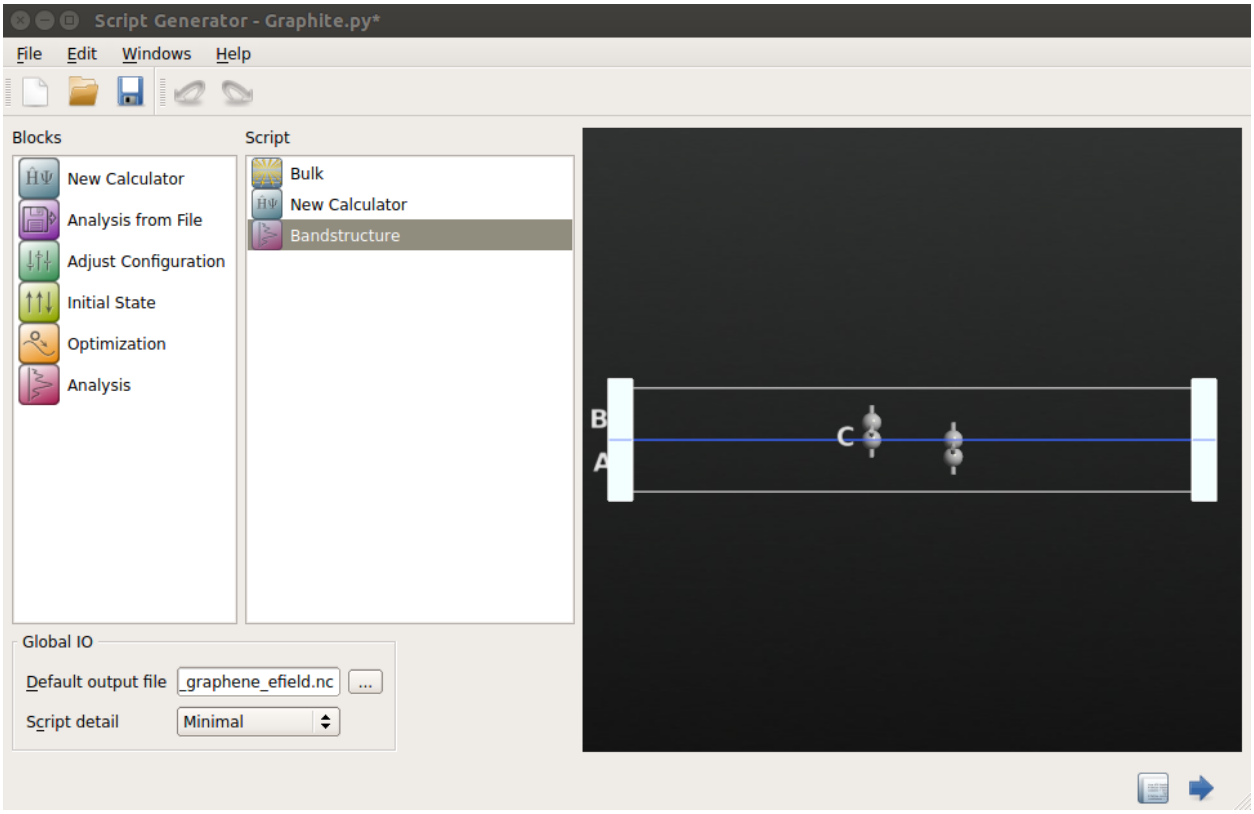
7. Add a **Bandstructure** block by clicking *Analysis* → *Bandstructure*.



8.Double-click the **Bandstructure** block and change the route to G, M, K, G. Also increase the number of points per segment to 200.



9.Name the output file *bilayer_graphene_efield.nc*.



10. Send the calculation to **Job Manager**, save the Python script in the window that appears and run the calculation. It should take no more than 20-30 seconds to run.

    After the calculation, visualize the band structure and zoom in around the K point, where a band gap is opening with increasing the strength of the electric field. The following figures, from top to bottom, show the band structure of the bilayer graphene with an applied electric field of 0, 10, and 20 Volts, respectively.

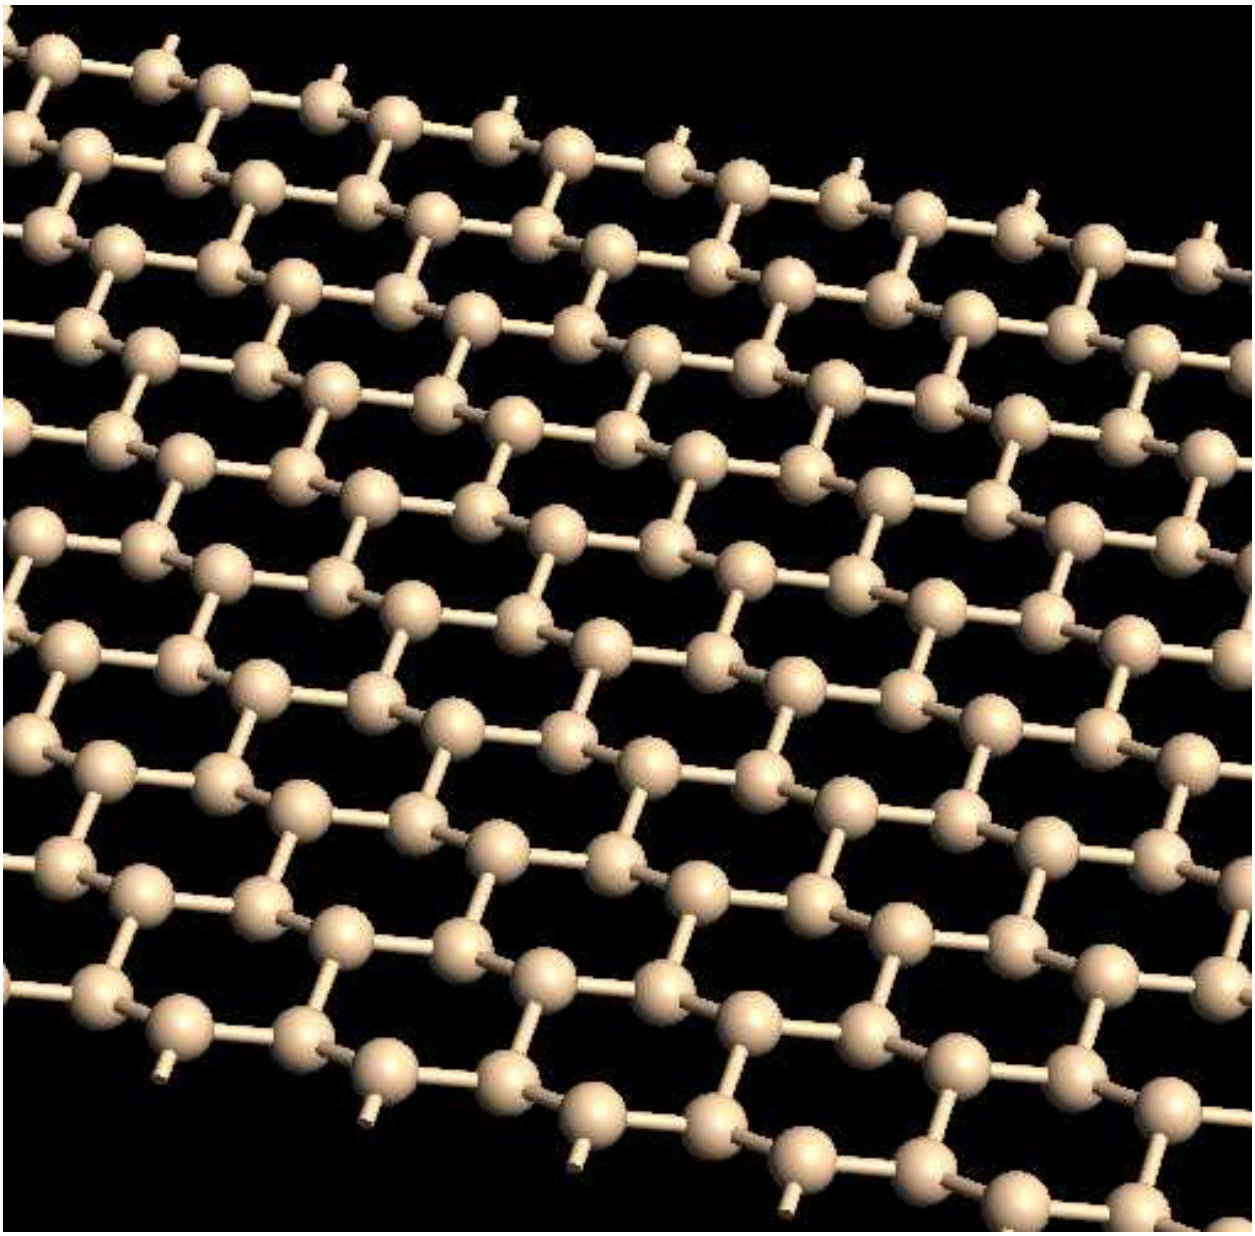
Note:

- You can use DFT as well, the results will be similar.
- No attention was paid to the interlayer distance. You can change it a bit to see how the band structure changes. Note, however, that you cannot use DFT/GGA to optimize this distance because no energy minimum will be found, due to the absence of dispersion corrections (the layers are bound by Van der Waals forces, not captured in standard GGA). LDA works, fortuitously, because of a cancellation of errors, but the results cannot really be trusted.

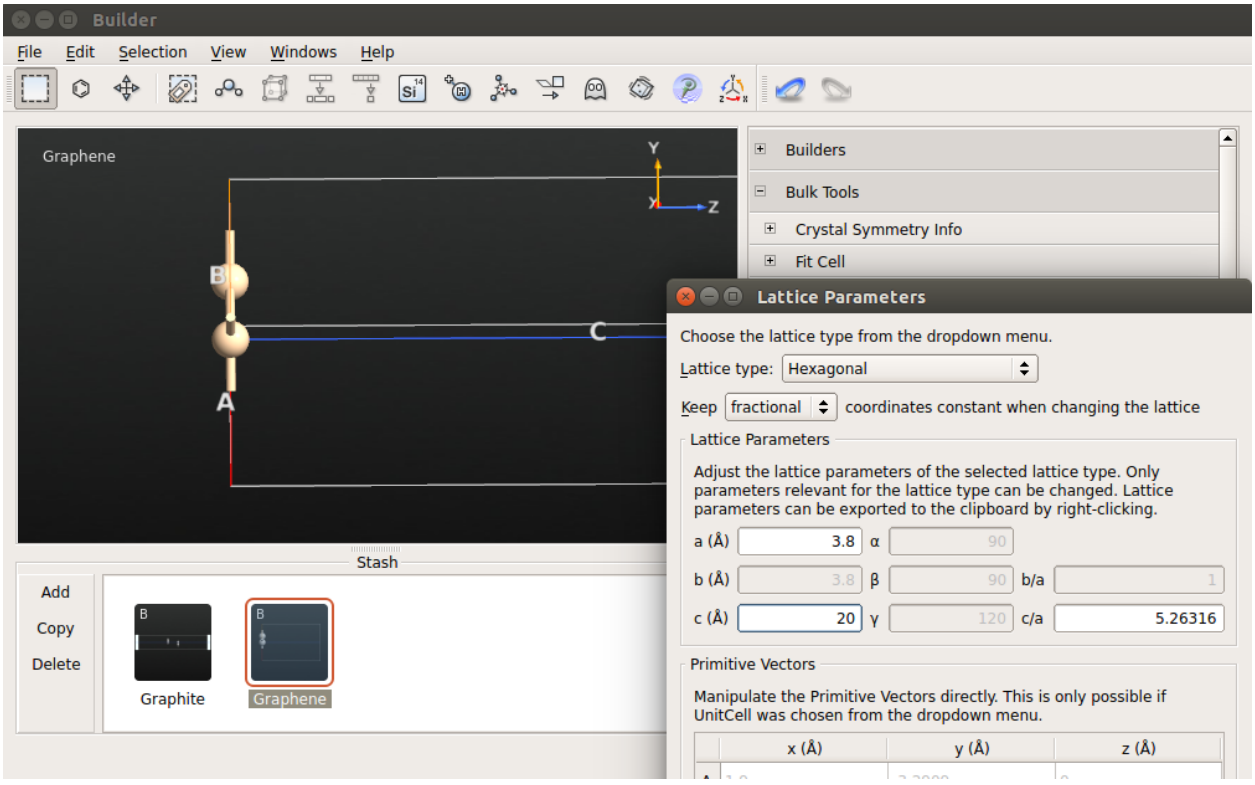
Silicene

To study the effect of electric fields on silicene you first need a good model of this material. The approach will be to start with graphene and turn it into silicene, optimize the geometry, and then repeat the same steps followed to calculate the bilayer graphene under the presence of an electric field.

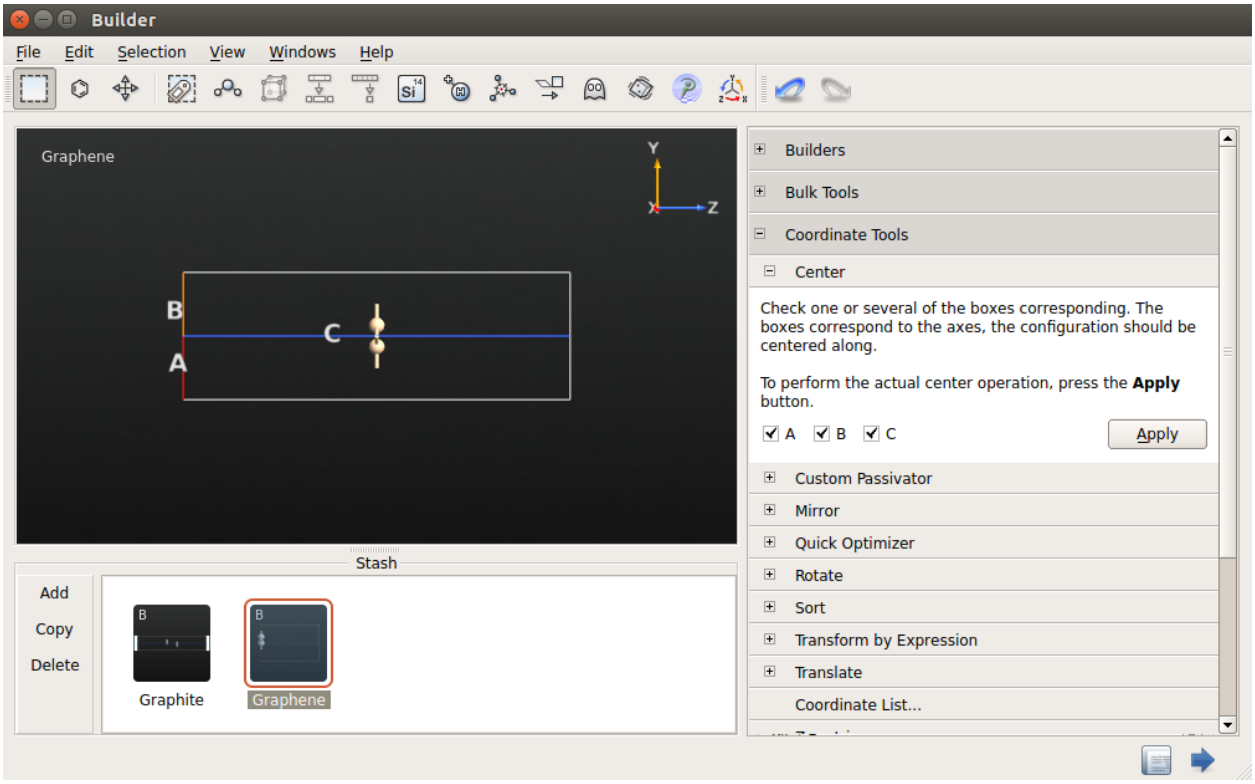


Optimizing the geometry

1. In **Builder**, add graphene (not graphite this time) from **Database** to **Stash** following the same steps explained above for the bilayer graphene.
2. Change the two C atoms to Si by selecting them (using the left mouse button while holding down the `Ctrl` button of your keyboard) and using the *Periodic Table* tool .
3. The lattice constant of silicene is not the same as for graphene, but rather than guess it, it will simply be part of the geometry optimization to determine it. To start from a reasonable guess, click *Bulk Tools* → *Lattice Parameters*. Make sure to keep the fractional coordinates constant, set the lattice parameter a to be 3.8 Å and increase the c lattice parameter to 20 Å.



4. In **Builder**, go to *Coordinate Tools* → *Center*, in order to center the configuration.



5. The flat geometry where both Si atoms are in the same plane is a local minimum in the potential energy surface. Therefore, click the *Rattle* tool a few times to add a small perturbation to the coordinates. This ensures that the geometry optimization will converge to the global minimum.

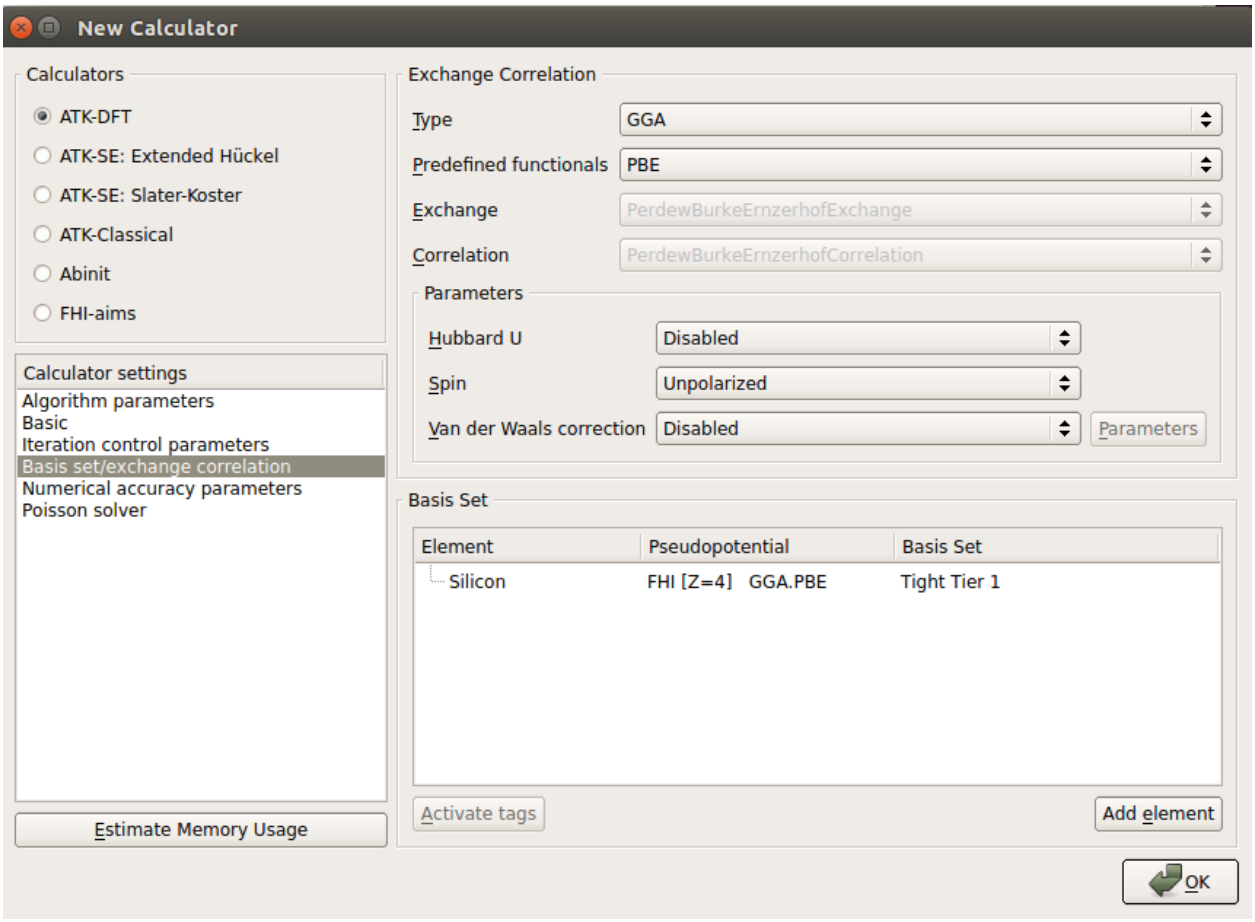
6. Send the geometry to **Script Generator** by using the *Send To* button .

7. In **Script Generator**, insert **New Calculator** and **OptimizeGeometry** blocks by double-clicking the icons in the *Blocks* panel:

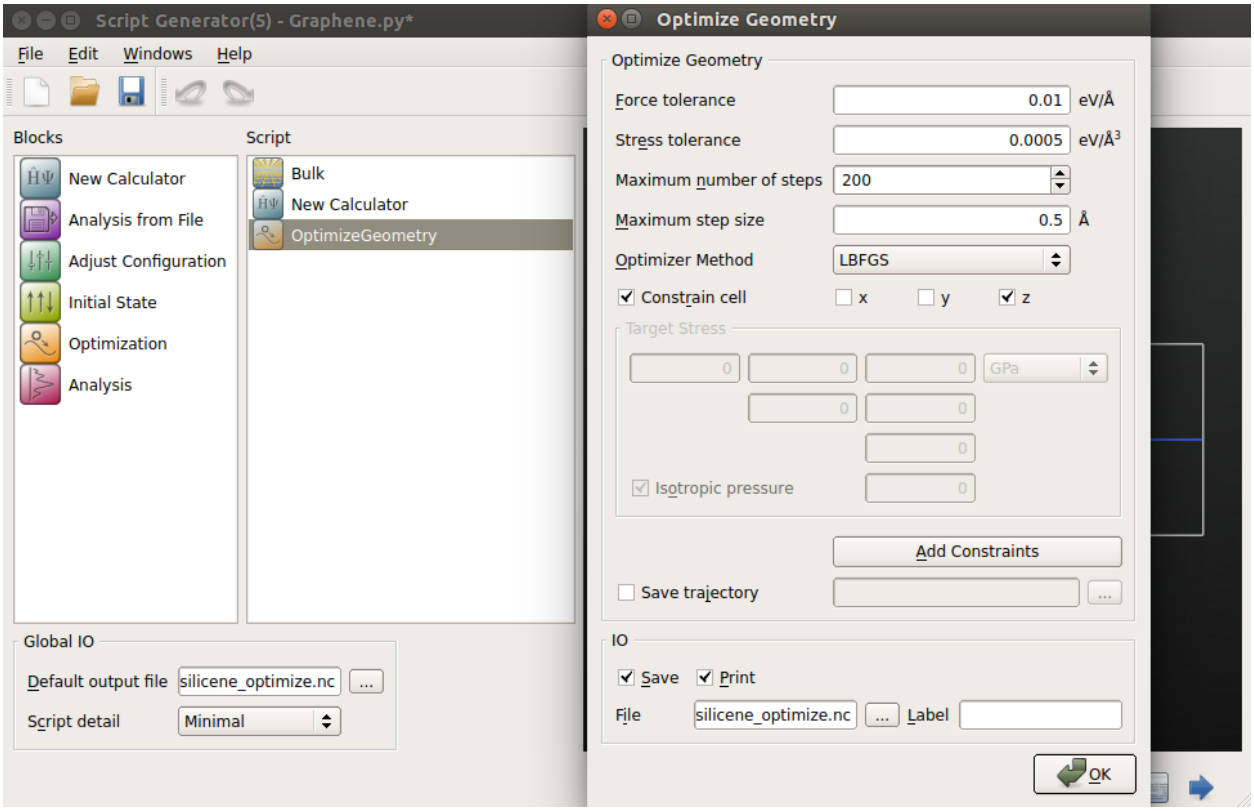
- New Calculator.
- *Optimization* → *OptimizeGeometry*.

8. Use 21x21x1 k-points for good accuracy, and choose GGA-PBE for exchange-correlation. You can in principle use the default DoubleZetaPolarized basis set, but here you will use the Tight Tier 1 basis set, which provides slightly better

results.



9. In the **OptimizeGeometry** block, set the force tolerance to be small (0.01 eV/Å) and the stress tolerance to be even smaller (0.0005 eV/Å^3). Unconstrain the cell in the x and y directions.



10. Name the output file *silicene_optimize.nc* and save the Python script.

11. Send the script to **Job Manager**, save the script and run the job. The calculation will take about 10 minutes. When it finishes, drop the Bulk Configuration with ID *gID001* on **Builder**, and inspect the geometry. You will find a nicely optimized silicene sheet with a buckling of about 0.5 Å and an optimized lattice constant of 3.86 Å. Both values are in good agreement with those reported in the literature in[1] and[2].

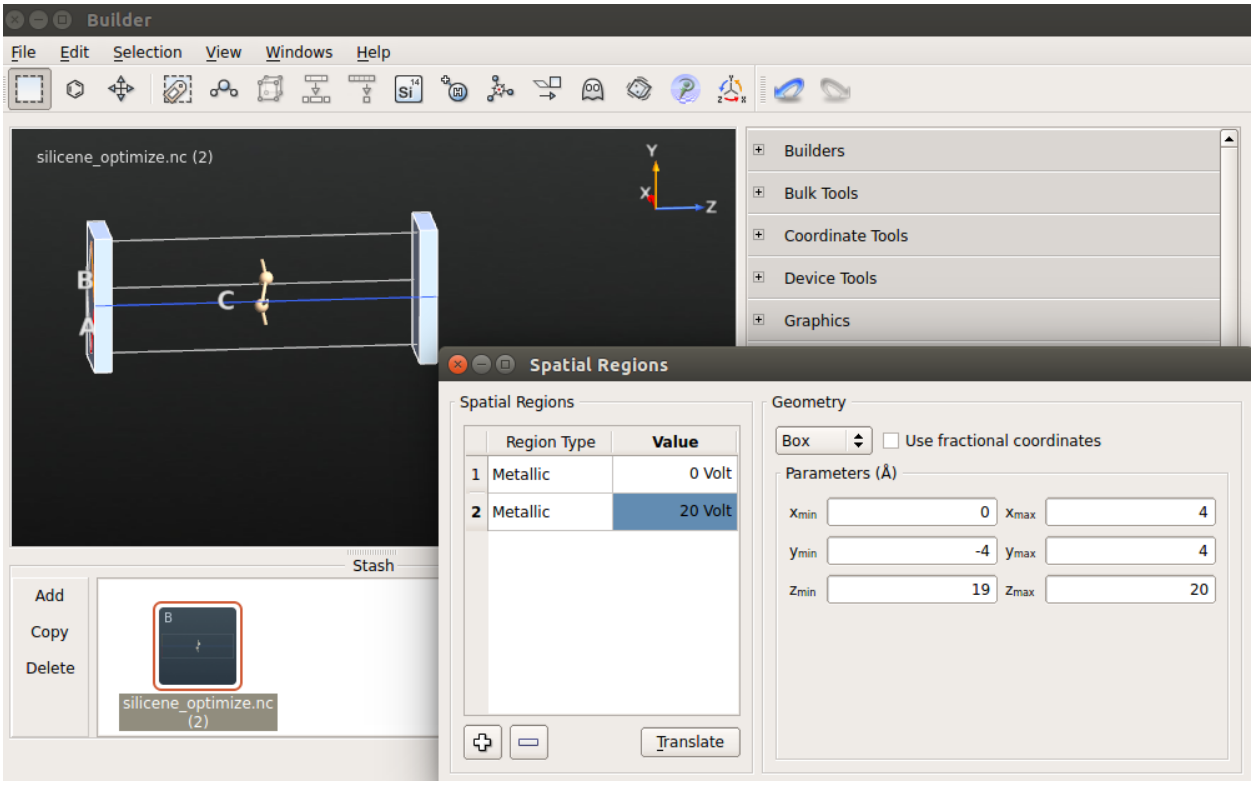
[2] N. D. Drummond, V. Zolyomi, and V. I. Falko, Electrically tunable band gap in silicene, Physical Review B 85, 075423 (2012)

Band structure

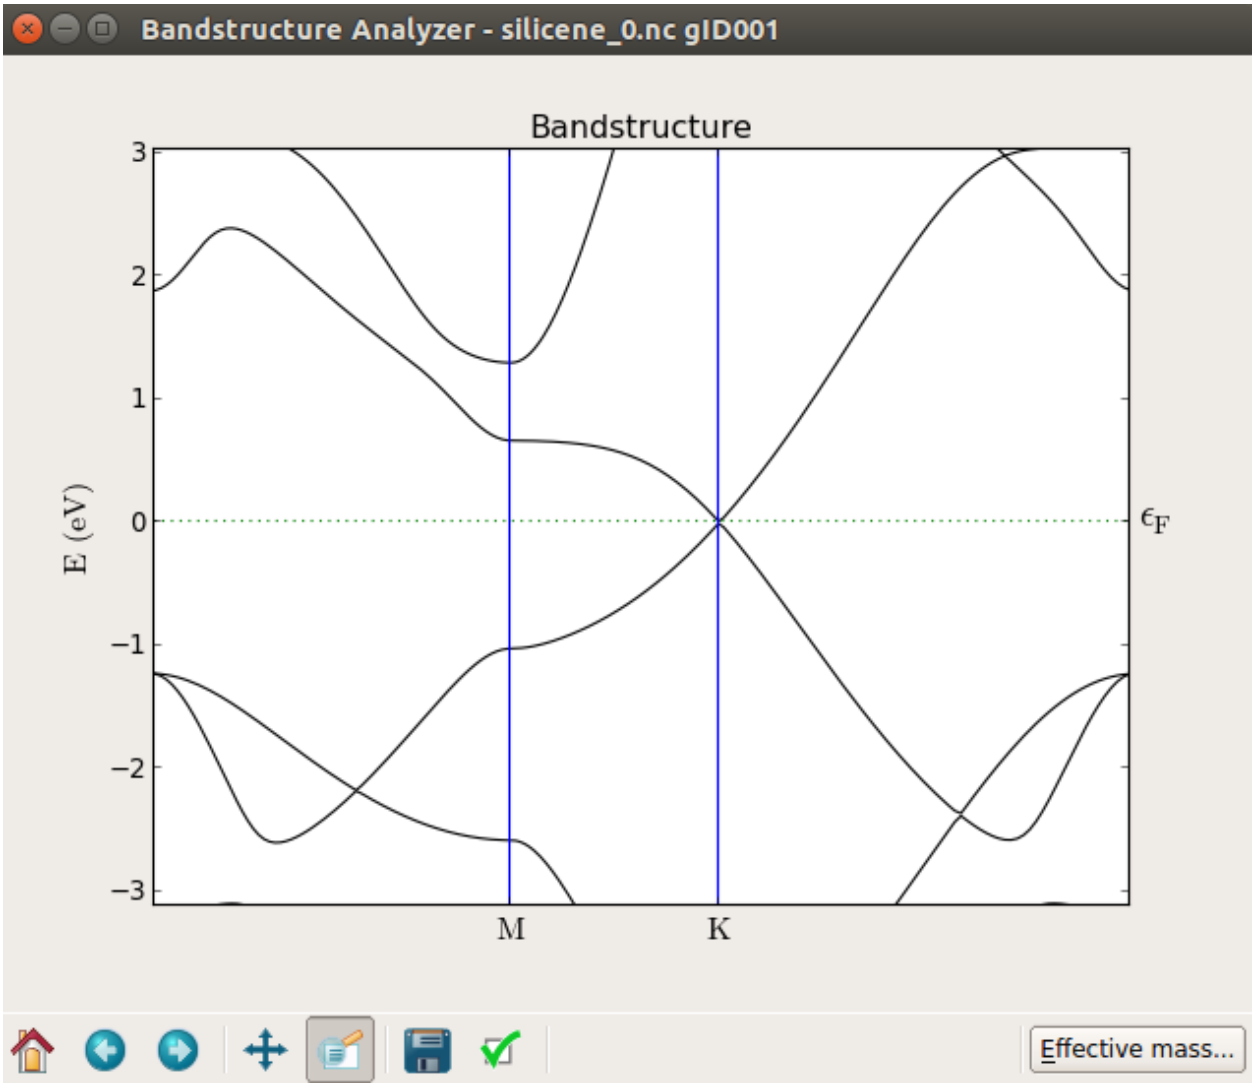
Using the optimized structure, repeat the steps above for the bilayer graphene to insert metallic gates and compute the band structure with electric fields. Notice that, in the case of silicene, you need to make the spatial region larger in the XY plane, since the cell is also larger. Use 20 V as the voltage on the second electrode.



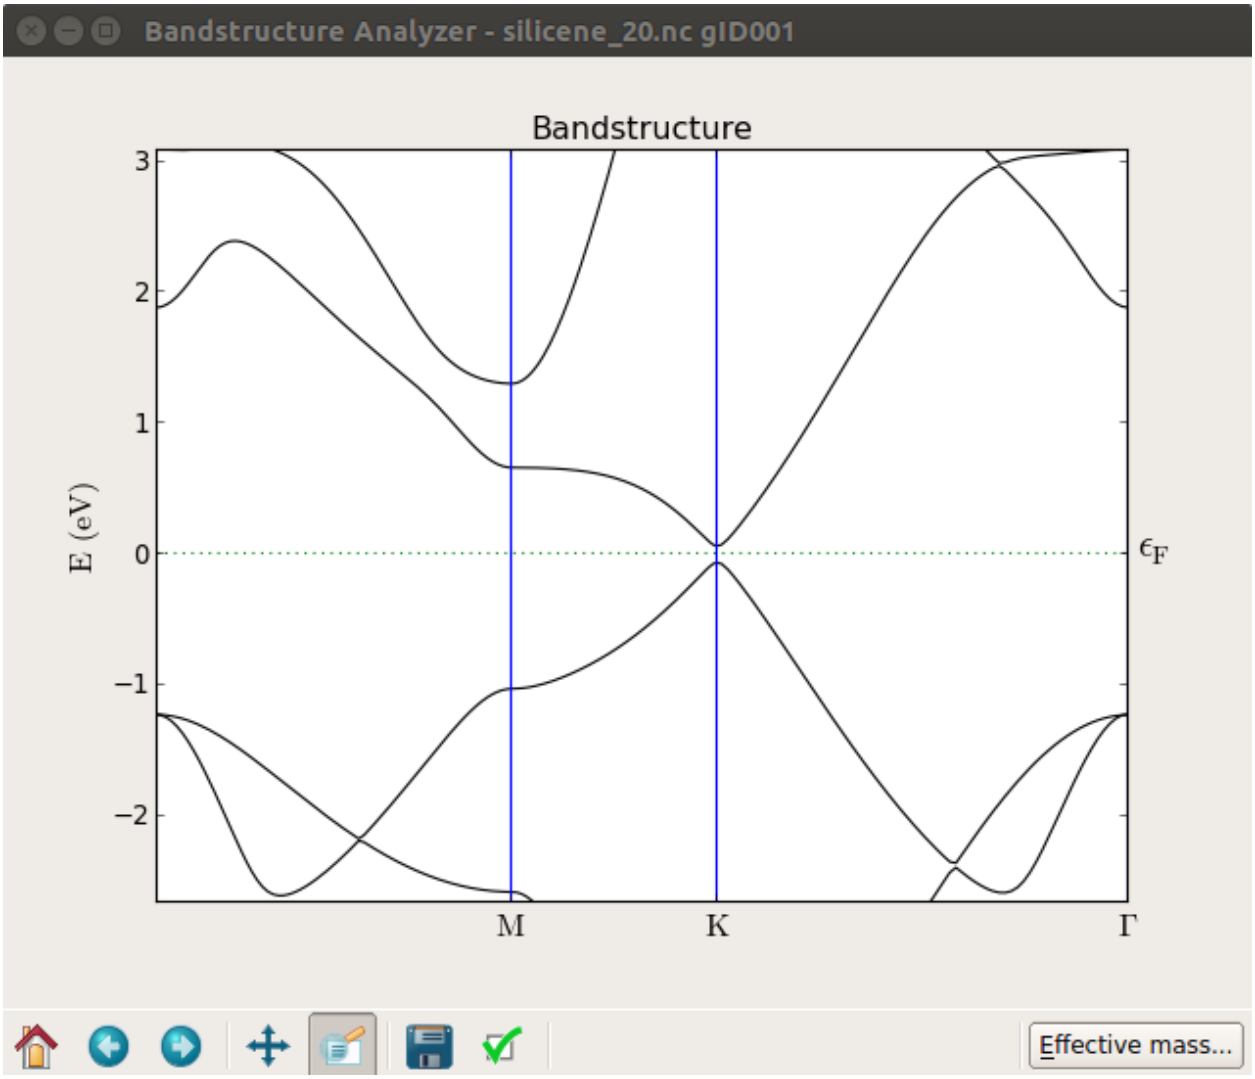
Note: You should use the same calculator settings as for the optimization. The calculation will take less than a minute.

In the plot below you can see the band structure at zero field (top) and with 20 V applied on the gate (bottom), which produces a band gap of about 0.1 eV. By trying different values of the voltage you will find that the band gap increases essentially linearly with the field as shown in[3].

[3] R. Zhou, Structural And Electronic Properties of Two-Dimensional Silicene, Graphene, and Related Structures, Master Thesis, Wright State University, Electrical Engineering, Dayton OH, USA (2012)



Bandstructure Analyzer - silicene_0.nc gID001
Bandstructure
E (eV)
3
2
1
0
−1
−2
−3
M
K
ϵ_F
Effective mass...



Notice that in this case, if you look closely, the band gap is not exactly at the K point.

Note: If you apply a transverse field to a single graphene layer, no gap opens up. The reason is that the graphene is completely flat, and so the field just gives a constant shift of the potential. In the case of silicene the gap appears because the sheet is naturally buckled.

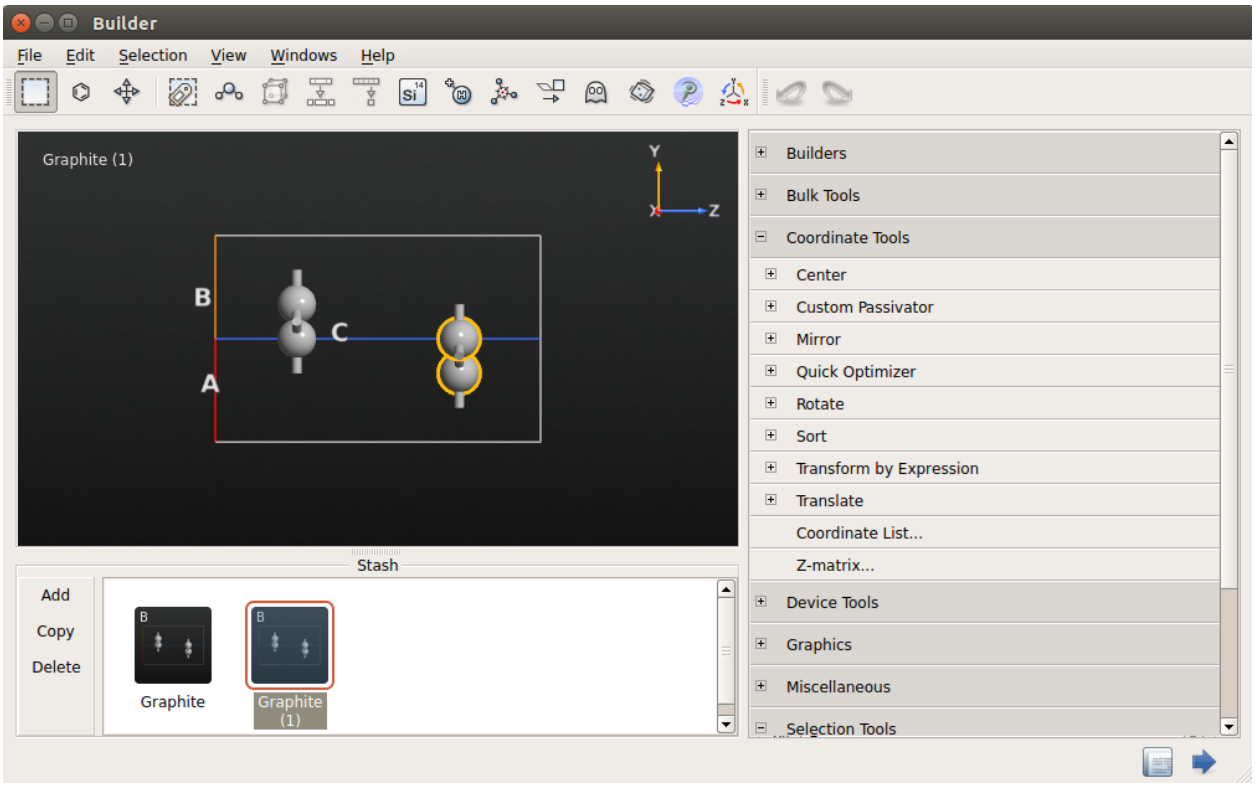
3.6.3 Commensurate supercells for rotated graphene layers

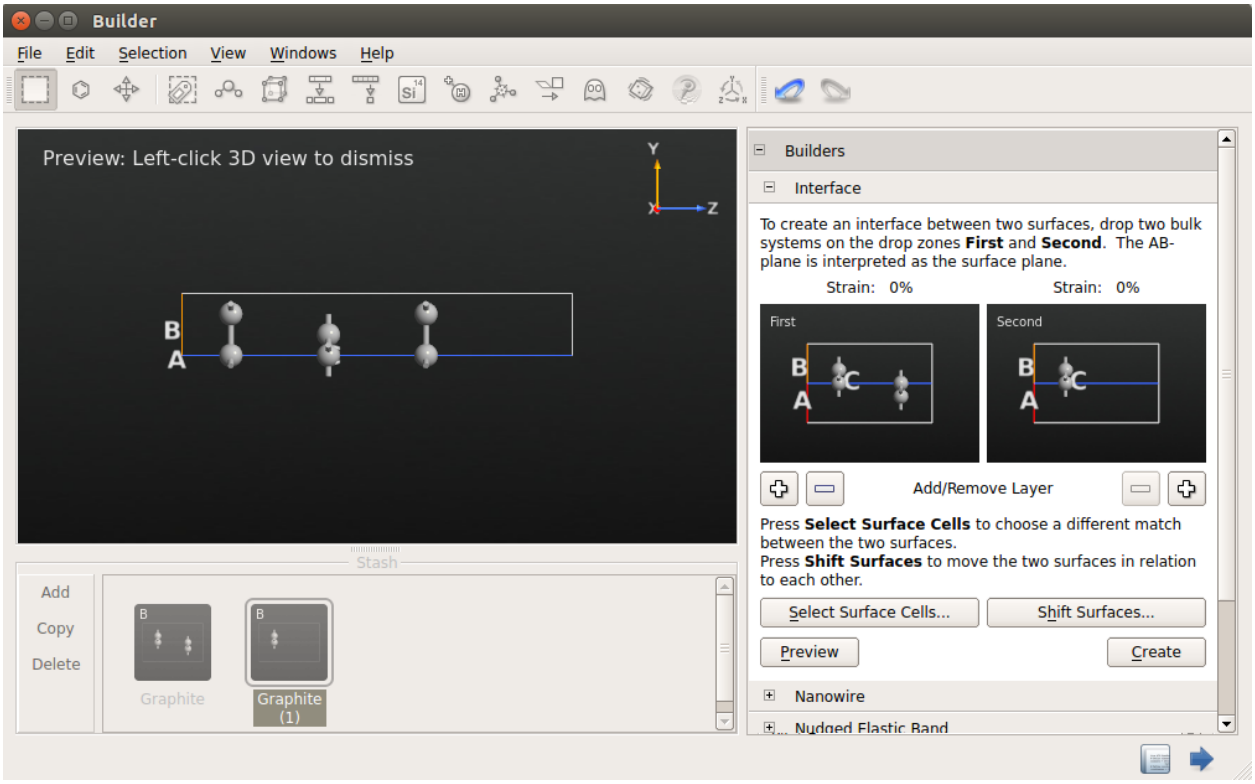
QuantumATK: Interface builder Platforms: In this tutorial you will learn how to set up a commensurate supercell for rotated graphene layers. You will consider a case from Ref.[1] as an example in which the topmost layer of a three layer graphene stack is rotated by 21.8ř with respect to the other two layers.

1. In the **Builder**, Click *Add* → *From Database*. Locate *graphite* and add it to the **Stash** by clicking the icon in the lower right-hand corner.
2. In the **Stash**, select the newly added item and click *Copy* to make an identical copy of the graphite structure.
3. Select the copied structure and delete the uppermost layer of carbon atoms highlighted in the picture below.

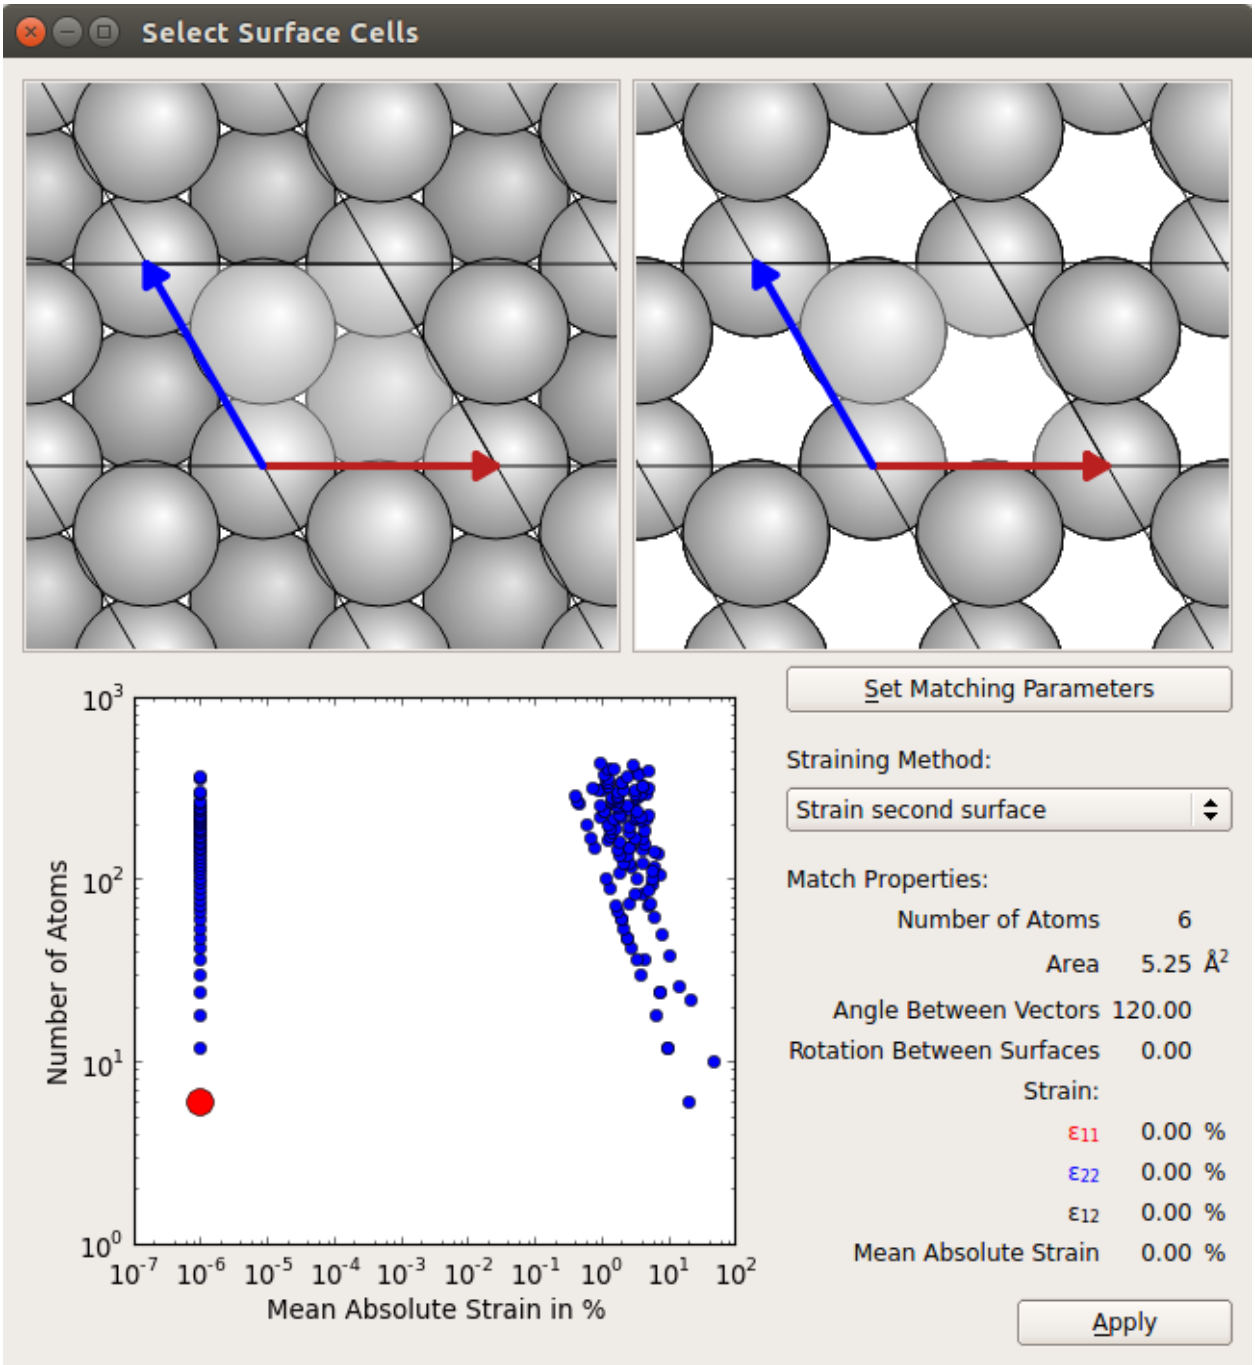


[1] E. Cisternas, M. Flores and P. Vargas, Phys. Rev. B 78, 125406 (2007)

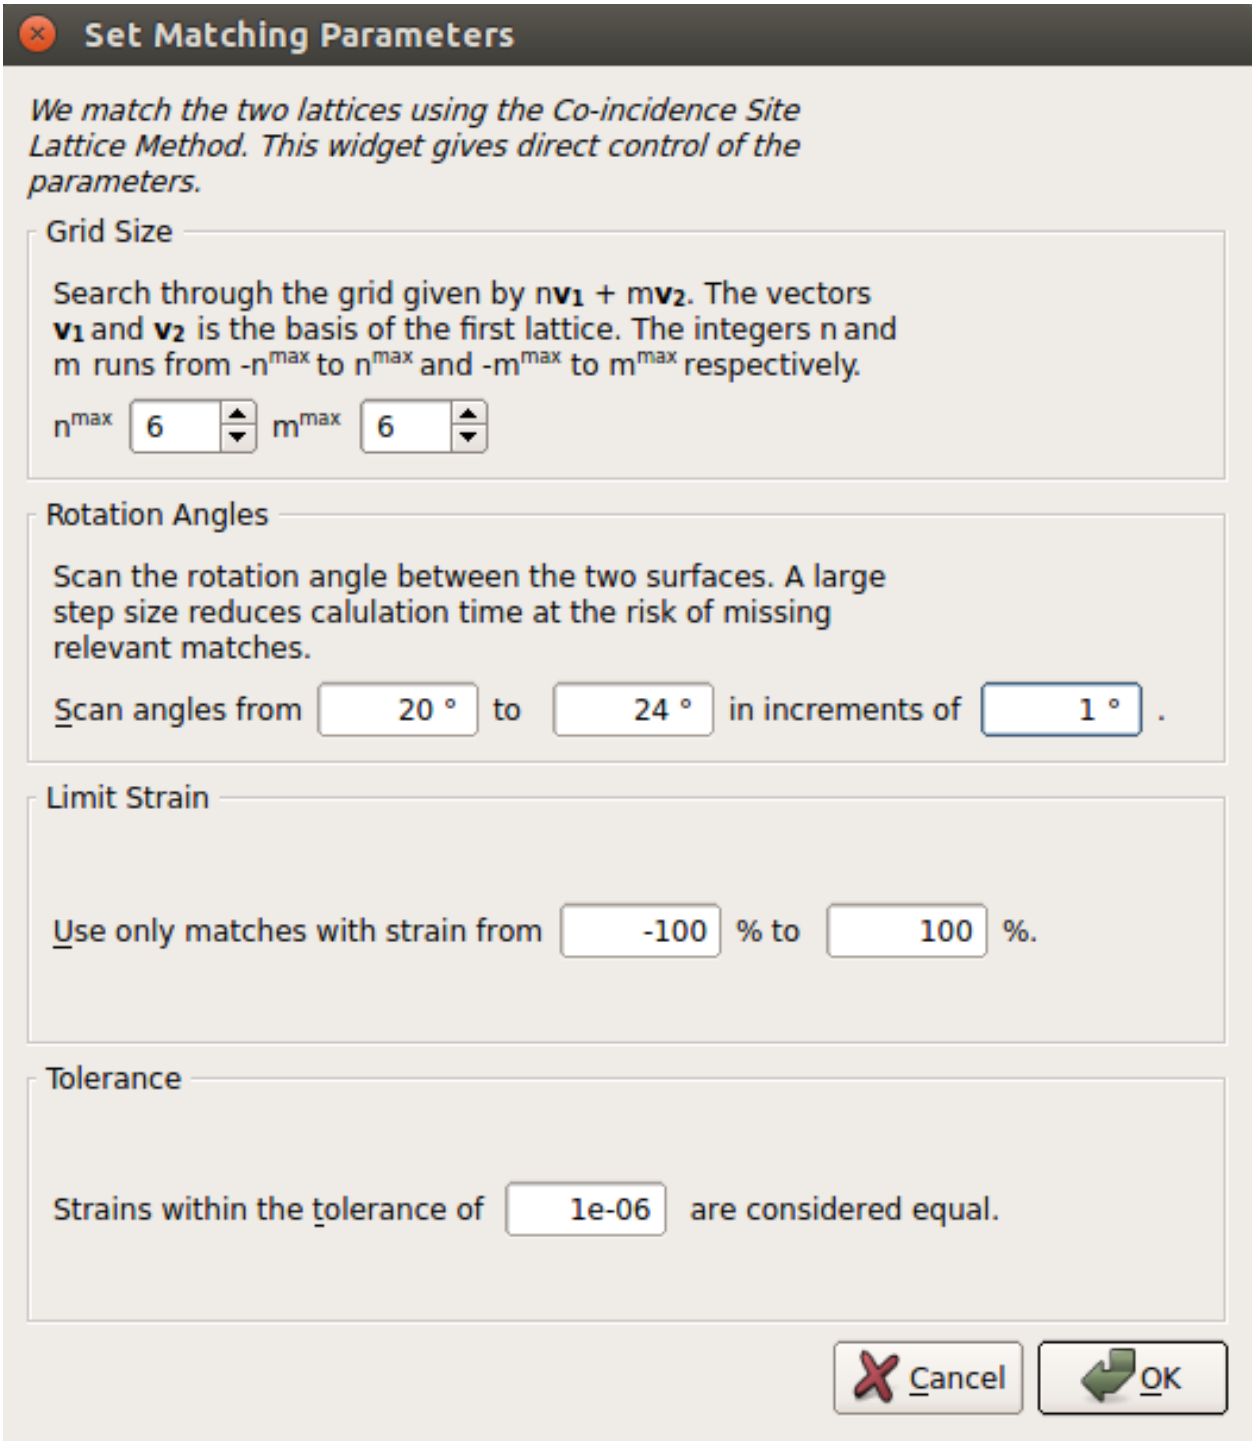
4.Click on *Builders* → *Interface tool*. Drag the 2-layer structure and drop it in the first slot, and the 1-layer structure in the second, as shown in the figure below.



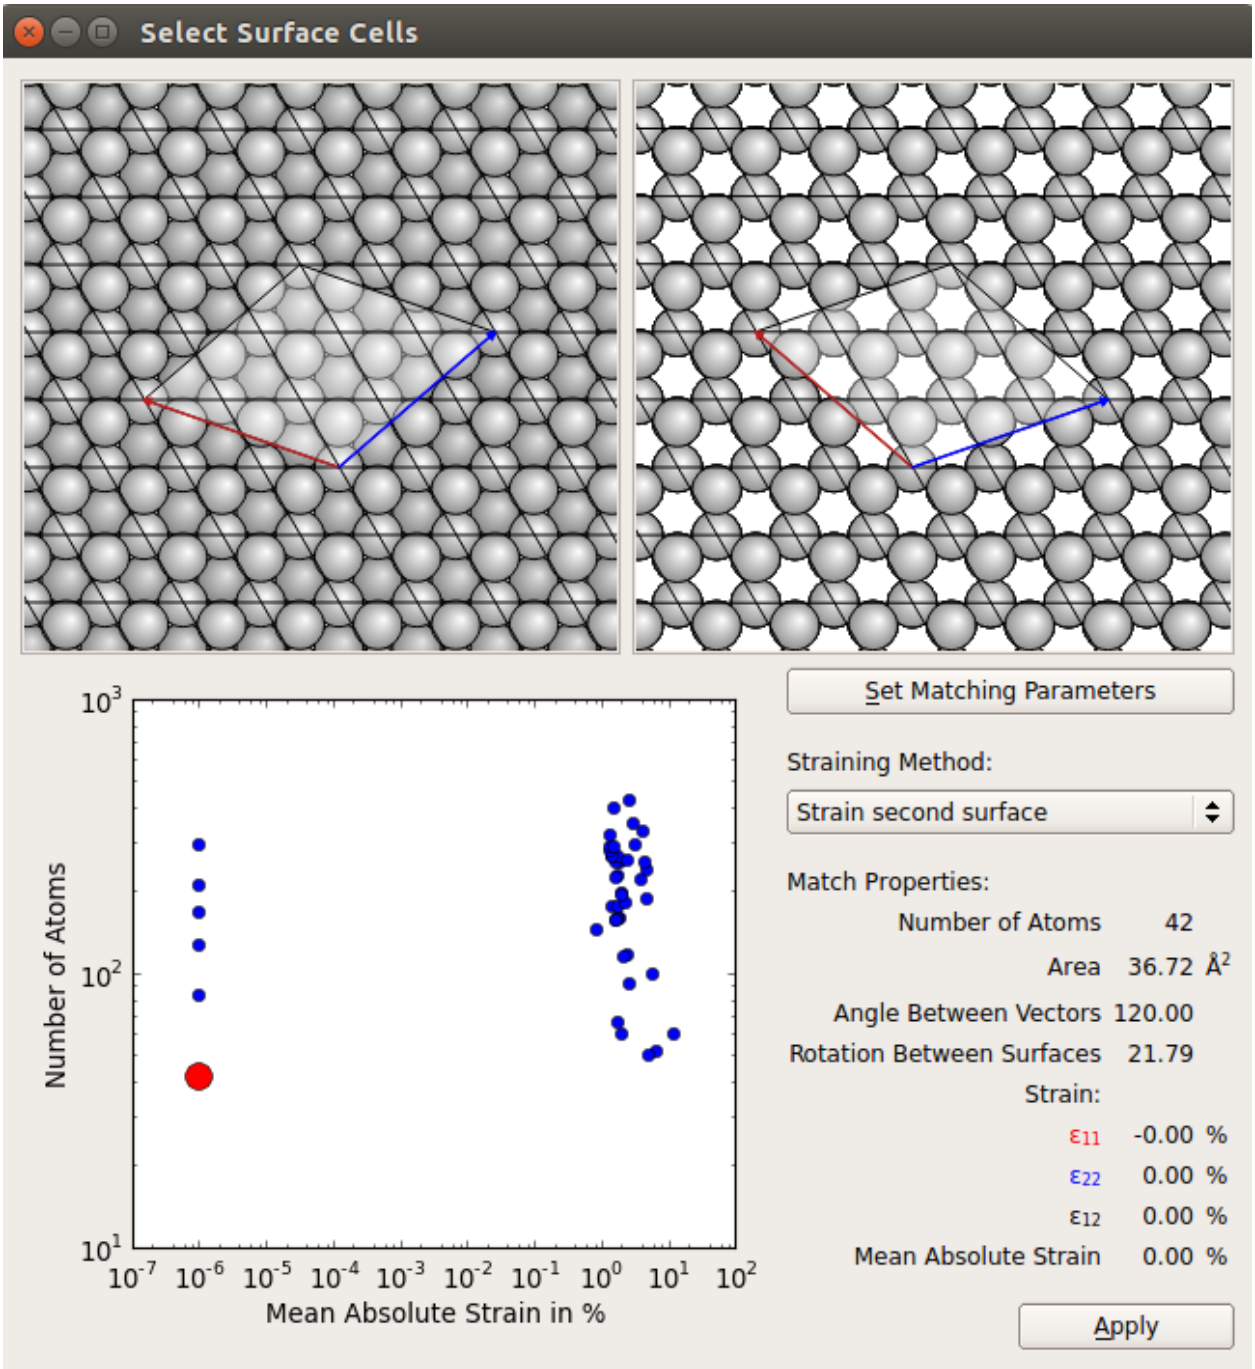
5.Click the button *Select Surface Cells*, and in the window that opens up click the button *Set Matching Parameters*.



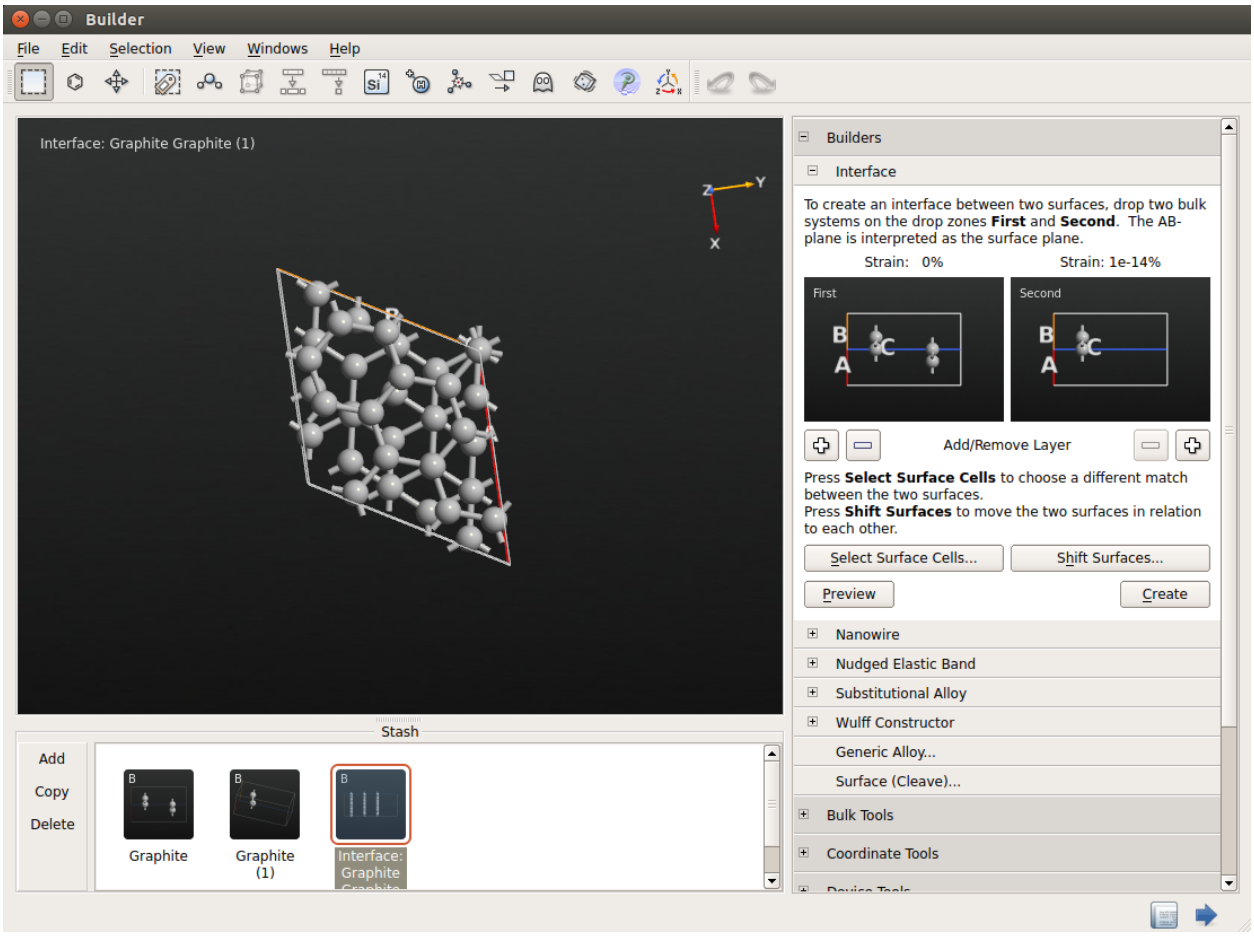
6. In the **Set Matching Parameters** widget that opens up, set the range of rotation angles to be searched from 20ř to 24ř, in increment of 1ř, and click *OK*.



7. The structure with the lowest number of atoms is normally selected by default in the 2D plot on the left-hand bottom side of the **Select Surface Cells** widget (the red spot in the figure below). In this case this is also the structure with the lowest strain (in fact, no strain at all, i.e. its a perfectly commensurate match). This is indeed the geometry you want, with the two lattices rotated by 21.79ř one with respect to each other. Click *Apply* to select this cell.



8. In the 3D window in the **Builder** you will now see a preview of the structure. You can rotate it, and if you would prefer to change some parameters you can still do it (for instance, you can add more layers of graphite to the substrate by clicking the plus button on the left under the first slot). Otherwise press *Create* to finalize the geometry.



Additional rotated structures

For more ideas on commensurate structures, see e.g. Ref.[2]. All the structures reported in the paper can easily be built using the procedure shown above. However, as noted in the article, the number of atoms becomes very large in many cases. The simple cases shown in Figure 7 in Ref.[Page 1070, 2] are quite manageable - note that in these structures there are only 2 layers rotated with respect to each other, not 3 as above. Both A-A and A-B stacking sequences can be used, so the easiest way is actually still to build the structure as above, and then remove either the middle or bottom layers, and adjust the layer separation.

Note that in these systems it will be necessary to increase the parameters nmax and mmax too in the **Set Matching Parameters** widget. For instance, to find the 5.1ř supercell shown in Figure 7a in Ref.[2], you need to set them to 14. Notice that in this case the default suggestion in the **Select Surface Cells** widget may not be the structure with zero strain, if there are strained structures with a smaller number of atoms. So make sure to always select a structure with no strain (there may be a few, naturally take the one with the smallest number of atoms), by clicking the blue dots in the plot (the active choice is indicated by the red dot as shown above).

[2] J. M. Campanera, G. Savini, I. Suarez-Martinez, and M. I. Heggie, Phys. Rev. B 75, 235449 (2007)

Here below you can find a few examples of the rotated bilayer graphene structures that can be created using QuantumATK and the procedure explained above.

3.6.4 Spin-dependent Bloch states in graphene nanoribbons

Version: 2017

Graphene nanoribbons (GNRs) are very interesting systems for novel electronics applications. Depending on the shape of the ribbon edge, the ribbons can have metallic or semiconducting characteristics. As we will see in this tutorial, spin also plays an important role for the transport properties of GNRs.

You will use the capabilities of **QuantumATK** and **ATK** to study the spin-dependent bandstructure of a zigzag GNR. These ribbons are metallic if the calculation is performed without accounting for spin, but when spin is included, a band gap opens up. By plotting conduction and valence band Bloch states for various k-points, You will see how the two spin-components are localized on opposite sides of the ribbon.

Note: This tutorial will involve calculations that take at most 5-10 minutes on a usual laptop, so there is no real need to use a separate, more powerful computer or to run the jobs in parallel.

It will be assumed that you are familiar with the basic operations in the software corresponding to the level of experience gained from completing the basic QuantumATK Tutorials. No proficiency in programming will be necessary.

Band structure of a zigzag nanoribbon

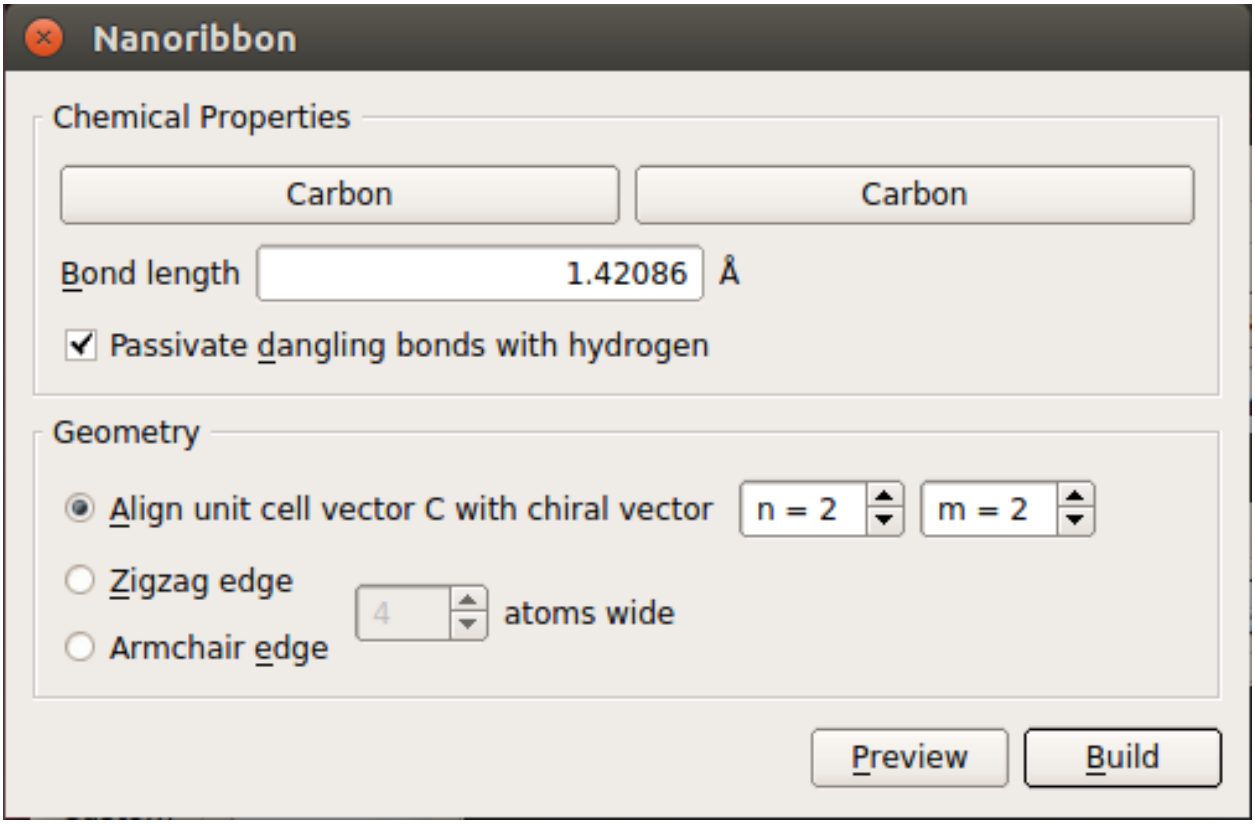
We will begin by constucting a graphene zigzag nanoribbon and calculate the bandstructure. Spin will be added in the next section.

Constructing the Graphene Nanoribbon

Start **QuantumATK**, create a new project and give it a name, then select it and click *Open*. Launch **Builder** by clicking the Builder icon on the tool bar.

In the Builder, click *Add* → *From Plugin* → *Nanoribbon*. This launches the Graphene Ribbon builder tool.

Leave all parameters at their default values and click *Build*.



The repetition is automatically set to the minimal value. This reduces calculation time and makes it easier to analyze the band structure.

There are periodic boundary conditions perpendicular to the ribbon, and the unit cell padding distance is automatically set to 10 Å, to reduce any residual electrostatic interactions with the periodic images of the ribbon.

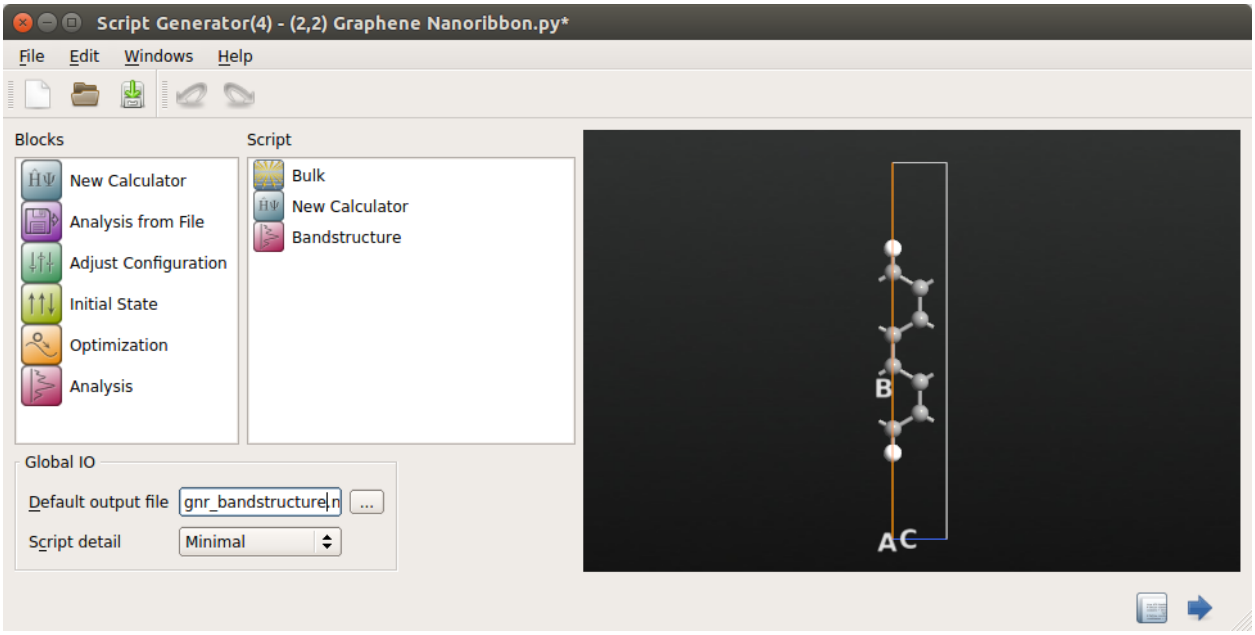
Calculating the graphene band structure

Now send the structure to the **Script Generator** by clicking the Send To icon in the lower right-hand corner of the window, and select **Script Generator** (the default choice, highlighted in bold) from the pop-up menu.

In the Script Generator,

- Add a New Calculator block .
- Add an *Analysis* → *Bandstructure* block .
- Change the default output filename to `gnr_bandstructure.hdf5`.

The Script Generator should now look like this:



Open the **New Calculator** by double-clicking it.

Most of the default parameters are good enough, but a few of them need adjustment.

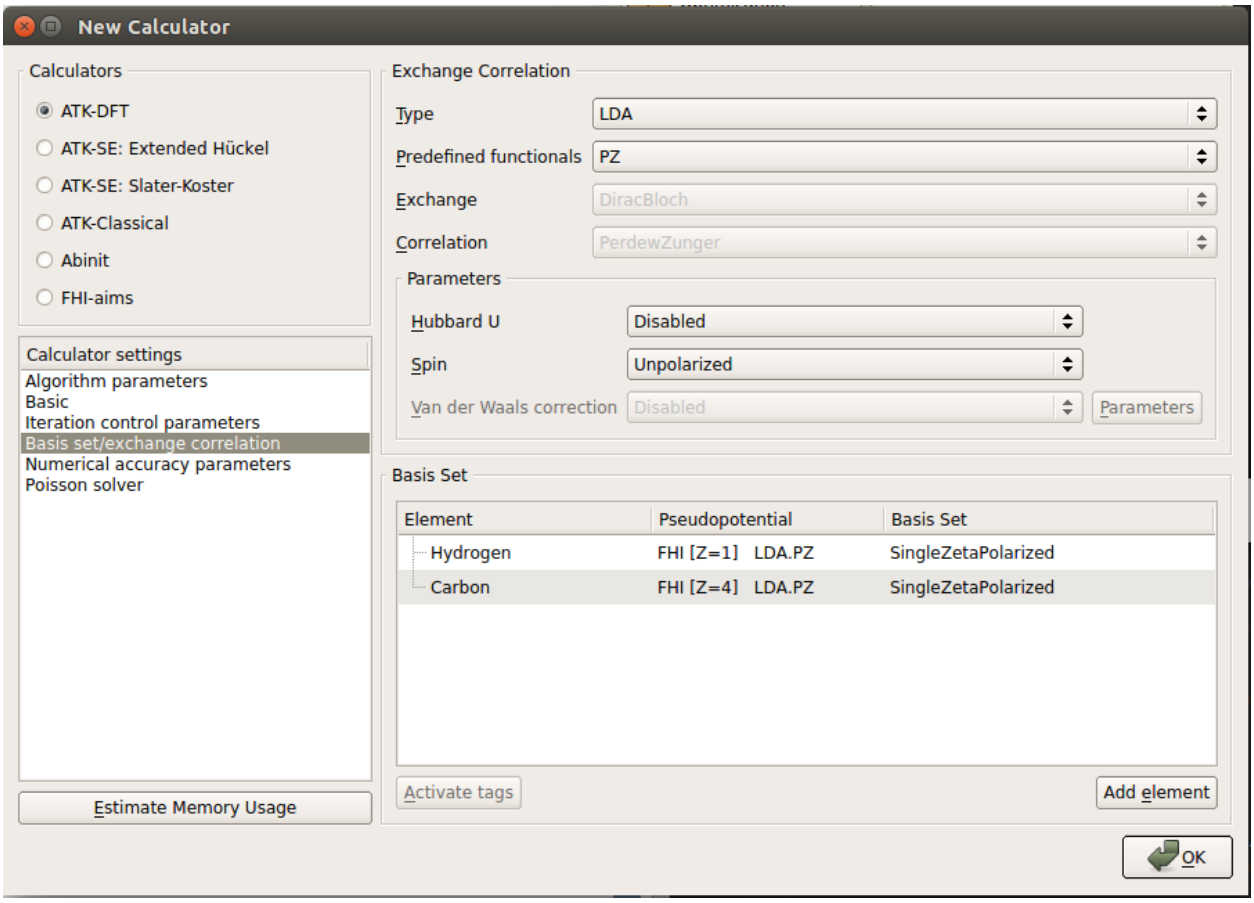
- You must carefully consider the **k-point sampling**. Since the unit cell along the ribbon is quite short, there must be a large number of k-points along the C-direction (along the ribbon).

Select 50 k-points in the C-direction.

This is a good trade-off between calculation time and accuracy. You only need a single point along the transverse A- and B-directions, since the system is not periodic in these directions.

- Next, under **Calculator settings**, choose **Basis set/exchange correlation** and reduce the basis set to SingleZetaPolarized for each element in the box on the lower right. This is to gain some speed; for this particular system, that level of accuracy is sufficient.

The calculator dialog should now have the following settings

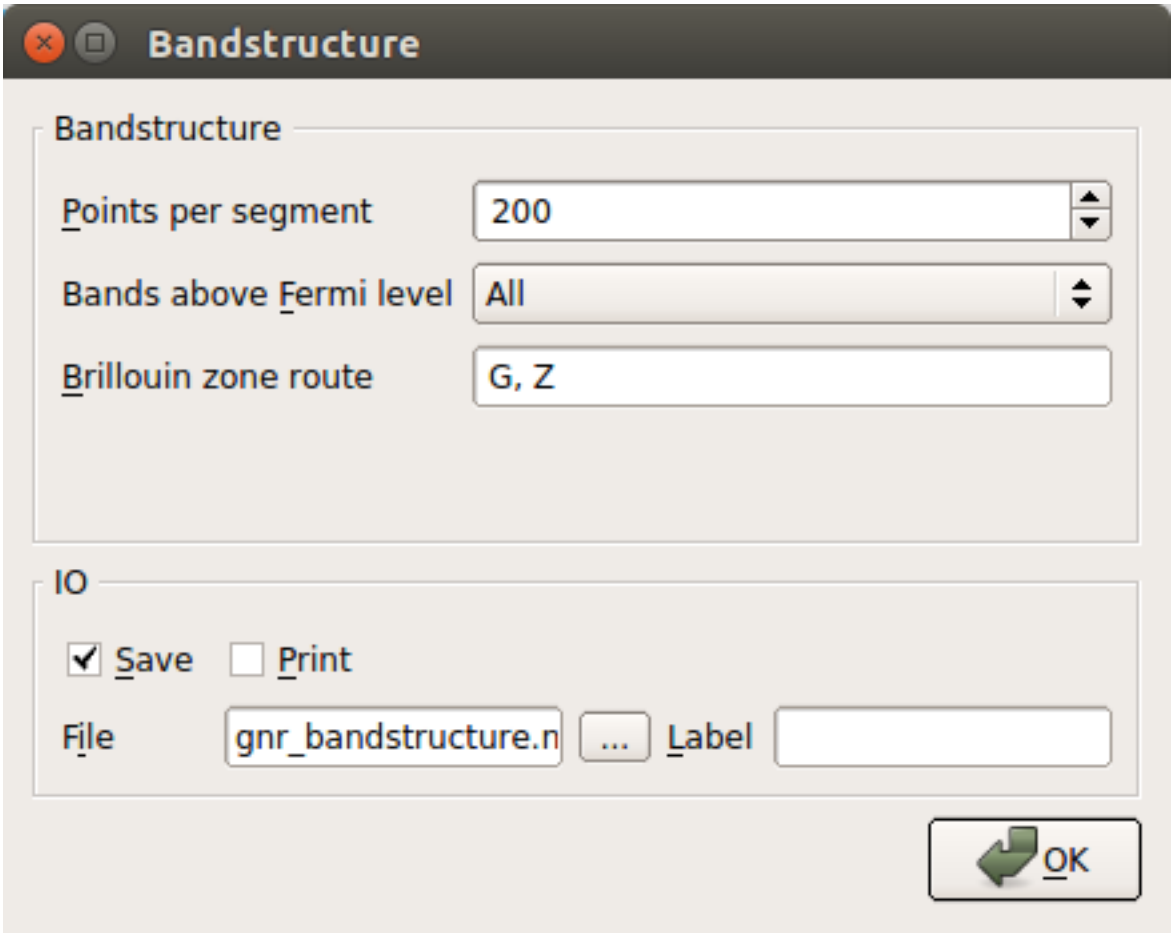


•Finally, click the **OK** button.

To specify the band structure calculation, double-click the **Bandstructure** block.

•In the appearing dialog, change **Points pr. segment** to 200. This implies that each band will be calculated with a resolution of 200 points. Also notice that the default suggested route in the Brillouin zone (from G (0,0,0) to Z (0,0,1/2)) is the appropriate one.

Note: The label G is used in **ATK** (and **QuantumATK**) to designate the Γ point, when setting up the script. In the band structure plot, the proper Greek label will be shown (see below).



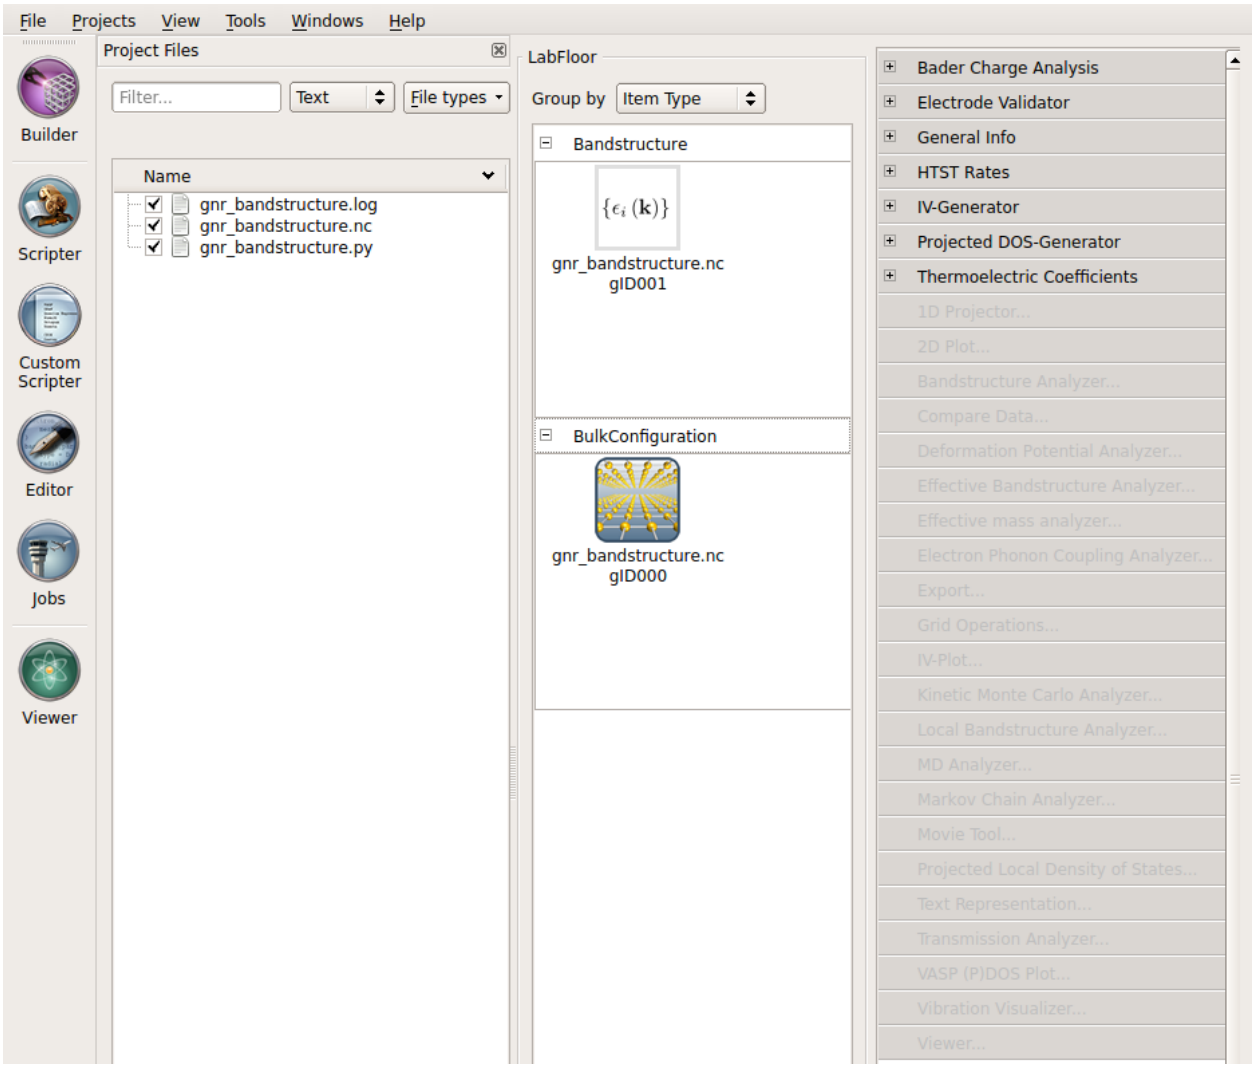
•Finally, click the **OK** button.

Now run the calculation by clicking the *Send To* icon and select **Job Manager** from the pop-up menu. Save the Python script under an appropriate name, such as `gnr_bandstructure.py` and click **OK**.

In the Job Manager, click the Start icon to run the job; the calculation takes only seconds to complete.

Analyzing the results

Return to the main QuantumATK window. The file `gnr_bandstructure.hdf5` should now be visible under Project Files in the left column. In the middle column, called the LabFloor, select *Group by Item Type*.



On the LabFloor, you can see that the file contains two objects: the calculated Bandstructure and the BulkConfiguration itself. The latter object contains not only the geometry, but the full state of the calculation. We will use this in the next chapter to calculate the Bloch functions without having to rerun the self-consistent calculation. For this, you will need to know the Id of the BulkConfiguration, which is shown after the file name; it is gID000 in this case.

Now, to plot the band structure, select the **Bandstructure** object (gID001), and click the **Bandstructure Analyzer** button in the plugin panel on the right.

The resulting plot is shown in the figure below. Note how the conduction and valence bands stick together for high values of k_z. This is a characteristic feature of zigzag ribbons (in our model) and clearly makes our ribbon metallic.

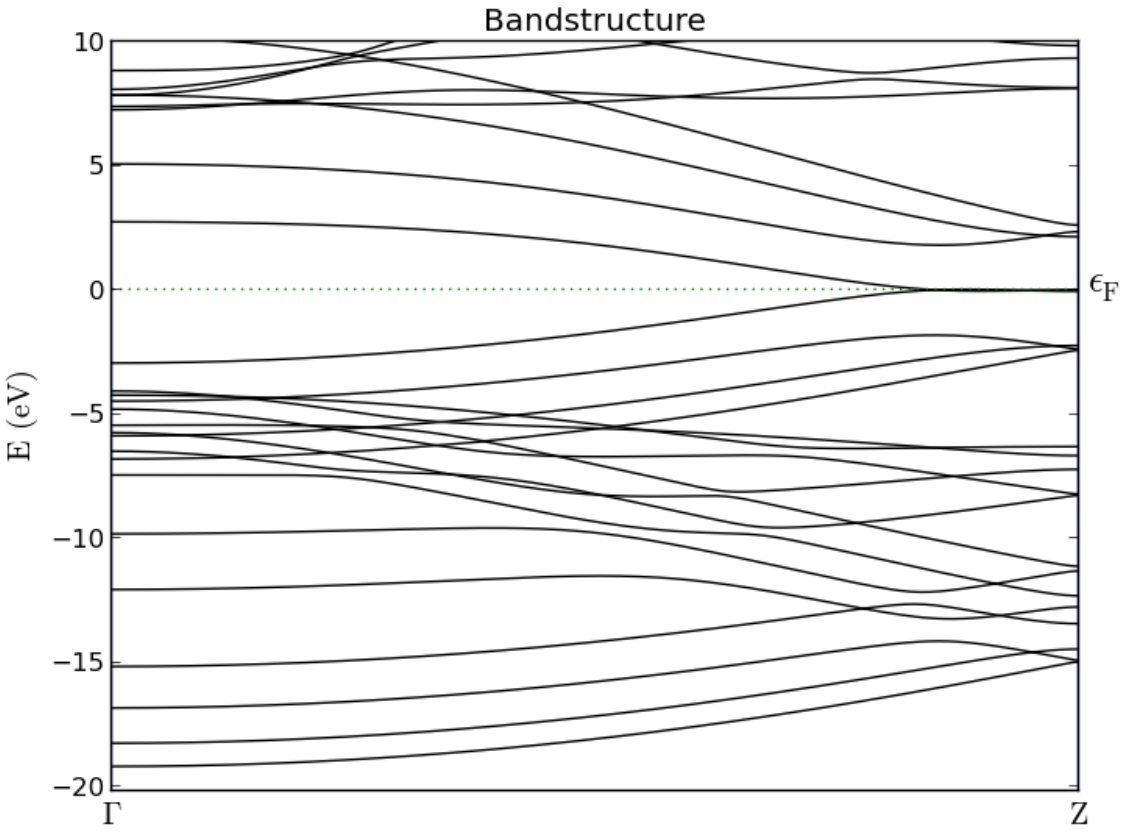


Fig. 3.89: Band structure of a zigzag graphene nanoribbon. The band gap at the Γ- point is roughly 5 eV, but closes entirely at the Z-point.

Bloch states

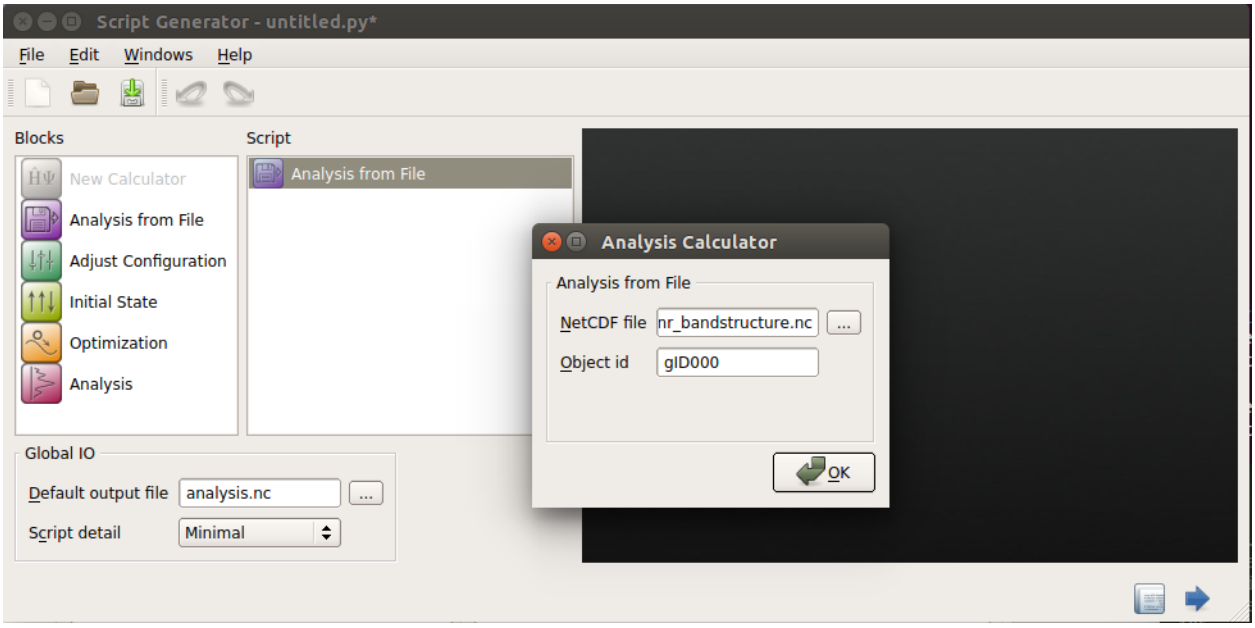
A very useful feature in **ATK** is its ability to calculate and plot Bloch states, which can be used to investigate the symmetry of certain bands and how this may relate to the transport properties. You will now use this capability to see how Bloch states close to the Γ point are delocalized across the ribbon, while states with higher k_z become increasingly localized towards the edges.

The ribbon consists of 8 carbon and 2 hydrogen atoms in each unit cell. A carbon atom contributes four valence electrons ($2s^2 2p^2$) and hydrogen only one (1s). Thus there are 34 electrons in the system. Each band is doubly degenerate (due to spin) and hence there will be 17 valence bands. Counting from 0, the band index of the highest valence band is 16 and the index of the lowest conduction band will be 17.

Setting up the calculation

You will now set up a script that computes the Bloch functions of these two bands, in three different k-points. The self-consistent state of the ribbon was saved in the file `gnr_bandstructure.hdf5`, and you can just restore it for this analysis, instead of rerunning the self-consistent loop. This is a very convenient way to separate the actual self-consistent calculation, that you perhaps prefer to run on a cluster (at least for a bigger system), and the subsequent analysis that often requires less resources and can be run directly via the Job Manager in **QuantumATK**.

- From the main QuantumATK window, launch **Script Generator** by clicking the Script Generator icon .
- The double-click the **Analysis from File** icon (it is the only available choice when we start the Script Generator in this way and without dropping a configuration on it).
- Double-click the icon and specify the file name `gnr_bandstructure.hdf5` in the appearing dialog.
- You should also specify the object ID of the configuration in this file you want to use for the analysis. As we found out in the previous chapter, this is gID000 for our case (it usually is, if the HDF5 file only contains one configuration).



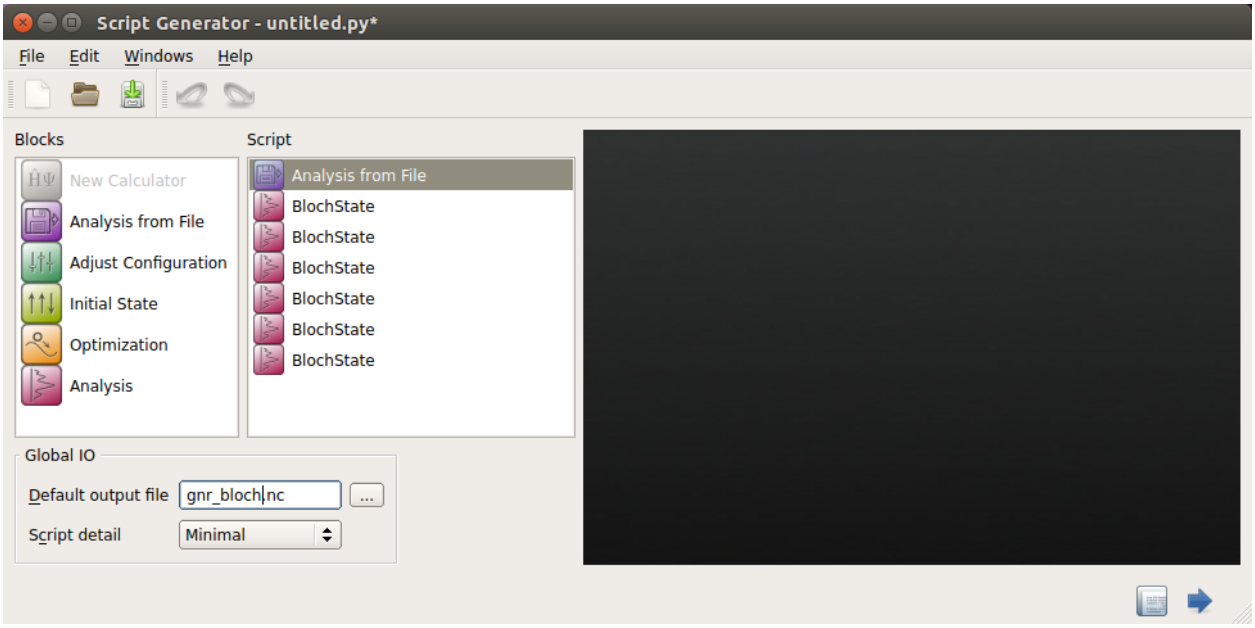
- Then click the **OK** button.

Now, we need to set up the calculation of the Bloch states.

•Add *Analysis* → *BlochState* 6 times. This should give 6 **BlochState** icons in the middle area of the Script Generator.

•Change the output file to `gnr_bloch.hdf5`.

The Script Generator window now loooks as follows:



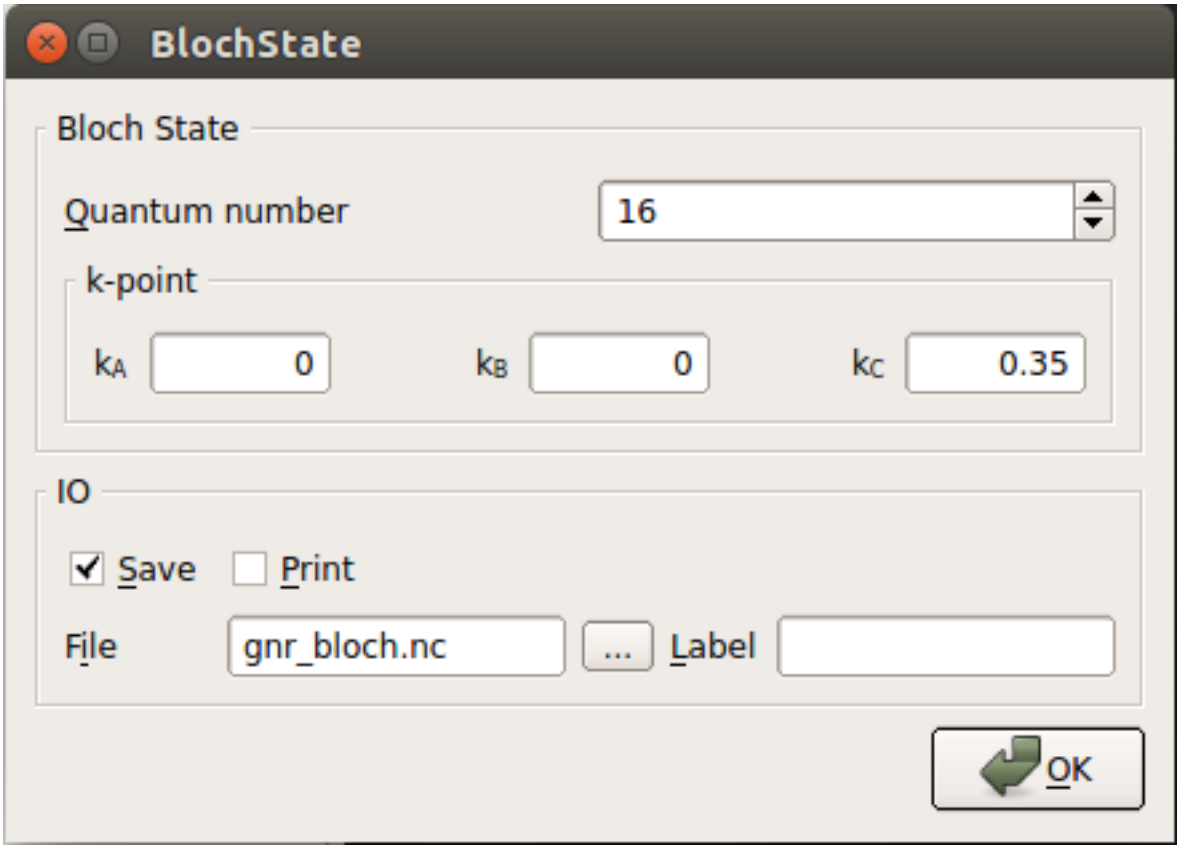
Double-click each of the first three Bloch state icons, enter 16 as the Quantum number (i.e. the band index), but give each one different k-points:

•(0, 0, 0)

•(0, 0, 0.35)

•(0, 0, 0.5)

In the second case, the BlochState window should look like the one shown below:



Repeat this procedure for the three remaining Bloch state icons, but this time enter 17 as the value for the Quantum number.

Finally, like before, send the job to the Job Manager and start the execution of the job.

Note: The calculation is very fast, but the generated HDF5 file will be quite large (about 120 Mb), which is why the data is saved in a separate file. This way, we avoid bloating the original file containing the self-consistent calculation (which would make it slower to read, if you desire to do some other analysis).

Analyzing the results

Once the job finishes, return to the main QuantumATK window. The results from `gnr_bloch.hdf5` should automatically be included in the LabFloor (see that the `gnr_bloch.hdf5` is checked under the under Project Files). Select Group by Item Type and expand the BlochState block.

Click on the last (`gnr_bloch.hdf5` gID005) of the six BlochState objects and select **Viewer** and then make sure the Plot type is set to Isosurface before pressing **OK**. Do this for each of the others, continuing with gID004, until all 6 are shown in the Viewer window. Now, select *Scenes* → *Tile* from the menu at the top of the Viewer window, in order to arrange the plots neatly. Note that the plots are now arranged with the newest window in the upper left corner, meaning that we have the valence band in the top row and the conduction band in the bottom row, with the gamma point to the left and the Z point on the right.

Tip: You may also add the subsequent Bloch state objects to the Viewer window by drag-and-drop. However, in this case you need to make sure that you do not drop the objects on an existing plot, as it will then be added to this instead

of being created as a separate plot.

To adjust the properties of each plot, click **Properties** from the menu on the right. This must be done separately for each window.

- Under **Isosurface** (the first tab), set the **Isovalue** to 0.05 and select the HSV color map.
- You can also go to the **Scene** tab and hide the axes by removing the tick from **Compass enabled**.

Below the visualization of the 6 different Bloch states are shown in the viewer. The quantum number is 16 for the top three and 17 for the bottom three, and the k-point coordinates are: (0,0,0), (0,0,0.35) and (0,0,0.5), starting from the left.

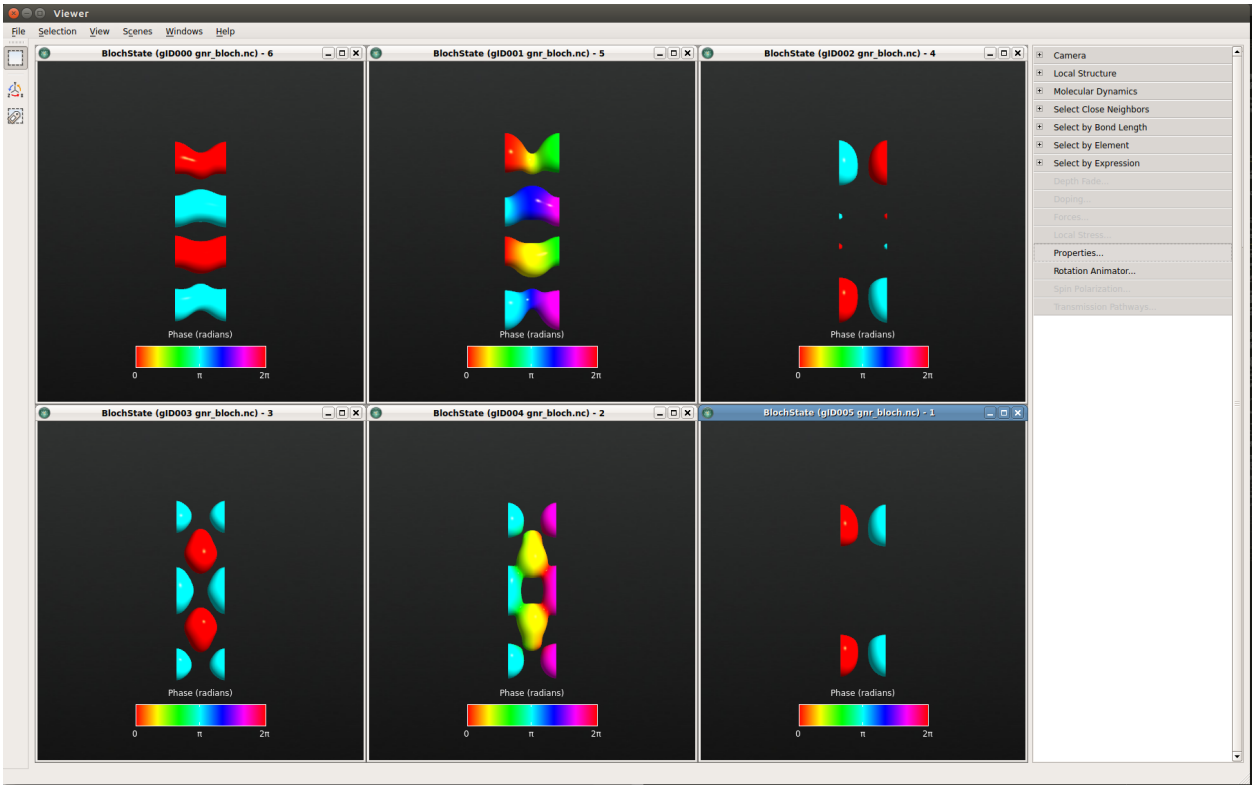


Fig. 3.90: From left to right: The Γ point, k=0.35, and the Z point. The top and bottom rows display the valence and conduction bands, respectively. (You may obtain a phase shift of π in your figures compared to this image; this has no physical relevance, of course.)

Looking at the respective Bloch functions, first note that the wave functions at G and Z are real (as expected), and second that there is a distinct difference between valence and conduction band Bloch functions. The occupied valence band states appear to be connected in the ribbon direction, while the (unoccupied) conduction band states are more oriented across the ribbon. At Z, the states become localized towards the edges of the ribbon.

In the next section, you will see how spin splits the degeneracy around Z, and how the two spin states become localized on opposite edges.

Tip: To superimpose the geometry of the ribbon on the plot, drag the BulkConfiguration object from the file `gnr_bandstructure.hdf5` onto a BlochState window in the open Viewer window.

Introducing spin

Setting up the calculation

You will now redo the entire calculation with spin-polarization included. The work-flow is very similar, and each step is therefore only outlined this time.

1. Set up the calculation like you did for the bandstructure calculation: Go to the builder and send the graphene nanoribbon to **Script Generator** (the builder stash should still contain the graphene nanoribbon from last time).

2. Add a **New Calculator** block and set the same parameters as before (SingleZetaPolarized basis set and (1,1,50) k-points). In addition, in the **New Calculator** dialog window, set Spin to Polarized and check that the exchange-correlation functional has automatically changed to LSDA.

3. The default in **ATK** is to start a spin-polarized calculation with a symmetric initial spin density. However, in this case, this will result in a local minimum corresponding to a symmetric (ferromagnetic) state. To get the real anti-ferromagnetic ground state of the graphene nanoribbon we have to set up the initial spin configuration with opposite polarizations on the two nanoribbon edges (the middle carbon atoms and the hydrogen can be left unpolarized).

   To set up the initial spin state of the system:

   - Double-click the **Initial State** icon to add it and then open it.
   - Set **Initial state type** to User spin, and then under **Spin**, set the default spin of both carbon and hydrogen to 0.
   - Then in the 3D view, select (by using Ctrl+left-mouse click) the two upper carbon atoms and verify that their numbers are 0 and 7 in the list. Set their spin values to 1. Repeat this procedure for the two lower carbon atoms (they should be number 1 and 2 in the list) setting their initial values to -1. The hydrogen atoms and the four middle carbon atoms can be left with spin values equal to 0. The Initial State dialog now look as shown below: (dont be confused by the fact that the carbon atoms are not ordered by Y coordinate).

Tip: If you have no idea about the spin state of the system, you may select Random spin. It sets a random spin on each atom, and dependent on the random values, the system may converge to different spin states of the system. The spin state with lowest total energy is the ground state.

---

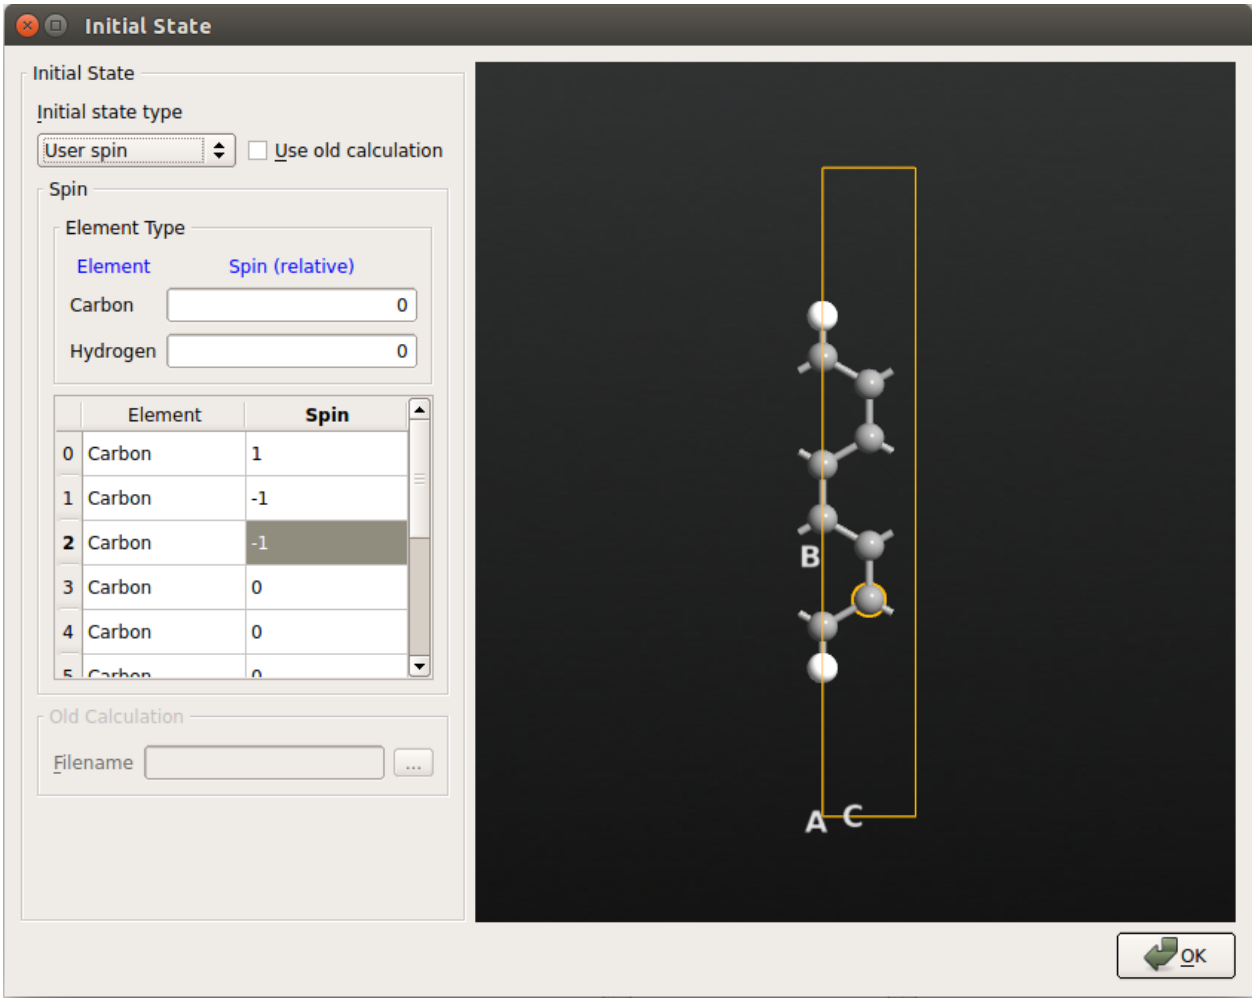
4. Add a **Bandstructure** calculation for the spin polarized calculation and again set **Points pr. segment** to 200.

5. This time, you may just as well include the Bloch states from the beginning to get everything done in one script. For the following analysis, it is sufficient to only calculate the Bloch functions in the Z point. Add two Bloch state icons all defined at the Z point (0,0,1/2). Let one of these have Quantum number 16 and the other have the Quantum number 17.

6. We will also need the electron density later, so add also an *Analysis→ElectronDensity* object.

7. Another way to look at the spin density is through the Mulliken populations, so add also an *Analysis→MullikenPopulation* object.

8. Then set the name of the output file for the calculation in the Script Generator window to `gnr_spin.hdf5`. The Script Generator window should now look like the one shown below.



Initial State

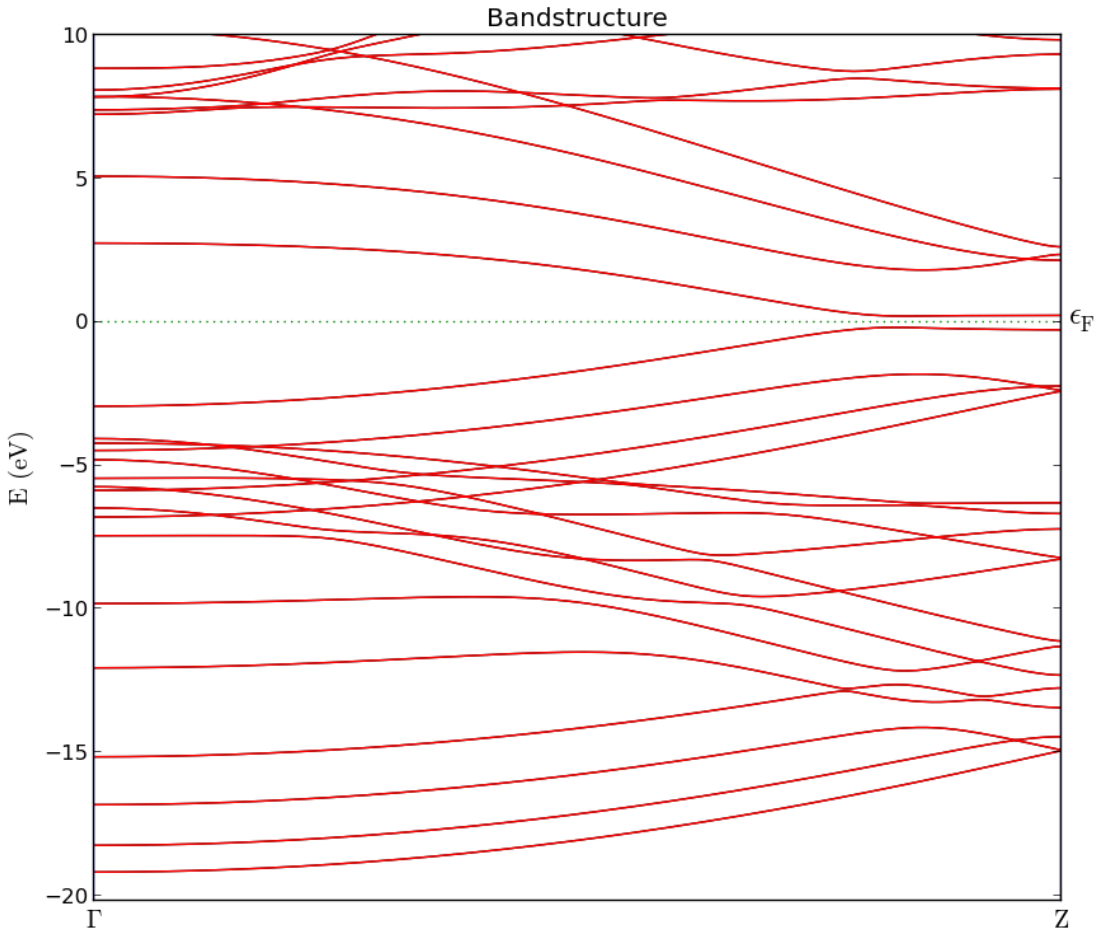
9.Send the script to the Job Manager and run the calculation.

Analyzing the results

By inspecting the column DD in the calculation log you will see, by summing the entries, that there is no total spin-polarization in this system (the total spin up and down will both be 17), which is very reasonable; carbon is not magnetic.

By plotting, you can also observe that there is no spin-dependence in the band structure; the up and down states are completely degenerate (otherwise you would see both blue and red curves in the band structure plot).

However, the inclusion of spin does have a profound effect on the bandstructure. The earlier degeneracy of the conduction and valence bands close to k_z =0.5 is broken, and a band gap has opened up.



Plot the corresponding Bloch states at the Z point and select to plot spin up and down for each of the two BlochState objects. If you adjust the view properties as in the previous chapter, you clearly see how the two spin valence states are localized on opposite edges of the ribbon. The conduction band states behave completely analogously, but are localized on opposite edges compared to the valence band states.

Electron density and Mulliken populations

Since the up and down Bloch states are localized on opposite edges, there must be a difference in the total spin up and down electron density.

The Mulliken populations is the easiest way to get a first view of this, and it is most conveniently viewed by selecting the MullikenPopulation object on the LabFloor and selecting **Text Representation** on the right. The resulting window is shown below. Under the column Total, the two spin-channels are shown on seprate lines, and we find that the two edge carbon atoms (numbers 0 and 1) have a surplus population of 0.25 of either spin-up or spin-down.

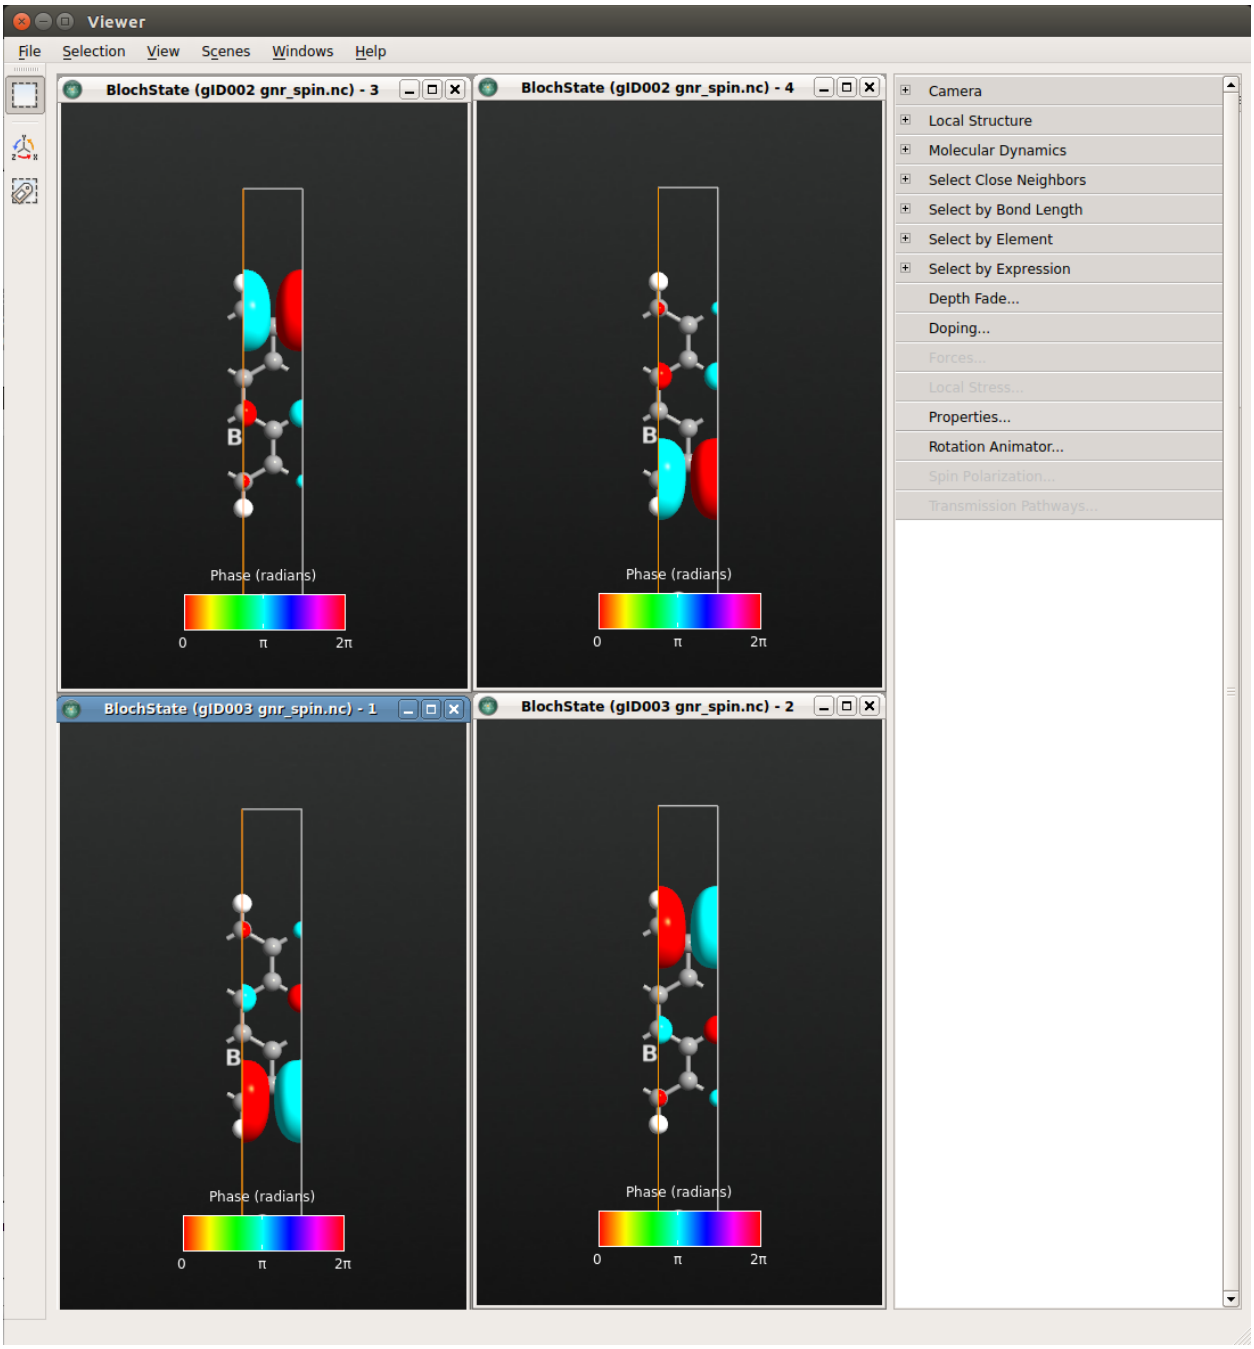


Fig. 3.91: Spin up (right) and down (left) states at the Z point for the highest valence band (bottom) and lowest conduction band (top).

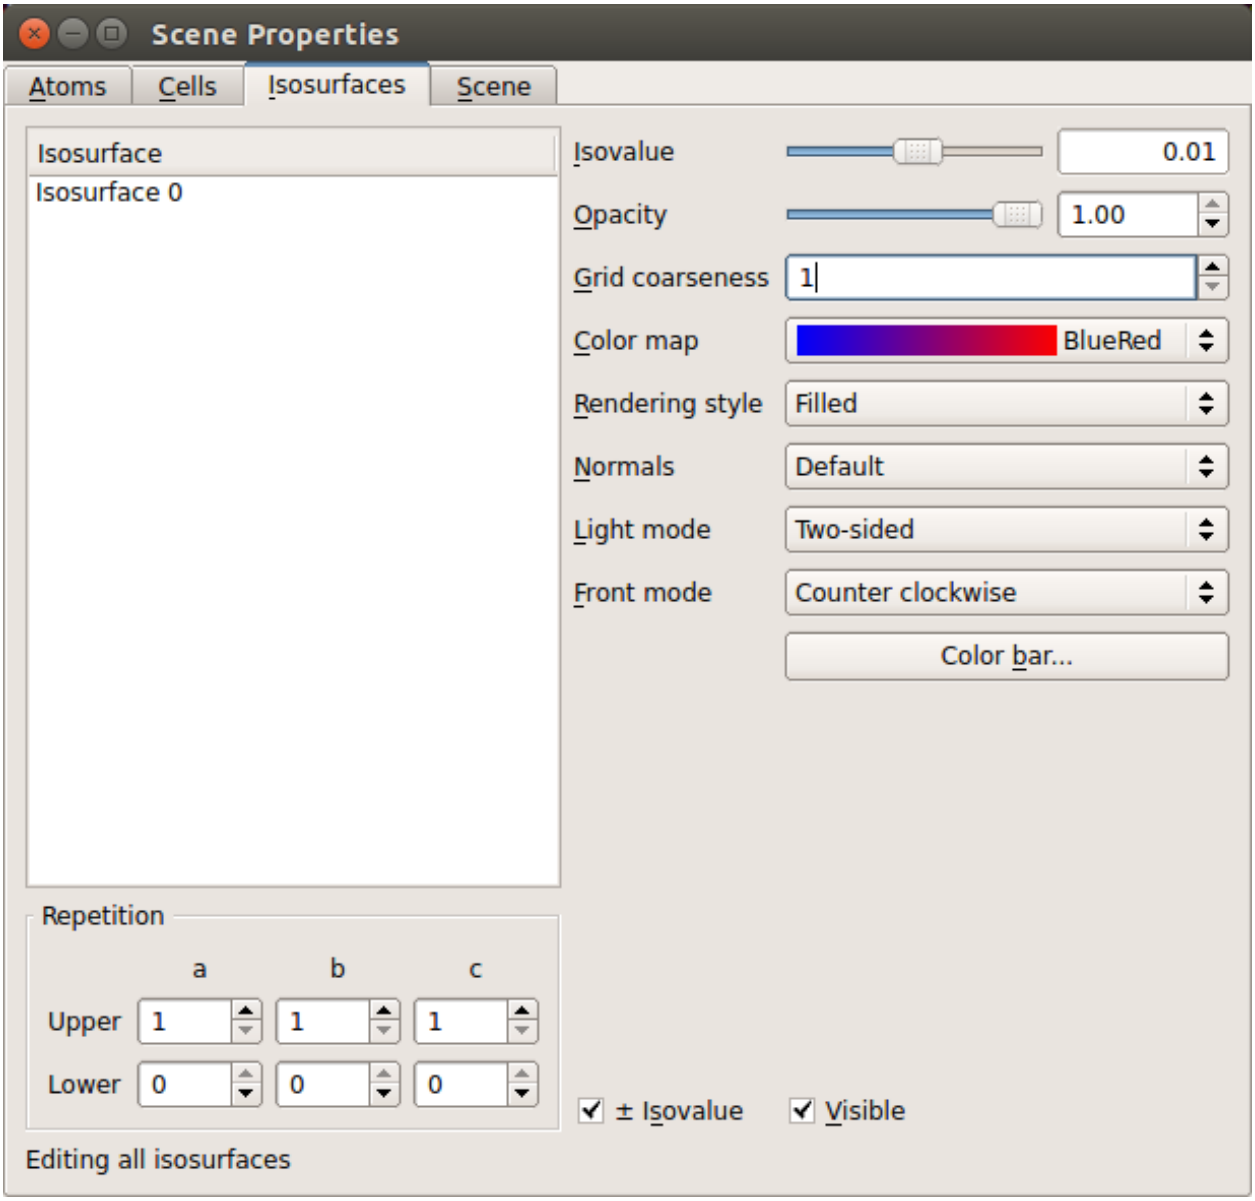
|           2.170  0.498   |  0.498                                             |
|                          |      y       z       x                             |
|                  1.410   |  0.534  0.499  0.376                               |
```

You can also choose to plot the spin difference density, $\rho_\uparrow - \rho_\downarrow$, or the normalized difference between the spin up and down density, $(\rho_\uparrow - \rho_\downarrow)/(\rho_\uparrow + \rho_\downarrow)$.

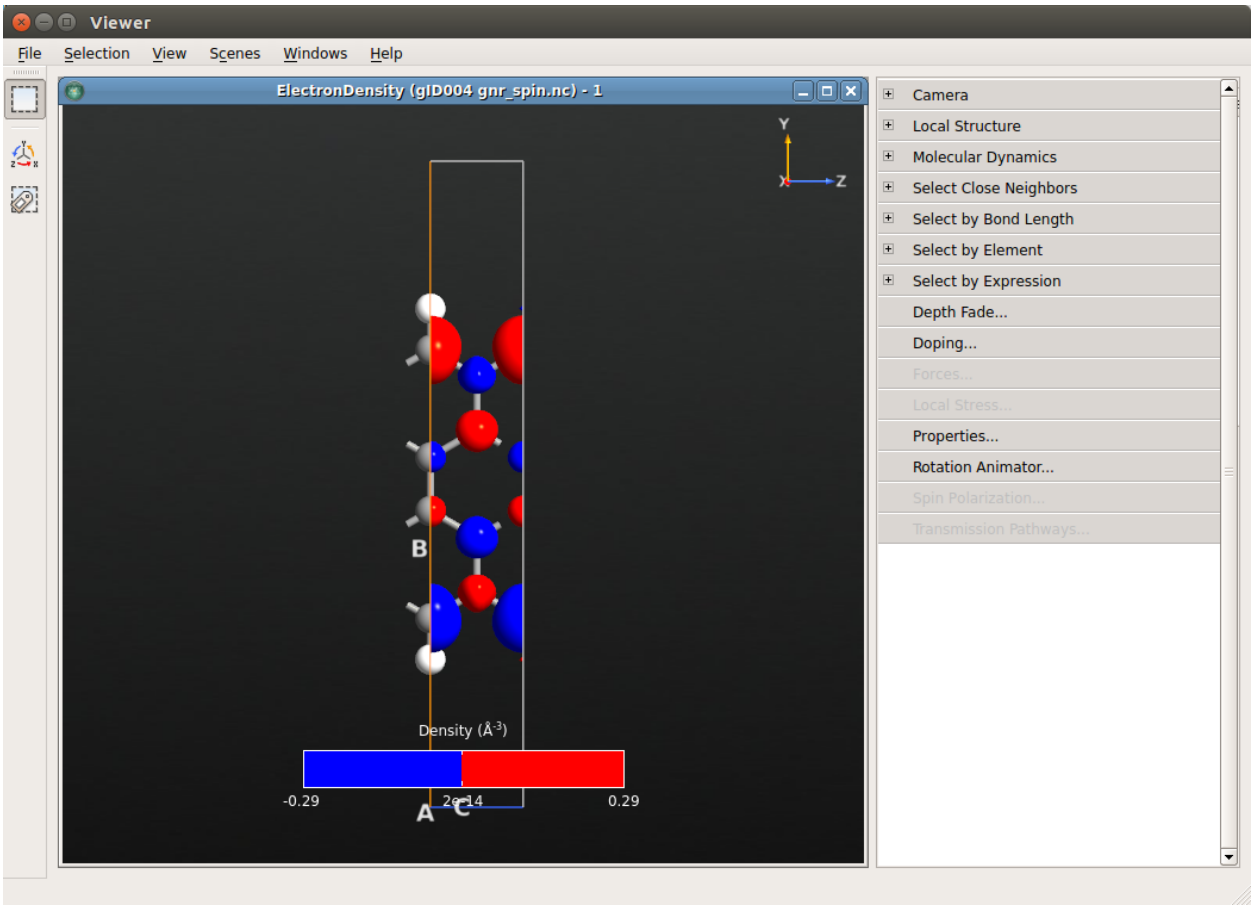
All the information you need is contained in the ElectronDensity object saved in the `gnr_spin.hdf5` file.

Plotting the spin density

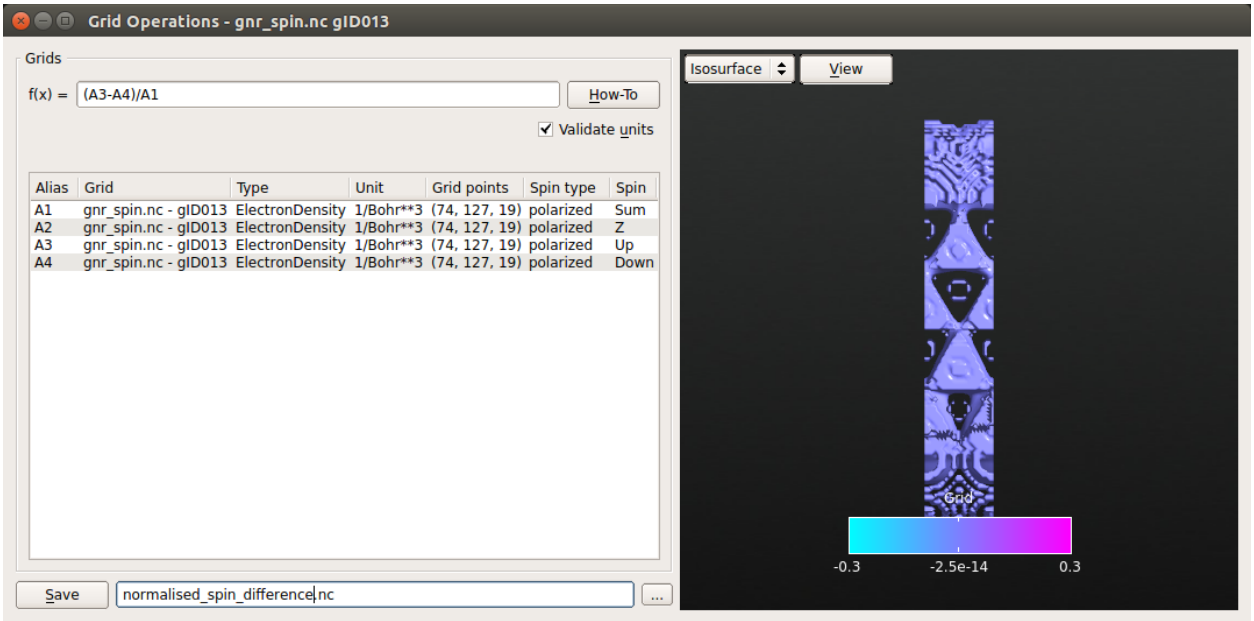
First we plot the direct spin difference density. Select the ElectronDensity object on the LabFloor and click **Viewer**. Go to properties and set the *Isovalue* to 0.01, the *Color map* to BlueRed and check the box for $\pm$ *Isovalue* at the bottom. The window should now look as the one shown below.



If you also overlay the bulk configuration as explained previously, you should get a plot like the one shown below.

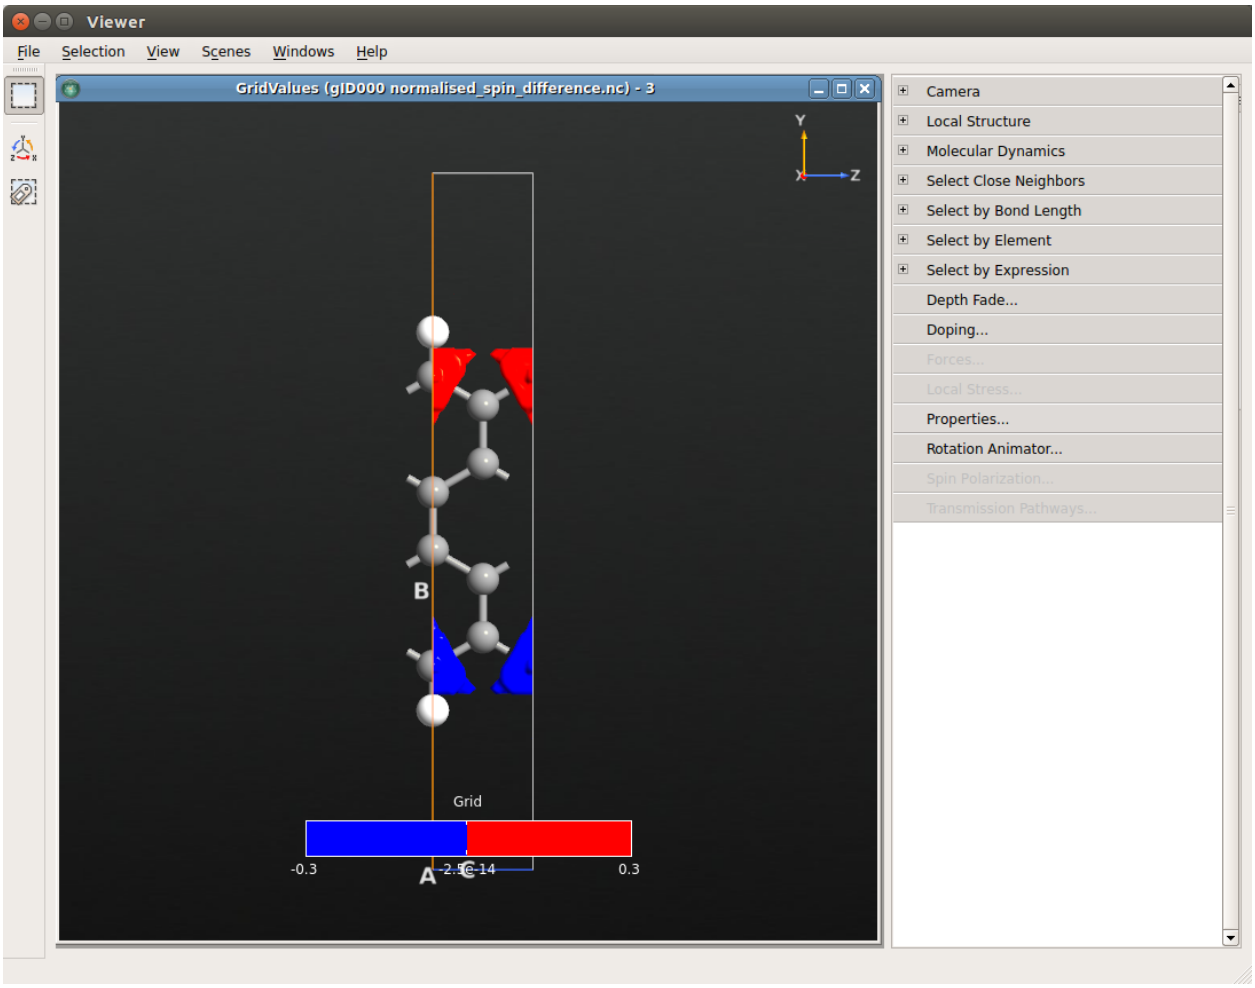


In order to plot the normalised spin difference density, go to LabFloor and select ElectronDensity in the `gnr_spin.hdf5` file and click on **Grid Operations**. Here, you can see the elements that are contained in the ElectronDensity object which are marked by an alias. In the *f(x)* field you can now write any mathematical expression. In this case write (A3-A4) / A1. Finally, save the result in a new file called `normalized_spin_difference.hdf5`.



Note: You can select more then one object present in the LabFloor by holding Ctrl and click on **Grid Operations**. In this way you will be able to operate on different data set from different calculations. However, note that the dimensions of the grids must be the same and the units of the grids in the expression must be consistent.

The new file will appear in the LabFloor. Select it and plot the content with the Viewer. In order to get a better view, open **Properties** on the menu in the right-hand side. Again, check ± *Isovalue* at the bottom, change Isovalue to 0.02 in the upper right and change the color map to BlueRed.



You can also average the spin polarization along the x-axis (perpendicular to the graphene sheet). The following script will generate the plot below, using the matplotlib module which is integrated in **ATK**.

`density_average.py`

Drop the script on the Job Manager, and it will generate the plot. The plot will be saved in the file `av.png`.

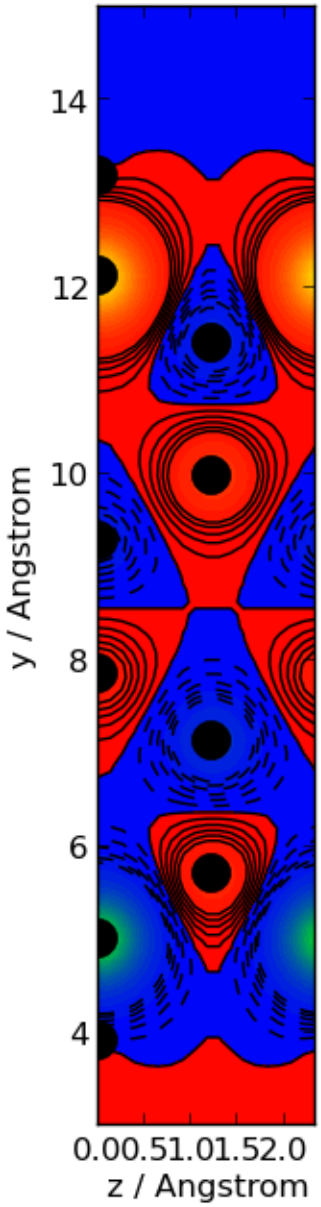


Fig. 3.92: Averaged spin polarization density. The filled circles indicate the atom positions.

3.7 Phonons & Thermal Transport

3.7.1 Calculating and using Dynamical Matrix

Version: U-2022.12

Downloads & Links

DynamicalMatrix

The *DynamicalMatrix* is an object that is used to calculate many properties related to dynamics of the crystal lattice e.g *Mobility*, *RamanSpectrum*, *DeformationPotential*, *DielectricTensor* and more. In this tutorial you will learn how to calculate the dynamical matrix and use it to perform a *PhononBandstructure* calculation. In particular, you will learn how to set up the calculation and which parameters are critical. You will also learn how to optimize the performance of this type of calculations by an optimal parallelization strategy.

- You will first perform a **DFT-LCAO** calculation with the LDA exchange-correlation functional. You will go through all the relevant parameters used in a phonon calculation.
- Towards the end, you will use the classical potentials available in the **ForceFieldCalculator** and compare the results.

Prerequisites

This tutorial is an introduction to the Dynamical Matrix functionality in QuantumATK and only requires basic familiarity with the QuantumATK interface. This can be achieved via the following basic tutorials and guides:

- *Introduction to the Workflow Builder*
- *Introduction*
- *Organize your data in the Nanolab data view*
- *Geometry optimization: CO/Pd(100)*
- *Job Manager for local execution of QuantumATK scripts*

Create the Workflow

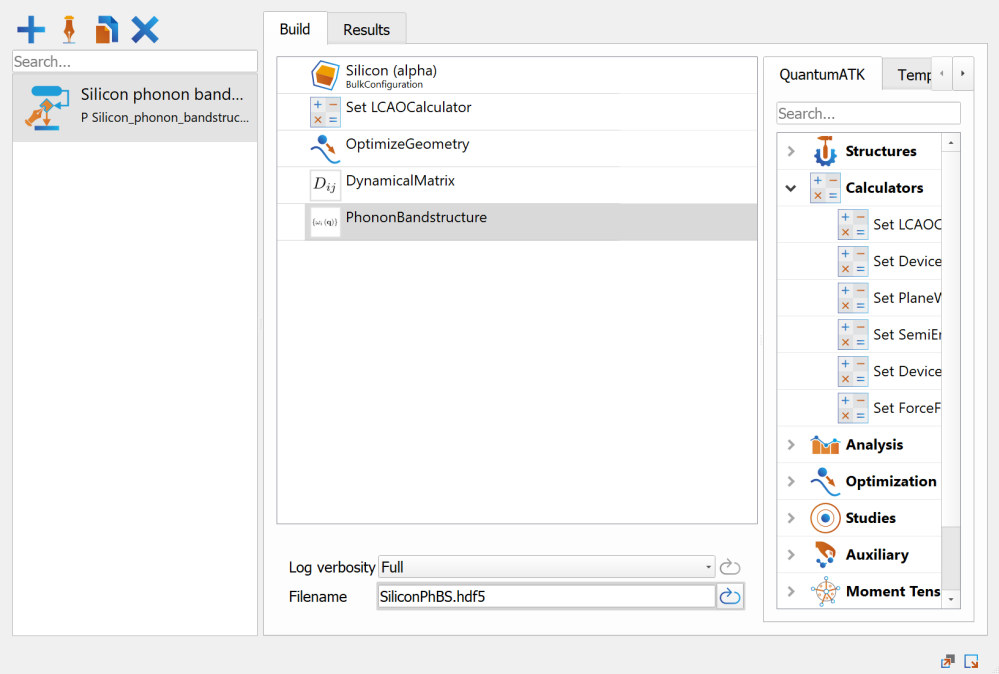
Go to the **Builder** and import the *Silicon (alpha)* structure from the built-in database. Then send the structure to the *Workflow Builder* and add the following script blocks:

1. **LCAOCalculator**
2. **OptimizeGeometry**

3. **DynamicalMatrix**

4. **PhononBandstructure**

The resulting workflow should look like this:



Now we will go through the settings of each block and edit the important parameters.

LCAOCalculator Settings

To get good results for the dynamical matrix one has to converge the computational settings with respect to a few key parameters:

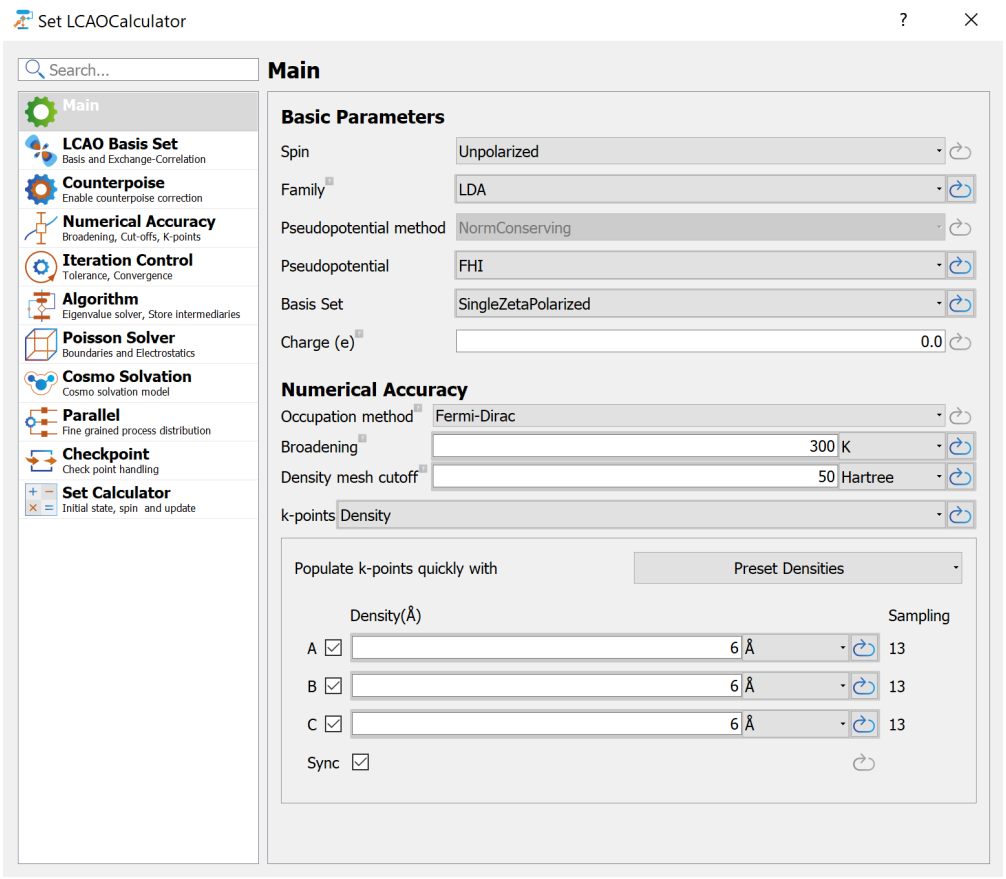
Note:

- In this example we use the light weight Single Zeta Polarized basis set. This basis set will result in a decent phonon-bandstructure at low computational cost. For production simulations we would recommend using e.g. the default PseudoDojo-Medium basis set which is generally more accurate.
- Please also note that the **Density mesh cutoff** needed is material and pseudo potential specific, so while 50 Hartree is enough for SIlicon, it is too low for other materials. Generally one should start from the default value and increase until convergence is reached.

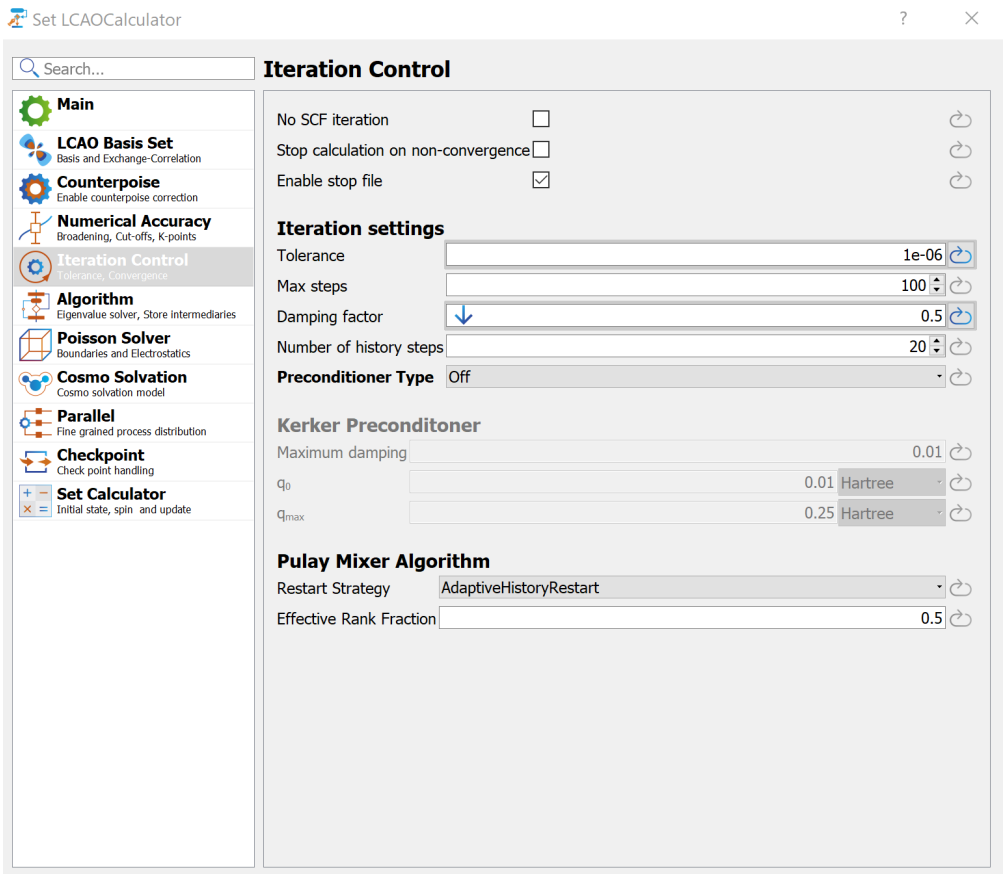
In the *Workflow Builder* do the following:

- Open the **LCAOCalculator** block.
- In the **Main** section, in **Basic Parameters** select *LDA* under **Family**, *FHI* under **Pseudopotential** and *SingleZetaPolarized* under **Basis Set**.

•In the **Main** section, in **Numerical Accuracy** set **Broadening** to *300 Kelvin*, Increase **Density mesh cutoff** to *50 Hartree* and k-point density to *6 Angstrom*.



•In the **Iteration Control** section, set a **Damping factor** of *0.5*. Also reduce the **Tolerance** to *0.000001*.

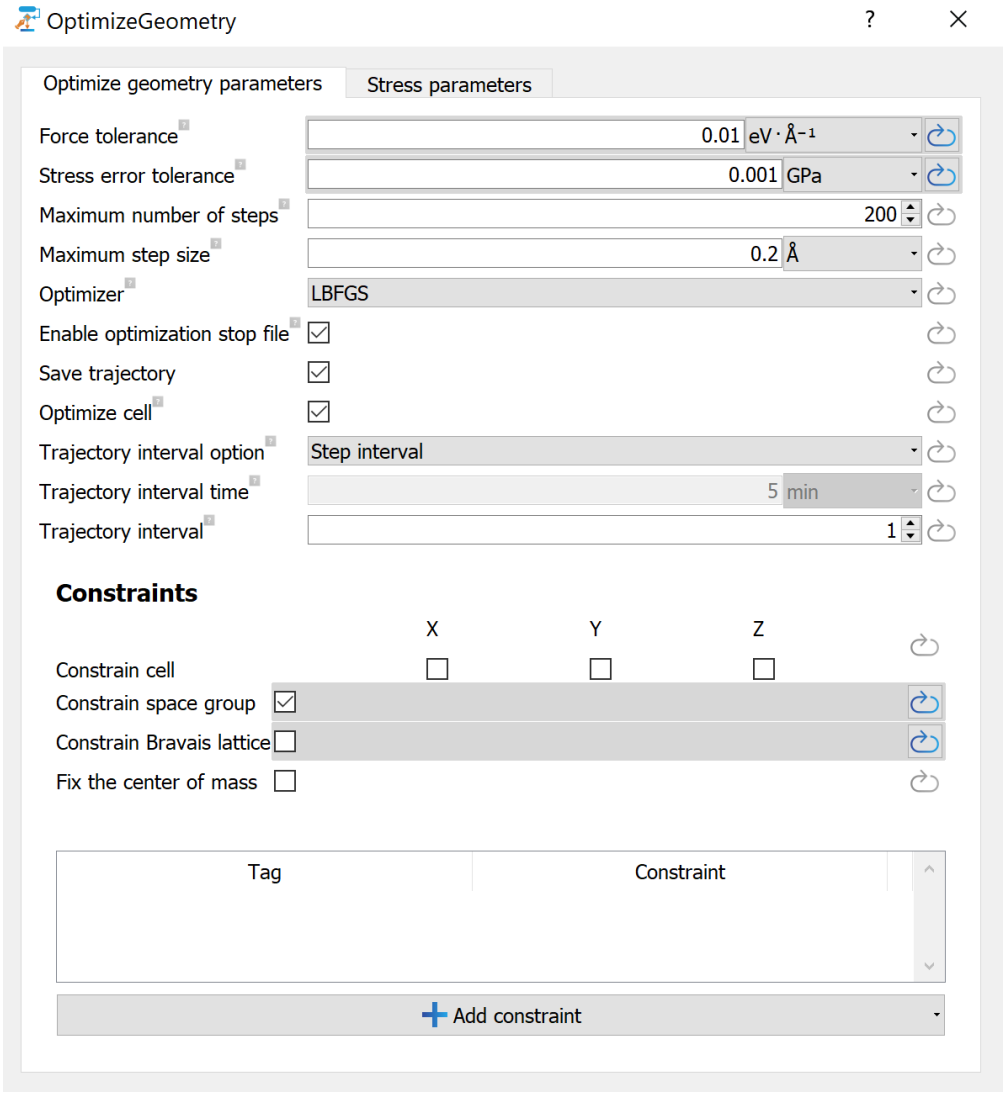


Tip:

- It can often be necessary to increase mesh cutoff and k-point density from the default values for DynamicalMatrix calculations to ensure convergence of the phonon bandstructure.
- For non-metals in general we recommend using *300 Kelvin* broadening.
- For DynamicalMatrix calculations it is generally recommended to use a tighter tolerance than the default one.
- It is possible to reduce the number of iteration steps by tuning the damping factor and number of history steps used.

Lattice optimization Settings

Open the **OptimizeGeometry** block, and modify the parameters as in the figure below to perform a force and stress minimization with tighter-than-default convergence parameters.



Tip:

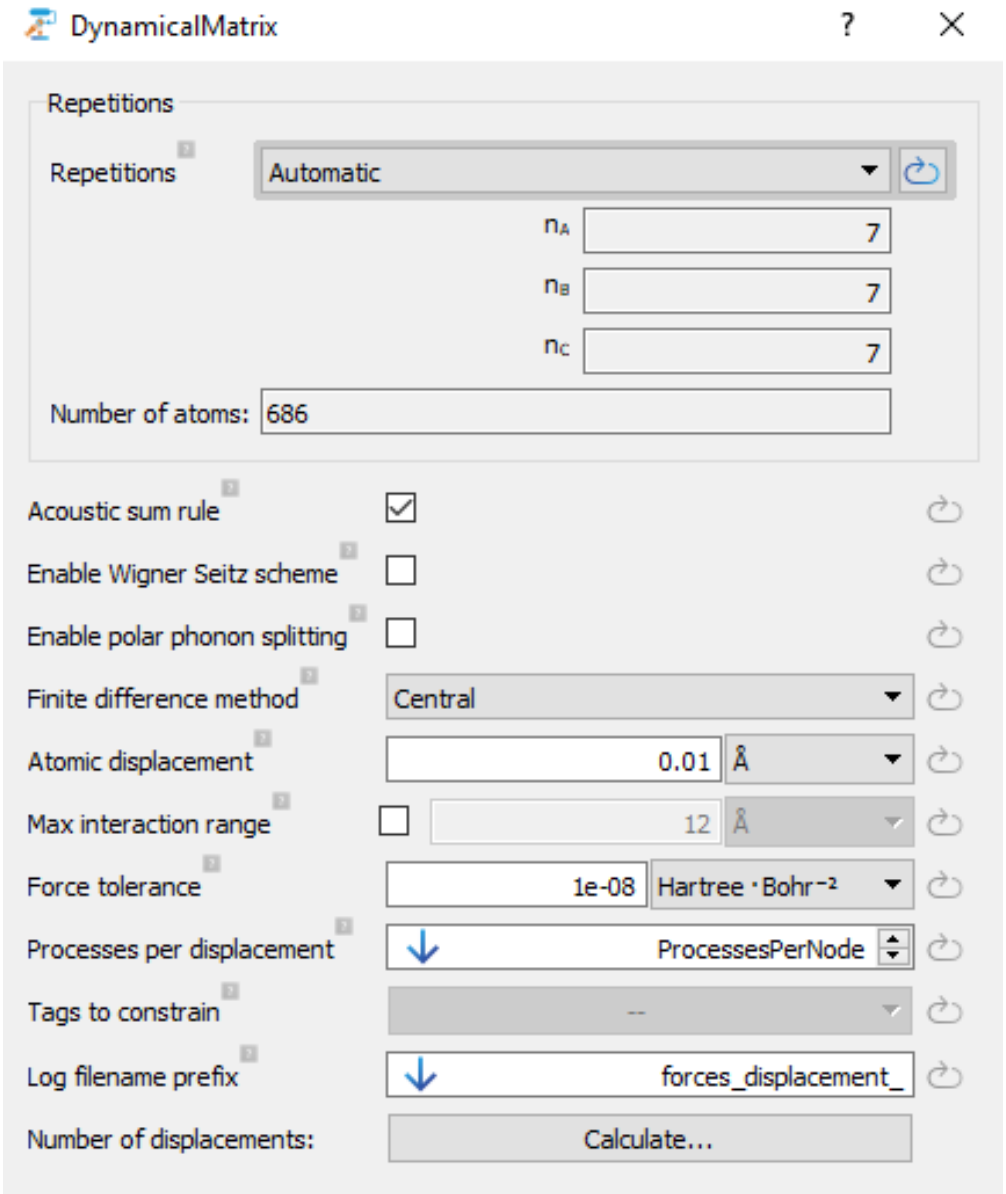
- We generally recommend reducing the target stress and forces when calculating the dynamical matrix.
- To get good structures for calculations of electronic properties the default settings are usually sufficient.

Dynamical matrix Settings

The dynamical matrix is the second derivative of the energy, corresponding to the first derivative of the forces. The first derivative of the forces are calculated using a finite difference scheme, where each symmetrically unique atom in the central cell is displaced along all cartesian directions, also called frozen phonon calculations.

For crystals with small unit cells, a periodically repeated super-cell of the unit cell is often needed to accurately account for long-range interactions in the dynamical matrix. **QuantumATK** can handle this automatically. By default cell is repeated such that all atoms within a pre-defined element-dependent distance from the atoms in the unit cell are included in the repeated cell. This is enough for most systems. It is also possible to directly set the number of repetitions used in each direction. You can see more details in the *Notes* section of the manual entry for `DynamicalMatrix`.

•In the D_{ij} **Dynamical Matrix** object we will use the default settings.



•Open the $\{\omega_\nu(\mathbf{q})\}$ **PhononBandstructure** block and choose 400 points per segment and the G, X, K, G, L Brillouin zone

route.

Note: The TAT of the calculation is highly sensitive on the number of repetitions for the simple fact that the repeated system can become very large. For highly complex or large systems where the automatically detected repetitions result in a very high TAT one can sometimes reduce the number of repetitions. It is however important for production calculations to always check convergence with respect to e.g. phononbandstructure.

To test the effect of using different numbers of repetitions, we repeat the calculation setting **Repetitions** to 3x3x3 and 5x5x5. The full workflow can be downloaded here `Silicon_phonon_bandstructure.hdf5`. To change the repetitions set **Repetitions** to *Custom* and choose the desired numbers.

Running the calculation

You are now ready to run your DFT phonon bandstructure calculation. This can be done by sending the script to the **Job Manager** using the **Send To** icon .

However, there are a couple of details to consider before running the job:

Parallelization

In **QuantumATK**, the dynamical matrix can be calculated by parallelizing over displacements. The number of displacements needed depends on the system and can be calculated by opening the **Dynamical Matrix** object and pressing the *Calculate* button under **Number of Displacements**.

The amount of processes reserved for each displacement can be controlled using the **Processes per displacement** parameter. In general we recommend one of two parallelization strategies:

1. The default setting *ProcessesPerNode* divides the the displacements across nodes. When running on a single node this will result in all displacements being calculated in serial.
2. Depending on the system considered and the hardware setup it is sometimes advantageous to run all displacements in parallel on as many processes as possible. For that strategy one should take the total number of processes subtract one which will be reserved as a delegator and then evenly distribute the remaining processes on the number of displacements.

   For this tutorial, we will use the default *ProcessesPerNode* setting on a single 20 core node.

System size

The three systems run in this tutorial, 3x3x3, 5x5x5 and 7x7x7 repetitions, consists of 54, 250 and 686 Silicon atoms, respectively. Besides the running time you should also consider the amount of memory required.

Timing

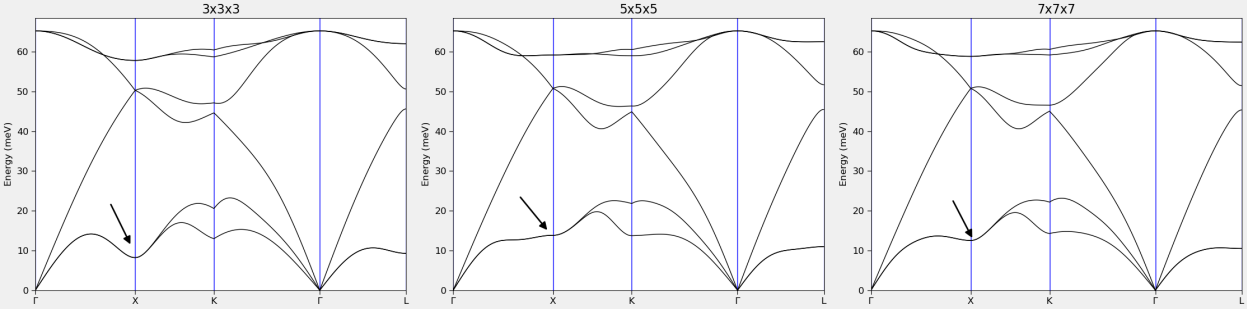
The table below reports the total time required to run the entire phonon bandstructure workflow with the parameters set above. The calculations are run in parallel with 20 MPI processes:

Repetition	3x3x3	5x5x5	7x7x7
Total time	1m29s	22m26s	1h39m44s

Analyzing the results

When the job is done you will find in the **Data** view the **PhononBandStructure** object. Highlight it and press *Open* to display it.

The figure below reports results for the 3x3x3, 5x5x5 and 7x7x7 systems defined above.



You immediately notice that the 3x3x3 repetition is too small to give even qualitatively good results, while the intermediate size system is already a pretty decent approximation. However, you can also notice that a small difference exists between the acoustic modes near the X-point for the 5x5x5 and the 7x7x7 systems.

The dynamical matrix is now stored together with the **BulkConfiguration**. This means you can read the dynamical matrix and perform another **PhononBandstructure** calculation (on a different Brillouin path for example) or a **PhononDensityOfStates** calculation in just a few seconds.

Speeding up the calculation with ForceFields

QuantumATK offers a large set of classical potentials in the **ForceFieldCalculator**. These potentials are well suited to study vibrational properties of materials, such as the phonon bandstructure of silicon calculated in this tutorial.

Note: Classical potentials are available only for a limited amount of systems. As your system becomes more complex including e.g. interfaces, defects or many elements you will often find that no relevant classical potentials exist. In this case **QuantumATK** offers the ability to train your own machine learned potential using Moment Tensor Potentials. Please get in touch if you would like to try out this functionality and do not have access already.

Send the silicon bulk configuration to the **Workflow Builder**. Add a **ForceFieldCalculator**. Now a stress optimization and phonon bandstructure calculation can be set up as explained above.

In **ForceFieldCalculator** select the most appropriate potential available for silicon, such as the Tersoff or the Stillinger and Weber potentials.

Each potential is provided with a literature reference, which you should check to determine if the potential is well suited for your system and for the property you are interested in.

Set up the **OptimizeGeometry** block and the **PhononBandstructure** analysis object exactly as for the **LCAOCalculator** case and run the calculation. The calculation will take just a few seconds on a normal desktop machine.

The phonon bandstructure of silicon calculated with the *Tersoff_si_2005 potential*[1] is reported in the figure below.

3.7.2 Vibrational modes and Vibration Visualizer

In this tutorial you will study the vibrational properties of nanoscale systems using the **VibrationalMode** analysis object and the **Vibration Visualizer** plugin. Two systems are investigated:

1. Monolayer MoS_2.
2. A nanophononic metamaterial

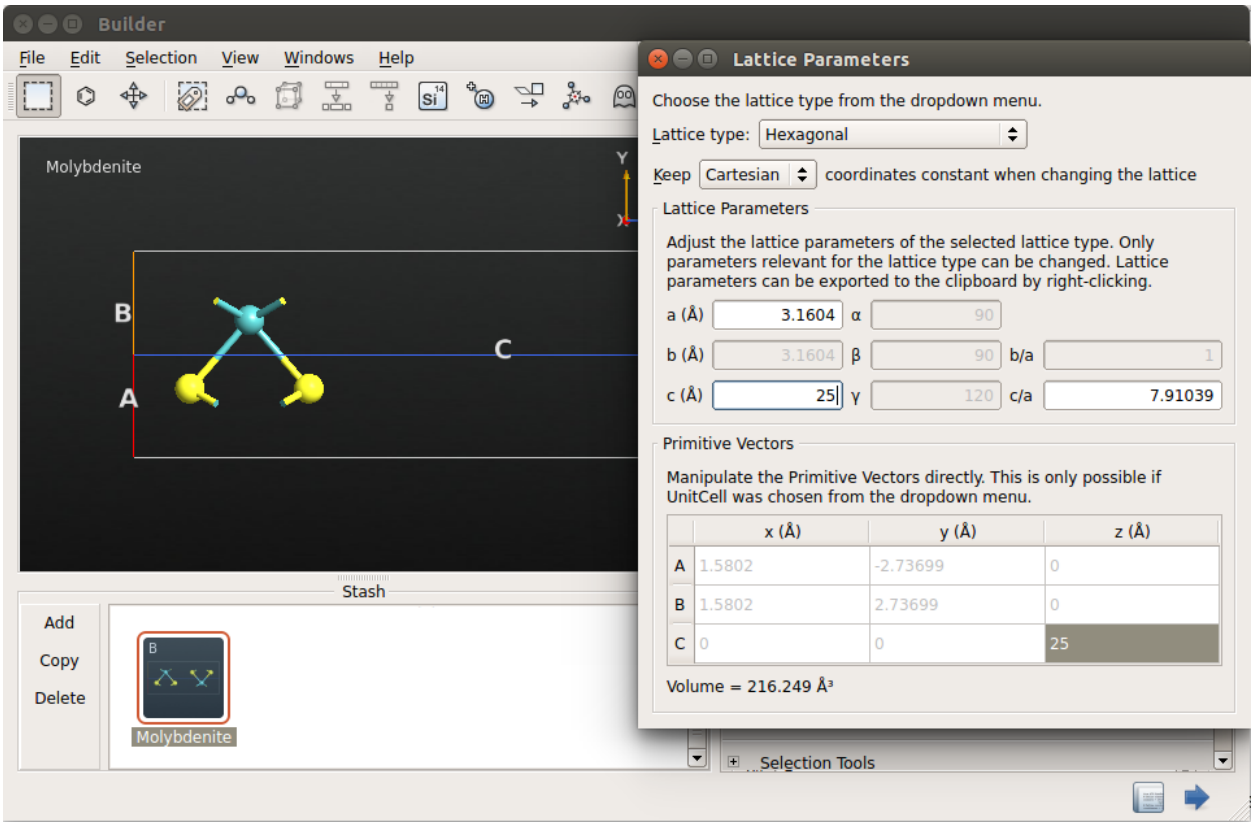
Note: Calculation of vibrational properties relies on the **dynamical matrix** of the configuration, which describes the force response on all atoms due to out-of-equilibrium displacements of all other atoms.

MoS_2 monolayer

Generate the MoS_2 structure

Open the **Builder**, and do the following:

- Use the *Database* plugin via *Add* → *From Database* and locate molybdenite. Add it to the Stash.
- Use the mouse to select and delete the 3 atoms to the right in the cell. This leaves a single layer of MoS_2.
- Open *Bulk Tools* → *Lattice Parameters* and change the z direction to 25 Å.



•Center the structure using *Coordinate Tools* → *Center*.

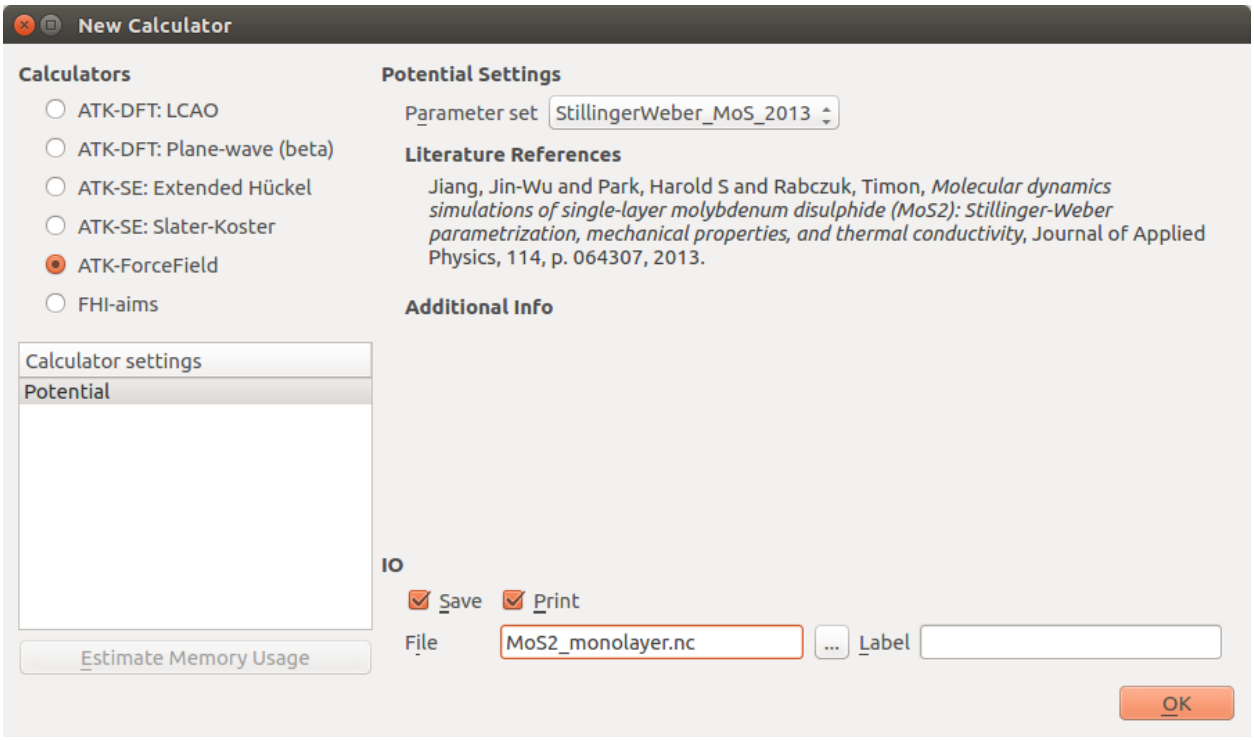
•Send the structure to the **Script Generator** by using the icon. The next step is to create the script to optimize the structure.

Optimize the MoS_2 structure

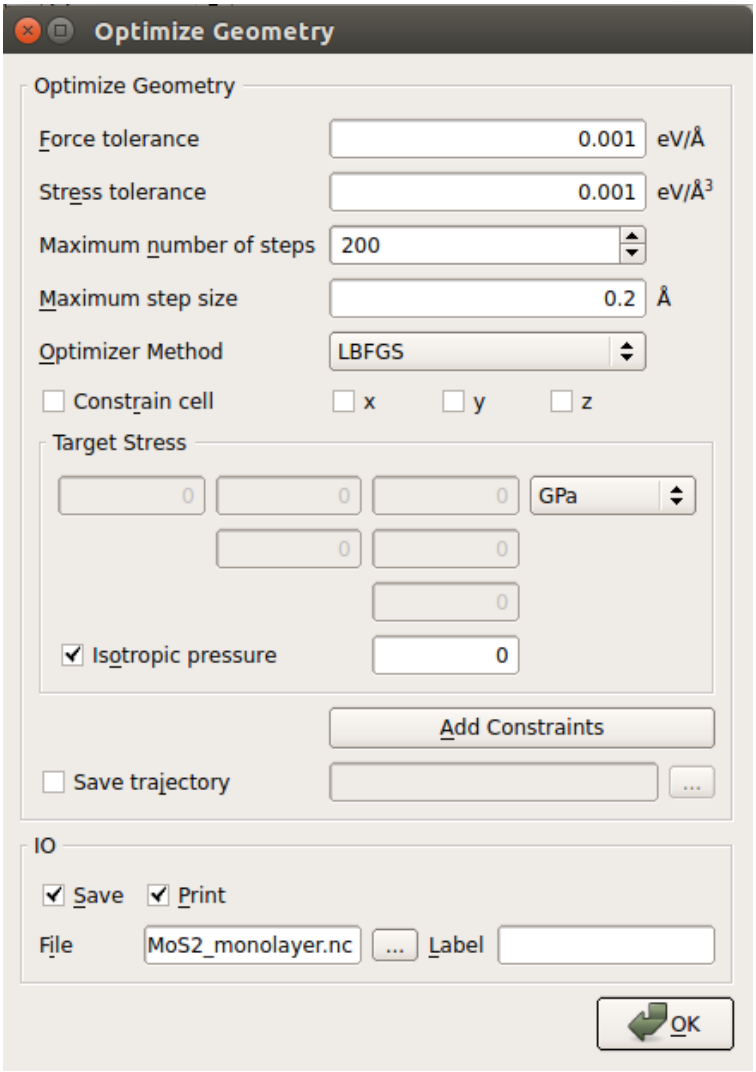
•Add **New Calculator** and **OptimizeGeometry** blocks.

•In New Calculator, use the **ATK-ForceField** engine and in particular the StillingerWebber_MoS_2013 potential`.

Note: For QuantumATK-versions older than 2017, the **ATK-ForceField** calculator can be found under the name **ATK-Classical**.



•In **OptimizeGeometry**, reduce the force and stress tolerance to 0.001 eV/Å and 0.001 eV/Å^3, click OK and save the script before running the optimization.



•Save the script as `mos2_relax.py`. Run the script by sending it to the Job Manager, or from a terminal with the command

```
$ atkpython mos2_relax.py > mos2_relax.out
```

An example script `mos2_relax.py` is available to download.

Note: In the case of monolayer, the potential agrees exactly with Ref.[1]. However, the Lennard-Jones potential reported in the reference for the inter-layer coupling has not yet been implemented.

---

[1] Jin-Wu Jiang, HaroldăS. Park, and Timon Rabczuk. Molecular dynamics simulations of single-layer molybdenum disulphide (MoS2): Stillinger-Weber parametrization, mechanical properties, and thermal conductivity. *Journal of Applied Physics*, 114(6):, 2013. doi:10.1063/1.4818414.

Phonon band structure and density of states

The phonon band structure and the phonon density of states are now easily obtained:

•Drop the optimized MoS_2 `BulkConfiguration` onto the Scripter and add a New Calculator by double clicking it.

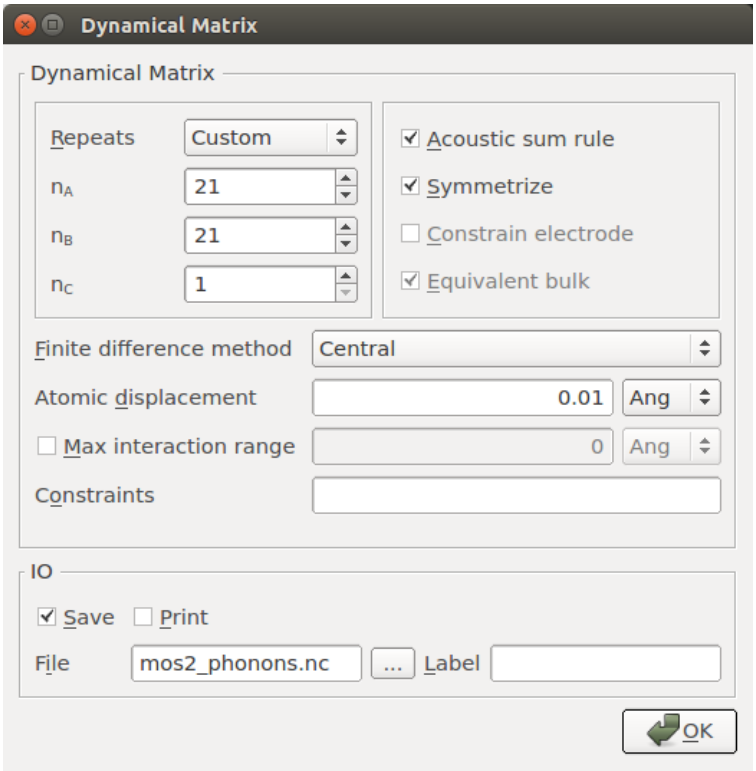
•Change the default output file to `mos2_phonons.nc`.

•Check if the calculator is set to **ATK-ForceField**.

•Add the *Analysis → PhononDensityOfStates* and *Analysis → PhononBandstructure* analysis objects.

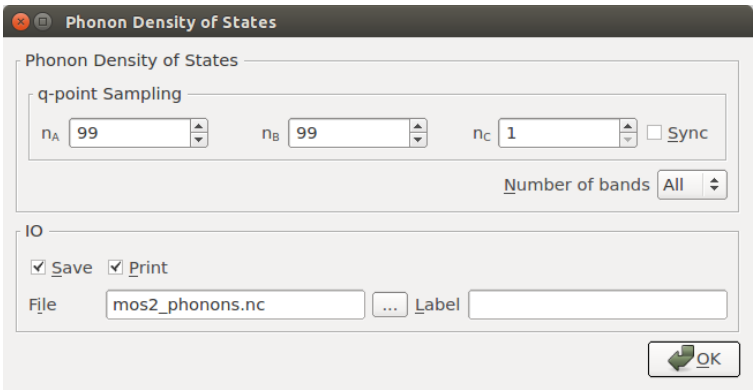
•Note that the *DynamicalMatrix* was automatically added also.

•Open the DynamicalMatrix block and select *Repeats → Custom* and set the repeats to (21,21,1).



•Open **PhononBandstructure** and set Points pr. segment to 400 and set the Brillouin zone route to the sequence [G, M, K, G].

•In *Analysis→PhononDensityOfStates*, untick Sync and set the q-point sampling to (99, 99, 1).



Run calculation and analyze results

Run the calculation. Once finished, the **LabFloor** should contain the **PhononBandstructure** and **PhononDensityOfStates** objects:

- PhononBandstructure

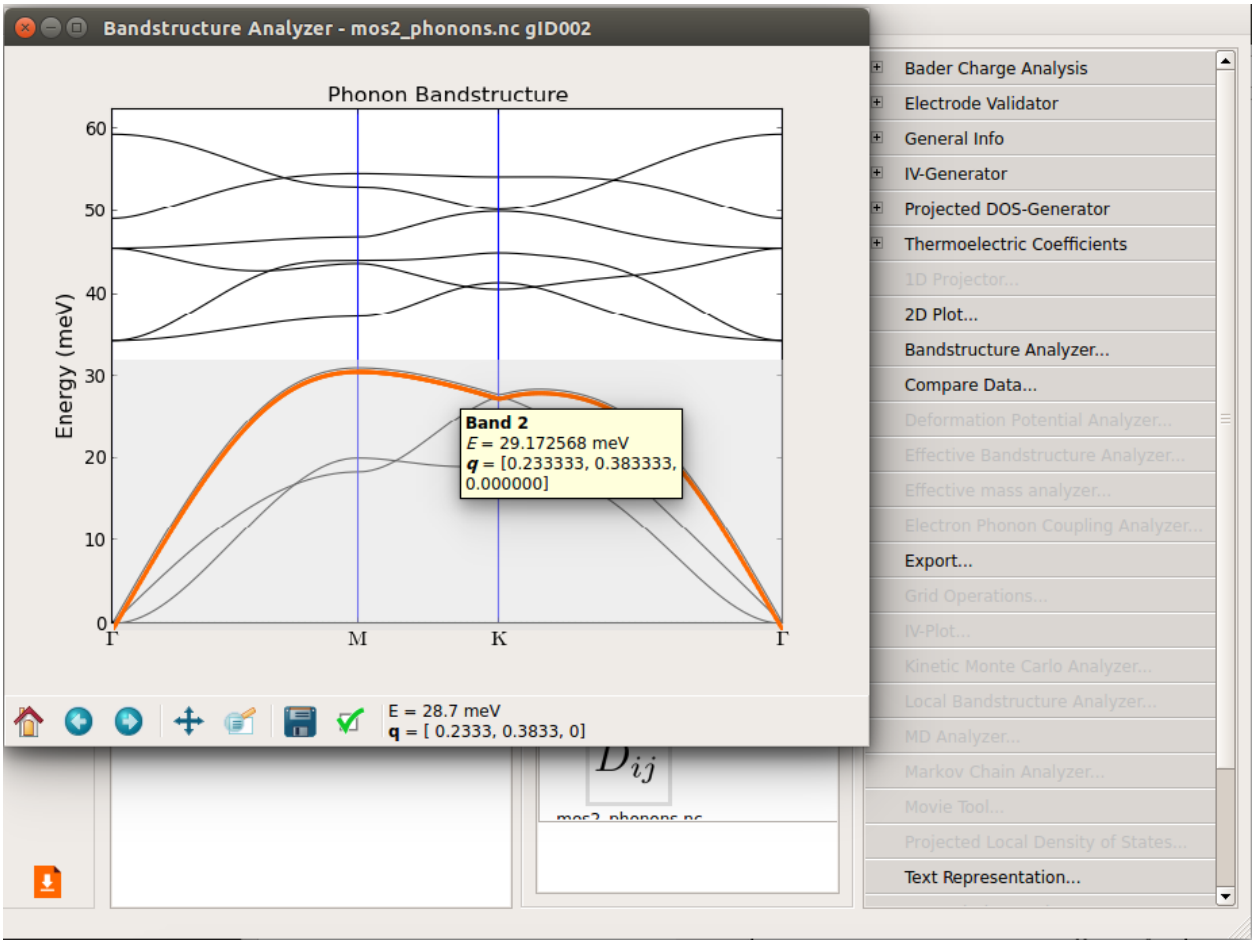
$$\{\omega_i(\mathbf{q})\}$$

- PhononDensityOfStates

$$D(\omega)$$

Inspect the phonon band structure and density of states using the **Bandstructure Analyzer** and **2D Plot** tools. The results are in complete agreement with literature data[2].

[2] Jin-Wu Jiang, HaroldăS. Park, and Timon Rabczuk. MoS2 nanoresonators: Intrinsically better than graphene? *Nanoscale*, 6:3618–3625, 2014. doi:10.1039/C3NR05991J.



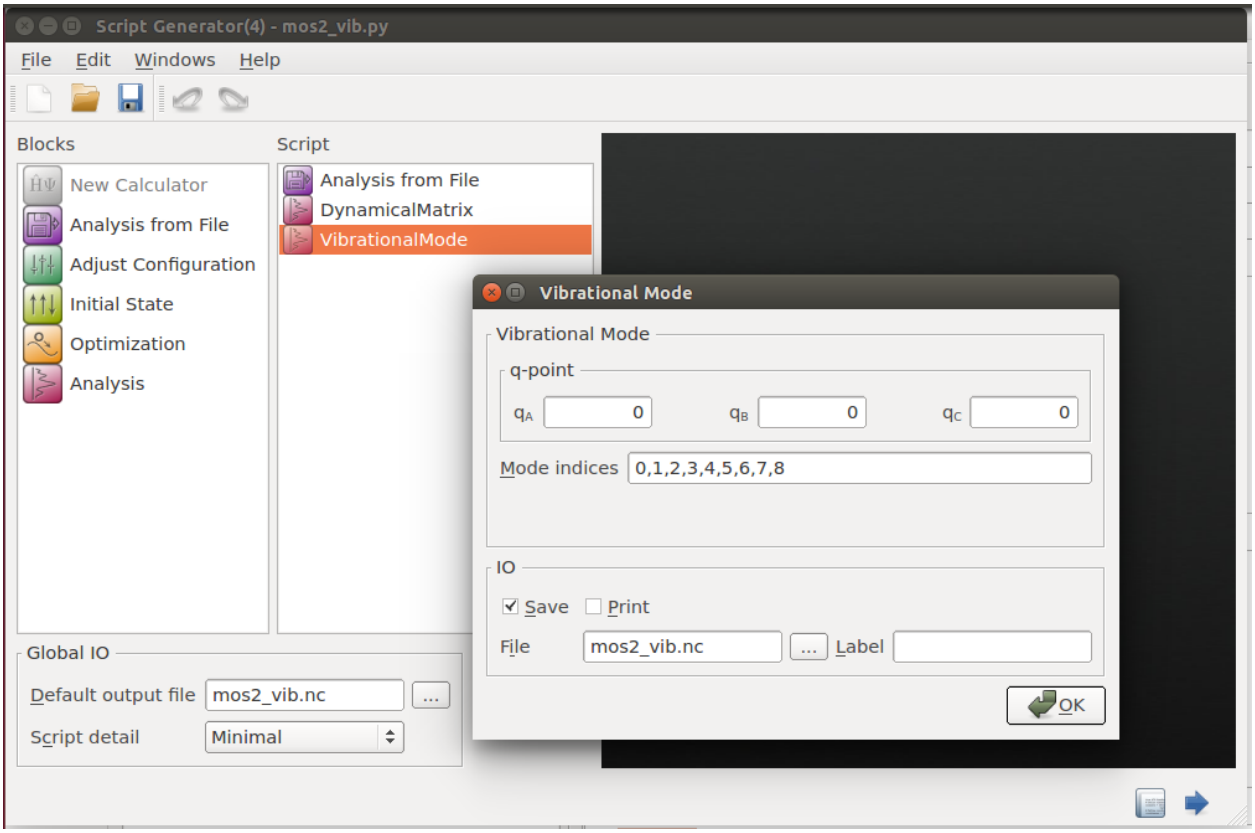
Vibrational Modes

To visualize the vibrational modes, a simple post-processing is sufficient:

•Open the Script Generator and do the following:

•Add an **Analysis from File** block, double click to open it, select the output file `mos2_phonons.nc`, and choose the subject id as gID000.

•Add a *Analysis→VibrationalMode* analysis object and select the q-point coordinates and mode indices of interest.



The script will recalculate the dynamical matrix, which is inconvenient. To reuse the already calculated dynamical matrix, send the script to the editor and change the line defining the dynamical matrix such that it reads object gID001 from the file `mos2_phonons.nc`.

```
# ------------------------------------------------------------
# Analysis from File
# ------------------------------------------------------------
configuration = nlread('mos2_phonons.nc', object_id='gID000')[0]

# ------------------------------------------------------------
# Dynamical Matrix
# ------------------------------------------------------------
dynamical_matrix = nlread('mos2_phonons.nc', object_id='gID001')[0]

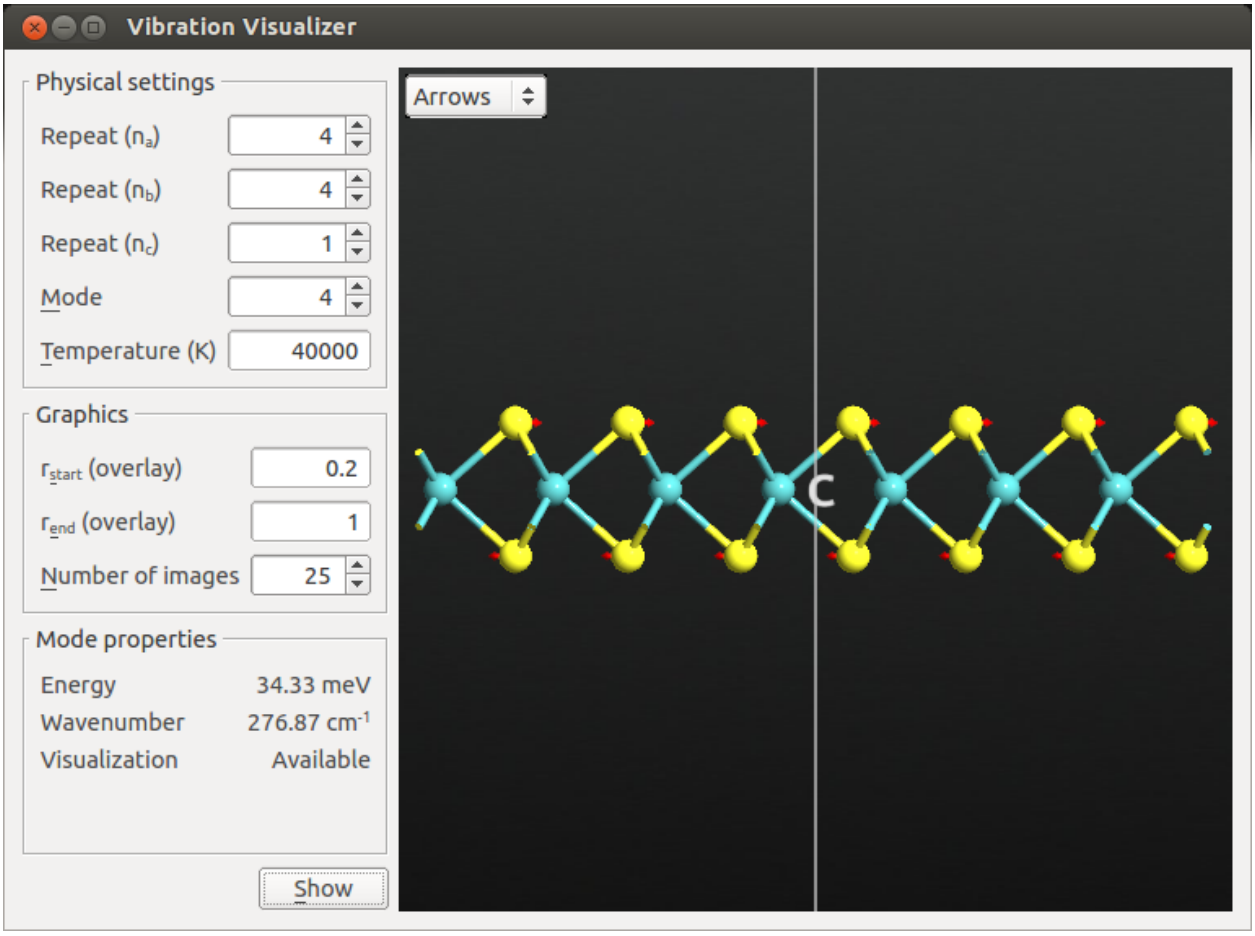
# ------------------------------------------------------------
# Vibrational Mode
# ------------------------------------------------------------
vibrational_mode = VibrationalMode(
    configuration=configuration,
    dynamical_matrix=dynamical_matrix,
    kpoint_fractional=[0, 0, 0],
    mode_indices=[0,1,2,3,4,5,6,7,8]
    )
nlsave('mos2_vib.nc', vibrational_mode)
```

Execute the script, and when the calculation is complete you will find the **VibrationalMode** object on the **LabFloor**:

- VibrationalMode

$\mathbf{u}_{i,\mathbf{q}}(\mathbf{r})$

Select it and open it by clicking the **Vibration Visualizer** plugin. You can then visualize the vibrational mode as an animation.



Once you are done with the settings you can right click on the plot to export as a picture or as an animated gif. The two animated gifs below illustrate mode 4 at (276.87 cm^{-1}) and at M (252.32 cm^{-1}), respectively.

You can play around with the Vibration Visualizer and compare the results with the literatures values in[Page 1110, 234].

Thermal Conductivity of Monolayer Molybdenum Disulfide Obtained from Temperature-Dependent Raman Spectroscopy. *ACS Nano*, 8(1):986–993, 2014. doi:10.1021/nn405826k.

Nanophononic metamaterials

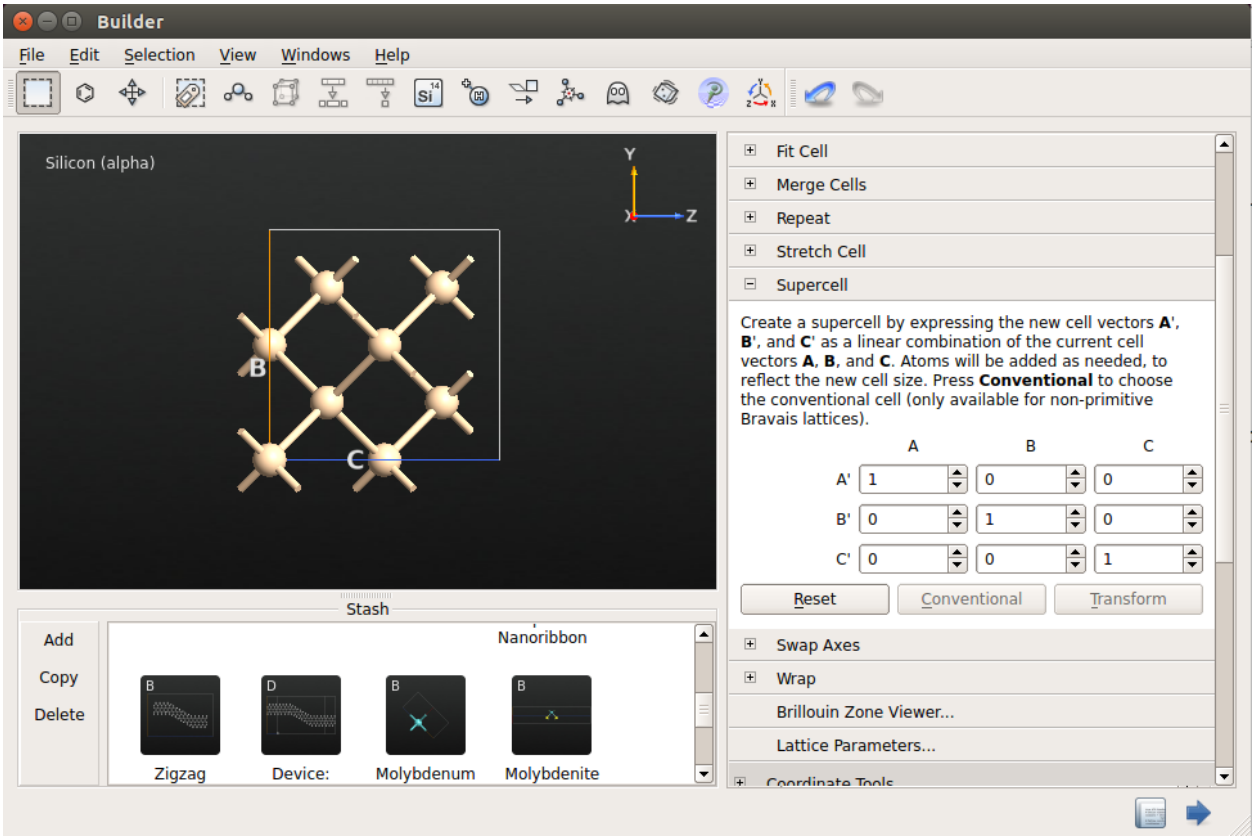
Another great example of the vibrational mode analysis is simulation of a nanophononic metamaterial. Bruce L. Davis and Mahmoud I. Hussein recently reported that specific vibrational modes of pillared silicon thin films will strongly suppress the thermal conductivity of the films due to the local resonance[5]. Lets study the vibrational feature of the structure using **ATK**:

Calculation Setup

Open the **Builder** and do the following:

•Use *Add* → *From Database* to add Silicon (alpha) to the Stash.

•Transform the primitive cell into the conventional cell using *Bulk Tools* → *Supercell*.



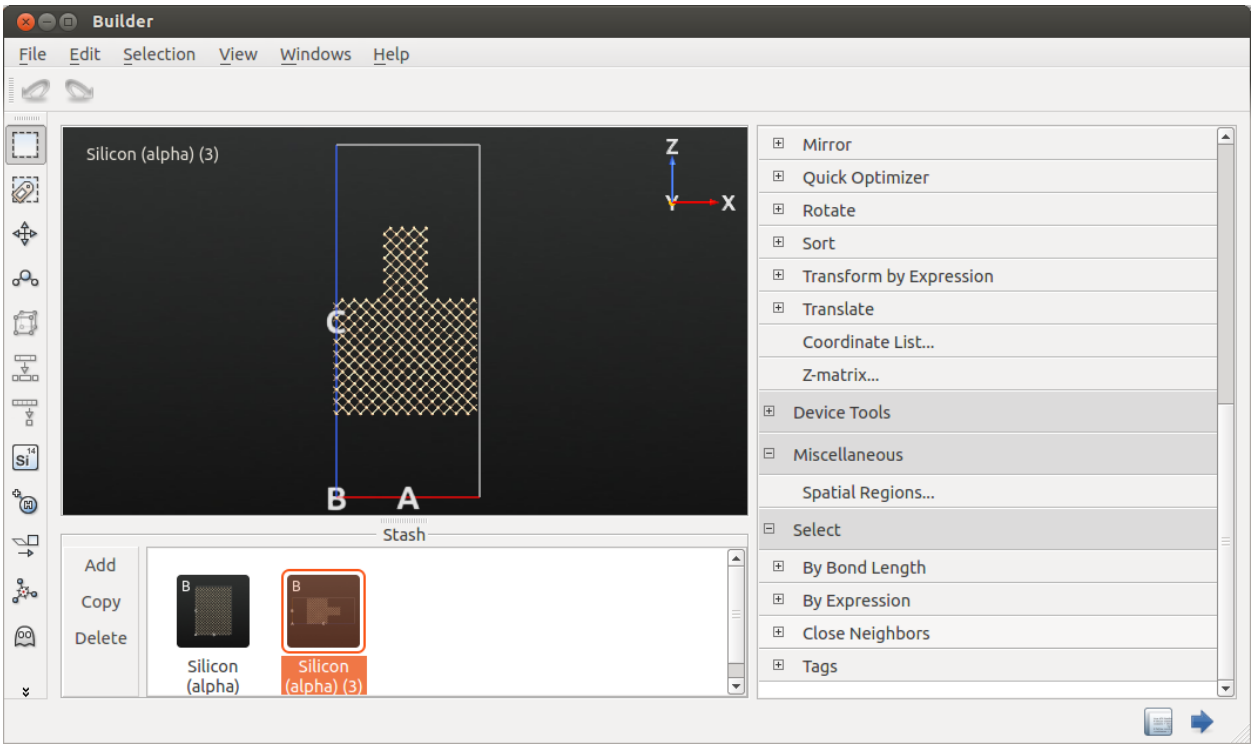
•Use the *Bulk Tools* → *Repeat* to repeat the structure 6x6x8 times to create a configuration with 2304 silicon atoms.

•Use the **Selection Tools**, in particular *Selection by Expression*, to cut out a pillared structure.

Tip: The expression z > 20 and x < 10 will select one particular part of the configuration that could then be removed by *Edit* → *Delete Atoms*.

•Adjust the structure by increasing the lattice vector and pillar pointing direction to create a vacuum region above and below the pillared film.

[5] BruceăL. Davis and MahmoudăI. Hussein. Nanophononic Metamaterial: Thermal Conductivity Reduction by Local Resonance. *Phys. Rev. Lett.*, 112:055505, Feb 2014. doi:10.1103/PhysRevLett.112.055505.



•Send the configuration to the **Scripter** and add a **Calculator**, a **PhononBandstructure** analysis object and two **VibrationalMode** objects.

•Setup the calculator to use ATK-ForceField.

Tip: You can leave the settings in **DynamicalMatrix** by defaults when calculating a 3D structure.

•Open **PhononBandstructure** and

–set Points pr. segment to 100,;

–set Number of bands to 50;

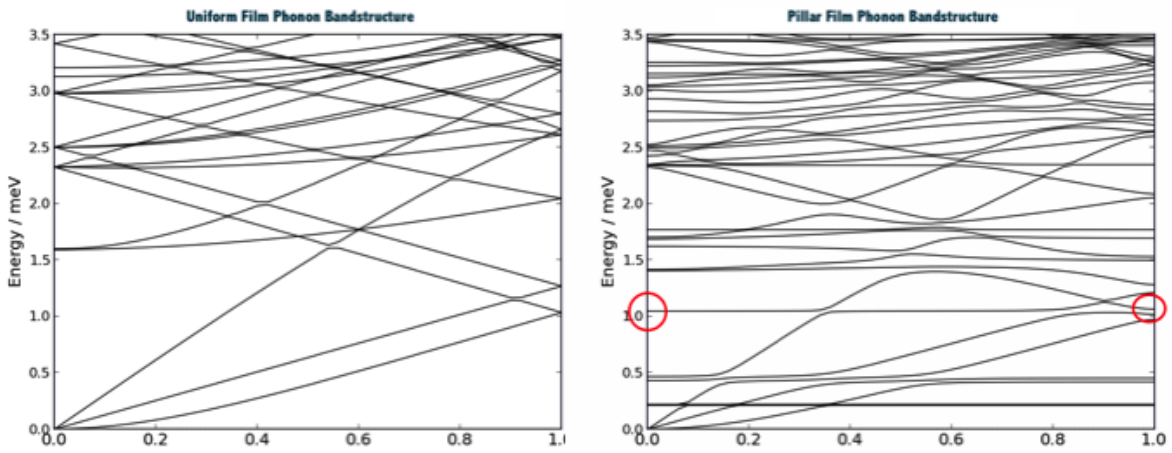
–set the Brillouin zone route to [G, X].

•Edit both **VibrationalMode** objects such as to calculate the vibrational modes in the point (0, 0, 0) and in the X point (0.5, 0, 0) and select mode indices [0,1,2,3,4,5,6,7,8] in both objects.

•Run the calculation. It will take a while for a single CPU core, but will be very efficient if the job is parallelized.

Results

Plot the calculated phonon bandstructure, and compare it with the phonon bandstructure of a uniform film. You can see that the array of pillars introduces a series of localized states (without dispersion), which are the states that lower the thermal conductivity of the silicon film, as explained in Ref.[Page 1114, 5].



The vibrational modes illustrated below are calculated for the localized state marked in the bandstructure plot above at and X points, respectively. The displacements are enhanced for a clearer view. This is controlled by the Temperature setting in the Vibration Visualizer plugin.

ATK Reference Manual Basic QuantumATK Tutorial

Introduction

The purpose of this tutorial is to illustrate the use of the **ATK** phonon module. The tutorial is applied to small toy problems such that the calculations are very fast. In the first chapter you will calculate the phonon bandstructure and density of states, and learn about how these modules work. In the second chapter you will study a device system and calculate the electronic and phonon thermal transport coefficients, as well as the electrical transport coefficients. From those coefficients you obtain the thermoelectric figure of merit ZT.

Note: You will primarily use the graphical user interface **QuantumATK** for setting up and analyzing the results. To familiarize yourself with **QuantumATK**, it is recommended to go through the Basic QuantumATK Tutorial.

The underlying calculation engines for this tutorial is **ATK-ForceField** and **ATK-SE**. A complete description of all the parameters, and in many cases a longer discussion about their physical relevance, can be found in the ATK Reference Manual.

In order to run this tutorial, you must have a license for ATK-SE. If you do not have one, you may obtain a time-limited demo license by contacting us via our website: Contact QuantumATK.

Phonon Bandstructure of a Graphene Nanoribbon

Setting up the geometry

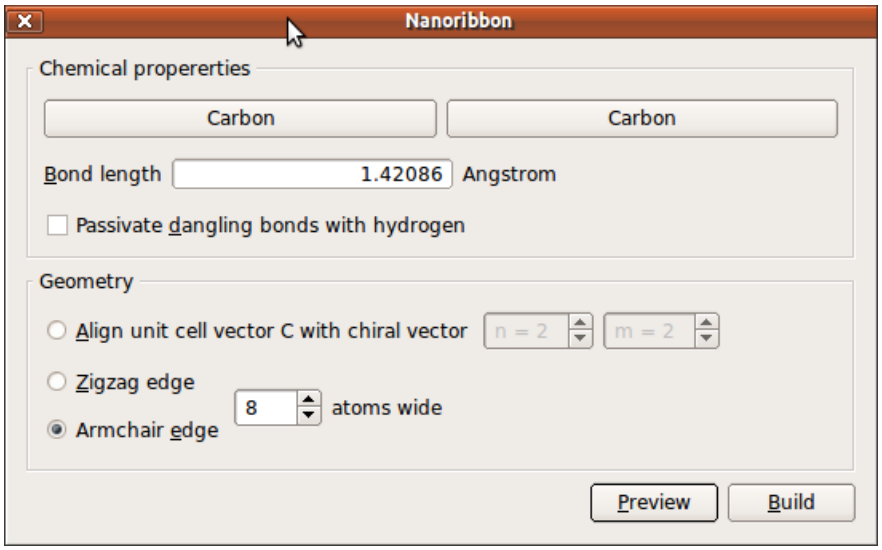
Start **QuantumATK** and create a new project. Launch the **Builder** by clicking the icon on the toolbar.

In the builder, click *Add* → *From Plugin* → *Nanoribbon*.

•Uncheck the `Passivate dangling bonds with hydrogen` checkbox.

•Select `Armchair` edge.

•Select the structure 8 atoms wide.



Press the `Build` button to build the structure.

In order to make sure that the phonon module can detect that the structure is one dimensional, you need to have ~ 7 Å vacuum on both sides of the structure. To this end open *Bulk Tools* → *Lattice Parameters*.

•Increase A-x to 20 Å.

•Increase B-y to 30 Å.

and close the widget.

Next, open *Coordinate Tools* → *Center*, and press `Apply` to center the nanoribbon in the unit cell. Send the structure to the **Script Generator**, by using the **Send To** icon in the lower right-hand corner of the **Builder** window.

Defining the phonon calculation

In the following you will optimize the geometry and calculate the Phonon bandstructure and DOS of the nanoribbon using a Tersoff potential.

In the **Script Generator**

•Add a **ForceFieldCalculator**

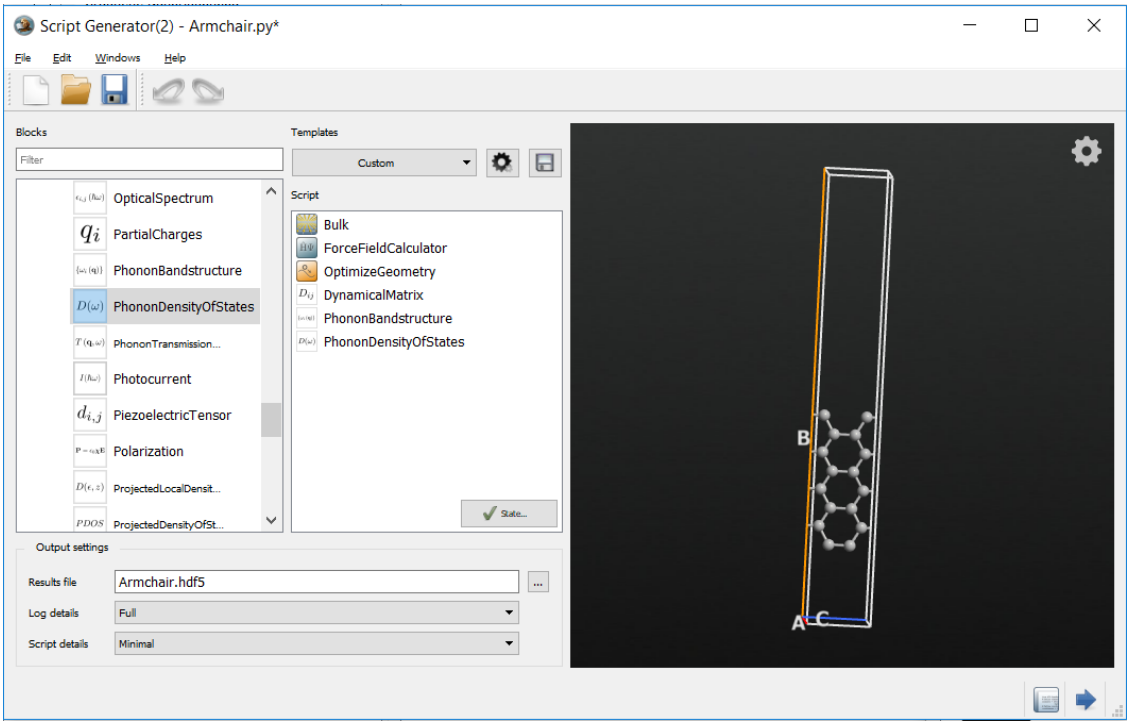
•Add an **Optimization > OptimizeGeometry**

•Add an **Analysis > PhononBandstructure**

•Add an **Analysis > PhononDensityOfStates**

•Change the output file to `armchair.hdf5`.

If you take a look at the blocks in the **Script Generator**, you will notice that a **DyamicalMatrix** block has automatically been added as the selected phonon analysis functions require the calculation of the dynamical matrix.

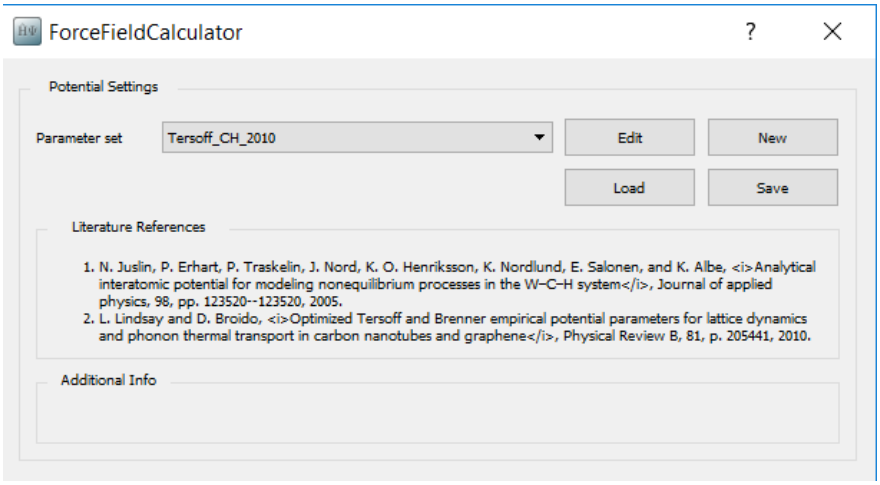


Adjusting script components

To set up the calculation parameters, make the following changes:

•Double-click the **ForceFieldCalculator** block and select the *Tersoff_C_2010* potential.

Note that depending on the elements present in your configuration you will be able to choose among several potentials. A literature reference is also shown, giving you the possibility to check exactly how the potentials have been generated. It is very important that the potential you will use has been generated for a similar system or for similar conditions as your system.



In this case you can immediately see that the *Tersoff_C_2010 potential* is potentially well suited for your phonon analysis: Optimized Tersoff and Brenner empirical potential parameters for lattice dynamics and phonon thermal transport in carbon nanotubes and graphene.

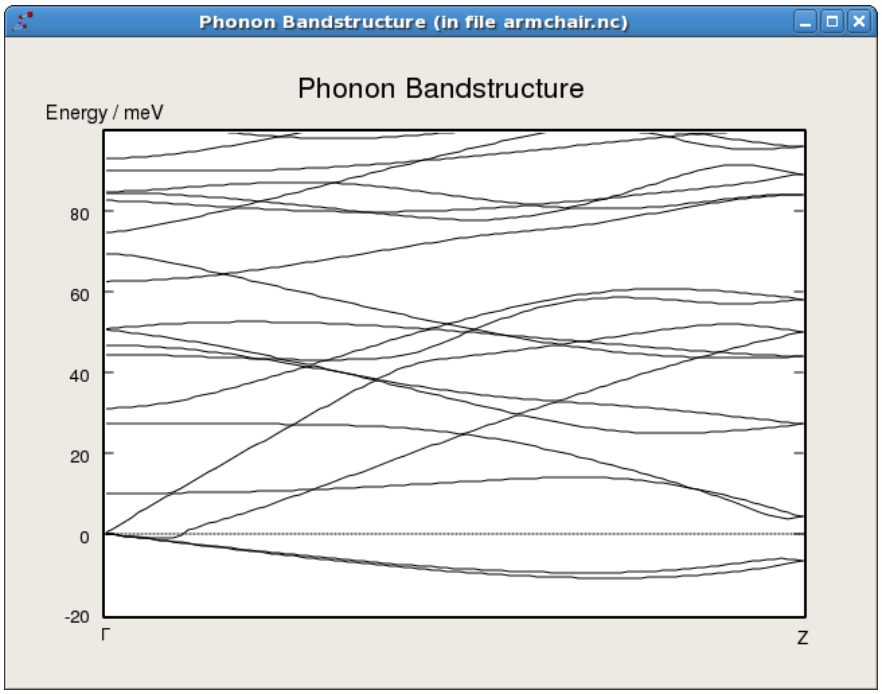
Note: For QuantumATK-versions older than 2017, the **ATK-ForceField** calculator can be found under the name **ATK-Classical**.

- Double-click the **OptimizeGeometry** and set maximum force to 0.01 eV/Å.
- Double-click the **PhononBandstructure** and set `Points per segment` to 100.
- Double-click the **PhononDensityOfStates**. In the *q-point Sampling* box select `Sampling`, uncheck the `Sync` box, and set `qc` to 51.

Transfer the script to the **Job Manager** (again using the Send To icon) and run the calculation.

Analyzing the Results

The generated output file `armchair.hdf5`, visible on the **LabFloor**, now contains a *PhononBandstructure* object. Select this PhononBandstructure object on the **LabFloor** and press **2D Plot** in the plugin panel. Zoom into the low frequency area to get the figure below.



Note the negative bands arising from stress in the nanoribbon which makes it unstable perpendicular to the plane.

Origin of negative phonon bands

The negative bands seen in the phonon spectrum indicate that the structure is at a saddle point and can gain energy by further relaxing. The problem is that you only performed a force optimization and not a stress optimization, thus there is a large stress in the structure and it would like to release the stress by relaxing perpendicular to the graphene plane.

Relaxing the stress in the configuration

In order to relax the stress in the configuration, open the **Script Generator** again.

Tip: All open tools are available from the *Windows* menu at the top of each **QuantumATK** tool.

Next open the **OptimizeGeometry** block.

- Set `Maximum stress` to 0.0001 eV/Å ^{3}.
- Remove check from `z` in `Constrain cell` to allow optimization of the z-component of the cell.

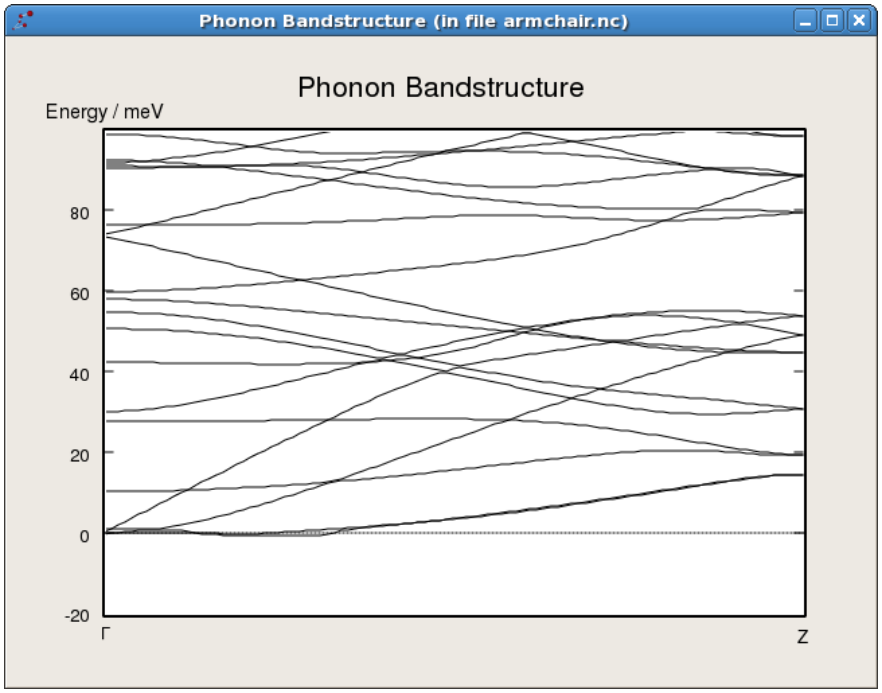
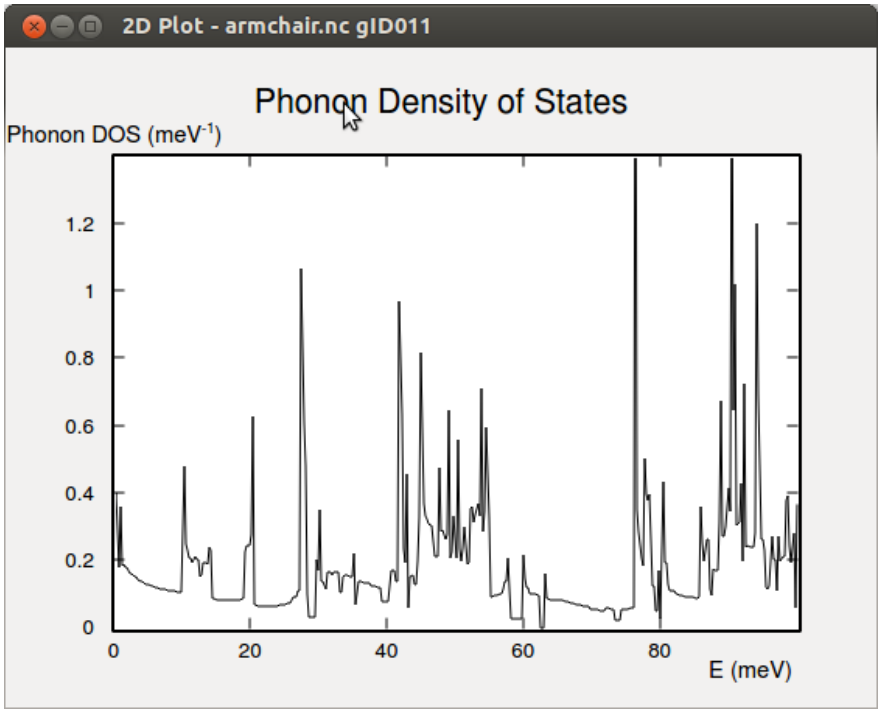
Press OK to close the widget, transfer the script to the **Job Manager** and run the calculation. When you open the phonon bandstructure you will see that the the negative bands are now gone.



The density of states

The `armchair.hdf5` file also contains the phonon density of state (DOS) of the armchair nanoribbon with and without stress relaxation. Below the phonon DOS of the fully (i.e. forces- and stress-) optimized system is shown.



From the phonon DOS it is possible to calculate the free energy, entropy, and zero point energy of the system. In QuantumATK this is implemented in the methods `freeEnergy()`, `entropy()`, and `zeroPointEnergy()` of the PhononDensityOfStates object. The script below shows how to evaluate the entropy:

```
# Read the last configuration in the output file
configuration = nlread('armchair.hdf5', BulkConfiguration)[-1]
# Read the last phonon DOS in the output file
phonon_dos = nlread('armchair.hdf5', PhononDensityOfStates)[-1]

# Define the temperature
t = 300*Kelvin

# Calculate the entropy
s = phonon_dos.entropy(t)

# Print results
print 'Entropy = ', s
```

Execute the script by dropping it on the Job Manager, and in the **Log** you will get the output:

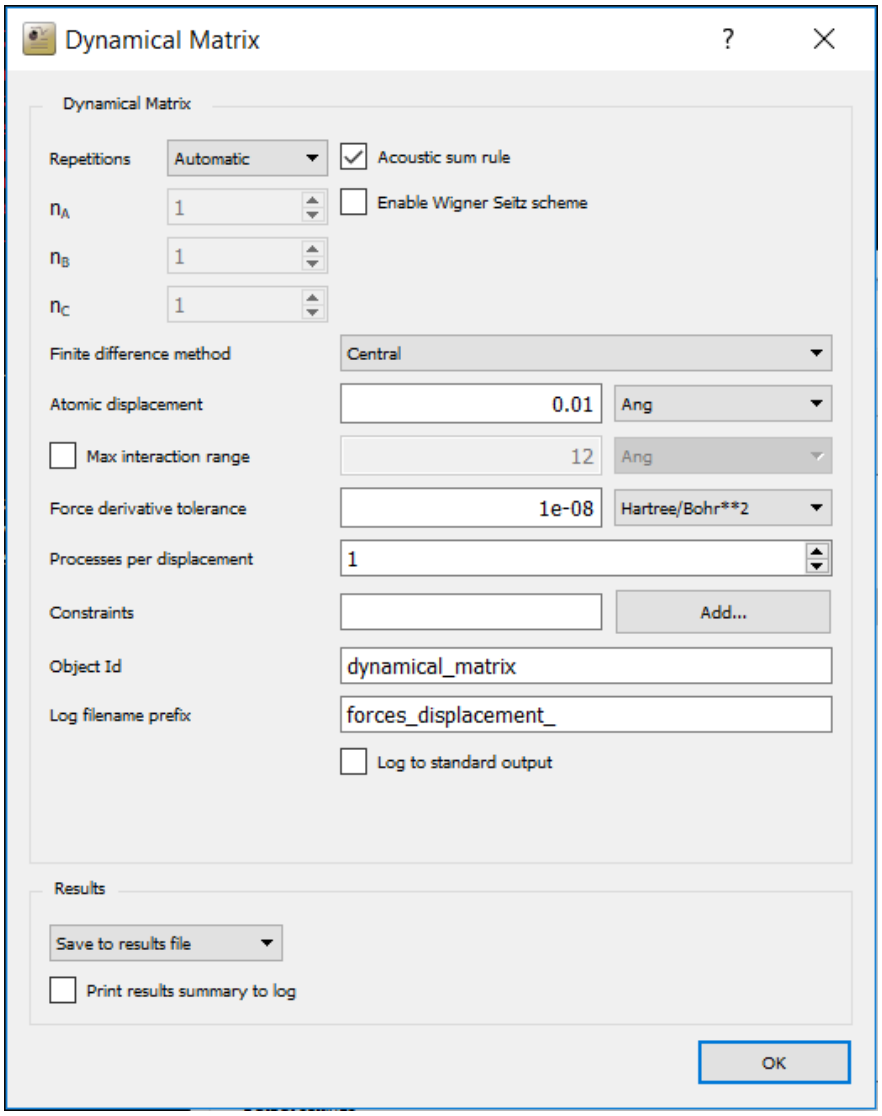
```
Entropy =  4.36888578559 meV/K
```

Algorithmic Details of the Phonon Calculator

The phonons are calculated from the dynamical matrix of the system. The dynamical matrix is the second derivative of the system, corresponding to the first derivative of the forces. The first derivative of the forces are calculated using a finite difference scheme, where the system is displaced along each degree of freedom in the system, also called *frozen phonon* calculations.

When you add a new phonon analysis in the **Script Generator**, it checks if a dynamical matrix is already present. If this is not the case, a **DynamicalMatrix** study object will automatically be added to calculate the dynamical matrix. The **DynamicalMatrix** object of a configuration can be stored in an `.hdf5` file and read again to be used in another calculation.

The details of the calculation of the dynamical matrix is controlled by the parameters in the **DynamicalMatrix** object.



The `Repetitions` parameter allows you to specify how many repetitions of the central cell are employed to calculate forces when the atoms in the central region are displaced. Setting it to `Automatic` will make sure that enough repetitions are used, to fit around each atom in the central region a buffer zone of four times its covalent radius, in which the force derivatives are taken into account. For the current system the **Log** file reports:

```
| Phonon: Automatically detected repetitions = [1 1 5]                    |
```

The size of this buffer region can be changed either by using `Custom` repetitions or by enabling and setting the `Max interaction range` parameter, which replaces the default buffer radius of four times the covalent radius. Furthermore, you can change some other parameters, that determine e.g. whether the acoustic sum rule or symmetries are enforced, as well as numerical parameters, e.g. the finitie difference method or the displacement magnitude of the atoms in the central cell.

Note: In most cases the default values should work well. However, if you are using classical potentials with a long interaction range (e.g. potentials which include coulomb interactions), then it might be necessary to increase the `Max interaction range` to a value somewhat larger than the largest cutoff-radius of the potential. You can normally tell if this is necessary by unchecking `Acoustic sum rule` and inspecting the acoustic bands at the gamma point. If these

bands are not zero, in most cases the maximum interaction range is too low.

K-points used for ATK-DFT and ATK-SE

From QuantumATK-2019.03 onwards, the k-point sampling and density-mesh-cutoff will be **automatically** adapted to the given number of repetitions when setting up the super cell inside *DynamicalMatrix*. That means you can specify the calculator settings for the unit cell and use it with any desired number of repetitions in dynamical matrix calculations.

In previous versions of the code the number of k-points had to be adapted for the dynamical matrix calculation. This is now handled automatically, so the k-points used for phonon calculations do not need to be modified.

Calculating Electrical and Heat Transport for a Graphene Nanoribbon

In this section we will calculate the phonon transmission coefficient for the armchair nanoribbon from which the phonon thermal conductance can be obtained. This will be combined with a calculation of the electron transmission coefficient from which the conductance, Peltier coefficient and electron thermal conductance can be obtained. The different parameters are combined for calculating the thermoelectric figure of merit, ZT. The methodology for the calculations are described in Ref.[1].

Setting up the graphene nanoribbon device

The first step is to build a device geometry from the relaxed armchair nanoribbon. In the **QuantumATK** main window select the last configuration in the `armchair.hdf5` file and drag and drop the configuration onto the **Builder**.

In the builder perform the following operations:

•*Bulk Tools* → *Repeat*: Repeat 5 times in **C**-direction.

•*Device Tools* → *Device From Bulk*: Default values are fine, press `OK` to create the device.

Send the resulting device configuration to the **Script Generator**.

Defining the transmission calculations

In the following you will setup the phonon and electron transmission calculations. For the phonon calculation you will use the Tersoff potential while using a carbon pi tight-binding model for the electron transmission calculation.

•Add a **ForceFieldCalculator**.

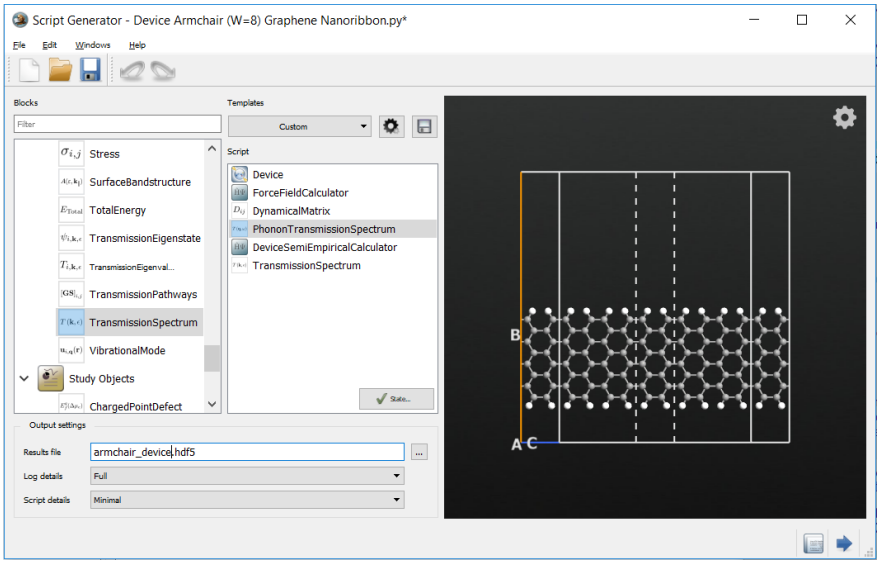
•Add an **Analysis > PhononTransmissionSpectrum**.

•Add a **SemiEmpiricalCalculator**.

•Add an **Analysis > TransmissionSpectrum**.

•Change the output file to `armchair_device.hdf5`.

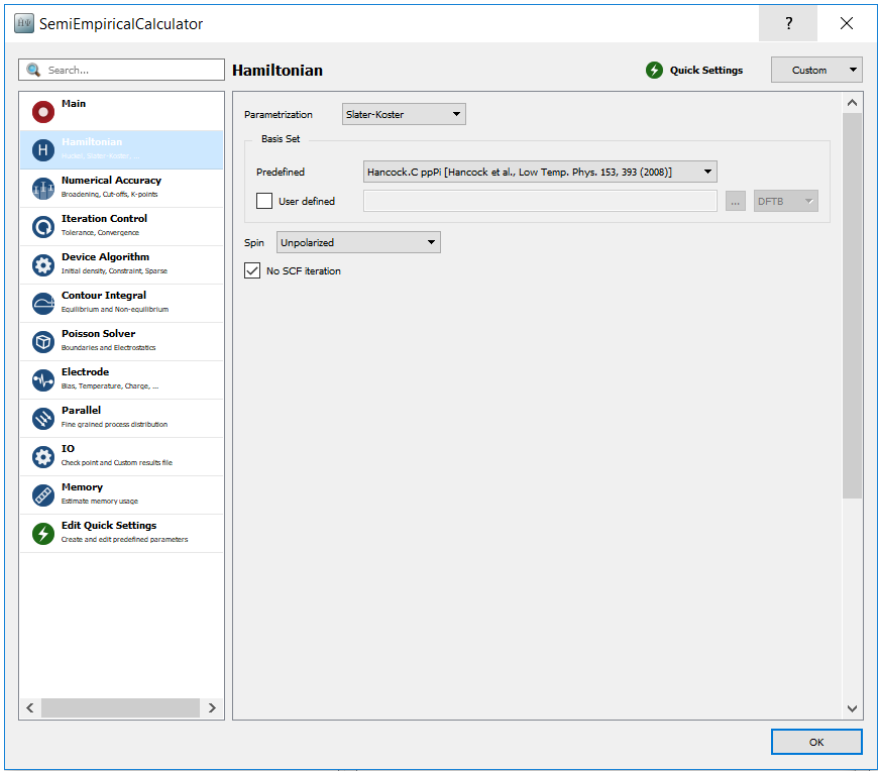
[1] T. Markussen, A.-P. Jauho , M. Brandbyge: Surface-Decorated Silicon Nanowires: A Route to High-ZT Thermoelectrics Phys. Rev. Lett 103, 055502 (2009)



Adjusting script components

To set up calculation parameters, make the following changes:

- Double-click the **ForceFieldCalculator** and select the *Tersoff_C_2010* potential. In the results box select `Do not save` and uncheck the `Print results summary to log` box.
- No changes need to be made to the **PhononTransmissionSpectrum**.
- Double-click the second **SemiEmpiricalCalculator** and select the `Hamiltonian` settings. In the *Basis Set* box select the *Hancock.C ppPi* basis set.

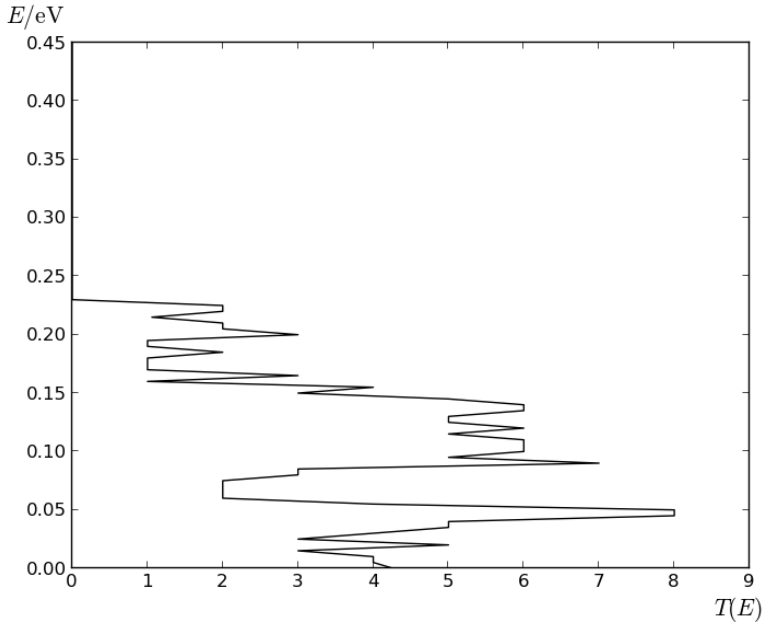


•No changes need to be made to the **TransmissionSpectrum**.

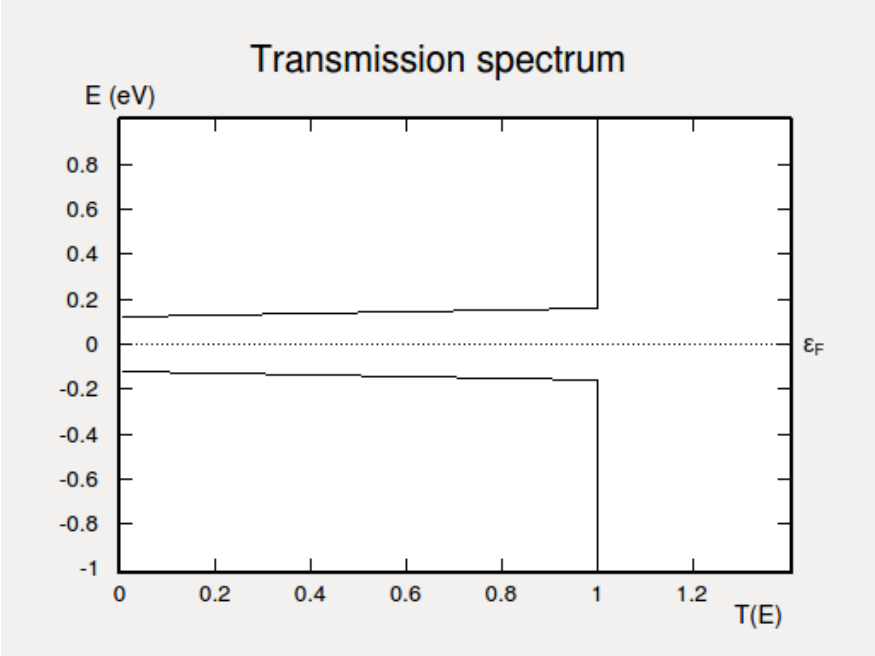
Transfer the script to the **Job Manager** and run the calculation.

Analyzing the results

Now inspect the result file `armchair_device.hdf5` in the **QuantumATK** main window. You may select the *Phonon-TransmissionSpectrum* and the electron *TransmissionSpectrum* and plot them using the **Transmission Analyzer** or the **2D Plot** analysis plugin.



The phonon transmission spectrum of the armchair nanoribbon.



The electron transmission spectrum of the armchair nanoribbon, zoomed into the energy range from -1 to 1 eV.

The thermo-electric figure of merit

In this section you will calculate the linear response transport coefficients of an applied voltage difference (dU) or temperature difference (dT) between the two electrodes. The coefficients are:

The conductance,

$$G_e = \left.\frac{dI}{dU}\right|_{dT=0} .$$

The Peltier coefficient,

$$\Pi = \left.\frac{I_Q}{I}\right|_{dT=0} .$$

The Seebeck coefficient,

$$S = -\left.\frac{dU}{dT}\right|_{I=0} = \frac{\Pi}{U} .$$

The heat transport coeficient of electrons, κ_e, and phonons κ_{ph},

$$\kappa = \left.\frac{dI_Q}{dT}\right|_{I=0} ,$$

where $I_Q = dQ/dT$ is the heat current.

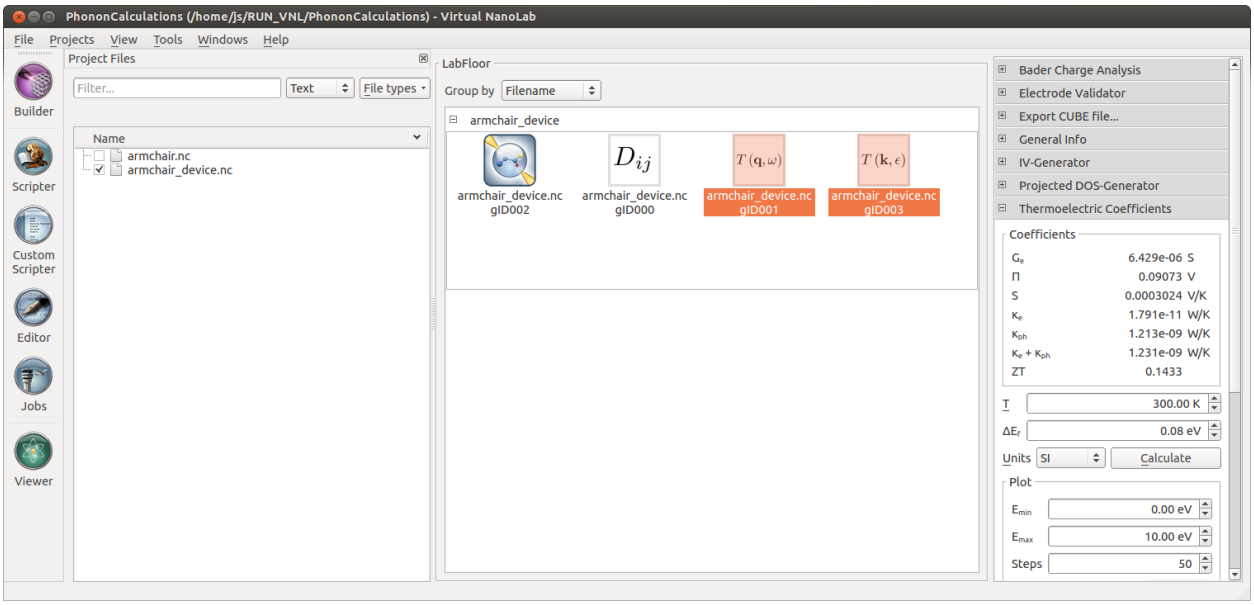
From these coefficients ypu can obtain the thermoelectric figure of merit

$$ZT = \frac{G_e S^2 T}{\kappa} ,$$

which quantifies how efficient a temperature difference can be converted into a voltage difference in a thermoelectric material.

These linear response coefficients are calculated by the **Thermoelectric Coefficients** plugin. To perform the calculation, select the *PhononTransmissionSpectrum* and the electron *TransmissionSpectrum* objects simultanously and press the `Calculate` button of the plugin.

For an undoped nanoribbon, the Fermi level is in the middle of the band gap. To get a significant Peltier coefficient the Fermi level must be at a band edge, corresponding to a doped nanoribbon. The plugin allows for shifting the Fermi level, and the following shows the result for $\Delta E_F = 0.08eV$, corresponding to an n-doped nanoribbon.



The **Thermoelectric Coefficients** plugin allows you to plot the different thermoelectric coefficients as a function of the energy. For example, the figure below reports the figure of merit ZT at 300K as a function of the energy. The peaks corresponding to the band edges are clearly visible.

3.7.4 Inelastic Electron Spectroscopy of an H_2 molecule placed between 1D Au chains

Version: 2017

This tutorial is focused on simulating inelastic electron tunneling spectroscopy (IETS)[1] for a device consisting of two one-dimensional (1D) gold electrodes and an H_2 molecule placed in between. After DFT calculations of the dynamical matrix and the Hamiltonian derivatives with respect to vibrations of the H_2 molecule, IETS is computed and analyzed based on the lowest-order expansion (LOE)[2] and extended LOE (XLOE)[3] approximations.

Note: It is assumed that you are familiar with QuantumATK. If not, go through the basic QuantumATK Tutorials first.

Introduction

We consider electron transport through a device consisting of an H_2 molecule clamped between 1D gold electrodes. In a spectroscopy experiment, if the applied bias is comparable to the energy of one of the vibrational modes of the H_2 molecule, a new inelastic transmission channel opens in which the transmission of electrons is mediated by the emission of a phonon. The coupling process is due to the coupling between electronic and vibrational degrees of freedom, that is, to the electron-phonon coupling. At a voltage where an inelastic channel opens, the derivative of the conductance, i.e., the second-derivative of the current has a peak. In experiments, IETS is defined by

$$\mathrm{IETS} \equiv \frac{dI^2/dV^2}{dI/dV},$$

and is measured to investigate, e.g., the electron-phonon coupling strength, heating, configuration, and local doping.

In the tutorial, you will first compute the dynamical matrix and the Hamiltonian derivatives with respect to vibrations of the H_2 molecule by DFT calculations, and then calculate and analyze the IETS signal based on two different approximations: LOE and XLOE. The rest of this tutorial is hence organized as follows:

1. Device setup,
2. Calculation of the dynamical matrix and the Hamiltonian derivatives,
3. Calculation of IETS based on LOE and XLOE,
4. Analysis of IETS based on the vibrational modes of the H_2 molecule,
5. Comparison between the LOE and XLOE results.

Device setup

Start up **QuantumATK** and create a new project. Instead of using **Builder** to create the device configuration, we use the QuantumATK Python script `au-h2-au_0.py`, which provides the Au|H_2|Au device. Download and save the script in the project folder, and open it from **Script Generator**.

•Add a **New Calculator** block and select GGA as the exchange correlation functional in the setting.

Note: The k-point sampling is by default 1x1x93, which should, however, be modified properly if the device is periodic in the A and/or B directions.

•Set the output-file name *au-h2-au.nc*, and save the python script as *au-h2-au.py*.

Note: The python script must now be the same as `au-h2-au.py`. To save time, one may just download the script and use it.

•Send the script to **Job Manager** and run it.

Calculation of IETS

The IETS calculation requires information of the dynamical matrix, which is defined in terms of the force for displacing the hydrogen atoms back and forth in each spatial direction. The computation involves six DFT calculations, which are all independent with each other, and is hence performed efficiently by using six CPU cores.

•In the **Script Generator**, click on *Analysis* from File and select *au-h2-au.nc*.

•Add a *Analysis* → *DynamicalMatrix* object and set it as follows:

•Add also a *Analysis* → *VibrationalModes* object and keep the default settings.

The IETS calculation requires information of the Hamiltonian derivatives as well. This calculation also consists of six independent parts, and is hence carried out efficiently using six CPU cores.

•Add a *Analysis* → *HamiltonianDerivatives* block and set it as follows:

•Add an *Analysis* → *InelasticTransmissionSpectrum*, choose LOE as the method, and set the rest as follows:

•Add another *Analysis* → *TransmissionEigenstates* block, and set it in the same way except choosing XLOE as the method.

•Set the output-file name *analysis.nc*, and save the python script as *analysis.py*.

Note: The python script must be the same as `analysis.py`. To save time, one may just download the script and use it.

The calculation will take less than one hour if six CPU cores are used, and save every result in *analysis.nc*.

Note: See *InelasticTransmissionSpectrum* in QuantumATK Manual, which provides a brief description about IETS and how it is computed from the dynamical matrix and the Hamiltonian derivatives. See also, e.g., Ref.[Page 1130, 2] for more details.

Analysis

Vibrational modes of the H_2 molecule

In the Labfloor, look at the vibrational modes of the H_2 molecule by selecting the $\mathbf{u}_{i,\mathbf{q}}(\mathbf{r})$ Vibrational Mode object in the *analysis.nc* file with the help of **Vibration Visualizer** plugin.

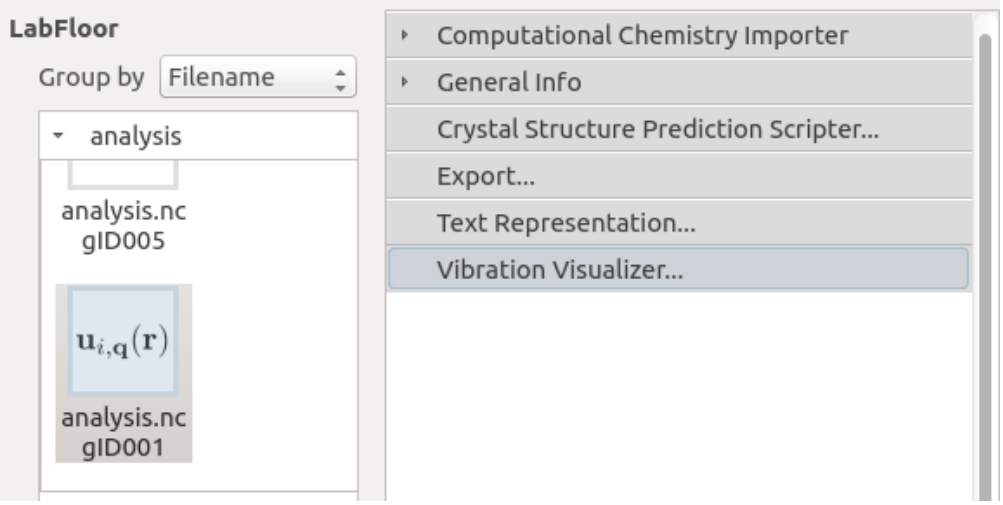
There are, in total, six modes: Four transverse modes 0, 1, 2, 3; two longitudinal modes 4 and 5. The two pairs of modes (0 and 1) and (2 and 3) are, respectively, doubly degenerated. Note that the temperature is set $T = 1000\ K$ in the movies below to see the vibrations clearly.

Mode 0: 25.44 meV; Mode 1: 25.63 meV (the small energy difference is due to numerical error)

Mode 2: 60.54 meV; Mode 3: 60.56 meV (the small energy difference is due to numerical error)

Mode 4: 127.46 meV

Mode 5: 264.06 meV



IETS

Then look at IETS. Select one of the $T(\mathbf{k},\mathbf{q})$ InelasticTransmissionSpectrum objects $T(\mathbf{k},\mathbf{q})$ in LabFloor and click on the **Inelastic Transmission Spectrum Analyzer** plugin, a new plugin available from **ATK2017**.

Set the panel as follows and click **Show**.

> **Attention:** Because the density of states (DOS) of the gold electrodes is almost flat within this bias window, there only exists a minor difference between the LOE and XLOE results. See the discussion below for more details.

There appear three significant inelastic features (steps in conductance and peaks in IETS). Note that the inelastic conductance is increased by the coupling to the low-frequency transverse modes 0-3 and decreased by the coupling to the high-frequency longitudinal mode 5. Analyzing the scattering states clarifies the reason of the increases.

- Drag the $\psi_{i,\mathbf{k},\epsilon}$ TransmissionEigenstates object $\psi_{i,\mathbf{k},\epsilon}$ in LabFloor into **Viewer**. Then drag the DeviceConfiguration into **Viewer**.
- Go to properties and, under the Isosurface flag, set the Isovalue to 0.5.

The scattering eigenstate has a clear *d*-symmetry on the gold chain. Hence, it couples only very weakly to the *s*-like states of the hydrogen atoms. The elastic transmission is thus small. The coupling to the transverse modes 0-3 can, however, open new inelastic channels and leads to positive steps in conductance and steps in IETS.

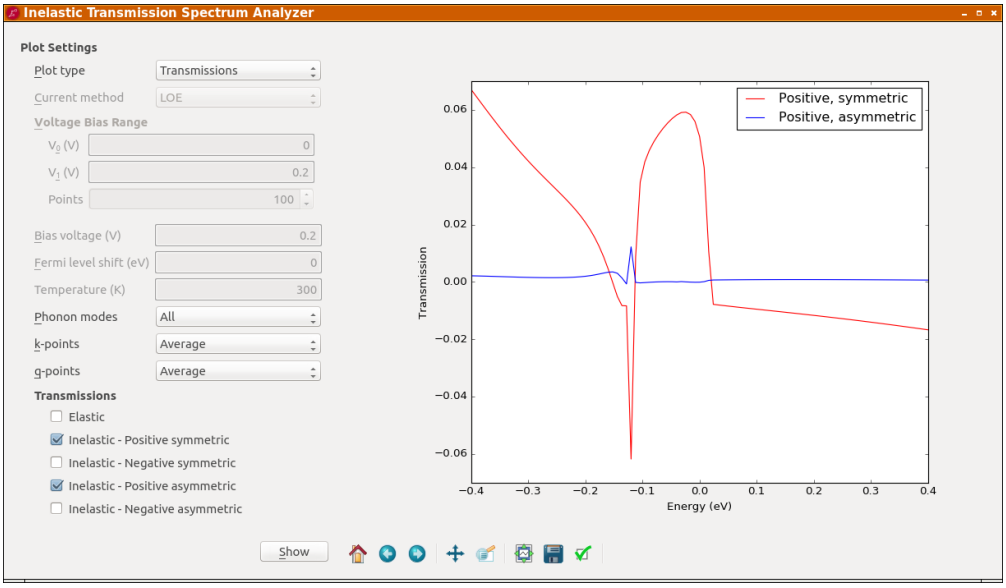
Detailed analysis of transmission: Comparison between LOE and XLOE

In the same window of the **Inelastic Transmission Spectrum Analyzer** plugin, now choose **Transmissions** in Plot type, set the options as shown below, and click **Show**. In this case, one will look at the positive symmetric and asymmetric parts of the inelastic transmission:



To understand some details of the transmission, note that, in either LOE or XLOE, the current as a function of the bias voltage V and the temperature T reads

$$I(V,T) = \sum_{\lambda} \left[\mathcal{I}_{\lambda}^{sym}(V,T)\mathcal{T}_{\lambda}^{sym}(\epsilon_F) + \mathcal{I}_{\lambda}^{asym}(V,T)\mathcal{T}_{\lambda}^{asym}(\epsilon_F) \right],$$

where ϵ_F is the Fermi energy, and the rest of the new symbols are defined as follows: In either approximation, the universal functions appear in the same form,

$$\mathcal{I}_{\lambda}^{sym}(V,T) = \frac{G_0}{2e} \sum_{\sigma=\pm} \sigma(\hbar\omega_\lambda + \sigma eV) \left(\coth \frac{\hbar\omega_\lambda}{2k_BT} - \coth \frac{\hbar\omega_\lambda + \sigma eV}{2k_BT} \right),$$

$$\mathcal{I}_{\lambda}^{asym}(V,T) = \frac{G_0}{2e} \int_{-\infty}^{\infty} d\epsilon \left[n_F(\epsilon - eV) - n_F(\epsilon) \right] \cdot \mathcal{H}_{\epsilon'} \left[n_F(\epsilon' - \omega_\lambda) - n_F(\epsilon' + \omega_\lambda) \right](\epsilon),$$

where $G_0 = 2e^2/h$ is the conductance quantum, $n_F(\cdot)$ is the Fermi-Dirac distribution function, and $\mathcal{H}_{\epsilon'}[\cdot](\epsilon)$ means the Hilbert transform. In XLOE, the transmission functions are given by

$$\mathcal{T}_{\lambda}^{sym}(\epsilon) = \mathrm{Tr}\left[M_\lambda \tilde{A}_L(\mu_L) M_\lambda A_R(\mu_R) \right] + \mathrm{Im}\, B_\lambda(\epsilon),$$

$$\mathcal{T}_{\lambda}^{asym}(\epsilon) = 2\mathrm{Re}\, B_\lambda(\epsilon),$$

with

$$\mu_L = \epsilon,$$

$$\mu_R = \epsilon \pm \hbar\omega_\lambda,$$

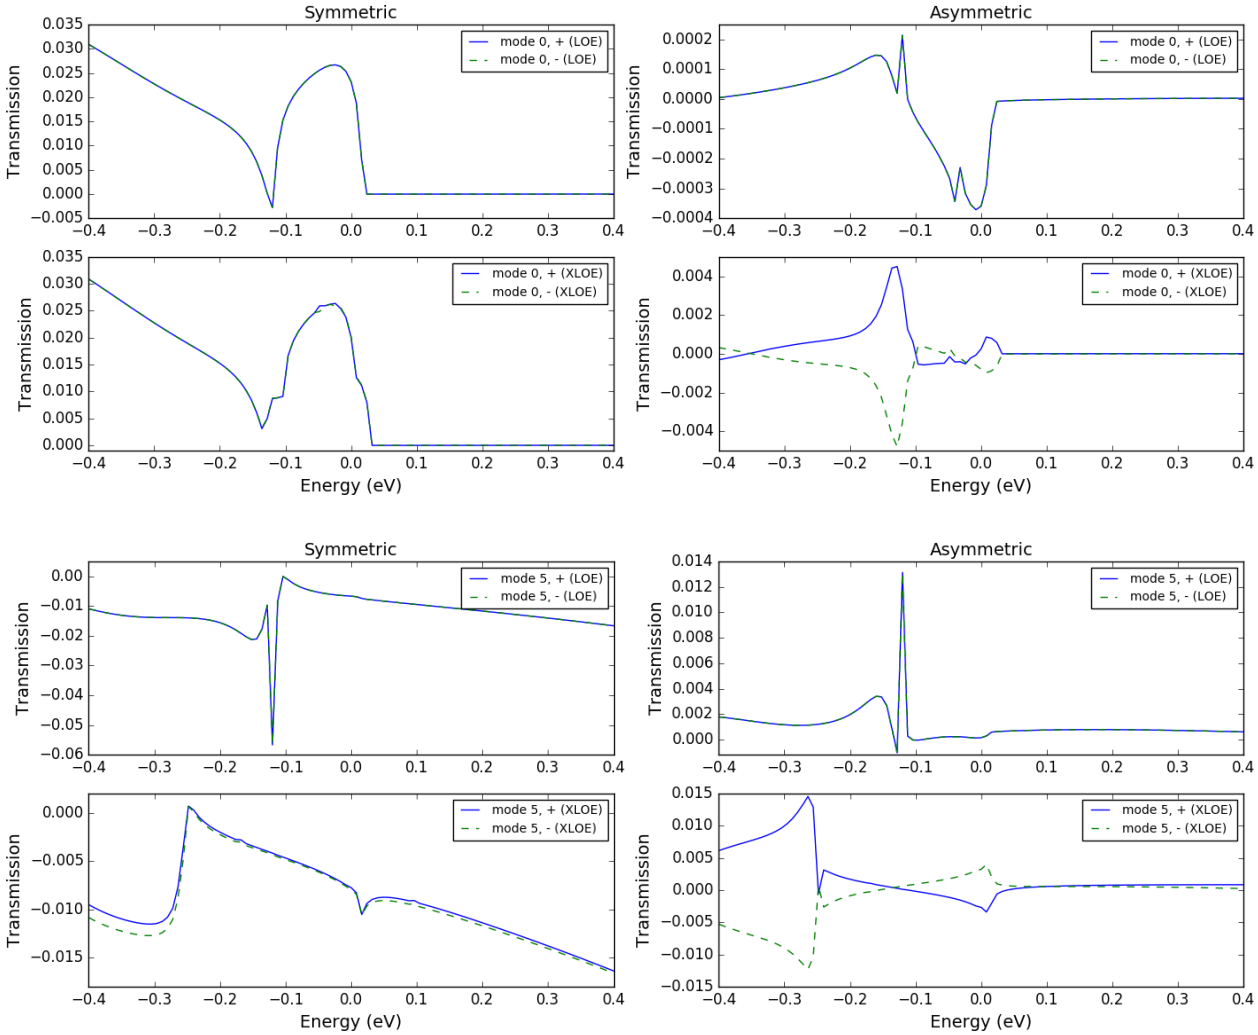
$$\tilde{A}_L(\epsilon) = G^a(\epsilon)\Gamma_L(\epsilon)G^r(\epsilon),$$

and

$$B_\lambda(\epsilon) = \mathrm{Tr}\big[M_\lambda A_R(\mu_L)\Gamma_L(\mu_L)G^r(\mu_L)M_\lambda A_R(\mu_R) - M_\lambda G^a(\mu_R)\Gamma_L(\mu_R)A_R(\mu_R)M_\lambda A_L(\mu_L)\big].$$

This XLOE expression of the transmission functions reduces to the LOE expression by setting $\mu_L = \mu_R = \epsilon$. Importantly, in the expression of the current, note that the Greens function, the self-energies, and the spectral functions in the transmission functions are evaluated at two different energies $\epsilon_F \pm \hbar\omega_\lambda$ in XLOE, whereas they are all evaluated at the same energy ϵ_F in LOE. See Ref.[Page 1130, 3] for more details.

For direct comparison between the LOE and XLOE results, see here below the inelastic transmissions for each phonon mode. The lines of positive/negative (a)symmetric transmissions indicate the plots of $\mathcal{T}_\lambda^{(a)sym}(\epsilon)$ as functions ϵ with setting $\mu_R = \epsilon \pm \hbar\omega_\lambda$. The positive and negative (a)symmetric parts are exactly the same in LOE by definition, but different in XLOE.



The LOE and XLOE results are in good agreement in areas where the transmission varies slowly as a function of ϵ. Around -0.11 eV, however, the wide-band approximation in LOE, i.e., the approximation $\mu_L = \mu_R = \epsilon$, breaks down due to the presence of a resonance in the DOS of the 1D gold chain. As a result, there appears a difference between the LOE and XLOE results. The symmetric and asymmetric inelastic transmissions for mode 5 show the difference very clearly. The single peak at -0.11 eV in LOE splits into two peaks in XLOE; the separation is about 264 meV, which corresponds to the phonon energy of mode 5.

References

3.7.5 Interfacial thermal conductance

Version: 2016.1

The continuous downsizing of modern electronic devices implies the increasing complexity of a nano-device. The thermal conductivity is hard to predict when the device is formed by more than one material. More often, device engineers want to maximize or minimize the thermal conductivity by constructing interfaces between different materials.

In this tutorial, you will learn how to use molecular dynamics with a classical potential to simulate the heat flow through an interface and calculate the interfacial thermal resistance.

Introduction

You will simulate the heat current through a model grain boundary in a silicon crystal by imposing a temperature gradient between a heat source and a heat sink.

Theory

With a given temperature gradient, the bulk heat conductivity κ_{bulk} of a material is related to the heat flux via the Fourier equation,

$$\frac{\langle dQ/dt \rangle}{A} = -\kappa_{bulk} \langle dT/dz \rangle,$$

where $\langle dQ/dt \rangle$ represents the average heat flux (i.e. transferred kinetic energy per time) along the gradient, and A is the area perpendicular to the direction of the heat flux.

The presence of an interface between the temperature source and sink often causes a discontinuity (a temperature jump) ΔT in the temperature profile, since the interface provides additional thermal resistance R to the heat current. In this case, the interfacial thermal conductance G, often referred to as Kapitza conductance, can be defined as

$$G = \frac{1}{R} = \frac{\langle dQ/dt \rangle}{\Delta T}$$

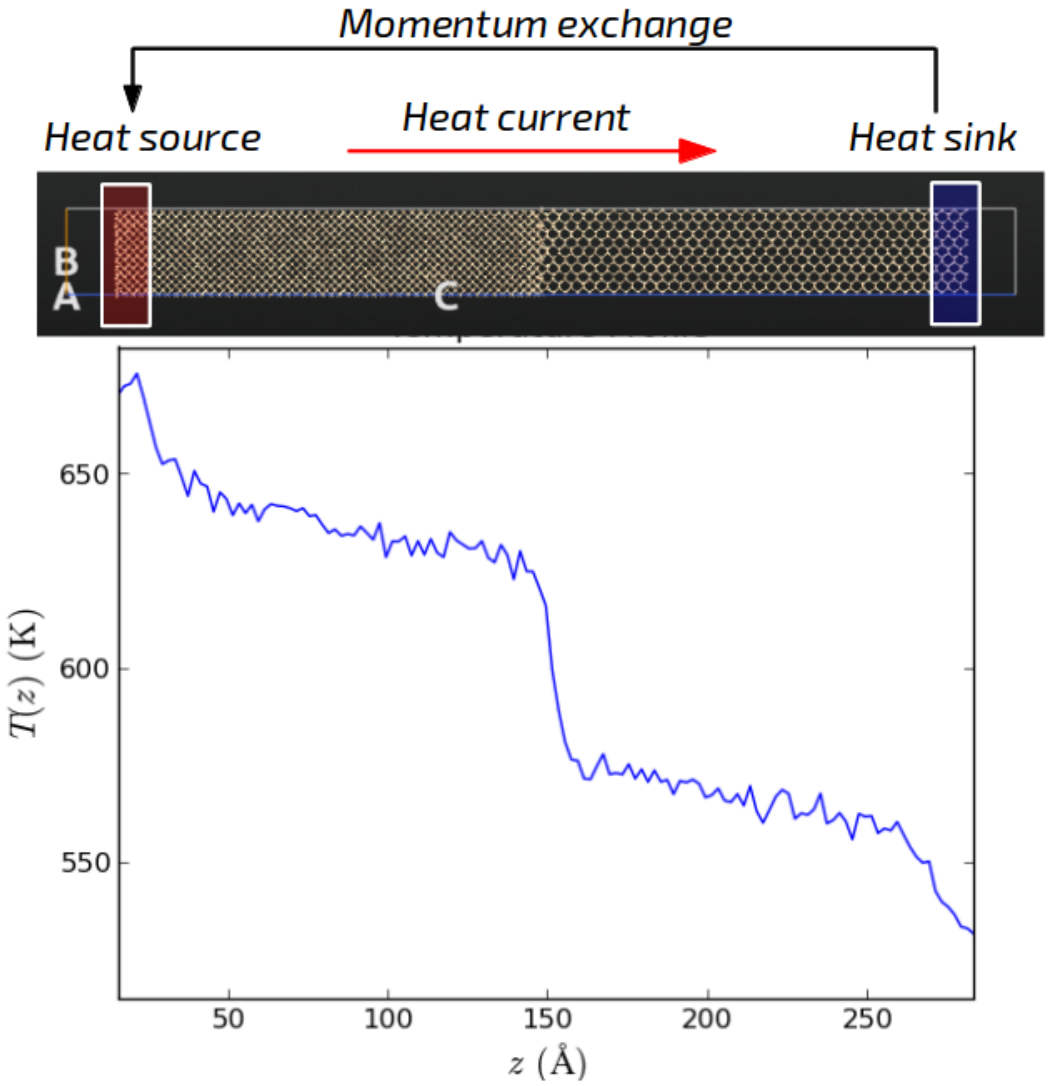
Note: Sometimes it makes sense to normalize G to the cross-sectional area, e.g. if you want to compare similar interfaces with different cross sectional areas.

Method

In this tutorial, we will use two different methods to calculate the heat conductivity. In *the first section*, we will use molecular dynamics simulations, and in *the second section* we will use the non-equilibrium Greens function method.

Reverse non-equilibrium molecular dynamics (RNEMD)

When using molecular dynamics (MD) simulations, the most common technique to impose a temperature gradient in MD simulations is the so-called non-equilibrium momentum exchange or reverse non-equilibrium molecular dynamics (RNEMD) method[1][2]. In this method two groups of atoms are selected as the heat source and the sink, respectively. During the simulation the momenta of the hottest atom in the sink and the coldest atom in the source are exchanged according to special criteria to conserve the total energy and momentum[Page 1140, 2]. This external heat flux is balanced by a heat current from source to sink within the system, causing a measurable temperature gradient (and a temperature jump if an interface is present).



[1] F.ăMueller-Plathe. A simple nonequilibrium molecular dynamics method for calculating the thermal conductivity. *J. Chem. Phys.*, 106(14):6082–6085, 1997. doi:10.1063/1.473271.

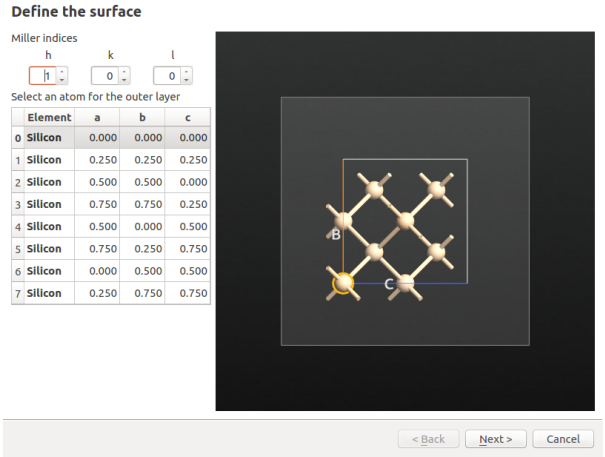
[2] C.ăNieto-Draghi and J.ăB. Avalos. Non-equilibrium momentum exchange algorithm for molecular dynamics simulation of heat flow in multi-component systems. *Mol. Phys.*, 101(14):2303–2307, 2003. doi:10.1080/0026897031000154338.

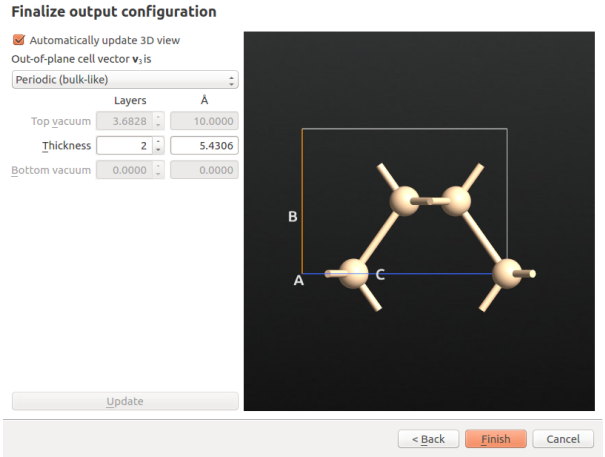
Preparing the grain boundary

You will consider a model grain boundary between two silicon crystal grains with different orientations. Although you can direct the thermal current in any arbitrary direction during the simulation, we will preserve the convention that current runs along the z-direction. Therefore, while building the system you should always make sure that the interface configuration is oriented correctly. If necessary, you should rotate the system to make sure the thermal current is oriented along the z-axis.

You will create an interface between a (100) and a (110) silicon surface. Open the **Builder** , and add Silicon (alpha) via *Add* → *From Database*, and

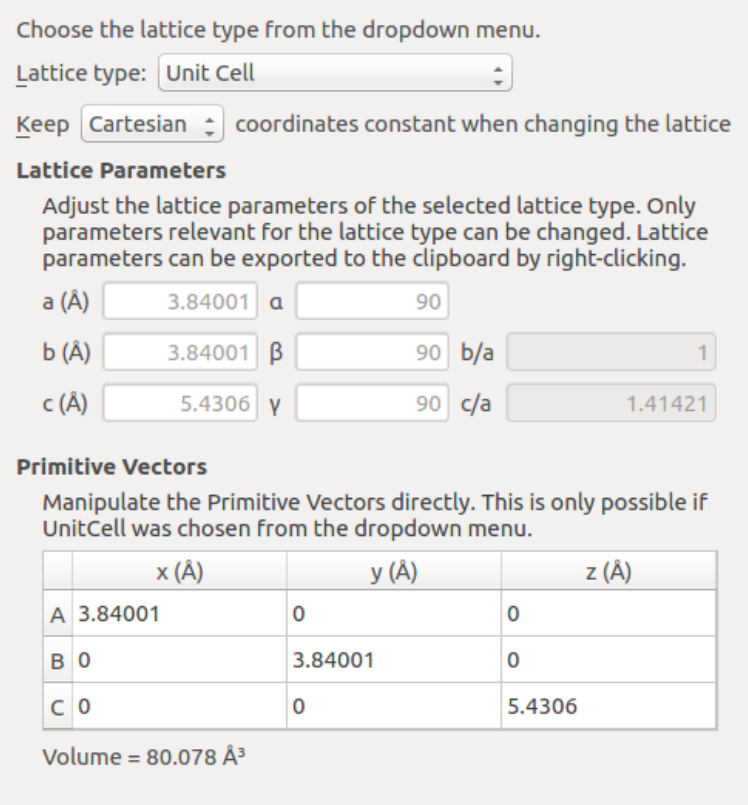
- To generate a (100) surface base cell make sure the newly added Silicon alpha configuration is selected and,
  - Open the *Surface (Cleave) tool* in the right-hand-panel under **Builders**.
  - Select the (100) Miller indices, click Next, leave the 1x1 surface lattice, click Next, and select Periodic (bulk-like).
  - Click Finish to complete the surface creation.





- Repeat the above steps for the (110) structure.

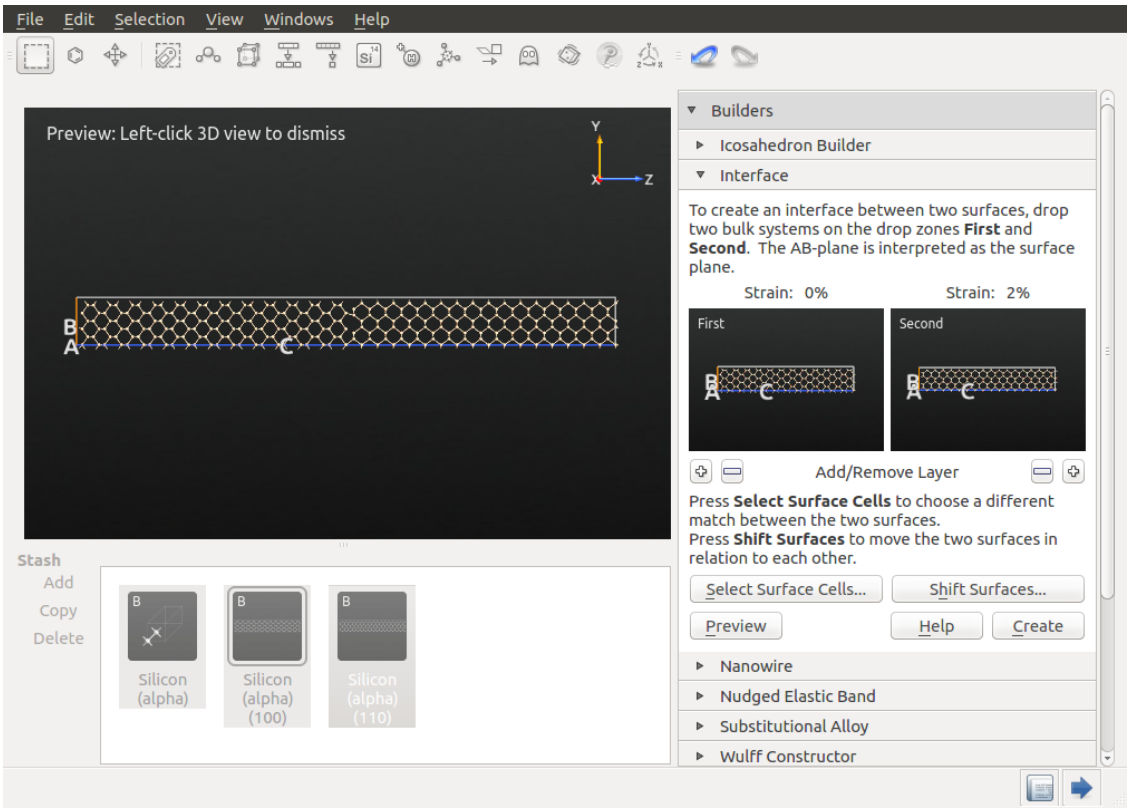
To avoid a large strain when joining the two cells with different lattice constants, you should choose suitable repetitions to obtain commensurate cell sizes. The cell sizes can be looked up and modified under *Bulk tools* → *Lattice parameters*.



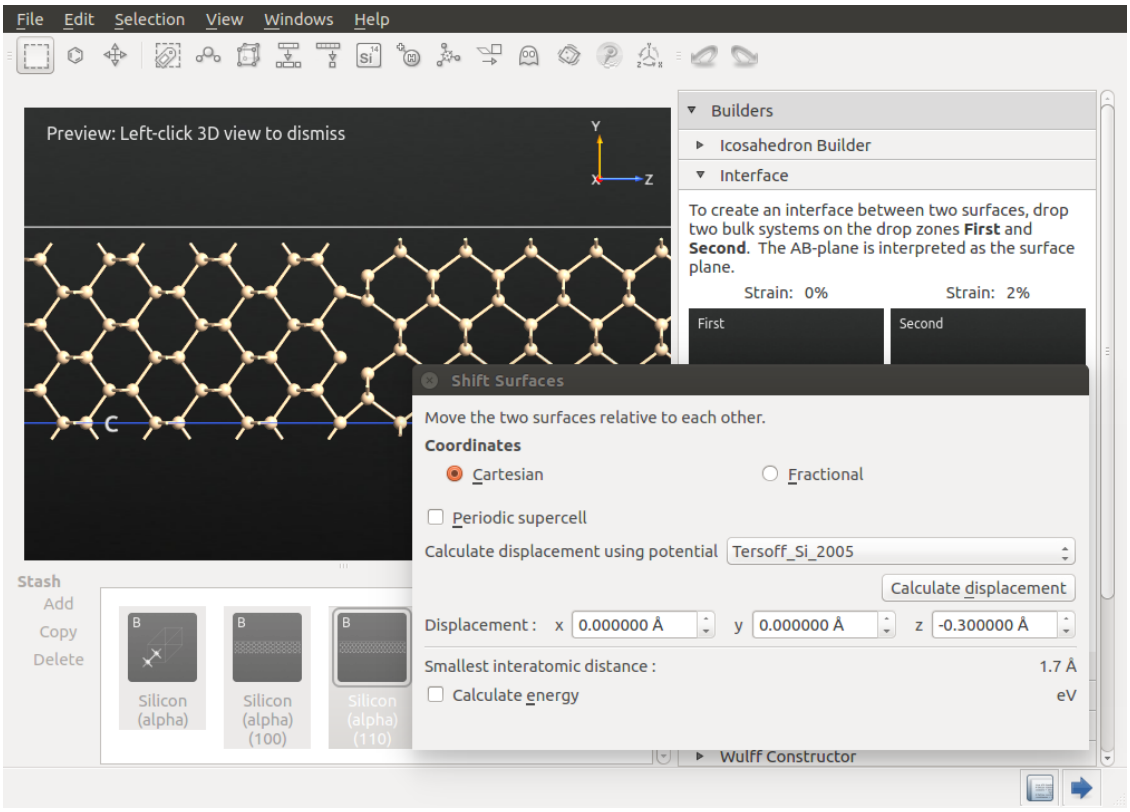
The cell of the (100) surface has dimensions 3.84 x 3.84 x 5.43 $Å^3$, while the (110) cell has a size of 3.84 x 5.43 x 3.84 $Å^3$. Therefore, a 3 x 3 x 12 repetition for the (100) cell, and a 3 x 2 x 17 repetition for the (110) cell, provides supercells of almost equivalent sizes. You can apply such repetitions using the *Bulk tools* → *Repeat plugin*. Set the desired number of repeats and click *Apply*.

Note: Generally, for such non-equilibrium thermal current simulations it is important to choose a sufficient cell length in the direction of the heat flow (in this case the C-vector), whereas the results are less sensitive to the geometry of the cross-sectional area (i.e. A x B). Therefore, the simulation cells employed typically have a stick-like shape.

Creating an interface with two structures could be a tedious task, but the **Interface Builder** helps you to complete it in a simple and flexible manner. Open *Builders* → *Interface* in the right-hand-panel and drag and drop the (100) supercell onto the left field and the (110) supercell onto the right field.



The preview of the interface should appear automatically (if not click Preview). If you zoom into the interface, you will notice a gap between the two surfaces. You can adjust this gap by clicking *Shift Surfaces* and adding a negative offset in the z-direction until bonds between the two surfaces are displayed. Moreover, you can align the two surfaces in the x and y-directions, as well. The proposed values should provide a good initial structure. Close the *Shift Surfaces* tool and click *Create* to create the interface structure.

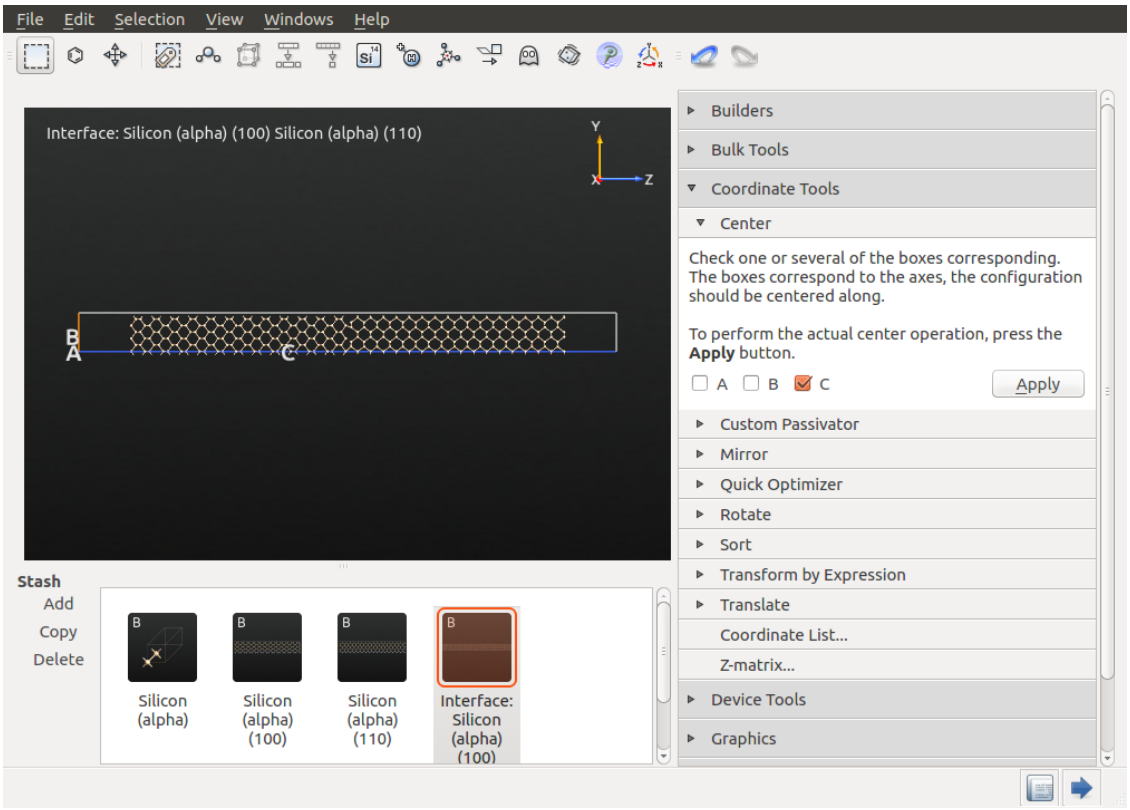


Note: The displayed bonds are visual guides only and do not have a strict physical meaning. For the interface creation the appearance of bonds simply indicates if the initial guess is reasonable. The interface will be optimized, annealed, and equilibrated using molecular dynamics to reduce spurious features to the largest extent.

The supercell in this calculation should be non-periodic in the C-direction, meaning that the system is terminated by vacuum at either end. The lateral dimensions (A and B) will remain periodic.

To obtain such a setup, simply increase the length of the C-vector. This can be done by opening *Bulk Tools* → *Lattice Parameters* and increasing the C_z entry from about 130 Å to 160 Å. Make sure that you keep the Cartesian coordinates.

Finally, the slab should be centered in the middle of the supercell. Therefore, open *Coordinate Tools* → *Center*, uncheck A and B and click *Apply*. The result should look like below.



Note: An alternative to this surface-terminated setup is to simulate a fully periodic system, where the heat flow is directed into both the positive and negative z-axes away from the heat source[3][4]. This setup requires two identical interfaces and a simulation cell which is twice as long.

Setting up the equilibration simulation

Prior to simulating the actual heat flow, the system has to be equilibrated properly in order to reduce artifical defects due to the interface generation, remove the lateral stress, and prepare a system which is equilibrated at the desired target temperature. To do this, send the final interface to the **Script Generator** by clicking the Send To icon, and add 3 blocks:

- New Calculator
- *Optimize* → *OptimizeGeometry*
- *Optimize* → *MolecularDynamics*

Change the Default output file name to `Silicon_grain_boundary.nc`, and open the **New Calculator** block.

[3] P.ăC. Howell. Comparison of molecular dynamics methods and interatomic potentials for calculating the thermal conductivity of silicon. *The Journal of Chemical Physics*, 137(22):, 2012. doi:10.1063/1.4767516.

[4] Akbar Bagri, Sang-Pil Kim, RodneyăS. Ruoff, and VivekăB. Shenoy. Thermal transport across Twin Grain Boundaries in Polycrystalline Graphene from Nonequilibrium Molecular Dynamics Simulations. *Nano Letters*, 11(9):3917–3921, 2011. doi:10.1021/nl202118d.

•Select *ATK-ForceField* and the *StillingerWeber_Si_1985 potential*.

•Uncheck *Save and Print* and close the widget by clicking OK.

Note: For QuantumATK-versions older than 2017, the **ATK-ForceField** calculator can be found under the name **ATK-Classical**.

Open the **OptimizeGeometry** block and set the Force tolerance to 0.1 eV / Å. The remaining parameters can be left at their default values. Uncheck *Save and Print* and close the widget.

Note: The optimization is necessary to remove initial large destabilizing forces that might occur after the interface generation. As an interfaced is introduced, a small force is most likely unavoidable.

The next step is to allow the lateral cell vectors to relax and equilibrate to the target temperature using the Molecular Dynamics method. The entire thermal transport simulation will be performed at an average temperature of 600 K. To do this, open the **MolecularDynamics** block to set up the parameter for the NPT simulation, i.e. a simulation at constant temperature and pressure.

•Select the Type as NPT Martyna-Tobias-Klein.

•Set the number of steps to 50 000 and the log interval to 1000.

•Choose a suitable trajectory name, e.g. `traj_grain_boundary_equilibrate_NPT.nc`.

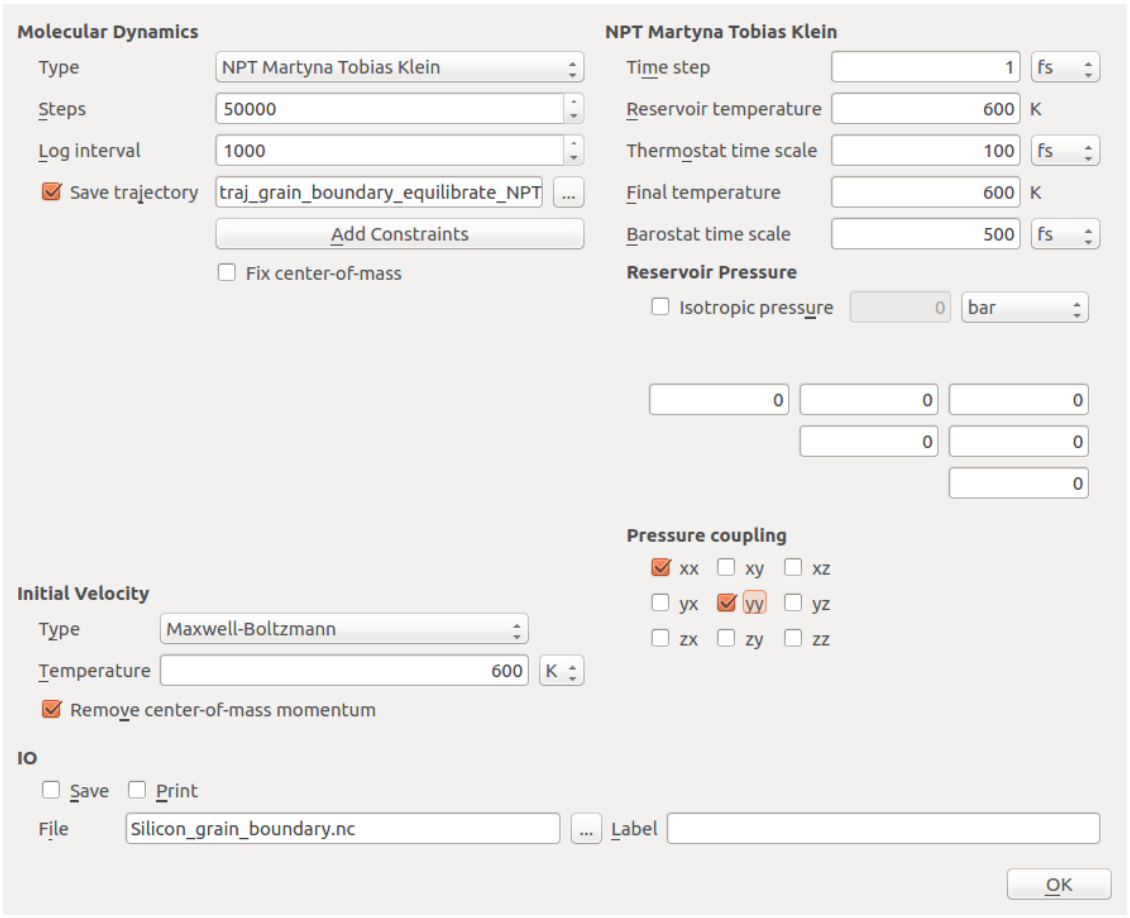
•Set the Reservoir temperature to 600 K, and the External stress to 0 bar.

•Uncheck Isotropic pressure and disable the Stress coupling in the zz-direction, as the free surface in this direction will automatically adjust.

•Select the Maxwell-Boltzmann-Distribution under *Initial Velocity*, set the temperature to 600 K, and make sure the box is checked to remove the center-of-mass momentum.

•Uncheck *Save and Print*, as the trajectory is saved anyway.

The final settings should look like the following.

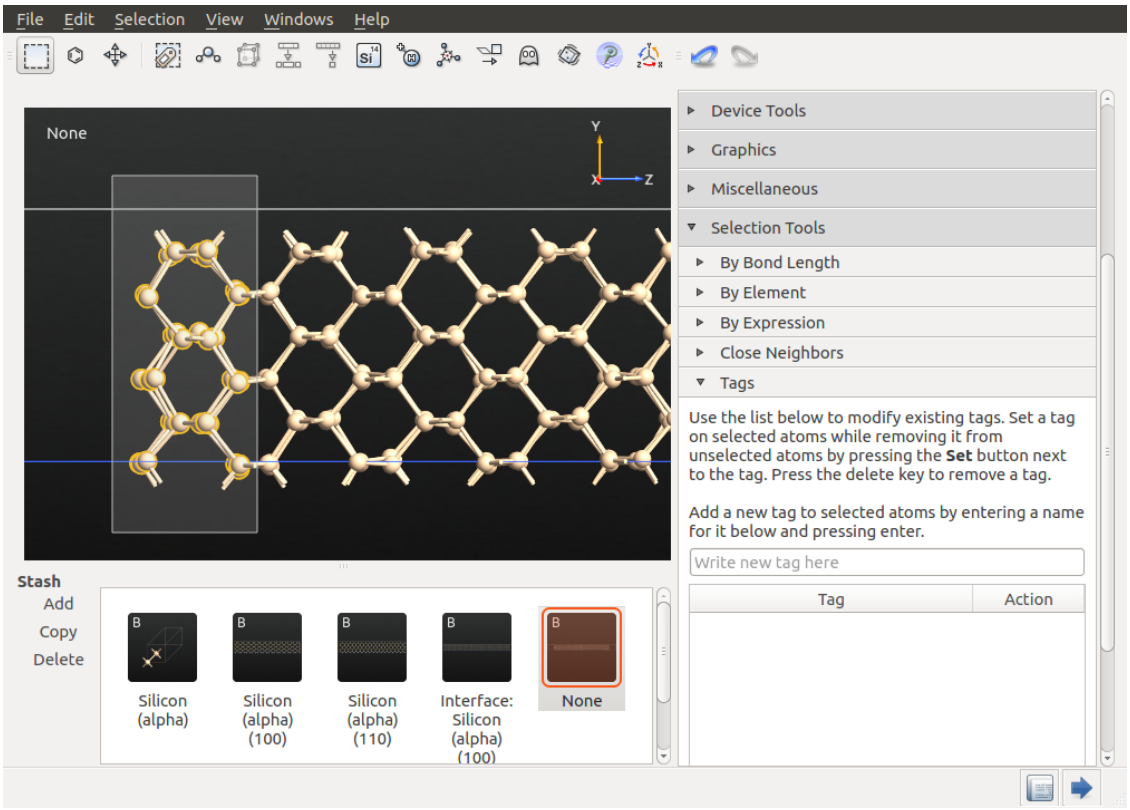


Send the script to the **JobManager** , save as `grain_boundary_equilibrate_NPT.py` when asked, and run it.

We will use the resulting structure from the NPT simulation for the following simulations. To this end, once the simulation has finished, select the trajectory on the Lab floor in the main QuantumATK window and open it with the Movie Tool. Play the trajectory and send the last snapshot to the **Builder** using the icon.

Setting up the non-equilibrium momentum exchange simulation

You now have to define the regions for the heat source and sink in the heat current simulations. Zoom into the left end of the configuration and select the last 4 atom layers (i.e. the first unit cell), as shown in the picture below.



•Open the *Select* → *Tags* plugin, enter a suitable tag name, e.g. heat_source, and press Return. The selected atoms will now be marked by this tag name and can be referred to during the simulation.

•Repeat the same procedure at the other end of the configuration. Use a different tag name this time, e.g heat_sink.

Send the configuration to the **Script Generator**, add a **New Calculator** and two **MolecularDynamics** blocks.

•Edit the calculator block in the same way as described above, i.e. selecting *ATK-ForceField* with the *StillingerWeber_Si_1985 potential*.

First, you will perform another equilibration simulation at 600 K, this time at constant volume, to prepare a well equilibrated system. Open the first **MolecularDynamics** block, and,

•Select the Type as NVT Nose Hoover.

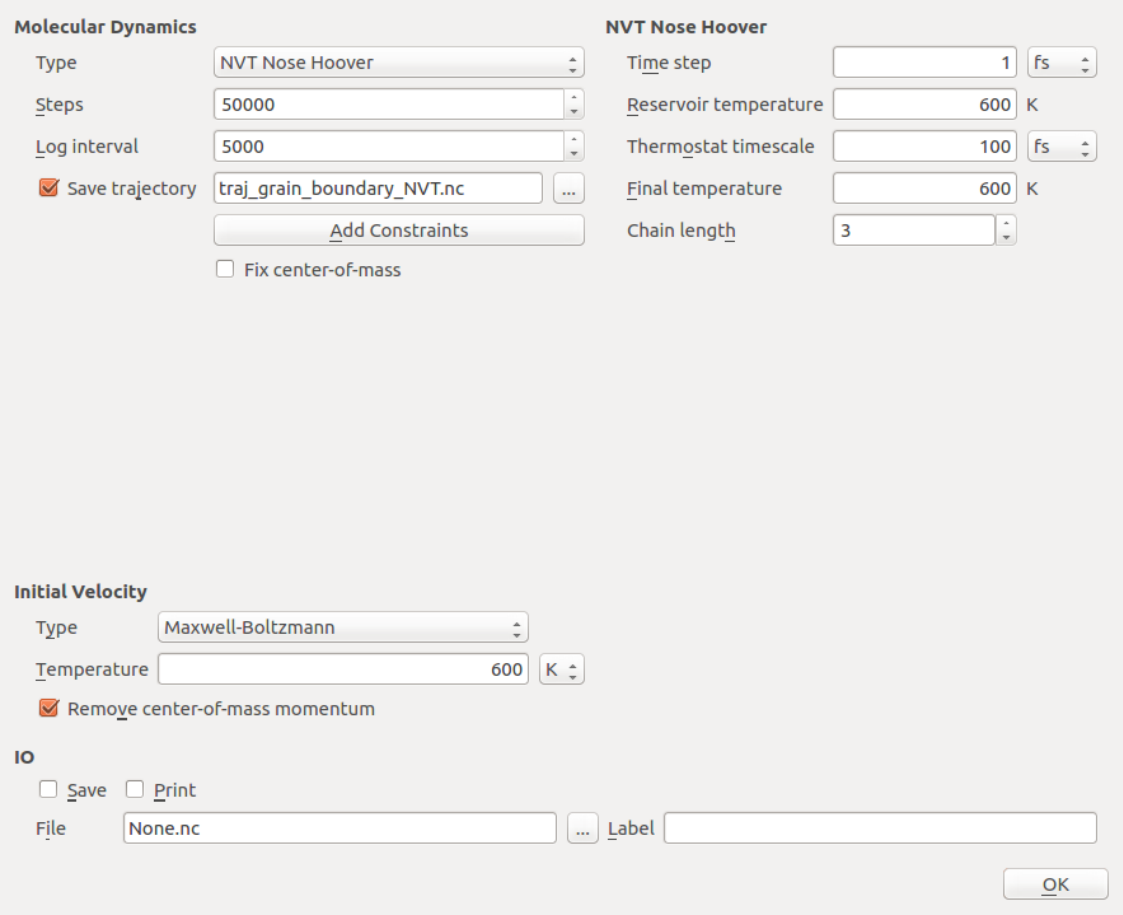
•Set the number of steps to 50 000, and the log interval to 5000.

•Choose a suitable trajectory filename, e.g. `traj_grain_boundary_equilibrate_NVT.nc`.

•Select Maxwell-Boltzmann initial velocities at 600 K, and make sure that the center-of-mass removal box is checked.

•Set the Reservoir temperature to 600 K, the final temperature will automatically change to 600K too. Leave the rest of the settings at default values.

•Uncheck Save and Print and close the widget by clicking OK.



In the second **MolecularDynamics** block, the actual non-equilibrium simulation will be set up. To do this:

•Select the type as Non-Equilibrium Momentum Exchange.

•Set the number of steps to 200 000, and the log interval to 1000.

•Select a suitable trajectory filename, e.g. `traj_grain_boundary_nonEq.nc`.

•Set the initial velocities to ConfigurationVelocities, which means that the velocities stored in the configuration will be used.

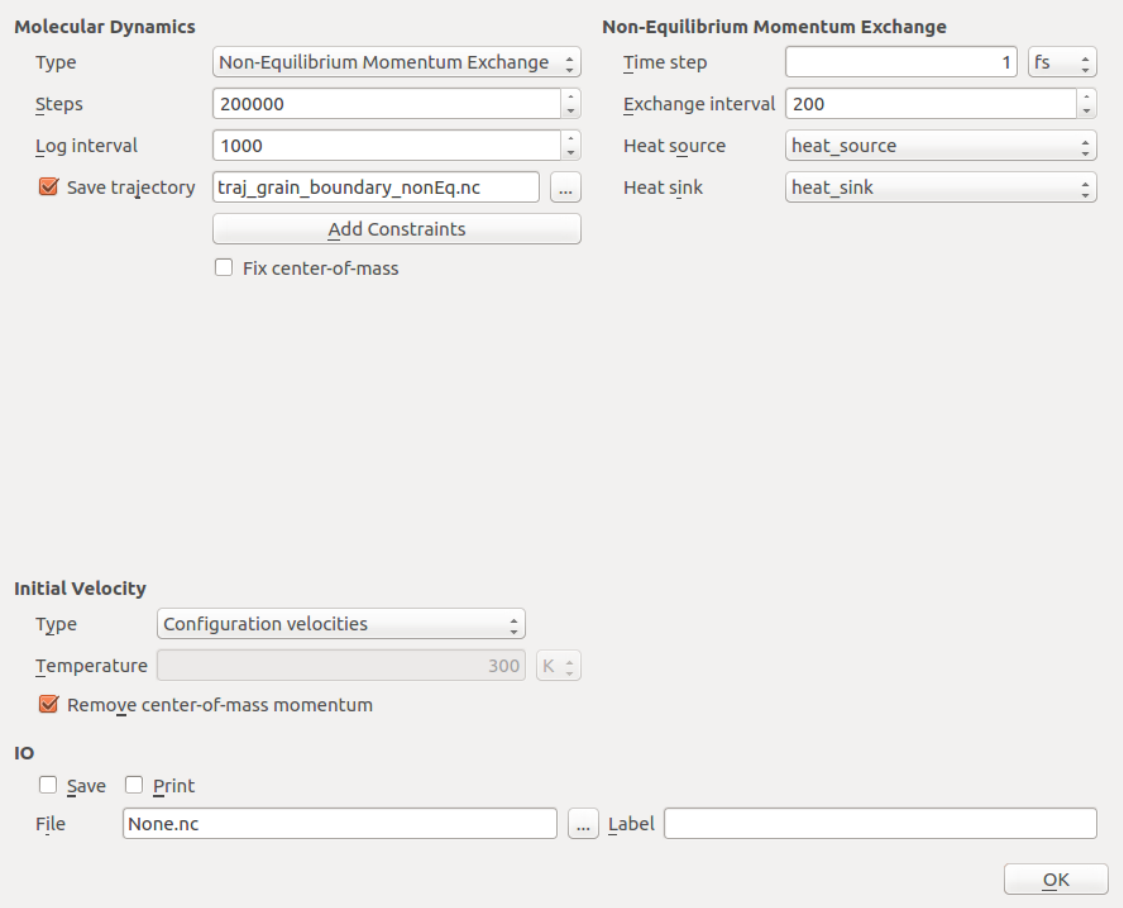
•Leave the Time step at the default value of 1 fs.

•Set Exchange interval entry to 200, meaning that the exchange is triggered every 200 steps.

•Uncheck Save and Print and close the widget by clicking OK.

Tip: Lowering the value of the *Exchange interval* entry will increase the transferred kinetic energy per simulation time, which causes a larger temperature gradient and a more distinct temperature profile. This will make the evaluation easier, but you generally should be careful with large temperature gradients, as their magnitude often by far exceeds the typical experimental temperature gradients.

Via the Heat source and Heat sink fields you can associate the tags, you have defined in the Builder, with heat source and sink, respectively. The final settings should look like the following.



Note: This simulation is set up for demonstration purposes to run reasonably fast - it should finish in about 10-15 minutes. For actual production simulations, you should use a larger (i.e. wider and much longer) system as well as a longer simulation time (e.g. 100 000 steps in the NVT equilibration and 800 000 steps or even more in the non-equilibrium simulation) to obtain reliable results and good statistics. As such NEMD simulations can be quite sensitive to finite size effects, you should always check your results for convergence with respect to system size and simulation time, if possible.

•Run the entire simulation via the **JobManager** or save the script and run it at a terminal using **atkpython**.

Analyzing the results

After the simulations have completed, the trajectory files will appear on the LabFloor. Open the non-equilibrium trajectory in the Movie Tool and you will see that the average temperature remains constants during the entire simulation and the slab does not drift, as this would blur the temperature profile.

Investigating the interfacial thermal conductance

Open the same trajectory with the **MD Analyzer** plugin to investigate the thermal conductivity,

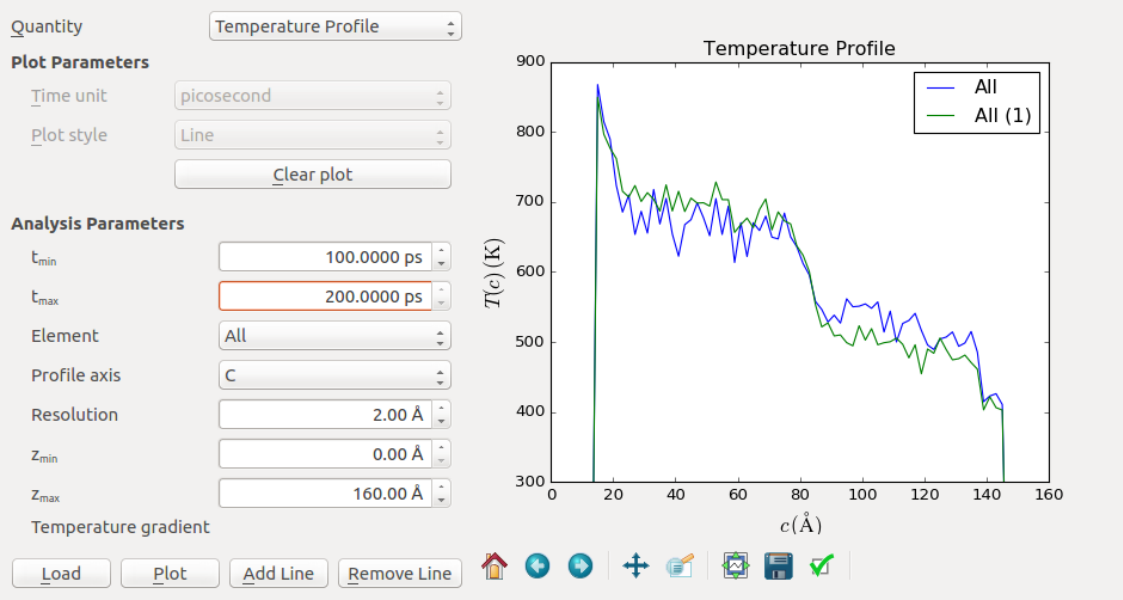
- Select the Temperature profile button and click *Load*. It may take some time.

> **Attention:** Here, you should carefully check the convergence of the temperature profile with respect to the simulation time. If you do not achieve a steady-state, you should run another non-equilibrium simulation with the same settings starting from the final snapshot of the previous one (in this case without the NVT equilibration).

To check whether the temperature profile has converged, you can compare the temperature profile between 1 and 50 ps, with that between 100 and 200 ps.

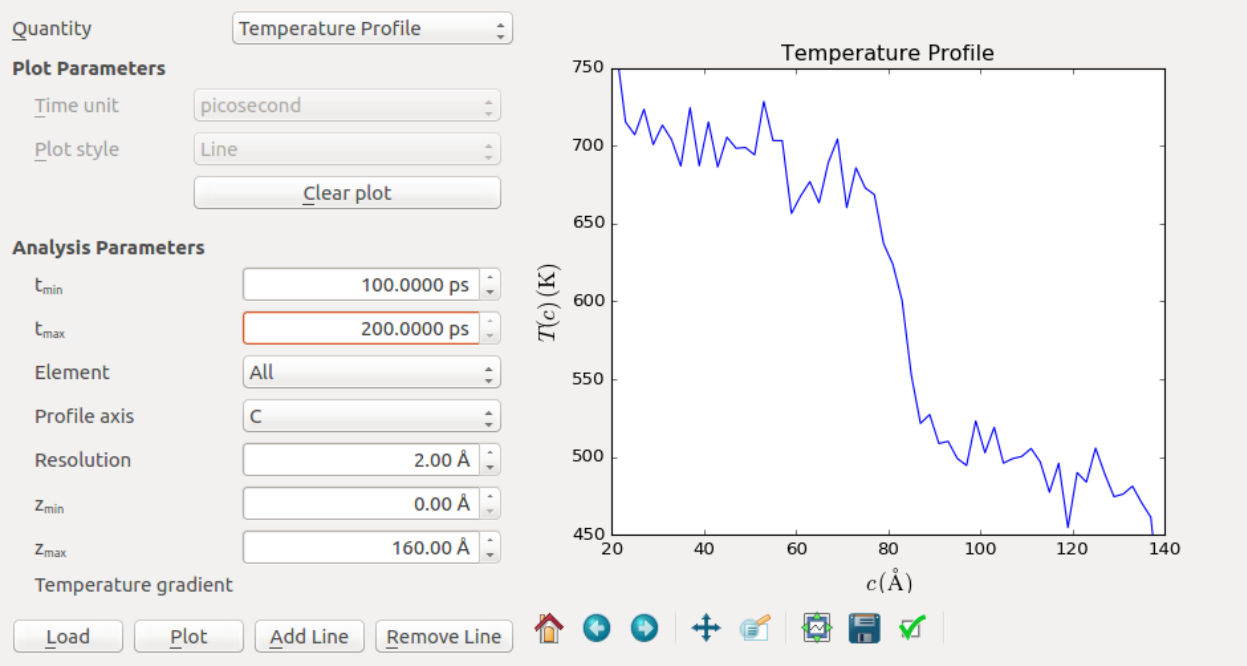
Tip: You can use the *Add Line* button to plot several curves on the same plot to make the comparison easier.

Use the zoom tool in the toolbar or the *Edit plot* button (on the bottom right) to zoom into the important features of the profile. Except for statistical fluctuations, your temperature profiles should be very similar to the plots shown here. In the plot below, the blue and green curve correspond to the intervals 1-50 ps and 100-200 ps, respectively.



The temperature profile shows several typical features. First, a positive and a negative peak are visible at the beginning and end of the profile. These regions designate the heat source and sink, respectively. This non-linear part arises from the artificial transfer of kinetic energy due to the momentum exchange. You should always discard these regions in your analysis.

The next prominent feature is the temperature jump around z=80 Å. This is the interface region which provides additional thermal resistance. Let us take a closer look by zooming into this region (shown below for the 100-200 ps curve). Here it can be convenient to use the *Edit plot* button to set the minimum and maximum and both the x and y-axis.



The temperature jump connects around $T_1 = 700$ K and $T_2 = 500$ K, so the jump is about $\Delta T = 200$ K. To calculate the Kapitza conductance you also need to know the average heat flux. This value can be read from the output at the bottom of the log file. In this example case, a value of $\langle dQ/dt \rangle = 0.0010$ eV/fs is obtained. These values can then combined to calculate the Kapitza conductance by using the formula above.

As the units have to be converted correctly, the most convenient way to calculate this value is to use the built-in unit engine of QuantumATK.

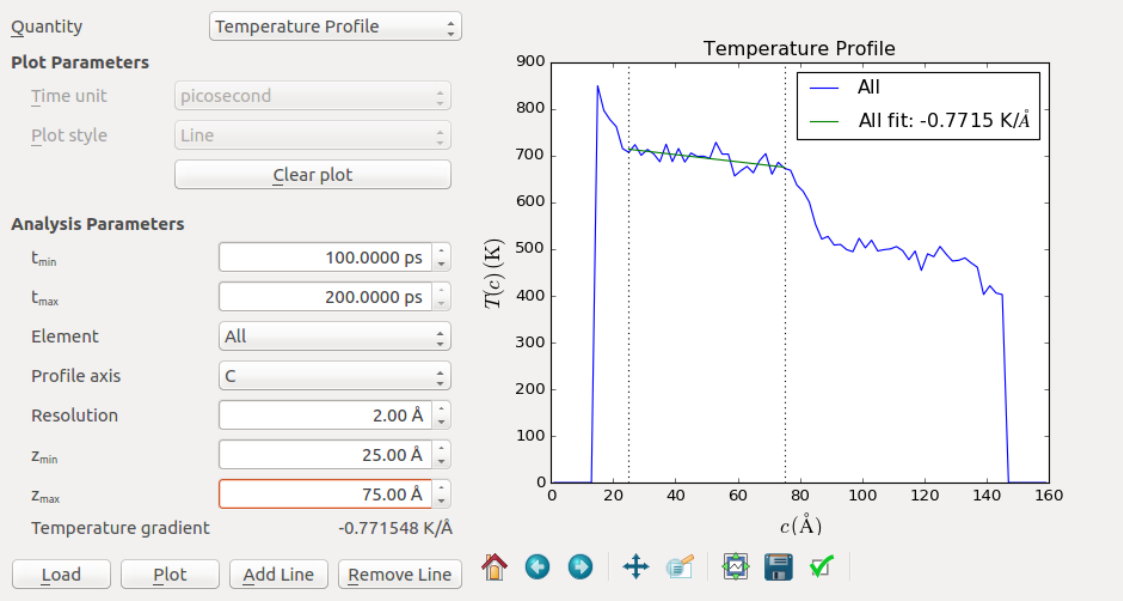
•Open the Editor and enter the following equation

```
dq_dt = 0.0010*eV/fs
delta_T = 200.0*Kelvin
G = dq_dt / delta_T
print("Kapitza conductance in Watt/Kelvin:  ",G.inUnitsOf(Joule/Second/Kelvin))
```

•Run this script via the **JobManager** (or atkpython) and save it as `kapitza.py`. The log file will display the calculated Kapitza conductance in W/K. In this example, the result is 8 x 10^{-10} W/K.

Investigating the grain size dependence of the thermal conductivity

You can also investigate the effect of the grain size, in this case modelled by the distance between the heat source or sink to the boundary, which is approximately 50 Å. Here, you will need to consider *thermal conductivity* instead of *interfacial conductance*. Use the MD Analyzer to extract the temperature gradient. Input reasonable numbers in Z_{min} and Z_{max} to select the linear region of the profile.



The program will automatically fit the slope and display the temperature gradient in the Parameters widget. A value of -0.77 K/Å is obtained for the (100) oriented grain in this example. You can repeat the procedure for the right grain and obtain a similar slope (around -0.90 K/Å). The slopes of the left and the right are unlikely to be identical, due to statistical fluctuations and different orientations.

We can now insert the calculated slope into the Fourier equation and, together with the average transferred energy per time and the cross-sectional area, calculate the thermal conductivity within the grain in a script. The cross-sectional area *A* can be obtained from the A and B cell vectors. You can find these by opening the *Bulk tools* → *Lattice parameters* for the interface configuration in the Builder. Open once again the `kapitza.py` and add the following lines in the bottom of the script. You can repeat the lines to make a calculation for both the (100) and (110) regions. When you have added the lines, send it to the Job Manager.

```
dq_dt = 0.0010*eV/fs
A = 11.46*11.24*Angstrom**2
dT_dz = 0.77*Kelvin/Angstrom
G = dq_dt / dT_dz / A
print("Grain conductivity in Watt/Kelvin/Meter:  ",G.inUnitsOf(Joule/Second/Kelvin/
↪Meter))
```

The result for this example is 16.1 W/K/m for the (100) region. For the (110) oriented grain the conductivity amounts to 13.8 W/K/m. These values are considerably smaller than the simulated bulk thermal conductivity for silicon at 600 K, κ_{bulk} = 150 W/K/m, reported in Ref[Page 1145, 3] using the same Stillinger-Weber potential. This behaviour is expected, since the thermal conductivity of a confined grain generally is lower than the corresponding bulk value[Page 1145, 4]. This is due to the fact that the mean free path of the phonons is often much larger than 1 μm, which means that the simulated grain size suppresses the thermal conductance[Page 1145, 3][Page 1145, 4].

To study the grain size dependence, you can repeat the simulation, preparing configurations with different lengths of the two crystal cells, as shown in Ref.[Page 1145, 4].

The bulk conductivity can be obtained by performing several simulations at increasing grain sizes l, plotting the inverse conductivity $1/\kappa(l)$ over the inverse grain size $1/l$ and extrapolating to infinite grain sizes[Page 1145, 3Page 1145, 4].

Non-equilibrium Greens function method

In this section you will apply another method, the non-equilibrium Greens function (NEGF) technique, to calculate the interface thermal conductance. You will use NEGF to calculate the phonon transmission spectrum and from that quantity obtain the thermal conductance. For more details about phonon transmission using the NEGF technique see e.g. Ref.[5] or the tutorial *Thermoelectric effects in a CNT with isotope doping*.

Preparing the configuration

For this method, we will set up a different calculation but the same interface configuration. Therefore, return to the **Builder** and select the interface configuration you created earlier.

This time, before setting up the script, convert this configuration into a device configuration by clicking *Device Tools* → *Device from Bulk*. Here you can leave all settings at default values and press OK.

Setting up the NEGF simulation

Send the device configuration to the **Script Generator** by clicking the Send To icon, and add 3 blocks:

- New Calculator
- *Optimize* → *OptimizeGeometry*
- *Analysis* → *PhononTransmissionSpectrum*

This will automatically add a **DynamicalMatrix** block as well.

Change the Default output file name to `Silicon_grain_boundary_NEGF.nc`, and open the **New Calculator** block.

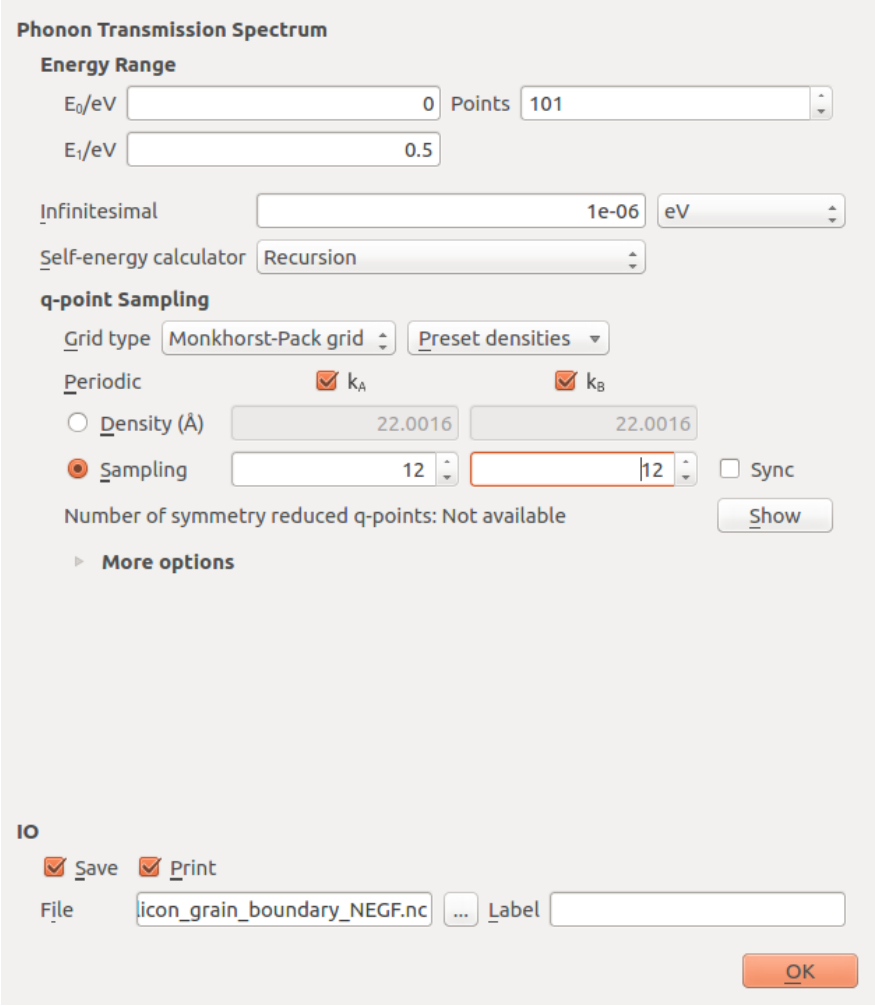
•Select *ATK-ForceField* and the *StillingerWeber_Si_1985 potential*.

•Uncheck *Save and Print* and close the widget by clicking OK.

Open the **OptimizeGeometry** block and set the Force tolerance to 0.001 eV / Å. The remaining parameters can be left at their default values. Uncheck *Save and Print* and close the widget.

Next, open the **PhononTransmissionSpectrum** block and set the **q-point Sampling** to *Sampling* and enter 12 for the sampling in both directions. The settings should look like below

[5] T.ăMarkussen, A.-P. Jauho, and M.ăBrandbyge. Electron and phonon transport in silicon nanowires: Atomistic approach to thermoelectric properties. *Phys. Rev. B*, 79:035415, Jan 2009. doi:10.1103/PhysRevB.79.035415.

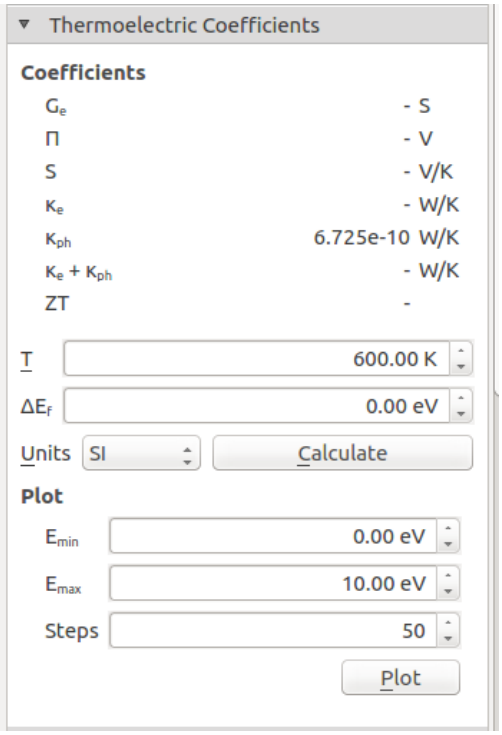


Click OK to close it. If you are running QuantumATK 2016.3 or earlier versions, then before running the script, you should make sure that *Auto scan project files* is unchecked under *File → Preferences* in the main QuantumATK window - this will prevent a slight bug form occuring during the simulation.

Then send the script to the **JobManager** . Save as `grain_boundary_NEGF.py` when asked, and run it. The simulation should finish in about 5-10 minutes.

Analyzing the results

After the simulations have completed, the phonon transmission spectrum object will appear on the LabFloor. Select it and expand the Thermoelectric Coefficients plugin on the right-hand panel. To compare with the MD calculation of the thermal properties, set the temperature to 600 K and click Calculate. The thermal conductance should be printed in the window, and should be similar to the one shown below



Comparing results between RNEMD and NEGF

From the NEGF calculations we find a conductance of 6.7 x 10 $^{-10}$ W/K, which is already quite close to the result calculated with RNEMD (which was 8 x 10 $^{-10}$ W/K). The slight deviation can be attributed, among others, to the absence of inelastic phonon scattering in NEGF, and to finite size effects in our small model system, which affects in particular the particular the NEMD simulations.

3.8.1 How to Setup Basic Molecular Dynamics Simulations

Version: U-2022.12

Downloads & Links

Molecular Dynamics `Silicon_bulk.py` `md_tutorial_nve_1fs.hdf5` `md_tutorial_nvt_300k.hdf5` `md_tutorial_nvt_1000k.hdf5` `md_tutorial_npt_300k_1bar.hdf5`

In this tutorial, you will learn how to setup basic molecular dynamics (MD) simulations and analyze the resulting trajectories using the NanoLab GUI in **QuantumATK** . At the end of this tutorial, you will be familiar with simulating systems in a microcanonical ensemble (NVE), canonical ensemble (NVT) and isothermal-isobaric ensemble (NPT), using **QuantumATK**.

Pre-requisites

•Basic familiarity with **NanoLab** and **atkpython**

•Basic familiarity with Molecular Dynamics simulations. If needed, you can read our *technical note on Molecular Dynamics* for a basic introduction to MD along with best practices, tips and tricks when setting up and analyzing MD simulations.

NVE Simulations

Let us setup a microcanonical ensemble simulation in which the number of particles (N), volume of the simulation cell (V) and energy of the system (E) remains constant. Import the geometry we will need, `Silicon_bulk.py`, to your Builder stash.

Workflow

1.Select the silicon supercell in **Builder** stash.

2.Click on the icon and send the bulk configuration to the **Workflow Builder**

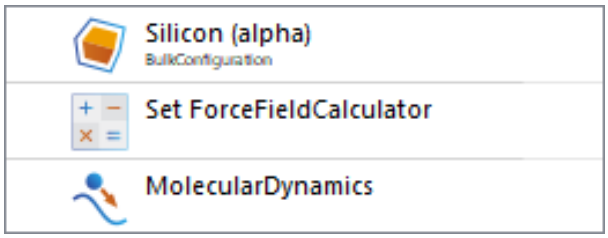
3.In the **Workflow Builder**, change the output **Filename** at the bottom of the middle panel to `md-nve-1fs.hdf5`.

4.Add the following blocks to the **Build** panel by double clicking on the corresponding icons in the **QuantumATK** tab in the right-hand panel:

•Under **Calculators**: *Set ForceFieldCalculator*

•Under **Optimization and Dynamics**: *MolecularDynamics*

The resulting workflow will look like the below picture



5.Double click the *Silicon (alpha)* block to visualize the bulk supercell. This is the system we will run MD for.

6.Double-click on the *Set ForceFieldCalculator* block and select the *Tersoff_Si_1988* parameter set as shown below

7.Double-click on the *MolecularDynamics* block, set the **Steps** to *1000*, **Log interval** to *5* and set *Fix the center of mass* constraint

8.Go to **Methods** tab and choose **Method** as *NVE Velocity Verlet* from the pull down menu, set **Initial velocity Type** to *Maxwell-Boltzmann Distribution* and **Temperature** to *300 K*.

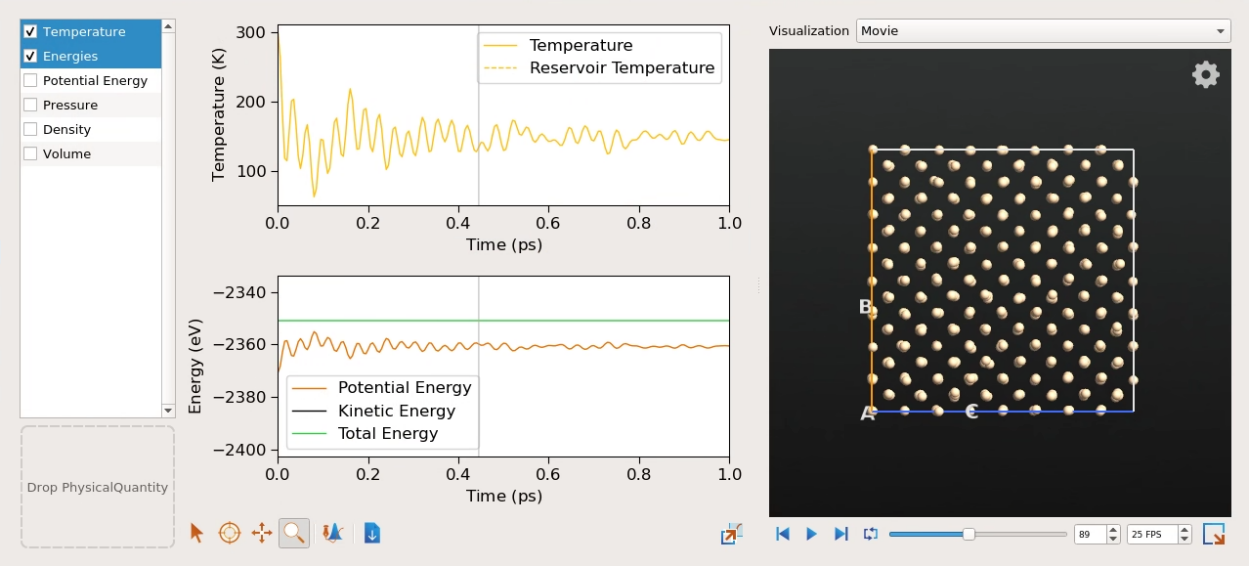
9. Send the workflow to the **Job Manager** as a script using and save the script as `md-nve-1fs.py`. This script runs in a few seconds, it can run locally.

   Alternatively, download the workflow `md_tutorial_nve_1fs.hdf5` to your project folder, open it in the Workflow Builder Tool in the Nanolab, export to script and submit the job.

Analyzing the Results

Once the simulation is finished, select the `md-nve-1fs.hdf5` file from the project folder and double-click the *MDTrajectory_0* object from the Data View. The trajectory will open in the **Movie Tool** plugin. Using the **Movie Tool** plugin, you can investigate the temperature as well as the kinetic, potential, and total energies of the system as a function of simulation time. Simultaneously, an animation of the motion of the atoms is displayed.



If you take a look at the temperature, you will observe the temperature dropping immediately and then oscillate around the set temperature. The reason is that the displayed temperature is the instantaneous temperature of the system, calculated from the kinetic energy of the atoms, via $E_{kin}(t) = 3/2Nk_BT(t)$. Since the atoms are not free but interact with the neighboring atoms in the lattice, their initial kinetic energy will be partially converted into potential energy. For an *NVE* ensemble, a crucial parameter to monitor is the conservation of the total energy and find that the total energy curve in the **Movie Tool** remains constant with only small oscillations which are acceptable.

Tip: Try changing some MD parameters and see how they affect dynamics. For more tips, refer to *Molecular Dynamics*.

NVT Simulations

In NVT, we keep the temperature constant instead of the energy as in the NVE case. Download the workflow `md_tutorial_nvt_300k.hdf5` to your project folder and open it in the Workflow Builder Tool in the Nanolab.

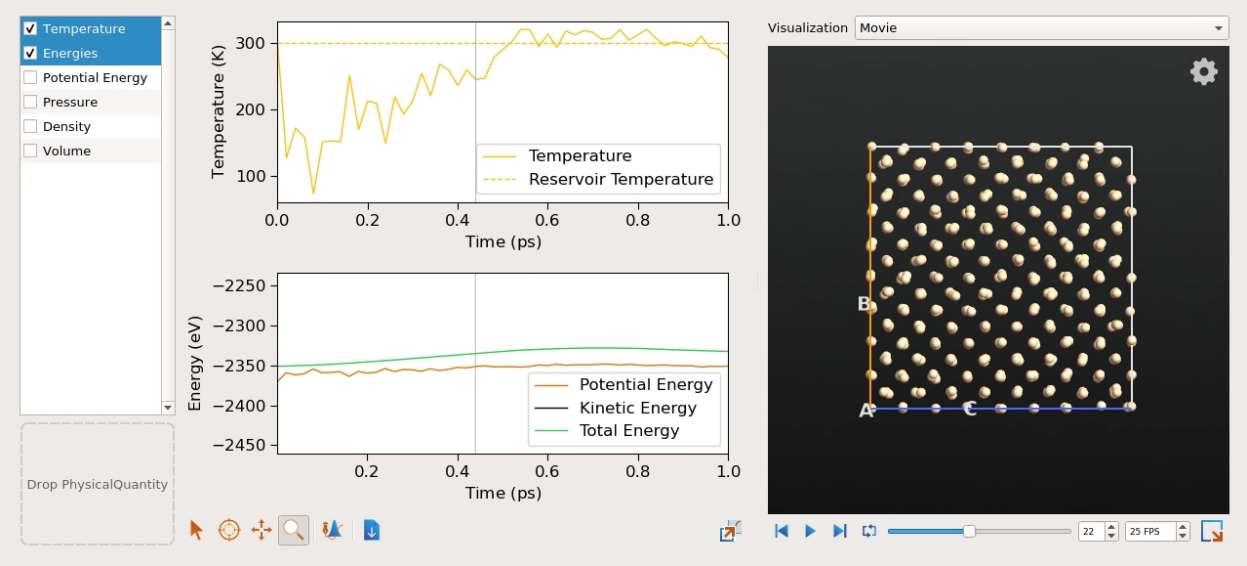
Workflow

The workflow should look similar to the NVE case, but the MolecularDynamics block should list *NVT* as the **MD method** and a **reservoir temperature** of *300 K* will be listed. In this example, we use the *Nose-Hoover* type thermostat coupling to the reservoir. For more details on this method and other available thermostats, refer to the technical note on *Molecular Dynamics*.

After loading the workflow, export it as a script and submit the job.

Analyzing the Results

After the simulation is completed, open the NVT MD trajectory object with the **Movie Tool** and take a look at the temperature curve.



You will find that after a short initial equilibration period the curve fluctuates slightly around the selected reservoir temperature of 300 K. In fact, it does not look very different from the results of the NVE simulation in the previous section. In contrast to the NVE simulation, however, the final equilibrium temperature of the system is independent of the initial value, set via the Maxwell-Boltzmann distribution, and is instead coupled to the reservoir temperature. Let us take a closer look at this now.

Download the workflow `md_tutorial_nvt_1000k.hdf5` in which the **reservoir temperature** is set to *1000 K*. Leave the **initial velocities** as a *Maxwell-Boltzmann* distribution at 300 K and run the script.

On opening the resulting trajectory in the movie tool, we see the temperature curve starting at an initial value of 300 K (as selected via the *Maxwell-Boltzmann distribution*).

Subsequently, as the system is in contact with the heat bath, the temperature quickly increases towards the reservoir temperature of 1000 K. You may also notice an increase in the total energy. In contrast to *NVE* simulations, this is not a sign of poorly chosen parameters, but reflects the fact that energy is exchanged with the virtual heat bath.

During the simulation at 1000 K, the motion of the atoms increases compared to the previous simulation at 300 K.

If you increase the reservoir temperature to even higher values (e.g 3000 K), you will find that the crystal will begin to melt and become partially amorphous. Annealing crystals at high temperatures is in fact a common way to generate amorphous structures of a material. You can learn more about this method in the tutorial *Generating Amorphous Structures*.

Warning: Setting too high a temperature on a minimum energy configuration might result in the generation of very large forces on the atoms which could destabilize the system. Instead, slowly heat up the system from room temperature using a suitable *heating rate*.

NPT Simulations

In this ensemble, we keep the number of particles, pressure and temperature constant. Download the workflow `md_tutorial_npt_300k_1bar.hdf5` to your project folder and open it in the **Workflow Builder** tool in the NanoLab.

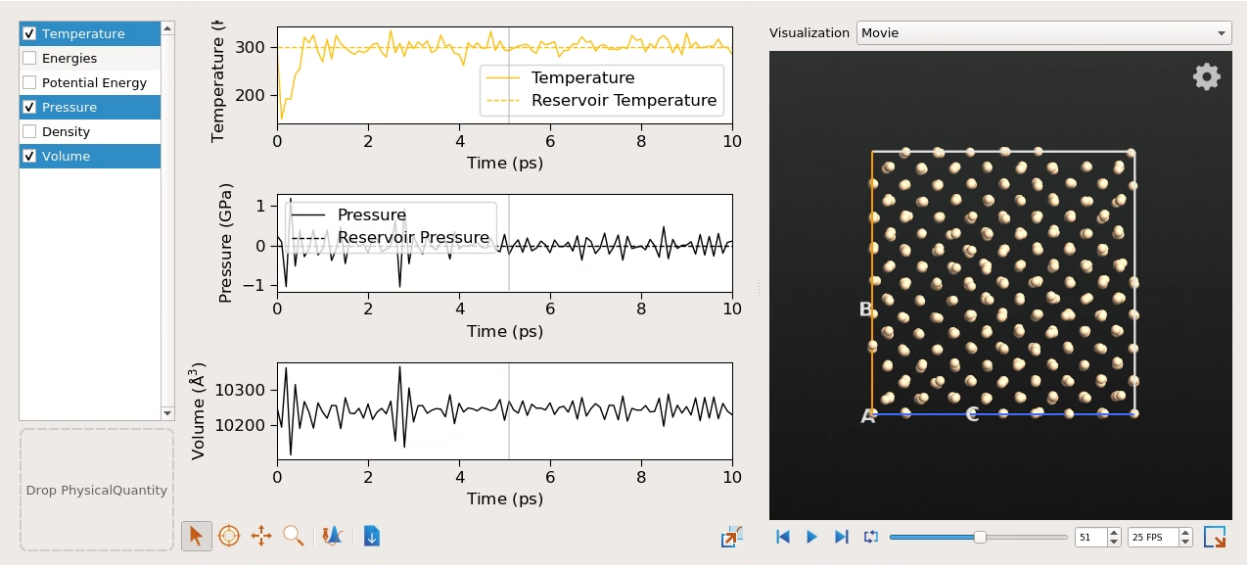
Workflow

The main difference you will observe in the MD block is the choice of NPT method. We use **NPT Martyna Tobias Klein** barostat in this example. For more details about this method and other NPT methods, refer to *Molecular Dynamics*. As you will notice the **reservoir temperature** and **pressure** are set to *300 K* and *1 bar*, respectively and an *isotropic coupling* is selected. This is because are simulating the system at standard temperature and pressure conditions and also allow the system to relax equally on all three lattice directions. Anisotropic coupling can be enabled to choose to fix some simulation cell boundaries.

Export the workflow as script and submit the job.

Analyzing the Results

Opening the trajectory with the **Movie Tool**, you can monitor the changes in the size and shape of the cell during the simulation. The temperature fluctuates around the selected reservoir temperature of 300 K.



To inspect the volume fluctuations you can select the *volume* measurement in the **Movie Tool**. The cell volume will show pronounced oscillations. These oscillations are a typical outcome of the *Nose-Hoover-like* temperature and pressure

control. As long as their magnitude stays within reasonable boundaries, and does not increase dramatically throughout the simulation, there is no need to worry. The period of these oscillations can be changed by the *Barostat timescale* setting. The amplitude and frequency of the oscillations increases with decreasing barostat timescale.

The pressure during the simulation, seen by selecting the *Pressure* measurement in the **Movie Tool**, shows a similar behavior. It oscillates around the target pressure of 1 bar, but the amplitude is large. Such large fluctuations of the instantaneous pressure values are in fact not unusual in MD simulations, as the pressure is calculated based on the stress, which varies considerably with small changes of the volume. Moreover, pressure is a macroscopic property, and for such a small system it is more reasonable to consider the corresponding average rather than the instantaneous values.

Conclusion

You have learnt how to use the Workflow Builder tool to set up basic molecular dynamics simulations of NVE, NVT and NPT ensembles. You also know how to view the resulting trajectories using the Movie tool and interpret the results.

Feel free to change the MD settings and run the simulations to see how the dynamics changes and to familiarize yourself with the method.

You can try adding multiple MD blocks within a workflow to simulate the system in different ensembles in a sequential manner. For more inspiration, checkout predefined MD templates in the Templates section of the Workflow Builder.

3.8.2 Simulating Thin Film Growth via Vapor Deposition

Introduction

In this tutorial you will learn how to use QuantumATK to run molecular dynamics (MD) simulations to simulate thin film growth onto a substrate via vapor deposition processes.

Vapor deposition is a widely used technique for the production of thin films composed of crystalline or amorphous solids on a substrate material. Simulations of such processes can help understand the underlying microscopic mechanisms, and the effect of the process parameters such as pressure, temperature, etc. on the resulting atomistic structure and kinetics.

In this tutorial you will simulate the growth of silicon carbide (SiC) onto a crystalline SiC substrate, similar to the study in Ref.[1]. You will use empirical potentials which facilitate the simulation of larger systems and time scales than accessible in ab-initio methods, such as DFT. The simulations shown in this tutorial primarily fall under the category physical vapor deposition (PVD). However, chemical vapor deposition (CVD) processes can, in principle, be simulated as well, given that either suitable force fields to describe the chemical reactions are involved, or sufficient computational resources for the use of ab-initio methods are available.

For this tutorial you should be familiar with the basic functionalities of molecular dynamics as described in the *How to Setup Basic Molecular Dynamics Simulations*. You will learn how to use Python scripting together with the hook functionality available in QuantumATKs molecular dynamics routines to run advanced simulations.

Note: The exact modified embedded atom model (MEAM) potential used in Ref.[Page 1165, 1] is currently not available in QuantumATK. Instead, you will use a Tersoff potential, which, unfortunately, will not produce the crystalline layers shown in the reference paper. The simulation technique, though, is of course independent of the exact potential, and can be used for all kinds of materials.

---

[1] Kang, K.-H; Eun, T.; Jun, M.-C.; Lee, B.-J.: Governing factors for the formation of 4H or 6H-SiC polytype during SiC crystal growth: An atomistic computational approach. J. Cryst. Growth, 389, 120 (2014)

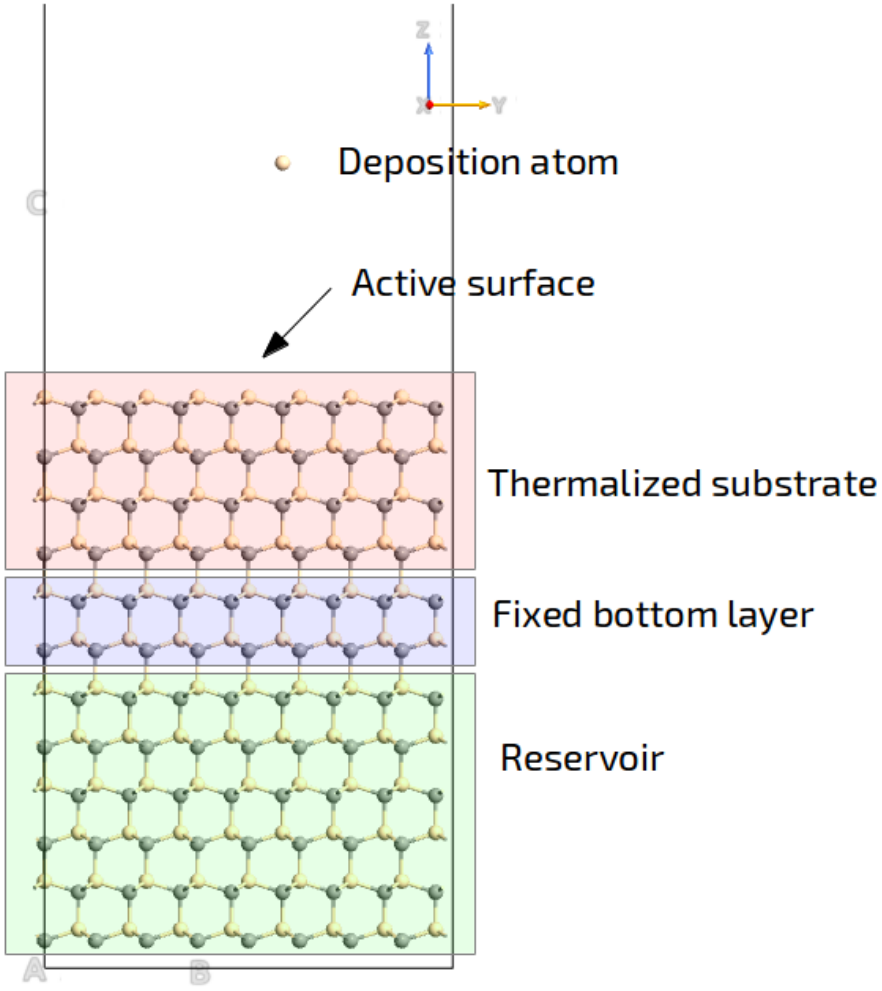
Note: The limited accessible simulation time requires to operate at vapor pressure values, which are considerably higher than in experiments. You should always keep this in mind when you interpret the simulation results. A more detailed discussion can be found in the general *remarks* section.

Simulation Strategies

There are different techniques to run a deposition simulation. The main difference to conventional equilibrium MD simulations is that the number of particles in the system increases due to the introduction of vapor atoms or molecules. In QuantumATK two strategies are possible in order to achieve this:

1. Run a new simulation for each newly introduced atom or molecule. The entire deposition simulation can then be performed in an outer loop over the deposited atoms/molecules.
2. Keep all atoms or molecules that should be deposited in a reservoir in the simulation cell. For each new deposition event, take one of these atoms out of the reservoir and place it above the substrate.

The first approach has the advantage that only the atoms that are really needed are present in the simulation cell, which improves the efficiency of the simulation. However, in QuantumATK it is not possible to save the entire simulation into a single *MDTrajectory* object for later visualization and analysis, due to the varying number of atoms. Therefore, the second approach is chosen in this tutorial. When preparing the simulation one has to pay attention that the atoms in the reservoir do not interact significantly with the active part of the system, in particular with the surface at which the adsorption takes place. In the present case, the reservoir will be represented by a crystal that is attached at the bottom of the substrate.



Preparing the System

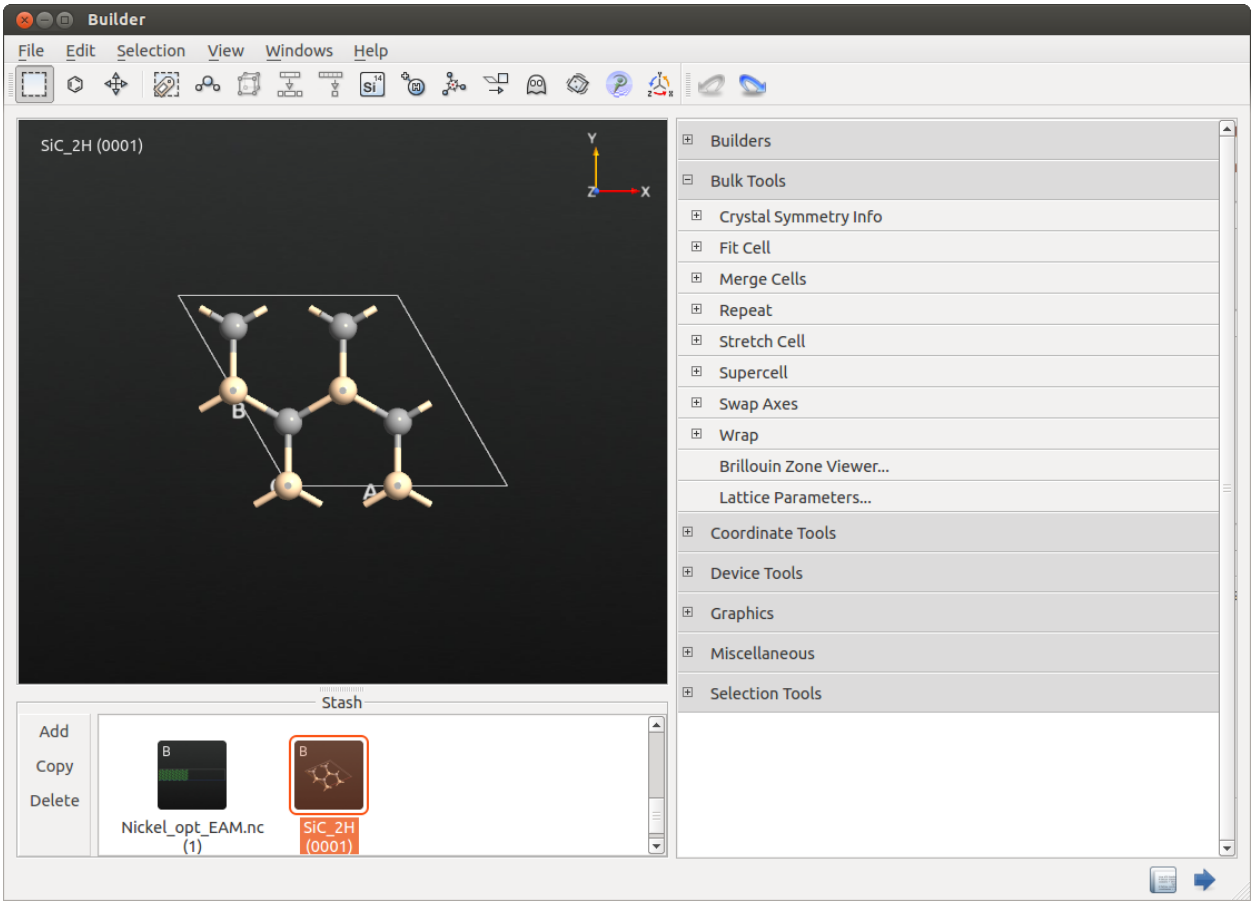
Silicon carbide crystals can occur in different polymorphs. In this tutorial, the substrate will be built from the basic *2H-SiC* crystal structure, which is in the configuration database in **QuantumATK**. You can of course also use a different SiC polymorph to prepare your substrate crystal.

Open the Builder, click *Add* → *From Database*, search for *SiC*, and add the *Wurtzite* structure.

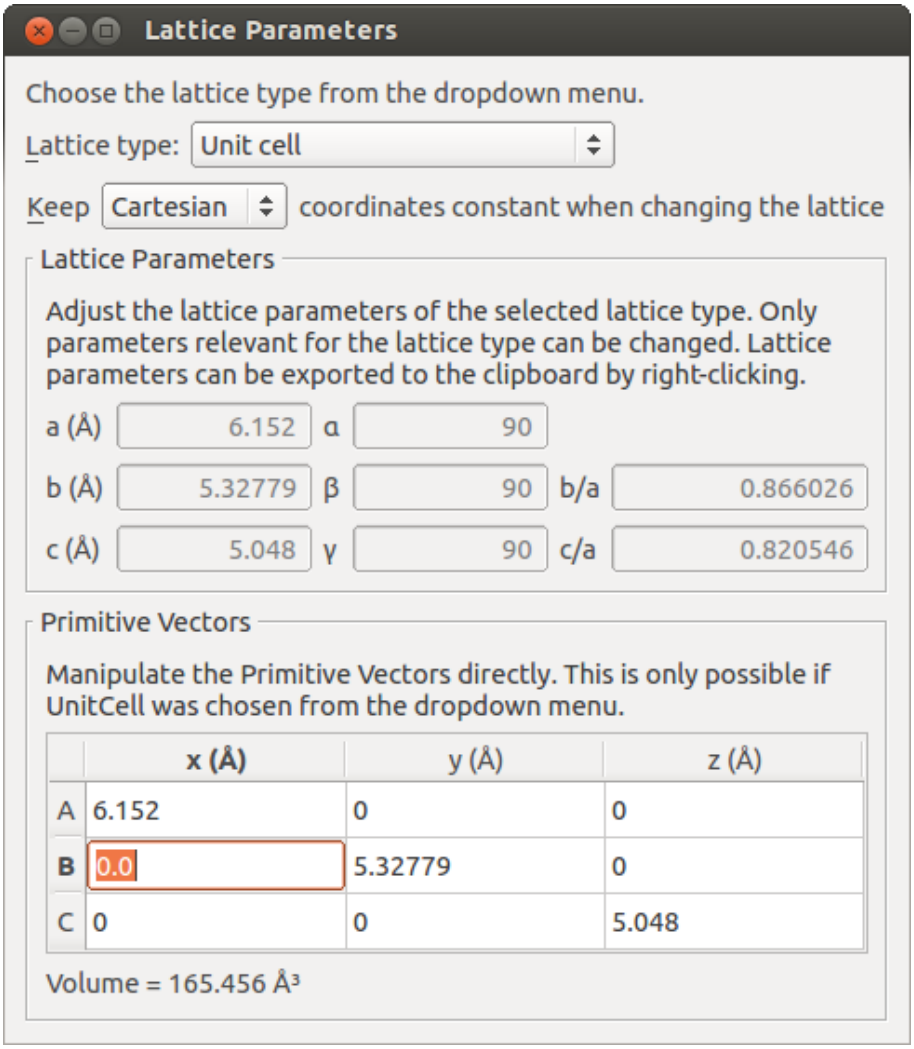
Preparing the Surface and Reservoir

For this simulation we will consider the (0001) surface of the SiC crystal. To build this surface use the *Builders* → *Surface (Cleave)* plugin in the panel bar on the right-hand-side. Select the (0001) Miller indices and a 2x2 surface lattice. Finally, select a *Periodic (bulk-like)* out-of-plane cell vector and a thickness comprising one layer. Click `Finish` to finalize the cleaving process.

The resulting cell still has a hexagonal shape in the x-y-plane, which can be inconvenient in MD simulations.

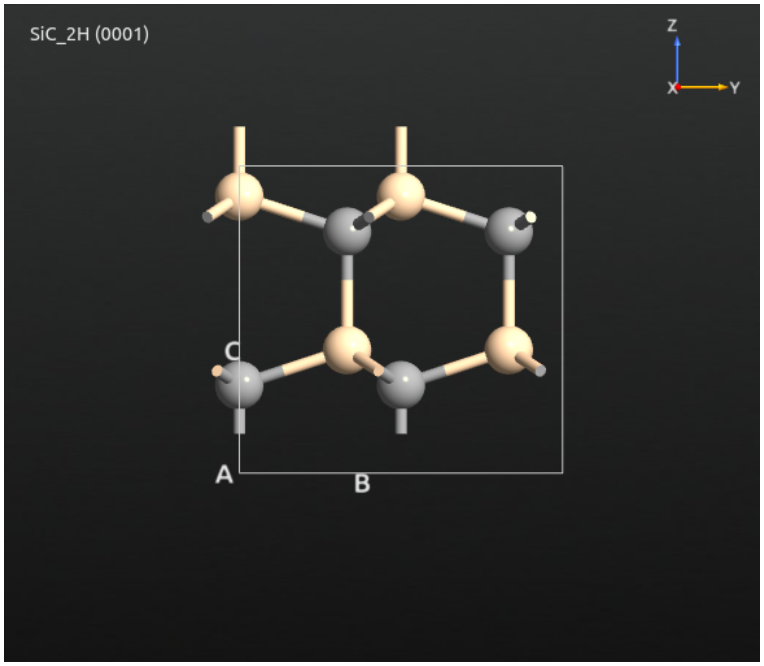


Due to the hexagonal symmetry, the surface lattice can easily be converted into an orthogonal lattice. To this aim open the *Bulk Tools* → *Lattice Parameters* widget, select to *Keep* → *Cartesian coordinates*, and set the x-component of the **B**-vector to zero.



Use the *Bulk Tools* → *Wrap* plugin to fold the atoms into the new simulation cell, and you will see that the crystal structures remains the same.

Due to the cleaving and wrapping, the termination of the top layer might not always be ideal. In this case, a termination with dangling, i.e. one-fold, coordinated carbon atoms is obtained, which most likely wont be stable in simulations. To obtain a better termination, shift the entire configuration by invoking *Coordinate Tools* → *Translate*, using a z-translation of -0.2 Å, and finally wrapping the configuration into the box via *Bulk Tools* → *Wrap*. The final termination should look like the following, featuring a more stable termination at bottom and top.



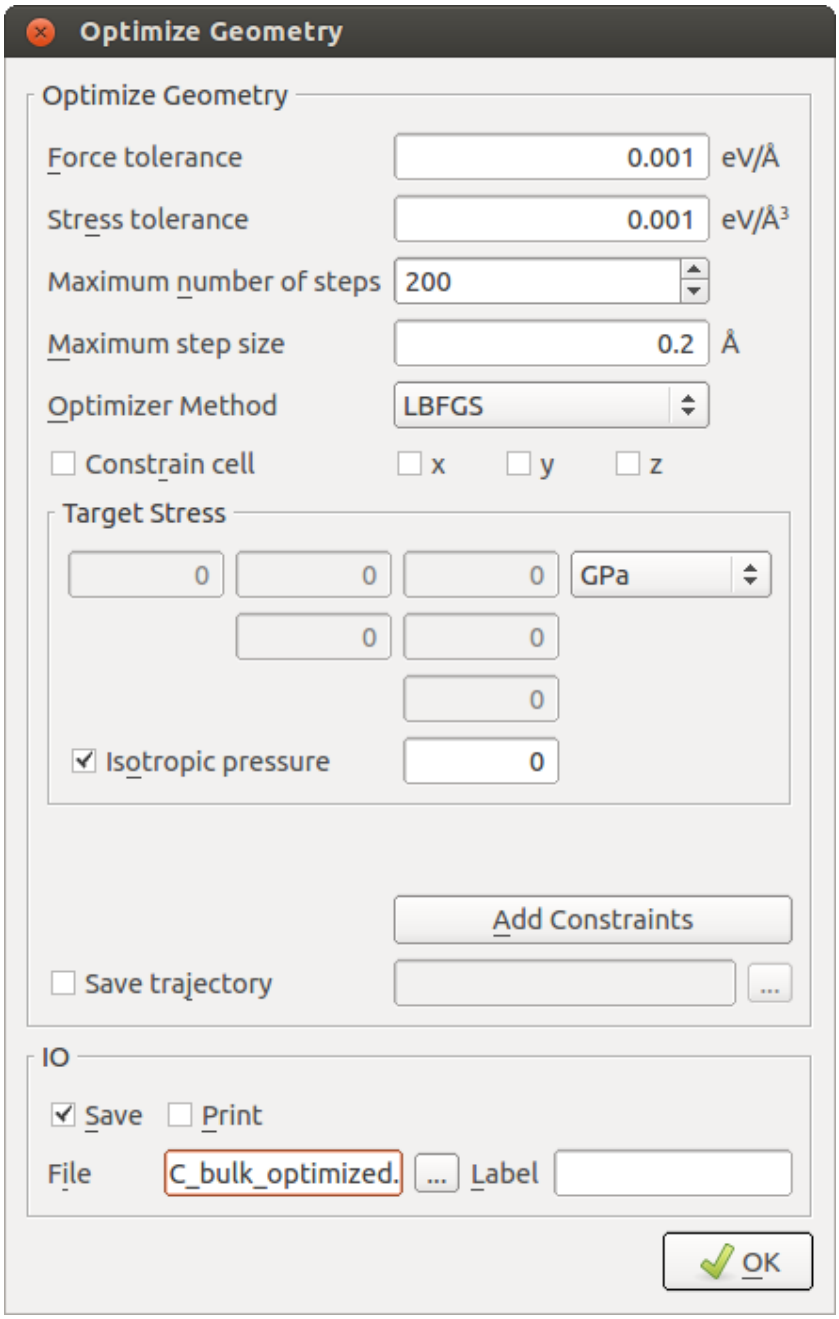
The next step is to create a supercell of suitable size via *Bulk Tools* → *Repeat*. Use a 3x3 repetition in the **A**-**B**-plane. The **C**-vector must be repeated in such a way that a substrate with sufficient crystal layers is created, as well as a reservoir containing enough of atoms to form the desired thickness of the deposited film. For the present example, use 3 layers for the substrate. To keep the simulation time reasonably short you will use only one layer for the reservoir, which gives a total number of 4 repetitions along he **C**-axis in total. If you later want to perform real production simulations, you may of course increase the number of reservoir layers (and the number of steps in the deposition simulation).

Now you need to mark the different parts of the system via tags. First select the upper two layers of the system to be the thermalized substrate, as shown in the schematic picture of the *reservoir* approach, and tag them with the name substrate. Then select the next lower crystal layer as the fixed bottom layer of the substrate, and assign the tag bottom. Finally, select the lowest crystal layer as the reservoir with the tag name reservoir.

Optimizing the Lattice Constants

Before building the slab configuration, the bulk system should be optimized under the potential used for the actual deposition simulation to obtain the optimal lateral lattice constants. To this aim send the prepared bulk crystal to the *ScriptGenerator*, and add a *NewCalculator* and an *Optimize* → *OptimizeGeometry* block. In the **New Calculator** settings, select **ATK- Classical** and choose *Parameter set* → *Tersoff_SiC_2005*[2]. Uncheck **Print** and **Save** and close the widget. In the **OptimizeGeometry** settings make the following changes.

[2] P. Erhart and K. Albe: Analytical potential for atomistic simulations of silicon, carbon, and silicon carbide. Physical Review B, 71, 035211, (2005)



Run the simulation and drag the final optimized configuration from the **LabFloor** to the **Builder**.

Setting up the Simulation Cell

Finally, a surface has to be created from the bulk crystal. This can easily be achieved by increasing the height of the cell of the optimized bulk system. To this aim, open the *Bulk Tools* → *Lattice Parameters* widget. After the optimization, some of the off-diagonal cell components might be slightly different from zero. For convenience they should be reset to zero, while keeping the fractional coordinates constant. To adjust the height of the cell, make sure that you select *Keep* → *Cartesian coordinates*. Increase the z-component of the **C**-vector to 100.0 Å to obtain a sufficient vacuum padding between the active surface and the reservoir.

Setting up the Equilibration Simulation

Before you can run a deposition simulation, the surface has to be thermalized at the desired temperature. In the present example, you will operate at a substrate temperature of 2400 K, as suggested in[1]. Send the prepared configuration from the **Builder** to the **Script Generator**. Add a *NewCalculator* and an *Optimize* → *MolecularDynamics* block. In the **New Calculator** settings, make the same changes as in the previous optimization simulation. In the **MolecularDynamics** widget, select *Molecular Dynamics* → *Type* → *NVT Nose Hoover* thermostat, 100 000 steps, a log interval of 5000 steps, and enter a suitable trajectory filename. Select *Initial Velocity* → *Type* → *Maxwell-Boltzmann* initial velocities at 2400 K and set the *reservoir temperature* to 2400 K. (Note that in this case the *reservoir temperature* does *not* refer to the particle reservoir in the simulation cell, but denotes the temperature of the virtual heat reservoir, cf. *How to Setup Basic Molecular Dynamics Simulations*). Uncheck the **Save** and **Print** boxes.

Open the constraints widget by clicking the **Add constraints** button. Both the bottom layer of the substrate and the reservoir atoms should be fixed during the equilibration. This is done by selecting *Constraint* → *Fixed* constraints for these two tagged groups and closing the constraints widget.

Run the simulation via the **Job Manager** or in a terminal using `atkpython` and use the **Movie Tool** to send the final snapshot back to the **Script Generator**.

Setting up the Deposition Simulation

The deposition simulation consists of a normal, long MD simulation, which uses the *hook* functionality to perform a custom operation after each MD step (cf. *MDTrajectory* in the reference manual). In this case, at regular intervals an atom is taken from the reservoir and placed above the surface with a random thermal velocity, which is directed towards the active surface. This customized hook function has to be defined in the script using the Python programming language.

To set up the MD simulation in the **ScriptGenerator**, add a *New Calculator* and an *Optimize* → *Molecular Dynamics* block, and adjust the calculator settings as shown above. In the **Molecular Dynamics** widget, select the *NVT Nose Hoover* type, 800 000 steps, a log interval of 2500 steps, and a suitable trajectory filename. Set a reservoir temperature of 2400 K and select *Configuration Velocities* as initial velocities. Uncheck **Save** and **Print**. Send the simulation script to the **Editor** to make the necessary modifications.

Implementing the Deposition in the Script

At first you have to import the `wrap()` function to wrap coordinates back into the simulation cell.

```
from NL.CommonConcepts.Configurations.Utilities import wrap
```

Then you have to define the class that implements the hook function (the general procedure is similar to the tutorial about *Youngs modulus of a CNT with a defect*). First, define the class name and its constructor method.

```
# ------------------------------------------------------------
# Define a hook class to deposit atoms from the reservoir
# onto the active surface of the substrate.
# ------------------------------------------------------------

class VaporDepositionHook:
    def __init__(self,
                 deposition_interval,
                 configuration,
                 substrate_atoms,
                 vapor_temperature=300.0*Kelvin):
        """
        Constructor
        """
        # Store the parameters.

        # The interval after which a new atoms is deposited.
        self._deposition_interval = deposition_interval

        # Store the original coordinates. They will be used to constrain the reservoir␣
↪atoms.
        self._original_coordinates = configuration.cartesianCoordinates().
↪inUnitsOf(Angstrom)

        # The indices of the atoms that should not be deposited
        self._substrate_atoms = substrate_atoms

        # The vapor temperature.
        self._vapor_temperature = vapor_temperature

        # Deposition count.
        self._deposited_index = 0

        # Get the atoms in the reservoir, i.e. all with z-coordinates lower
        # than the fixed bottom of the substrate.
        self._lowest_substrate = self._original_coordinates[self._substrate_atoms, 2].
↪min()
        self._reservoir_indices = numpy.where(self._original_coordinates[:, 2] < self._
↪lowest_substrate - 0.1)[0].tolist()

        # Get the lattice vectors.
        cell = configuration.bravaisLattice().primitiveVectors().inUnitsOf(Angstrom)
        self._lx = cell[0, 0]
        self._ly = cell[1, 1]
        self._lz = cell[2 ,2]

```

In the constructor, you essentially store the needed parameters for the deposition, such as the interval at which a new atom is taken from the reservoir, and the original coordinates to constrain the atoms in the reservoir.

Finally, you have to define a method that is called whenever the hook function is invoked. Since our hook is implemented as a Python class, the `__call__()` method must be defined to make it behave like a function. All hook functions must take the arguments `step`, `time`, and `configuration`. This method should be implemented as follows.

```
    def __call__(self, step, time, configuration, forces, stress):
        """ Call the hook during MD. """
        # Get the coordinates.
        coordinates = configuration.cartesianCoordinates().inUnitsOf(Angstrom)

        # The reservoir is composed of all atoms that are below the bottom
        # layer of the substrate
        # or above the ceiling of the cell.
        self._reservoir_indices = numpy.where((coordinates[:, 2] < self._lowest_
↪substrate - 0.1) |
                                              (coordinates[:, 2] > self._lz))[0]

        # Freeze the reservoir atoms and reset their positions at every step.
        velocities = configuration.velocities()
        velocities[self._reservoir_indices, :] = 0.0*Angstrom/fs
        configuration._changeAtoms(indices=self._reservoir_indices,
                                   positions=self._original_coordinates[self._reservoir_
↪indices]*Angstrom)

```

At first, the cartesian coordinates are extracted form the current configuration. Then the atoms in the reservoir are determined based on whether their current position is either underneath the substrate or outside the upper cell boundary. For all reservoir atoms the velocities are set to zero, as we do not want them to move, in particular when the reservoir is increasingly eroded by removing atoms from it. Additionally, their positions are reset to the original positions at the beginning of the deposition simulation.

The next part contains the actual deposition of a new atom from the reservoir, and it is therefore only executed once at the beginning of each deposition interval.

```
        # Check if it is time for the deposition of a new atom from the reservoir.
        if (step % self._deposition_interval) == 0:
            # Get elements and velocities.
            elements = numpy.array(configuration.elements())
            velocities = configuration.velocities().inUnitsOf(Angstrom/fs)

            # If the reservoir is empty, do nothing.
            if len(self._reservoir_indices) == 0:
                return

            # Decide which element to deposit next.
            possible_elements = [Silicon, Carbon]
            element_index = self._deposited_index % 2
            next_element = possible_elements[element_index]
            reservoir_elements = elements[self._reservoir_indices]

            # Get the element candidates.
            possible_atoms = numpy.where(reservoir_elements == next_element)[0]

            # If not avaiblable, try the other element.
            if len(possible_atoms) == 0:
                next_element = possible_elements[element_index-1]
                possible_atoms = numpy.where(reservoir_elements == next_element)[0]

```

(continues on next page)

(continued from previous page)

```
            # Return back the global atom indices.
            possible_atoms = self._reservoir_indices[possible_atoms]

            # Pick an atom at the bottom of the reservoir
            lowest_atom = numpy.argmin(coordinates[possible_atoms, 2])
            next_index = possible_atoms[lowest_atom]

            # Place the deposition atom above the surface at a random lateral position.
            new_coords = numpy.array([numpy.random.uniform()*self._lx,
                                      numpy.random.uniform()*self._ly,
                                      self._lz - 15.0])

            configuration._changeAtoms(indices=[next_index], positions=new_
↪coords*Angstrom)
            wrap(configuration)

            # Draw random velocities for the atom according to
            # Maxwell-Boltzmann at the specified temperature.
            m = next_element.atomicMass()
            sig = self._vapor_temperature*boltzmann_constant/m
            sig = sig.inUnitsOf(Ang**2/fs**2)
            sig = numpy.sqrt(sig)

            new_velocity = numpy.random.normal(scale=sig, size=3)
            velocity_norm = numpy.linalg.norm(new_velocity)

            # Set the velocity so that it points towards the active surface.
            new_velocity = numpy.array([0.0, 0.0, -velocity_norm])
            velocities[next_index] = new_velocity

            # Set the new velocities on the configuration.
            configuration.setVelocities(velocities*Angstrom/fs)

            self._deposited_index += 1

# ------------------------------------------------------------
# End of hook class definition
# ------------------------------------------------------------

```

We start by determining which element has to be deposited next. As silicon and carbon are deposited in an alternating manner, this can easily be detected by querying whether the current deposition index is an odd or even number. Then all reservoir atoms of this element are selected and the atom which resides deepest at the bottom of the reservoir is picked. If for some reason no element of the requested type is available in the reservoir, we simply pick the other element instead. New random lateral coordinates, as well as a height at 15.0 Angstrom below the cell ceiling are created and assigned to the deposition atom via the `_changeAtoms()` method of the configuration. For better visibility, the coordinates are folded back into the cell using the `wrap()` function. To model the vapor temperature of the deposition atoms, new velocities are drawn from a Maxwell-Boltzmann distribution and, to ensure that the atom travels towards the surface, the velocity vector is re-aligned. For simplicity, the vector always points vertically to the surface, but in general, different impact angles can easily be implemented, as well. The new velocites are assigned to the deposition atom and the configuration velocities are updated using the `setVelocities()` method. Finally, the running deposition index is incremented, completing the class definition.

After the definition of the VaporDepositionHook class, a new instance is initiated, and the parameters for the current simulation are specified. This should be done immediately before the *Molecular Dynamics* block in the script.

```
# Initialize the hook class.
deposition_hook = VaporDepositionHook(deposition_interval=5000,
                                      configuration=bulk_configuration,
                                      substrate_atoms=substrate+bottom,
                                      vapor_temperature=2400.0*Kelvin)

```

To run the simulation, use the pre-defined MD block from the **Script Generator** with only two slight modifications. In the method definition of the *Nose–Hoover* thermostat, the reservoir_temperature parameter is modified, so that only the group of atoms marked by the substrate tag is coupled to the thermostat.

```
# Define an NVT thermostat where only the substrate atoms are thermalized.
method = NVTNoseHoover(
    time_step=1*femtoSecond,
    reservoir_temperature=[('substrate', 2400*Kelvin)],
    thermostat_timescale=100*femtoSecond,
    heating_rate=0*Kelvin/picoSecond,
    chain_length=3,
    initial_velocity=initial_velocity
)
```

This is necessary, to ensure that the dynamics of the deposited atoms in the gas phase are not spuriously modified by the thermostat before they have adsorbed to the surface (i.e. the deposited atoms should be in the NVE ensemble). Finally, the deposition_hook object must be passed as an argument to the MolecularDynamics() function.

```
md_trajectory = MolecularDynamics(
    bulk_configuration,
    constraints=bottom,
    trajectory_filename='SiC_deposit_tutorial_md.nc',
    steps=800000,
    post_step_hook=deposition_hook,
    log_interval=2500,
    method=method
)
```

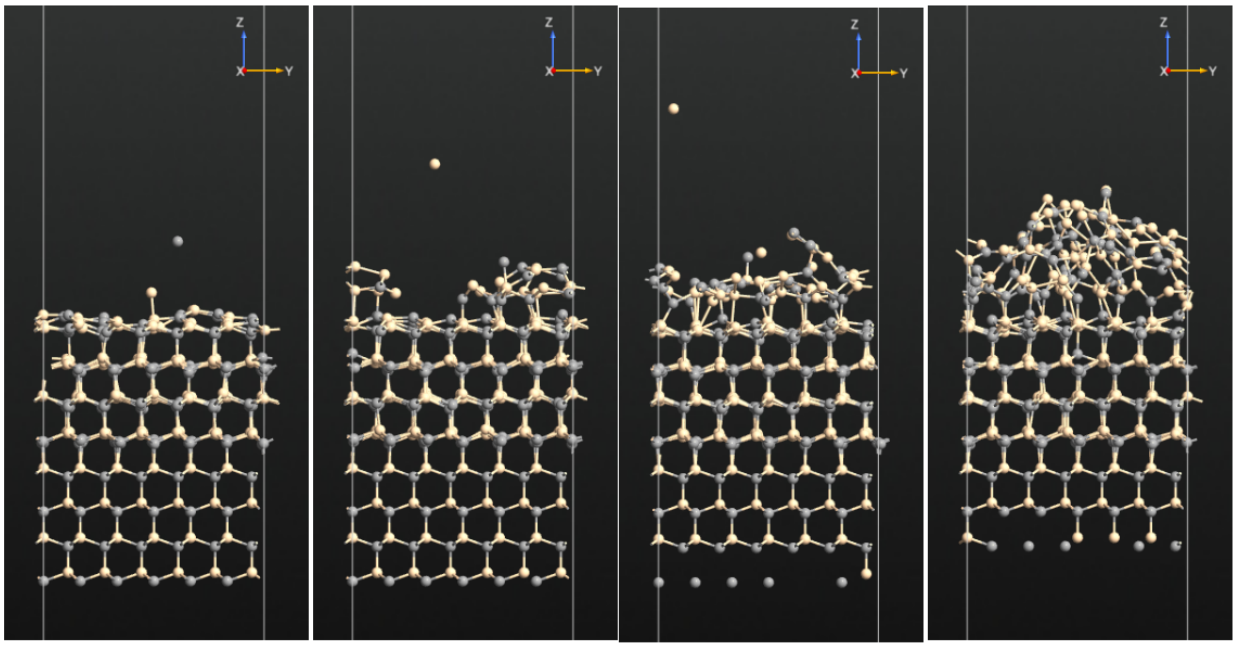
The complete script for the entire simulation can be found in the file Script_deposit_SiC.py.

Note: In QuantumATK version 2016, the NVT Nose–Hoover method is implemented in the NVTNoseHoover class, which is the one used in the script provided above. However, in QuantumATK version 2015 and earlier, that class is named NVTNoseHooverChain. The script provided above will therefore not work with QuantumATK 2015 and earlier. Use instead this script: Script_deposit_SiC_atk2015.py.

Running the Simulation

Run the script via the **Job Manager** or in a terminal. Such a long MD simulation might take a couple of hours to complete. You may notice that some atoms, instead of adsorbing to the surface, are scattered back into the vapor phase. This is not a problem, though, as these atoms, while travelling upwards, will eventually reach the reservoir, where they will automatically be treated as normal reservoir atoms again.

The following figure displays snapshots at different stages of the deposition simulation.



At first, only few atoms have been deposited onto the surface and adsorb forming single adatoms. With more and more atoms being deposited a first layer begins to form above the substrate surface. The first layer still resembles, at least partially, the crystalline structure of the substrate, whereas subsequent layers reveal a more amorphous structure. This must be attributed primarily to the employed potential (see the *note* at the beginning), but to some extent also to the high deposition frequency, as specified by the `deposition_interval` parameter. A larger value for this parameter will decrease the deposition frequency, which may allow for a more controlled integration of the deposited atoms. Remember, if you increase the deposition interval, you have to increase the total number of steps in the deposition simulation by the same factor to make sure all the atoms in the reservoir are being deposited.

Notice how at the same time as the film grows, the reservoir region at the bottom of the slab is depleted, as more and more atoms are taken away. However, the special constraints in the script make sure that the vanishing structure does not de-stabilize the entire system.

General Remarks

This simulation technique is, in principle, applicable to all kinds of materials. Of course, you might need to make several modifications in the script, such as adapting the elements. Instead of single atoms, you can also deposit entire molecules. For production simulations you may want to increase the number of layers in the reservoir to obtain a larger deposited film. Feel free to play around with other parameters, e.g. temperature, or the deposition interval. The deposition frequency, i.e. the inverse of the deposition interval, can be associated with the vapor pressure via the Hertz–Knudsen equation (cf. for instance[3]):

$$\frac{dN_i}{dt} = \frac{p_i A}{\sqrt{2\pi m_i k_B T}},$$

where p_i denotes the partial pressure of element/molecule *i*, *A* the surface area, and m_i the atomic/molecular mass.

Inserting the parameters from the simulation, you will find that the corresponding vapor pressure is around 66 bar, which is far away from the typical experimental near-vacuum conditions. This aspect represents a considerable shortcoming of such simulations, as the accessible simulation time in most cases prevents the use of realistic pressure values, rendering a *time-resolved* interpretation of the growth *kinetics* very difficult. Essentially, it means that the particles impact at a too high rate, which can, for instance, result in an increased local heating, as the reaction heat cannot be transported sufficiently fast from the surface to the thermostatted bulk substrate. However, the obtained *structural model* of deposited films can in most cases be considered a good approximation to the real film structure. You should bear in mind the conditions, though, under which the simulation has been performed and reconsider whether these conditions might have an influence on the deposited structure.

Furthermore, note that the use of a constant deposition interval provides another approximation, as the real process might rather follow a *Poisson distribution* than a uniform distribution. Although a Poisson distribution can easily be implemented into the script (using e.g. pythons `random.poisson` function), this would primarily make sense if the deposition interval can actually be chosen high enough to reproduce the desired real vapor pressure.

3.8.3 Simulating Ion Bombardment on Graphene Sheets

The properties of graphene sheets can be tuned by intentionally introducing defects to the material. A promising method to obtain defects in a controlled way is by bombarding the graphene sheet with high-energy ions. Molecular dynamics simulations can be used to elucidate the mechanisms involved in such processes and to improve our understanding of how external parameters, such as the kinetic energy of the incoming ion, affect the formation of defects. In this tutorial, you will simulate ion bombardment of graphene, following the protocol proposed in Ref.[1].

In particular, you will:

- Learn the basic steps required to set up the calculation using **QuantumATK**.
- Learn how to manually introduce modifications to the Python script generated by QuantumATK.
- Run the calculation using **QuantumATK**.

[3] K. Reuter: First-Principles Kinetic Monte Carlo Simulations for Heterogeneous Catalysis: Concepts, Status, and Frontiers. in *Modeling Heterogeneous Catalytic Reactions: From the Molecular Process to the Technical System*, Wiley-VCH (2011)

[1] EdsonăP. Bellido and JorgeăM. Seminario. Molecular Dynamics Simulations of Ion-Bombarded Graphene. *J. Phys. Chem. C*, 116(6):4044–4049, 2012. doi:10.1021/jp208049t.

Setting up the Graphene Sheet:

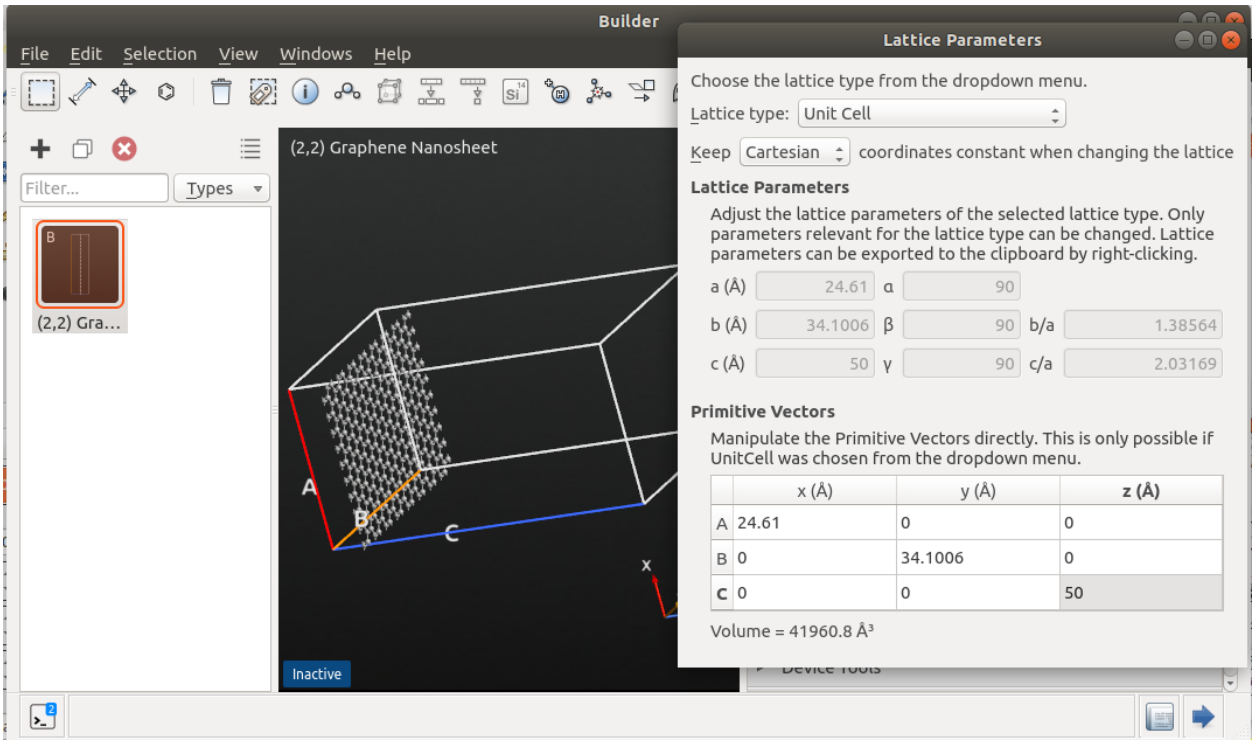
Open the **Builder** and do the following:

•Use the *Nanosheet* plugin via *Add* → *From plugin* → *Nanosheet* to create a graphene unit cell.

•Use the *Bulk Tools* → *Swap Axes* tool to rotate the structure and the cell vectors by clicking **C<->A** and then **Z<->X**. Now the surface is oriented along the Z-axis.

•Use *Bulk Tools* → *Repeat* to create a suitable supercell by giving a desired number of repetitions in the A- and B-directions, e.g. 10x4.

•Use the *Bulk Tools* → *Lattice parameters* widget to increase the z-component of the C-vector to 50.0 Å. Make sure to keep the cartesian coordinates when changing the lattice.



Adding a Bombardment Atom

Bombardment atoms can in principle be added at any location above the surface. In the following, you can choose to add a bombardment atom either above a graphene carbon atom (top site), or above the center of a graphene ring (hollow site).

•To add an atom at the top site:

–Select an atom in the center of the graphene sheet.

–Use *Coordinate Tools* → *Translate* to place the bombardment atom at the desired starting height above the graphene sheet (e.g. 30 Å), by entering a suitable z-component for the **translation vector**.

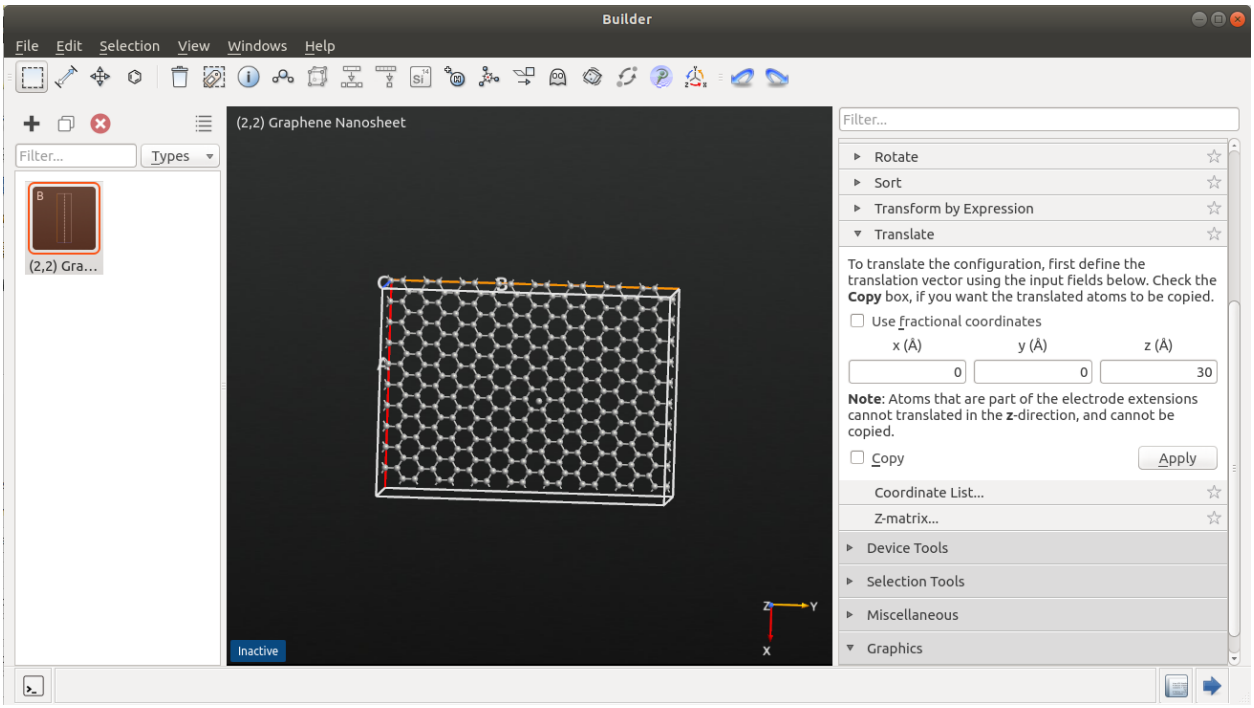
–Check **Copy** and click **Apply**.

•To add an atom in a hollow site:

–Select the atoms belonging to a carbon ring in the center of the sheet.

–Click the icon in the tool bar of the **Builder**.

–Translate the atom to the desired starting position above the surface by selecting the created atom and use the *Coordinate Tools* → *Translate* tool with the following settings.



Note: If you want to modify the exact position of the bombardment atom, you can do this easily, either by using the **Translate** tool, or by editing the coordinates of the last atom (using the *Coordinate Tools* → *Coordinate List* tool).

Setting up the Simulation

You will now set up the calculator for the simulation using the **Script Generator**. It is recommended to optimize the lattice of the graphene sheet with the classical potential before you start the simulations. Details about the calculator and the classical potential are explained below.

•First, send the structure from the **Builder** to the **Script Generator** by clicking the icon .

In the **Script Generator**:

•Add a *Calculators* → *ForceFieldCalculator* block.

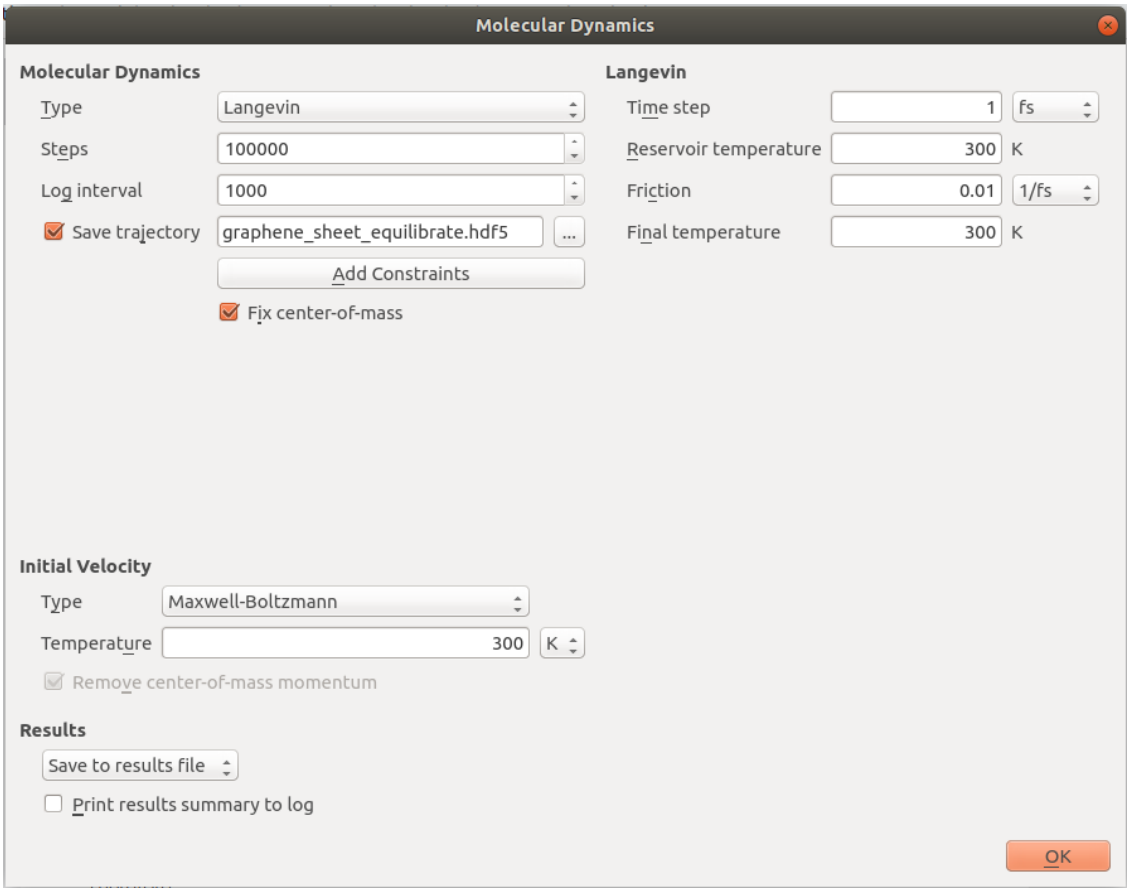
•Add two *Optimization* → *MolecularDynamics* blocks.

•Open the **ForceFieldCalculator** widget. Select the *Tersoff_SiC_1998* parameter set, then click **OK**.

Attention: The *Tersoff_SiC_1998* potential is very similar, but not identical, to the potential used in[Page 1178, 1]. If you feel like using the exact same potential, you can find it in this script: `ion_bombardment.py`.

Note: For QuantumATK-versions older than 2017, the **ATK-ForceField** calculator can be found under the name **ATK-Classical**.

•In the first **MolecularDynamics** block, set up the equilibration simulation with the following parameters.

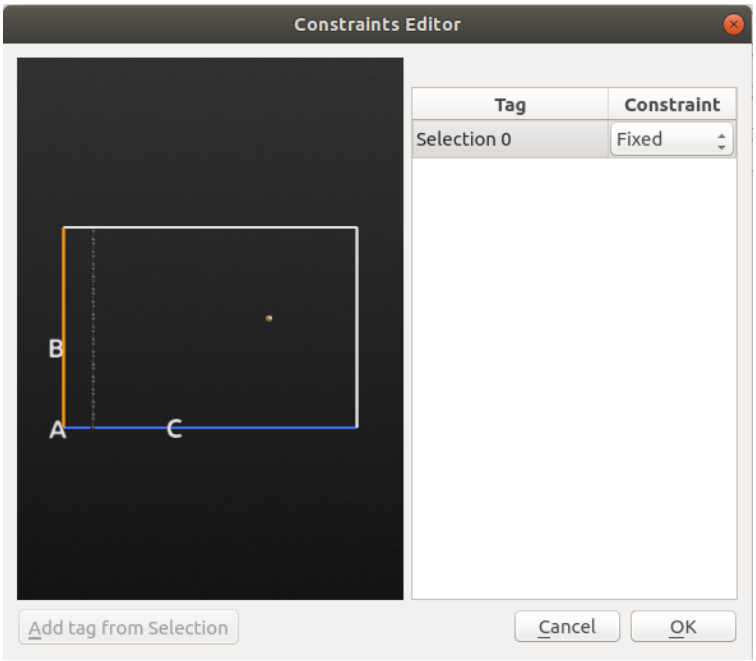


The position of the bombardment atom should be fixed during the equilibration calculation. Therefore:

•In the **MolecularDynamics** block, click **Add Constraints** to open the **Constraints** widget.

•Select the bombardment atom above the surface and click **Add tag from Selection**.

•Set the constraints field to **Fixed** and click **OK**.



In the second **MolecularDynamics** block, you should set the basic parameters of the bombardment simulation:

•Select the **NVE Velocity Verlet** type.

•Set 50000 steps and a log interval of 100.

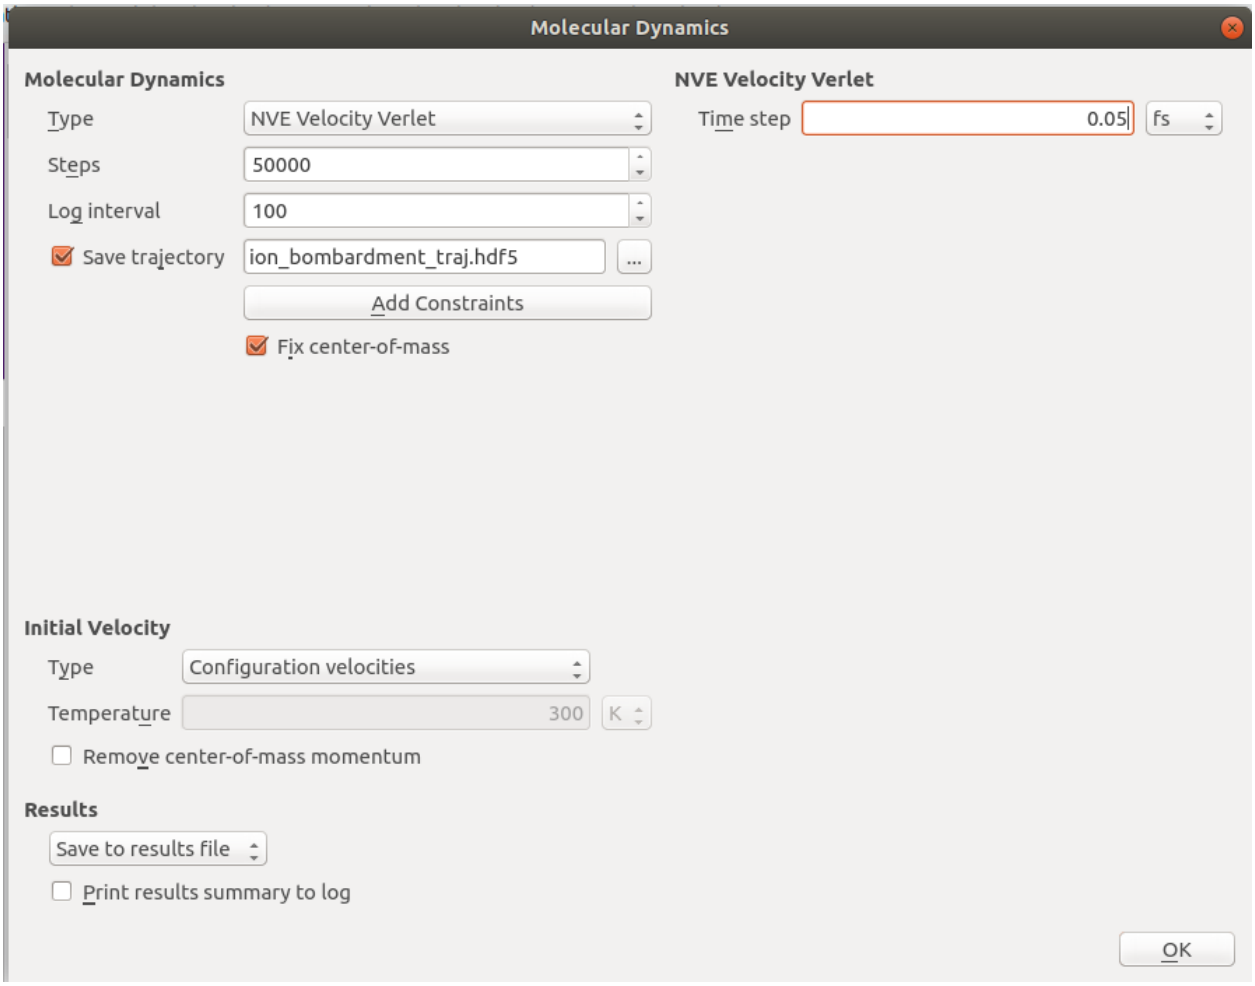
•Enter a suitable filename for the trajectory.

•Set the initial velocities to **Configuration velocities** to use the velocities after equilibration.

•Uncheck the **Remove center-of-mass momentum** box.

•Decrease the **time step** to 0.05 fs.

Note: The kinetic energy of the atom is expected to be very high in this simulation. That is why a relatively small **time step** is necessary to guarantee the convergence. For very high incident energies (>100 eV), the time step may have to be decreased even further to 0.01 fs (cf.Page 1178, 1).



•Send the script to the **Editor**, using the icon.

Modifying the Script

To let the bombardment atom approach the surface at the desired kinetic energy, a few modifications have to be made in the script.

•Right before the second **MolecularDynamics** block, insert the following lines.

```
# Get the velocities from the bulk_configuration
velocities = bulk_configuration.velocities()
# Define the incident energy of the bombardment atom.
incident_energy = 10.0*eV
# Calculate the corresponding velocity and apply it to the last atom.
incident_velocity = ((2.0*incident_energy/Carbon.atomicMass())**0.5).inUnitsOf(Ang/fs)
velocities[-1, :] = [0.0, 0.0, -incident_velocity]*Ang/fs
bulk_configuration.setVelocities(velocities)
```

Note: The velocity vector is set to be perpendicular to the surface in this calculation. Arbitrary incident direction can

be considered by modifying the velocity vectors in the script lines.

- Save the script under a suitable filename, and run the simulation via the **JobManager** or in a terminal.
- After the simulation has completed, you can visualize the trajectory using the **MovieTool** or the **Viewer** to inspect the damage.

3.8.4 Uniaxial and Biaxial Stress in Silicon

Introduction

In this tutorial you will learn how to use **QuantumATK** to study the electronic properties of silicon under uniaxial and biaxial stress.

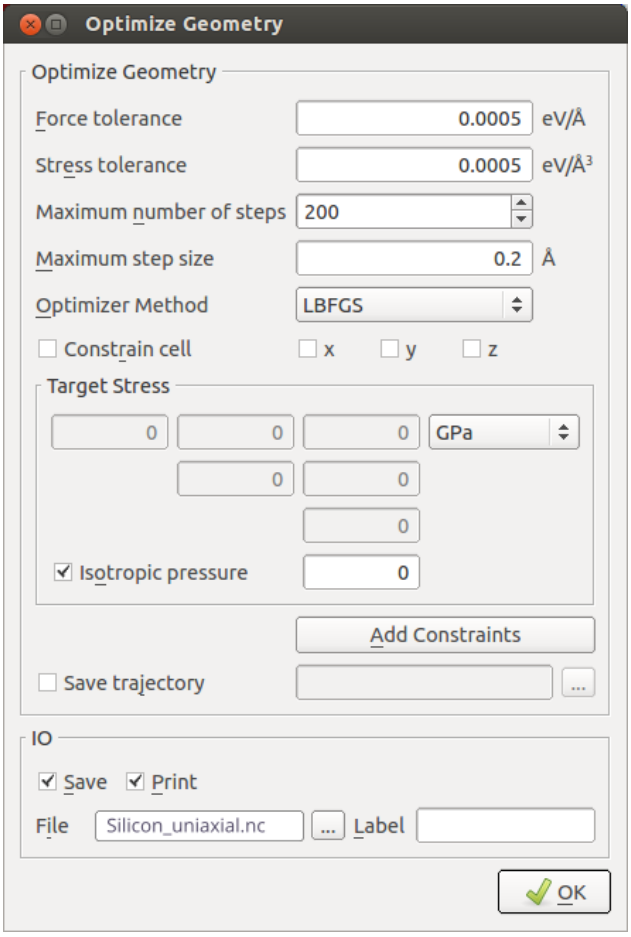
In particular, you will learn how to use the `Target Stress` option for a geometry optimization (**Optimize Geometry**) to apply a specific stress to a crystal. Then you will calculate and analyze the electronic band structure and effective masses in the strained system.

An important aspect of this tutorial is the symmetry of your crystal after the stress is applied. You will have to pay particular attention to this point, and to this end you will find the **Brillouin Zone Viewer** plugin very useful.

Uniaxial Stress

Set up the Calculation

1. In the **Builder**, import a silicon fcc bulk structure from the database and send it to the **Script Generator**.
2. Add a `New Calculator`:
   - use the default LDA exchange-correlation potential and select a 9x9x9 k-point sampling;
   - set the density mesh cut-off to 150 Hartree to have a better description of the silicon electronic structure.
3. Add `OptimizeGeometry` and set these parameters in order to perform a full optimization of the bulk structure:
   - set force and stress tolerances to 0.0005 eV/Å and 0.0005 eV/Å^3;
   - uncheck the `Constrain cell` but keep the target stress at zero.



1.Add `Bandstructure` analysis:

•choose 201 points per segment;

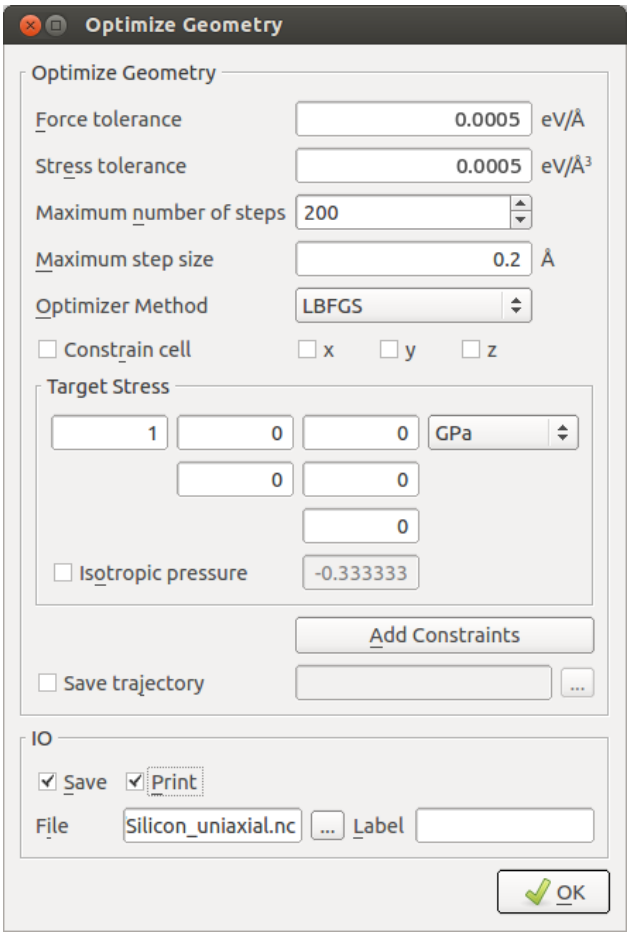
•choose the L, G, X path.

2.Add `OptimizeGeometry` and set these parameters in order to apply a uniaxial stress:

•set force and stress tolerances to 0.0005 eV/Å and 0.0005 eV/Å^3;

•uncheck `Constrain cell`;

•uncheck `Isotropic Pressure` and add a target stress of 1 GPa for the x component of the stress tensor.



Note: The definition of target stress (`target_stress`) is:

- if a single value p is given, it will be interpreted as an external pressure value from which the internal target stress tensor is calculated as $\sigma = \begin{pmatrix} -p & 0 & 0 \\ 0 & -p & 0 \\ 0 & 0 & -p \end{pmatrix}$;
- if a target stress tensor is given, it will be interpreted as the *internal* stress of the system, meaning that a negative entry on the diagonal will result in a compression in the corresponding direction and vice versa. Note that the stress tensor is symmetric, so its only necessary to define the upper triangle.

Pay attention to the fact that the sign convention is different in these two cases!

---

3. Add `Bandstructure` analysis:
   - choose 201 points per segment;
   - choose the L, G, X path.

Note: If a target stress tensor is given, the BravaisLattice of the configuration is automatically converted into a UnitCell, to enable changes in the shape of the cell.

As described below, the high symmetry points of the Brillouin zone will change, since the cell will no longer be fcc after the stress is applied. However, at this point in the setup, the symmetry of the new cell is not known, so you will

have to modify the symmetry points by hand in the Python script.

4. Send the script to the **Editor** and locate the last `Bandstructure` analysis block. Replace X by B in the route; see *the next section* for a detailed explanation on the modified Brillouin zone.

```
# -----------------------------------------------------------
# Bandstructure
# -----------------------------------------------------------
bandstructure = Bandstructure(
    configuration=bulk_configuration,
    route=['L', 'G', 'B'],
    points_per_segment=201,
    bands_above_fermi_level=All
    )
nlsave('Silicon_uniaxial.nc', bandstructure)
```

You can download the full script here: `Silicon_uniaxial.py`.

5. Save and send the script to the **Job Manager** to run the calculations, which should take less than a minute.

Symmetry Considerations

Before analyzing the electronic structure of strained silicon you will need to understand how the Brillouin zone and the notation of high symmetry points are dealt with by **QuantumATK**.

From the **LabFloor** drag and drop the optimized structure (`gID000`) and the strained structure (`gID002`) to the **Builder**.

Plot the Brillouin zone of each structure with the *Bulk Tools->Brillouin Zone Viewer*:

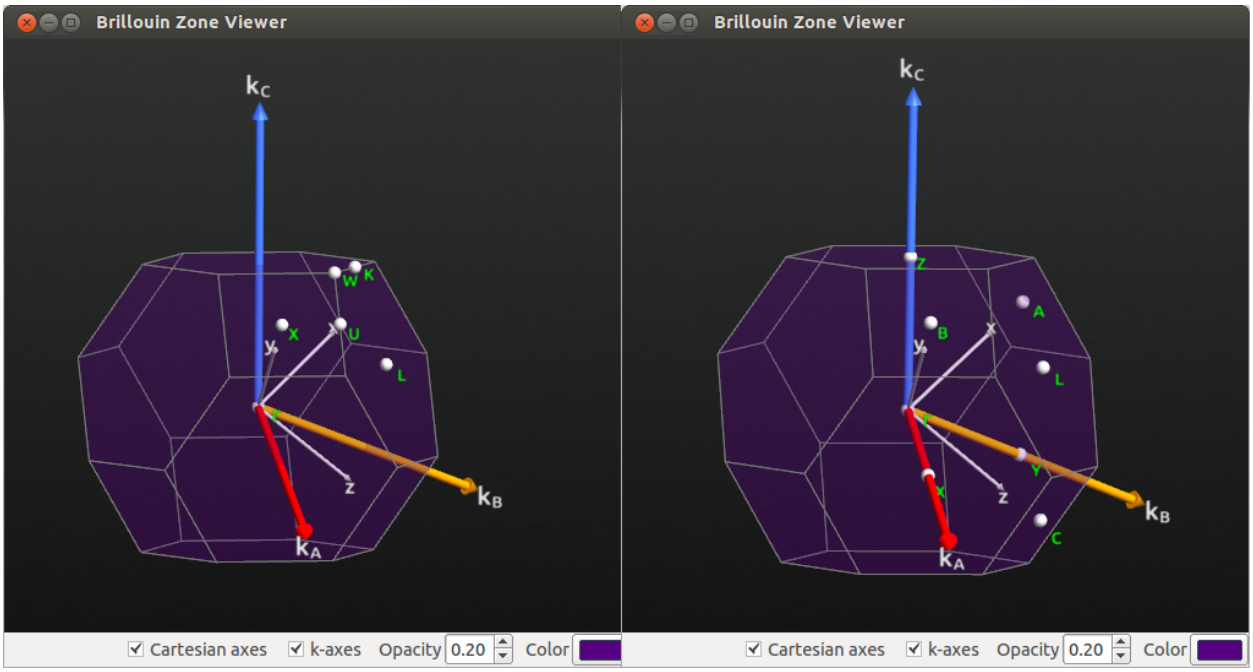


Fig. 3.93: Brillouin zone for fcc bulk silicon when `FaceCenteredCubic` Bravais lattice is used (left). When the Bravais lattice is changed to `UnitCell` type, the notation for high symmetry points is changed according to the figure (right).

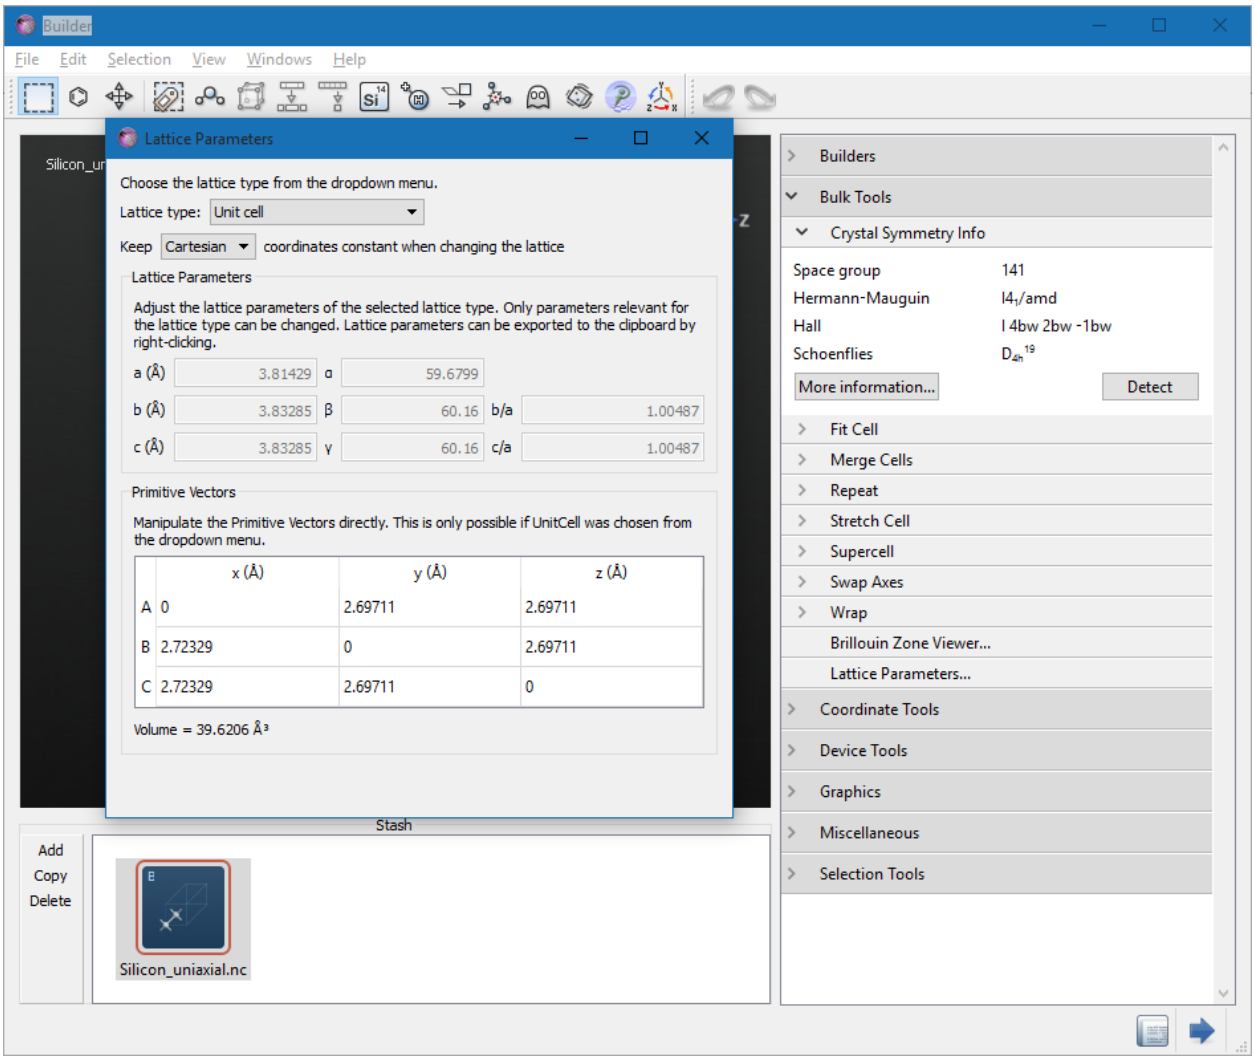
The high symmetry points in the UnitCell representation of the strained fcc crystal are related to the fcc symmetry points as follows:

- A, B, C all correspond to the X point in the unstrained fcc Brillouin zone.
- By increasing the stress you can see that B and C are still degenerate, but A is not degenerate with B and C. This is logical in the tetragonal symmetry.
- The L point is still called L, and degenerate with X, Y, Z in the UnitCell notation.

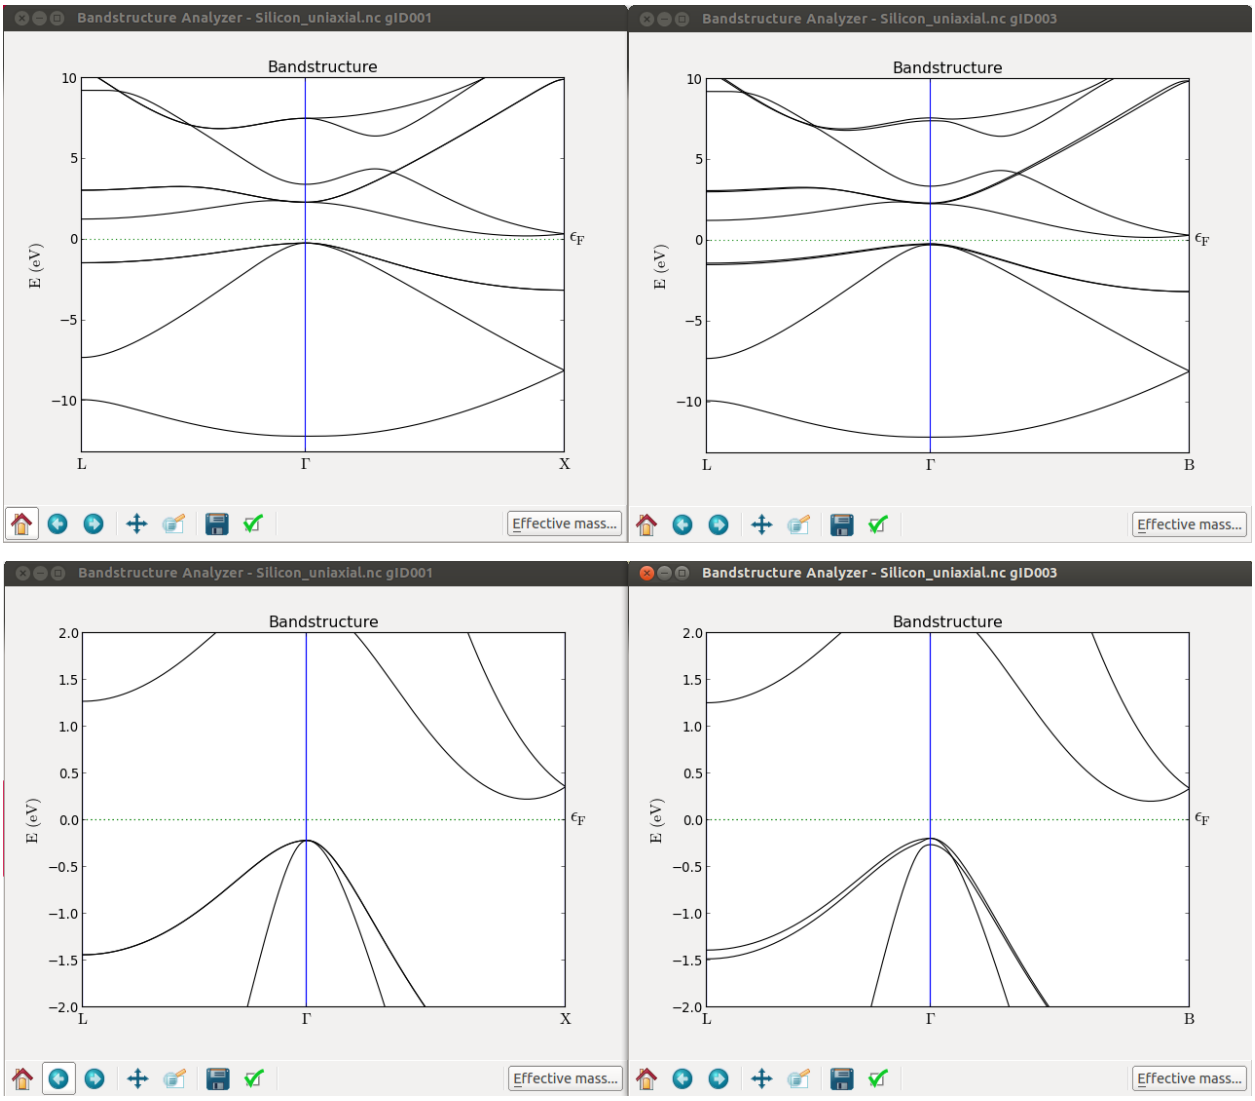
The symmetry of the crystal is actually, as expected, tetragonal (space group 141) after the uniaxial stress is applied, which can be verified by activating the strained crystal on the stash and using *Bulk Tools->Crystal Symmetry Information*, and clicking **Detect**. On inspection of the lattice parameters, you see that, again as expected, all 3 lattice vectors are elongated in the X axis, and contracted in Y and Z (elastic response, Poisson effect), due to the uniaxial deformation.



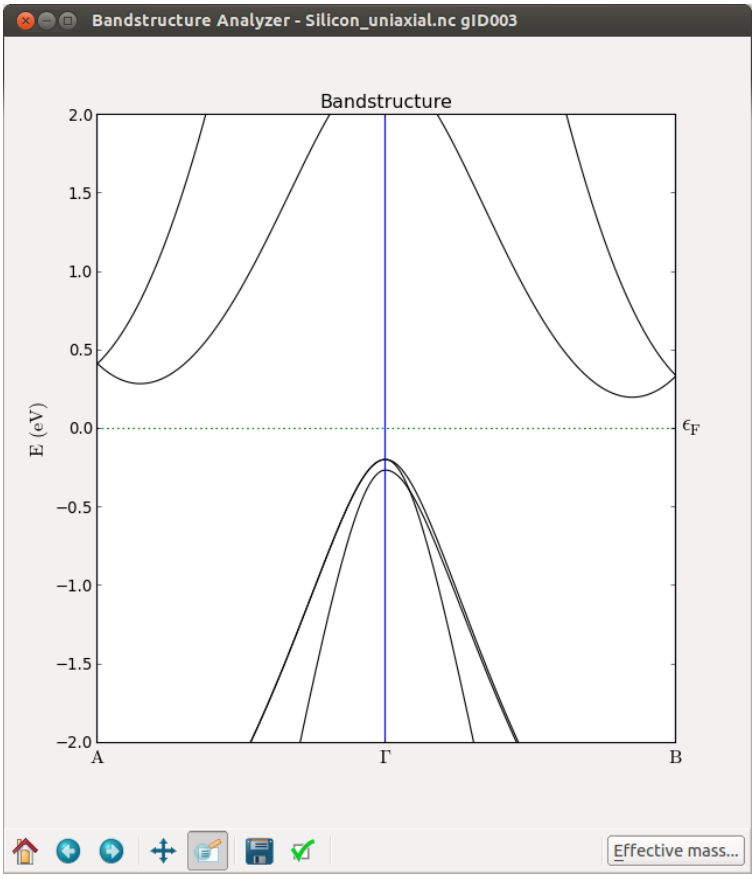
Analyze the Results

Electronic Band Structure

Now plot the band structure of the optimized cell and the uniaxial stressed cell. From the **LabFloor** select the calculated `Bandstructure` object and plot them with the `Bandstructure Analyzer` plugin.



From these plots you can immediately see that, at Gamma, the top of the valence band splits. It is however, more interesting to see that the Δ valley is not degenerate anymore. To see this effect more clearly you can calculate the band structure along the A-G-B path.



By further inspecting the band structure, you can conclude the following about uniaxially strained Si:

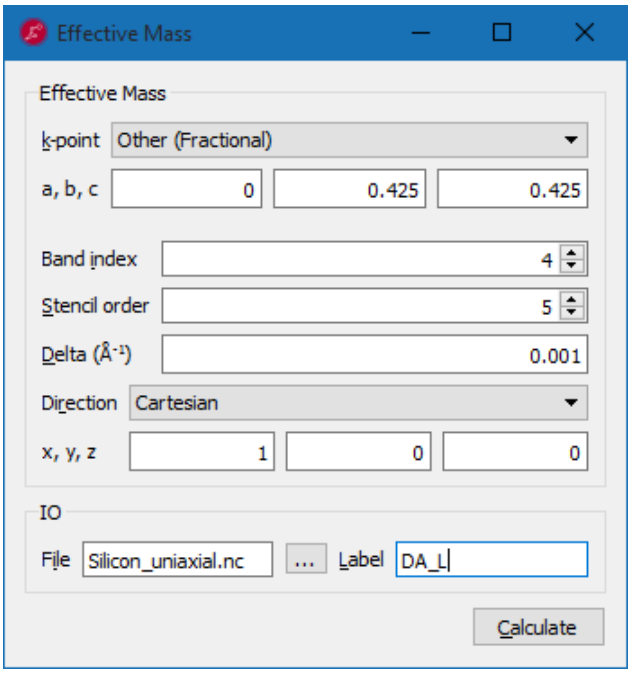
- L remains degenerate
- The 6-fold Δ valleys split into 2+4

The absolute values of the band gaps are however not correct in this simulation, since the LDA exchange-correlation functional was used for simplicity.

Effective Masses

It is also very interesting to consider the effects of strain on the effective mass.

From the band structure plot of the strained structure, click on the `Effective Mass` button.



Following the example in the figure above calculate the effective masses for the Δ valleys, band index 4, along different directions:

•Longitudinal mass at Δ_A: fractional coordinate [0, 0.425, 0.425], along the [1,0,0] cartesian direction;

•Transverse mass (1) at Δ_A: fractional coordinate [0, 0.425, 0.425], along the [0,1,0] cartesian direction;

•Transverse mass (2) at Δ_A: fractional coordinate [0, 0.425, 0.425], along the [0,0,1] cartesian direction;

•Longitudinal mass at Δ_B: fractional coordinate [0.425, 0, 0.425], along the [0,1,0] cartesian direction;

•Transverse mass (1) at Δ_B: fractional coordinate [0.425, 0, 0.425], along the [1,0,0] cartesian direction;

•Transverse mass (2) at Δ_B: fractional coordinate [0.425, 0, 0.425], along the [0,0,1] cartesian direction;

You will find the following results:

•Longitudinal mass at Δ_A (2-fold degenerate): 0.91

•Transverse masses at Δ_A: 0.185 (no split)

•Longitudinal mass at Δ_B (4-fold degenerate): 0.898

•Transverse masses at Δ_B: 0.188 and 0.186

So, while all longitudinal and transverse masses are very close to the original Δ valley masses (0.903 and 0.186, which you can compute from unstrained crystal), you see splittings due to the broken symmetry.

For a more detailed explanation on the calculation of silicon effective masses please refer to the tutorial *Effective mass of electrons in silicon*.

As an exercise, you are encouraged to study the masses at the L point, and investigate possible symmetry breakings.

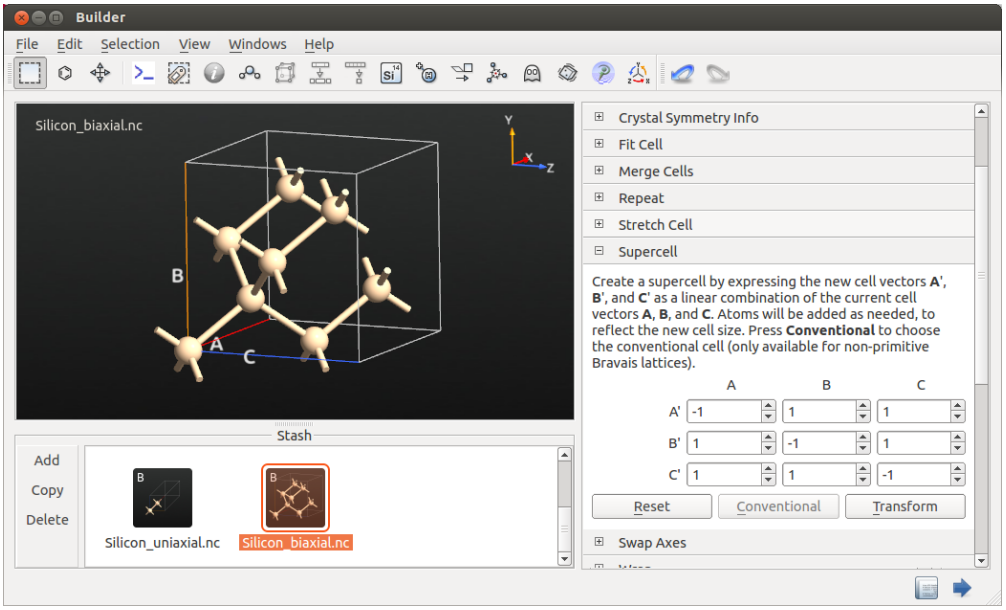
Biaxial Stress

Take the optimized (unstrained) silicon structure, send it to the **Scripter** and set `New Calculator`, `OptimizeGeometry`, and `Bandstructure` as you did in the previous section.

To apply a biaxial stress, set the xx and yy components in the stress tensor to 1 GPa in the `Target Stress` field in the `Optimize Geometry` dialog.

Before running the calculation, send the script to the **Editor** and modify the Brillouin zone path to L, G, B as described above and run the calculation.

Also in this case the cubic lattice distorted is to a tetragonal symmetry. To see that clearly, drag and drop the optimized stressed structure to the **Builder** and apply the supercell transformation as indicated in the figure below.



From *Bulk Tools->Lattice Parameters* you can see the distorted lattice parameters of 5.44 Å and 5.38 Å. Thus, effectively the biaxial stress is equivalent to a uniaxial stress along the [001] direction, with opposite sign.

3.8.5 Adding, Combining, and Modifying Classical Potentials

Introduction

The new **ATK-ForceField** package provides a lot of pre-defined classical potentials covering a broad range of elements and systems. However, if you are interested in a particular potential, which is not yet part of this pre-defined set, you can easily add these parameters and create your own potential, as long as the underlying potential functions are supported. You can also modify single parameters of existing potentials in order to tune the potential to a special reference system. Furthermore, you can combine different potentials to cover a broader range of elements. This tutorial provides a brief overview over this functionality of **ATK-ForceField**.

Note: For QuantumATK-versions older than 2017, the **ATK-ForceField** calculator can be found under the name **ATK-Classical**.

For a detailed overview and documentation of the available potential classes and functions in **ATK-ForceField** and the underlying **TremoloX** package, take a look at the TremoloX section of the ATK Reference Manual. There you will find definitions for all functions along with the corresponding parameters.

Note: Be aware that you should always read the underlying publication carefully, if you use a new potential, to ensure that the potential is suited for your desired application.

If possible, you should compare some benchmark values obtained with the classical potential to corresponding experimental values or the results of suitable higher-level calculations, e.g. DFT simulations. This holds in particular for the combination of different potentials, as they might have been parameterized in a certain context and they are not always guaranteed to work in entirely different environments.

Adding a New Classical Potential from Scratch

In this section, you will learn how to add a new parameter set, taken from a potential in the literature, to the **ATK-ForceField** calculator. You will be guided through the complete setup of a potential from scratch to explain the various contents of a **TremoloX** potential set. In practice, it is often more convenient to start from a similar potential, send it to the **Editor** with `Script details` set to Show defaults to report all details of the potential, and then merely edit the parameters in the **Editor**.

As a first example, you will consider a simple titanium oxide crystal. One of the most popular classical potentials for titania is the one proposed by Matsui and Akaogi (MA)[1], as it reproduces the essential properties of both crystal and amorphous titania systems quite well. Later on, you will set up a potential designed for the simulation of amorphous oxide systems[2].

[1] M Matsui and M. Akaogi: Molecular dynamics simulations of the structural and physical properties of the four polymorphs of TiO2. Mol. Sim. 6, 239 (1991)

[2] C.J. Fennell and J.D. Gezelter: Is the Ewald summation still necessary? Pairwise alternatives to the accepted standard for long-range electrostatics. J. Chem. Phys. 124, 234104 (2006)

Setting up the System

To set up a suitable test system, open the **Builder**, click *Add* → *From database*, search for TiO2, and select and add the *Rutile* crystal structure.

You can now send the configuration to the **ScriptGenerator** to set up the desired optimization, molecular dynamics, or analysis script. For now, you can select any arbitrary calculator as a place holder. A typical simulation script could consist of *Calculator*, *Optimization* → *OptimizeGeometry*, and *Analysis* → *ElasticConstants* blocks. For accurate results, set the maximum force and maximum stress values in the **OptimizeGeometry** settings and the maximum force value in the **ElasticConstants** settings to 0.001 eV/Å (respectively eV/Å^3). Furthermore, disable the `Constrain cell` checkbox in the **OptimizeGeometry** widget to optimize the cell parameters as well.

Send the script to the **Editor**.

Setting up the Potential

In the **Editor**, locate the block where the potential is defined (i.e. everything after the **BulkConfiguration** and before the **OptimizeGeometry** block) and delete it.

To define a new TremoloX potential you first need to initialize a new *TremoloXPotentialSet* object. You can do this by adding the following line:

```
potentialSet = TremoloXPotentialSet('MatsuiAkaogi_TiO')
```

The string in parethesis defines the name of the potential, but it does not have any influence on its functionality.

As the potential set is currently empty, you need to add all necessary components. You should start with adding the *ParticleType*. In this case, add one titanium and one oxygen particle type by inserting these two lines into the script:

```
potentialSet.addParticleType(ParticleType(symbol='O', mass=15.9994*atomic_mass_unit,␣
↪charge=-1.098))
potentialSet.addParticleType(ParticleType(symbol='Ti', mass=47.867*atomic_mass_unit,␣
↪charge=2.196))
```

The partial charges are taken from Ref.[Page 1193, 1]. The MA potential consists of two interaction types:

1. A Tosi-Fumi (often also called Buckingham) type potential (i.e. a combination of an exponential, repulsive contribution and an attractive van der Waals part)
2. Electrostatic coulomb interactions, which model the partial ionization of the atoms.

The first part can be added by using the *TosiFumiPotential*, which implements the potential function

$$V(r) = Ae^{B(\sigma - r)} - \frac{C}{r^6} - \frac{D}{r^8}\,.$$

If you compare this form to the equation given in Ref.[Page 1193, 1], you will notice that the last term is not required, implying that D must be set to zero. Take care with the energy unit in Ref.[Page 1193, 1], which is kJ/mol. The parameters must be given in that unit or converted to electron volt. The A, B, C, D, and σ parameters can be set as follows:

```
potentialSet.addPotential(TosiFumiPotential(particleType1='O',
                                            particleType2='Ti',
                                            A=0.811696*kiloJoulePerMol,
                                            B=5.154639*Angstrom**-1,
                                            sigma=2.8171*Angstrom,
                                            C=1215.0*kiloJoulePerMol*Angstrom**6,
                                            D=0.0*eV*Angstrom**8,
```

(continues on next page)

(continued from previous page)

```
                                                r_i=6.0*Angstrom,
                                                r_cut=7.5*Angstrom))
potentialSet.addPotential(TosiFumiPotential(particleType1='O',
                                                particleType2='O',
                                                A=0.979056*kiloJoulePerMol,
                                                B=4.27350*Angstrom**-1,
                                                sigma=3.2678*Angstrom,
                                                C=2916.0*kiloJoulePerMol*Angstrom**6,
                                                D=0.0*eV*Angstrom**8,
                                                r_i=6.0*Angstrom,
                                                r_cut=7.5*Angstrom))
potentialSet.addPotential(TosiFumiPotential(particleType1='Ti',
                                                particleType2='Ti',
                                                A=0.644336*kiloJoulePerMol,
                                                B=6.49351*Angstrom**-1,
                                                sigma=2.3664*Angstrom,
                                                C=506.25*kiloJoulePerMol*Angstrom**6,
                                                D=0.0*eV*Angstrom**8,
                                                r_i=6.0*Angstrom,
                                                r_cut=7.5*Angstrom))
```

The first two arguments in each potential determine which two particle types the potential is supposed to act between. The additional parameters $r_{*\mathrm{i}*}$ and r_{cut} determine the range and cutoff behavior. In this case, the potential follows the original form for distances below 6 Å, whereas for larger distances a smoothing function is invoked for ranges up to 7.5 Å. At larger distances these interactions are assumed to be zero.

The electrostatic interactions are taken into account by adding a suitable Coulomb solver. All Coulomb solvers use the partial charges that you have defined for the particle types. The default algorithm in **ATK-ForceField** is *CoulombDSF* employing a cutoff and a damped shifted force (DSF) to smooth the transition[Page 1193, 2]. To achieve a high precision with this method (which can be important particularly for static calculations, such as elastic constants, phonons, or lattice constants) the cutoff has to be chosen sufficiently high (e.g. 15 Å). Here, we will instead use the smooth-particle-mesh-Ewald method (*CoulombSPME*), which automatically takes care of the long-ranged contributions of the Coulomb interactions. This Coulomb solver is added via the line:

```
potentialSet.setCoulombSolver(CoulombSPME(r_cut=9.0*Angstrom))
```

Finally, you have to initialize the actual *TremoloXCalculator* and pass the created potential set as argument. Following that, you have to attach the calculator to the bulk configuration:

```
calculator = TremoloXCalculator(parameters=potentialSet)
bulk_configuration.setCalculator(calculator)
```

The remaining part of the script can be left as it is. An example script can be found in the file `TiO2_Matsui.py`.

Now, you can send the script to the **JobManager** and start the calculation. The results should be consistent with Ref.[Page 1193, 1].

A Potential for Amorphous Oxides

In this example, another potential is introduced, which is designed to simulate amorphous materials, such as titanium, silicon, hafnium, or tantalum oxide, as well as their mixed oxides[3].

Note: From **QuantumATK 2015** on, this potential is already available as the pre-defined potential *Trinastic_HfOSiTaTi_2013*.

To test the potential, you can, for instance, use the rutile configuration from the previous example. The potential is similar to the MA potential, shown above, but additionally it includes a *MorsePotential*.

$$V(r) = E_{ij}\left[\left(1 - e^{-k_{ij}(r-r_0)}\right)^2 - 1\right]$$

In fact, the formula presented in Ref.[Page 1196, 3] omits the the last contribution in the squared brackets. However, as this term only represents a constant offset in the energy, it has no influence on the forces in an MD simulation, and we shall therefore neglect this discrepancy here. Although the potential terms could in principle be set up similar to the previous example by using the TosiFumiPotential, we will present an alternative approach by adding all terms individually.

To obtain the potential, you need an exponential repulsive contribution, which will be taken from the *BuckinghamPotential*, a dispersion term, for which you will use a *LennardJonesMNPotential*, and finally a *MorsePotential*.

The potential set up is demonstrated for the example of the Ti-O interactions. The other elements follow the same scheme by inserting the corresponding element-pair-specific potential parameters from Ref.[3].

Start by initializing a new *TremoloXPotentialSet* and adding the particle types with the corresponding partial charges:

```
potential_set = TremoloXPotentialSet('Trinastic_JCP2013')
potential_set.addParticleType(ParticleType(symbol='O', mass=15.9994*atomic_mass_unit,␣
↪charge=-1.2))
potential_set.addParticleType(ParticleType(symbol='Ti', mass=47.867*atomic_mass_unit,␣
↪charge=2.4))
```

Then define the repulsive Buckingham term:

```
potential_set.addPotential(BuckinghamPotential(particleType1='O',
                                               particleType2='Ti',
                                               A=5105.12*eV,
                                               rho=0.2253*Angstrom,
                                               r_i=6.0*Angstrom,
                                               r_cut=7.5*Angstrom))
```

Add the dispersion term. You will only need the attractive part of the Lennard-Jones potential, i.e. the A-parameter has to be set to zero:

```
potential_set.addPotential(LennardJonesMNPotential(particleType1='O',
                                                   particleType2='Ti',
                                                   A=0.0*eV*Angstrom**12,
                                                   B=20.0*eV*Angstrom**6,
                                                   m=12,
                                                   n=6,
                                                   r_cut=10.0*Angstrom))
```

[3] J.P. Trinastic, R. Hamdan, Y. Wu, L. Zhang, H.-P. Cheng: Unified interatomic potential and enery barrier distributions for amorphous oxides. J. Chem. Phys. 139, 154506 (2013)

Add the Morse potential:

```
potential_set.addPotential(MorsePotential(particleType1='O',
                                          particleType2='Ti',
                                          E_0=0.3478*eV,
                                          k=1.9*Angstrom**-1,
                                          r_0=1.96*Angstrom,
                                          r_i=6.5*Angstrom,
                                          r_cut=7.0*Angstrom))
```

Finally, set up a Coulomb solver, e.g. *CoulombSPME* or *CoulombDSF* to calculate the electrostatic interactions, and initialize a new TremoloXCalculator with this potential set:

```
potential_set.setCoulombSolver(CoulombSPME(r_cut=9.0*Angstrom))
calculator = TremoloXCalculator(parameters=potential_set)
```

In Ref.[3], an alternative strong parameterization is proposed, which can be implemented by inserting the corresponding parameters instead of the ones shown above. The implementation of the interactions between the remaining element pairs works similarly. From the parameter table in Ref.[Page 1196, 3], you will find that for some element combinations the Morse energy parameter is zero, which means that no Morse potential is required between these elements.The full potential can be found in the file `script_Trinastic_potential.py.txt`.

Combining a Tersoff and a Lennard-Jones Potential

In this section, you will learn how you can combine Tersoff and Lennard-Jones (LJ) potentials, to simulate a single lithium atom in a graphite cell. This combination of materials is particularly interesting, as it provides a very simple model of a typical anode in lithium ion batteries. The combination of Tersoff and LJ-potentials is typically used for multi-component materials where the individual components interact only weakly with each other, predominantly via repulsive and van der Waals forces. The strong bonded interaction within a component, in this example graphite, can then be described by a Tersoff potential, or another suitable potential for that material.

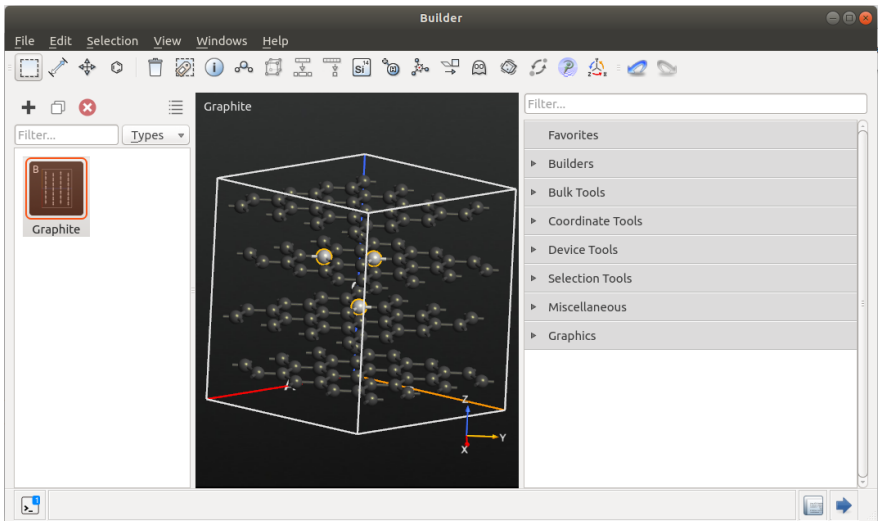
In this example, you will adopt the parameters of Ref.[4]. Be aware that they have not been tested extensively for this system. Therefore, they should only be considered a starting point for your own investigations.

Setting up the System

To set up a test system, open the **Builder** and add a graphite cell via *Add* → *From database*. Increase the size of the cell by clicking *Bulk tools* → *Repeat*, and make a 4x4x2 repetition of the unit cell.

Select a triangle of 3 atoms (one in the second layer, two in the third layer) as shown in the picture.

[4] O. N. Kalugin, V. V. Chaban, O. V. Prezhdo: Microscopic Structure and Dynamics of Molecular Liquids and Electrolyte Solutions Confined by Carbon NanoTubes: Molecular Dynamics Simulations. Carbon Nanotubes - Synthesis, Characterization, Applications (2011), Siva Yellampalli (Ed.).



Place an additional atom in the center of the selected atoms, by clicking on the icon in the toolbar (see picture). This atom will later be converted into lithium, but for now we will retain it as carbon.

Send the configuration to the **ScriptGenerator** using the button. In the **ScriptGenerator**, add a *Calculators* → *ForceFieldCalculator* object, and then the simulation task of your choice, e.g. an *Optimization* → *MolecularDynamics* block. Open the **ForceFieldCalculator** settings, and select the *Tersoff_C_2005* potential (this will be the base potential for the graphite). Under Results, select Do not save and uncheck `Print results to summary log`. In the *Output Settings*, set `Script Detail` to Show defaults, and send the script to the **Editor**.

At first, locate the element list. Change the name of the last element in the list from `Carbon` to `Lithium`. (If you had done this already in the **Builder**, it would not have been possible to select the Tersoff potential in the **ScriptGenerator**, since it doesnt support lithium.)

If you now take a look at the calculator section, you will find the detailed definition of the Tersoff potential. This is due to the *Show defaults* option. Locate the line where the C element definition is added via the `addParticleType()` method. Make a copy (to invoke two `addParticleType()` calls), and modify the relevant lines as shown below:

```
potentialSet.addParticleType(ParticleType(symbol='C',
                                          mass=12.0107*atomic_mass_unit,
                                          charge=None,
                                          # Sigma and epsilon from Ref [3].
                                          sigma=3.3611*Ang,
                                          epsilon=0.004207*eV))
potentialSet.addParticleType(ParticleType(symbol='Li',
                                          mass=6.941*atomic_mass_unit,
                                          charge=None,
                                          # Sigma and epsilon from Ref [3].
                                          sigma=0.826*Ang,
                                          epsilon=0.271115*eV))
```

For carbon, the LJ-parameters epsilon and sigma have been added and set to the values taken from Ref[4]. For lithium, you first have to change the symbol and the atomic mass and then set the corresponding LJ-parameters. Note that in this case, we consider neutral lithium atoms, i.e. without defining a partial charge, as this is the preferred state in the anode (in contrast to lithium ions in the cathode).

The LJ-potential does not become active by specifying the particle parameters alone. You additionally have to add the corresponding potential function. To this aim, add the following two lines:

```
potentialSet.addPotential(LennardJonesPotential(particleType1='C',
                                                particleType2='Li',
                                                r_cut=9.0*Ang))
potentialSet.addPotential(LennardJonesPotential(particleType1='Li',
                                                particleType2='Li',
                                                r_cut=9.0*Ang))
```

This will add LJ-potentials between carbon and lithium, as well as between lithium and lithium. Note that there is no LJ-potential between carbon atoms, as these interactions are sufficiently defined by the Tersoff-potential (the LJ would just be a tiny correction).

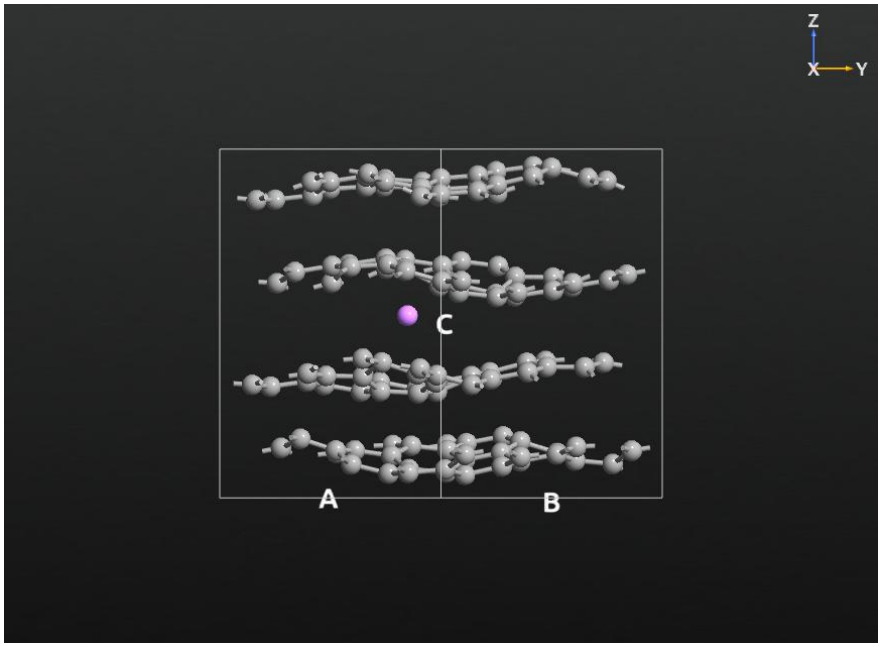
The Lennard-Jones potential in **ATK-ForceField** is defined as

$$V_{ij}(r) = 4\epsilon_{ij}\left[\left(\frac{\sigma_{ij}}{r}\right)^{12} - \left(\frac{\sigma_{ij}}{r}\right)^{6}\right]$$

and uses the combination rules to obtain σ_{ij} and ϵ_{ij} parameters between different elements that you can find in the *LennardJonesSplinePotential* documentation page.

You should always check whether the combination rules recommended for the chosen LJ-parameters agree with this definition. If not, you should use the more general *LennardJonesMNPotential*.

An example of the final script can be found in `Script_graphite_lithium.py`. You can add any optimization, molecular dynamics, or analysis block, compatible with **ATK-ForceField**. This picture shows a snapshot of an MD simulation of the lithium-graphite system.

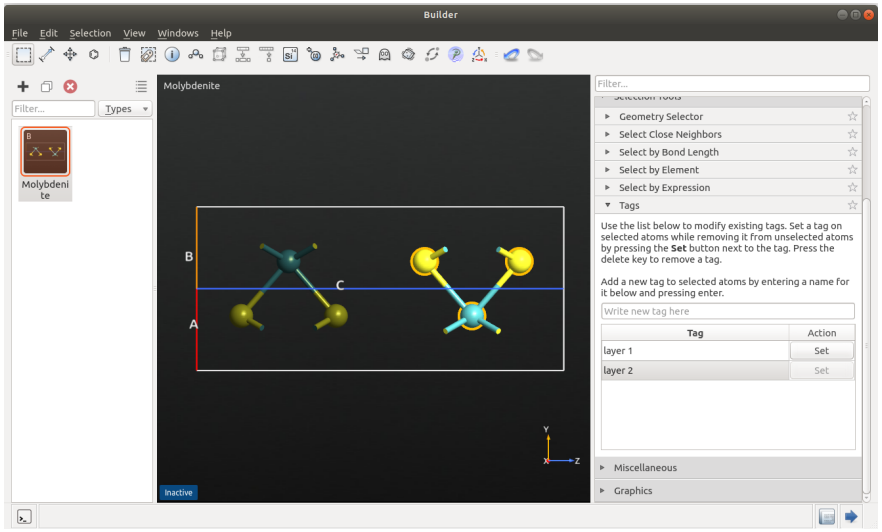


Intra- and Inter-Layer Cohesion in MoS_2

Note: If you are using **QuantumATK 2014**, you should make sure that you have ugraded to **QuantumATK 2014.3** (or later) to run this part of the tutorial, as earlier versions may cause some problems.

In this last example you will learn how to define a potential only on the selected atoms, using tags. We consider a molybdenite (MoS_2) crystal where the intralayer interactions are described by a *Stillinger-Weber* potential, while the comparably weaker inter-layer interactions are again modelled by a *Lennard-Jones* potential, as described in Ref.[Page 1197, 4].

To set up the system, open the *Builder* and search for and add the molybdenite structure from the database. Select one layer by drawing a rectangle around it and add a tag with the name layer1 (via *Selection Tools* → *Tags*). Repeat the procedure for the second layer, using the name layer2.



Send the configuration to the **ScriptGenerator**.

In the **ScriptGenerator** add a *Calculators* → *ForceFieldCalculator* and an *Optimization* → *OptimizeGeometry* block. Open the **ATK-ForceField** calculator and select the *StillingerWeber_MoS_2013* potential. Under Results, select Do not save and close the widget. Open the **OptimizeGeometry** widget and adjust the setting for a geometry and stress optimization, as described in the first example.

Send the final script to the **Editor**.

In the python-script, locate the line where the Stillinger-Weber-potential is defined. Copy the line, and adjust both lines in the following way:

```
sw_layer1 = StillingerWeber_MoS_2013(tags='layer1')
sw_layer2 = StillingerWeber_MoS_2013(tags='layer2')
```

This will define each potential only between the atoms belonging to the corresponding tagged group. Furthermore, you have to define a Lennard-Jones potential, which acts only between the sulfur atoms of different groups. This can be done by adding the following lines of code:

```
# Define a new potential for the interlayer interaction.
lj_interlayer_potential = TremoloXPotentialSet(name="InterLayerPotential")
# Add particle type definitions for both types.
lj_interlayer_potential.addParticleType(ParticleType.fromElement(Molybdenum))
lj_interlayer_potential.addParticleType(ParticleType.fromElement(Sulfur, sigma=3.
```

(continues on next page)

(continued from previous page)

```
↪13*Angstrom, epsilon=0.00693*eV))
# Add Lennard-Jones potentials between the sulfur atoms of different layers.
lj_interlayer_potential.addPotential(LennardJonesPotential('S', 'S', r_cut=10.0 *␣
↪Angstrom))
lj_interlayer_potential.setTags(['layer1', 'layer2'])
```

The Lennard-Jones parameters are taken from Ref.[5]. The last line ensures that the Lennard-Jones-potential only acts between alternating layers.

Finally, all three potential sets have to be combined in the TremoloX-calculator. To accomplish this, add the following lines:

```
# Combine all 3 potential sets in a single calculator.
calculator = TremoloXCalculator(parameters=[sw_layer1, sw_layer2, lj_interlayer_
↪potential])
```

After defining the potential, the script continues as usual, by adding the calculator to the bulk configuration and performing the geometry optimization. The final script can be found in the file `Molybdenite_SW_plus_LJ.py` for comparison.

If you run the script, you will obtain optimized lattice constants, which should be very similar to the ones reported in Ref.[Page 1201, 5].

3.8.6 Generating Amorphous Structures

Introduction

Amorphous solid materials become more and more important for a broad spectrum of technologies. In contrast to crystal structures, which are usually well- defined, it is, however, rather difficult to obtain the amorphous structure of a given material in order to perform atomistic simulations. This tutorial gives you some guidelines about generating amorphous structures in **QuantumATK** using molecular dynamics (MD) simulations at different levels of precision.

Amorphous structures, i.e. structures without any periodic order of the building atoms or molecules, can be found in various kinds of materials, e.g. glass or polymers. Their mechanical and electronic properties often differ quite substantially from the respective crystal. For example, the thermal expansion coefficient of amorphous silica is about one order of magnitude lower than the corresponding value for quartz-crystals.

Consequently, there is a growing interest in the employment in amorphous materials, to tailor various material and device properties in a desired way. In this effort, atomistic simulations can help to understand the behaviour of amorphous strucures at the nano- and microscale.

It is, however, not always straightforward to obtain a suitable amorphous structure of a given material for such simulations. In contrast to the corresponding crystal structure there is no unique unit cell or supercell representation, as the structure inherently bears large degree of randomness. Instead, one should ideally consider an ensemble of realizations of such structures, which is in reality often prohibited by the computational cost of the required calculations.

In this tutorial, you will learn how you can generate amorphous structures that can serve as representative examples and input configurations for further simulations, based on DFT or classical force field methods.

[5] J.-W. Jiang, H.S. Park, T. Rabczuk: Molecular dynamics simulations of single-layer molybdenum disulphide (MoS_2): Stillinger-Weber parameterization, mechanical properties and thermal conductivity J. Appl. Phys. 114, 064307 (2013)

You will learn how to use classical force field MD simulations to obtain a first starting structure of the amorphous material, which can in a second step be refined using semi-empirical or DFT molecular dynamics, when the focus is set on electronic properties.

As there is in general no universally valid recipe to create amorphous structures, the most suitable protocol for a given material depends on a lot of factors, such as the availability of a reliable empirical potential, the desired size of the supercell, the disposable computational resources, etc. This tutorial will therefore only provide a guideline, rather than a rigid protocol, to generate amorphous structures, which might have to be modified according to the particular application at hand.

You will simulate amorphous silicon dioxide, often referred to as *fused silica* or *fused quartz*, which is one of the most widely used amorphous materials, e.g. in conventional or specialized glass and also in the semiconductor industry.

You will also learn how to create interface structures between crystal and amorphous regions.

If you dont have much experience in MD simulations, you can start with the *How to Setup Basic Molecular Dynamics Simulations*, which will help you to become familiar with the MD functionality in **QuantumATK**.

Note: The simulations in this tutorial use a comparably small number of steps to demonstrate within a reasonable time the principle of generating amorphous structures. For actual production simulations, in order to achieve more reliable amorphous samples with a low amount of structural defects, you should use much longer simulation times. Typically, a melt-quench cycle comprises at least several hundred picoseconds, or even several nanoseconds. Take a look at the references of this tutorial to get an overview over common simulation protocols.

Amorphous Structure Generation with Classical MD Simulations

The most common way to generate amorphous structures is to mimic the experimental protocol of melting a crystal and cooling it down again by using MD simulations[1],[2]. Although cooling rates accessible in MD simulations can not be chosen as low as the experimental cooling rates, this procedure gives satisfactory results in many cases. The quality of the resulting amorphous structures of course depends much on the ability of the employed force field to describe the material, also further away from equilibrium conditions.

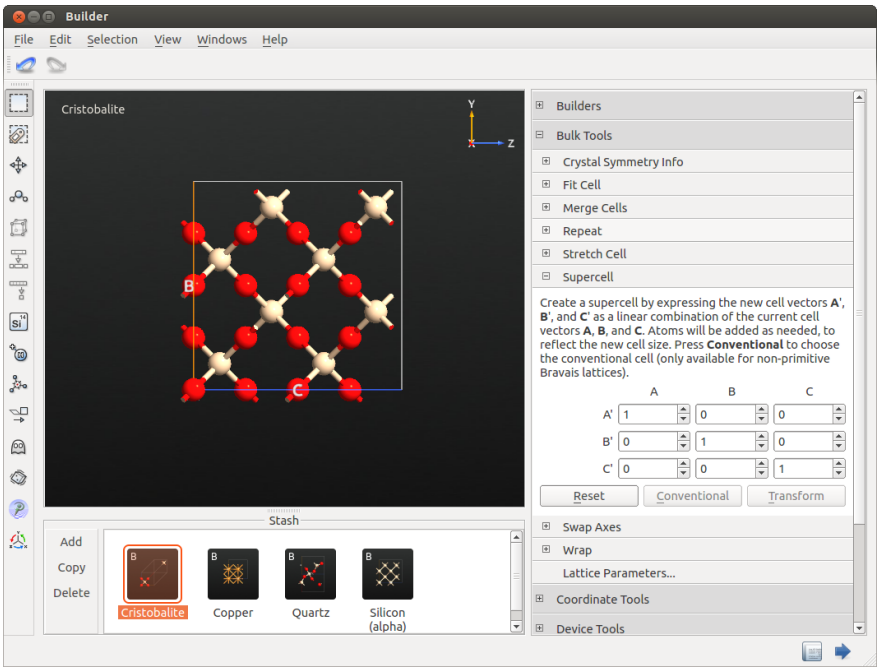
Setting up the Geometry

You will start from a crystalline SiO_2 system, specifically a cristobalite structure. In contrast to e.g. quartz, the cristobalite unit cell can easily be transformed into an orthogonal cell, which makes the simulation much more convenient. Moreover, the density of cristobalite is very similar to the experimental density of amorphous silica, being 2.2 g/cm^3.

Open the Builder and click *Add* → *From Database* and search for sio2. Select the cristobalite structure and add it to the **Stash**. To transform it into an orthogonal cell, click on *Bulk Tools* → *Supercell* on the right-hand-side panel. Click `Conventional` and then `Transform`. For cristobalite this will create a cubic supercell.

[1] E.ăA. Chagarov and A.ăC. Kummel. Generation of Realistic Amorphous Al2O3 And ZrO2 Samples By Hybrid Classical and First-Principle Molecular Dynamics Simulations. *ECS Transactions*, 16:773, 2008. URL: http://kummelgroup.ucsd.edu/pubs/papers/76.pdf.

[2] D.ăJ. Cole, M.ăC. Payne, G.ăCsányi, S.ăM. Spearing, and L.ăColombi Ciacchi. Development of a classical force field for the oxidized Si surface: Application to hydrophilic wafer bonding. *J. Chem. Phys.*, 127:204704, 2007. URL: http://dx.doi.org/10.1063/1.2799196.



The resulting cell is too small yet to be a useful container for an amorphous structure, as the periodic boundary conditions would still enforce a certain amount of crystallinity. Therefore, repeat the cell by opening *Bulk Tools* → *Repeat*, and apply a *3 x 3 x 3* repetition. This cell, containing 648 atoms, will be the starting structure for the MD simulations.

Setting up the Simulation

Send the configuration to the **ScriptGenerator**. Add a *NewCalculator* and an *Optimize* → *MolecularDynamics* block to the script panel.

Double-click on the **NewCalculator** block and select the **ATK-ForceField** calculator with the *Pedone_Fe2_2006* potential[3]. Uncheck `Print` and `Save`. Close the **NewCalculator** widget by clicking `Ok`.

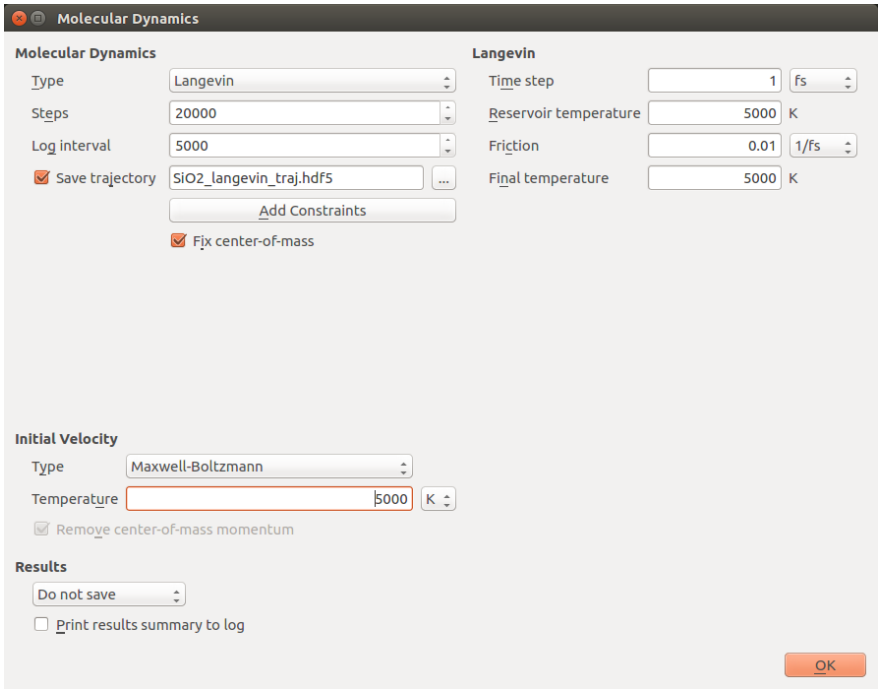
Note: For QuantumATK-versions older than 2017, the **ATK-ForceField** calculator can be found under the name **ATK-Classical**.

Now double-click on the **MolecularDynamics** block. To melt the crystal, you will start with simulations at a very high temperature of 5000 K. As the primary purpose of this initial simulation is to randomize the arrangement of the atoms, no pressure coupling is needed at this stage. Therefore you should select a `Type`, which gives you an *NVT* ensemble (take a look at the *How to Setup Basic Molecular Dynamics Simulations* for a more detailed documentation of MD simulation types in **ATK**). A good choice is the *Langevin* thermostat, as it produces a very tight coupling to the heat bath and therefore prevents single atoms from becoming too hot and possibly destabilizing the system.

Set the `Steps` to 20 000, the `Log interval` to 5000, and the filename to save the trajectory to `SiO2_5000K_langevin_traj.hdf5`. In the **Initial Velocity** group box, select the *Maxwell-Boltzmann* type at a temperature of 5000 K.

Enter the same temperature value of 5000 K in the **Langevin** group box in the `Reservoir temperature` field. Leave the remaining settings at their default values. Finally, select *Do not Save* under **Results** (as the trajectory is already being saved).

A New Self-Consistent Empirical Interatomic Potential Model for Oxides, Silicates, and Silica-Based Glasses. *The Journal of Physical Chemistry B*, 110(24):11780–11795, 2006. doi:10.1021/jp0611018.



Use the button to send the script to the **Editor** in order to make some additional changes.

Facilitating the Melting Process via Lowering the Density

In some cases, particularly when you attempt to melt comparably small supercells, you may sometimes observe that the crystal does not melt even at temperatures far beyond the experimental melting point. A possible reason for this behavior, apart from deficiencies of the employed classical potential, is that crystal structures are additionally stabilized by the periodic boundary conditions, and, generally, artifacts of the periodic boundary increases with decreasing size of the supercell. Another aspect that has to be kept in mind is that the fixed volume of the cell is likely to produce a large system pressure at high temperatures, which can additionally elevate the melting point temperature or in some cases thermodynamically favor another crystal phase over the liquid phase.

Note: If you dont expect or experience any problems with melting the structure, you can run the script as is, and skip the rest of this section.

To facilitate melting, you can slightly increase the cell volume to artificially lower the density. In the script this is achieved by multiplying the the lengths of the cell vectors by a factor of e.g. 1.1.

Modify the block in which the lattice is defined, as shown in the following script:

```
# Set up lattice
# Define a scale factor
scale_cell = 1.1
# Scale all 3 cell vectors by this factor
vector_a = [21.498*scale_cell, 0.0, 0.0]*Angstrom
vector_b = [0.0, 21.498*scale_cell, 0.0]*Angstrom
vector_c = [0.0, 0.0, 21.498*scale_cell]*Angstrom
lattice = UnitCell(vector_a, vector_b, vector_c)
```

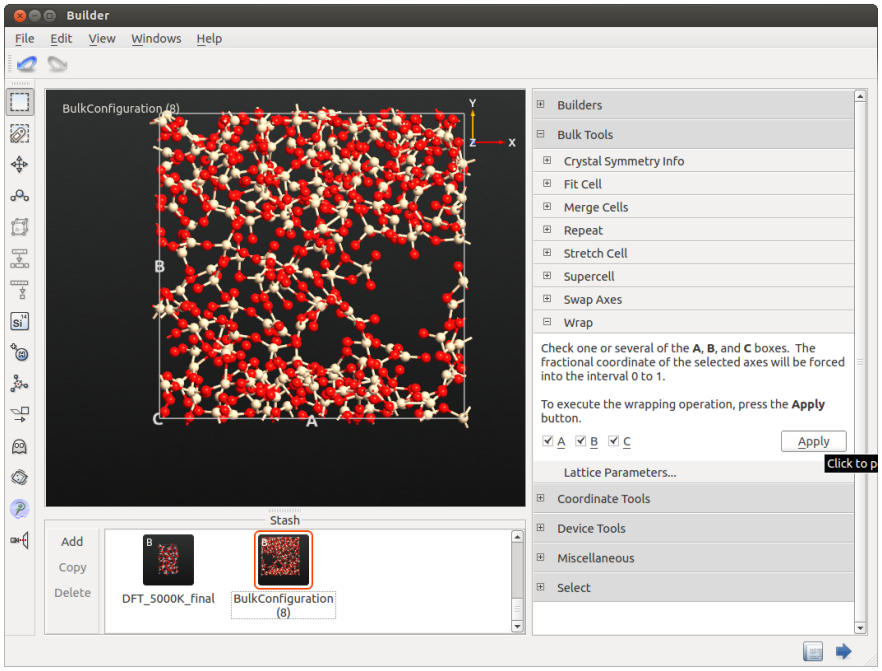
The exact value of the scaling factor does not play a crucial role, and can be increased as long as you still detect some residual crystallinity after annealing the system at 5000 K.

Send the modified script to the **Job Manager** and run the simulation.

It will take a couple of minutes to complete the simulation. If you select the produced trajectory file on the **LabFloor** and visualize it with the **Movie Tool**, you will see the atoms moving around in a chaotic fashion, as they frequently cross the periodic boundaries of the cell. To take a better look at the structure, send the last snapshot of the movie to the Builder via the button in the lower right-hand corner of the **Movie Tool**.

In the **Builder** you can fold all atoms that have crossed the periodic boundaries back into the simulation cell by clicking *Bulk Tools* → *Wrap* → *Apply*.

The final structure may look similar to the example below.



Due to the artificially decreased density the atoms cluster in certain regions, producing an inhomogeneous distribution. However, the purpose of the procedure, i.e. a complete randomization of the previously crystalline structure has been fulfilled very well.

To recover the original density, send this configuration to the **ScriptGenerator** and repeat exactly the same steps described above (i.e. prepare a script containing a **NewCalculator** and a **MolecularDynamics** block with the described settings and send it to the **Editor**), but now divide the cell vectors by the same scaling factor 1.1 (respectively the factor you have used to lower the density) instead of multiplying them. This procedure will compress the system and recover the original density of the cristobalite structure. Run this simulation at 5000 K for 20 000 steps to equilibrate the silica melt at the new density, send the final configuration from the **Movie Tool** to the **Builder**, and *Wrap* the configuration.

Cooling the Structure and Adjusting the Density

If you inspect the resulting structure with respect to the local atomic arrangements, you will encounter many structural defects, such as undercoordinated atoms (e.g. oxygen atoms with only one silicon neighbor).

This is because the resulting amorphous system represents a snapshot of the material in the liquid state at very high temperature. The ultimate goal is usually the generation of solid amorphous material, i.e. at temperatures well below the glass-transition temperature T_g. Therefore, you will perform a MD simulation where the temperature decreases linearly at each time step to cool the system to the desired temperature.

Although real amorphous structures always contain a certain amount of structural defects, the goal of such a cooling simulation is to perform the temperature change as slowly as possible to allow the system to reduce the number of defects as much as possible[Page 1202, 2]. Unfortunately, the limited accessible simulation time often requires the use of very high cooling rates compared to experimental settings. The parameters, suggested in the following paragraphs, have been chosen to allow for a rather quick demonstration of the principle of the structure generation, which may not be the optimal choice for production simulations. To obtain a more reliable amorphous structure, consider increasing the simulation time, which will decrease the cooling rate.

Another important parameter is the density of the amorphous structure. There are essentially two different possibilities for how to deal with this matter.

One way is to adjust the system volume a priori, to obtain the desired experimental amorphous density and leave the volume at this fixed density throughout the cooling simulation[Page 1202, 1]. This technique is the preferred method when the accessible simulation time is very limited, e.g. in DFT-MD simulations. However, it can lead to large residual stress values in the final systems.

The alternative way is to adjust the density continuously during the cooling simulation by coupling the system volume to a barostat at ambient pressure[Page 1202, 2]. Here, the resulting density will depend on the quality of the employed potential and you should check whether it is consistent with experimental values and, in case of large deviations, consider repeating the simulations at fixed volume.

In this example you will use the second technique, i.e. use a *barostat* to control the system pressure.

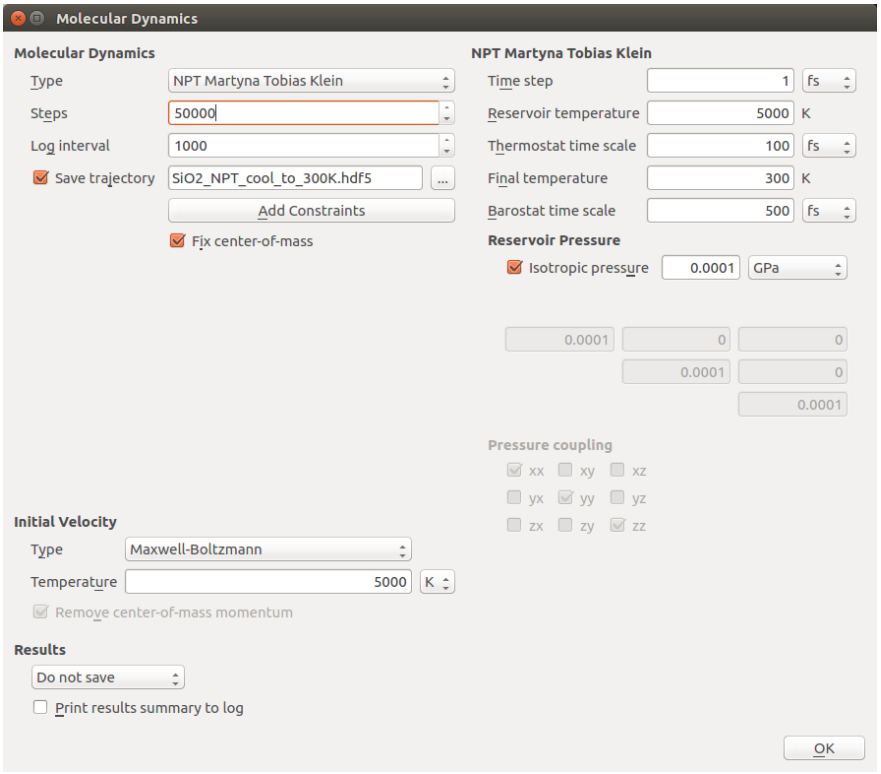
Prepare the cooling simulation by sending the last snapshot of the previous simulation to the **Builder** via the button.

Fold the coordinates back into the simulation cell by using the *Wrap* tool, as described above. Send the configuration to the **ScriptGenerator**. Add a *NewCalculator* and an *Optimize* → *MolecularDynamics* block. In the **NewCalculator** widget, use the same settings as in the previous simulations.

Open the **MolecularDynamics** settings. Select the *NPT Martyna Tobias Klein* type. Select 50 000 steps, a log interval of 1000, and set the trajectory name to `SiO2_NPT_cool_to_300K.hdf5`. Select *Maxwell-Boltzmann* initial velocities corresponding to 5000 K.

Change the `Reservoir temperature` to 5000 K. To cool the system down to room temperature you need to change the `Final temperature` to 300 K. This will result in a linear decrease of the current reservoir temperature from 5000 K to 300 K during the MD simulation.

Leave the remaining parameters at their default values.

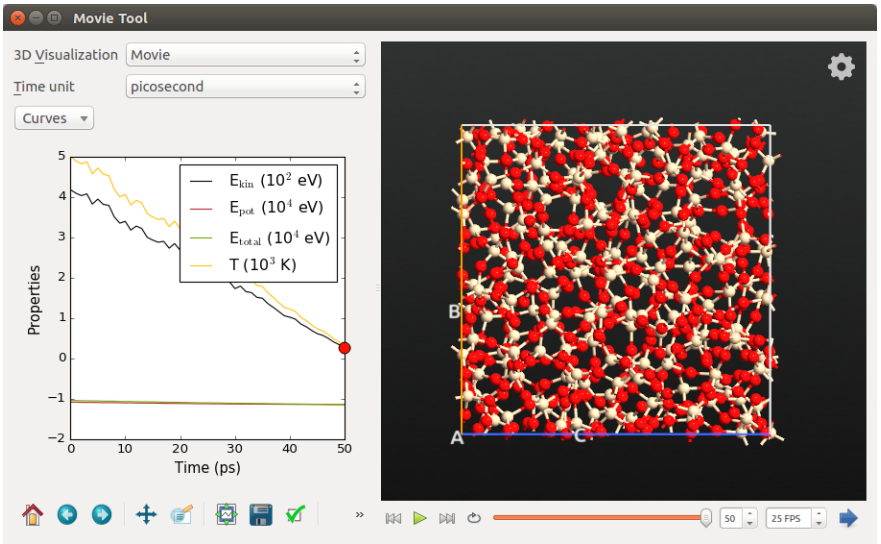


Send the simulation workflow to the **Job Manager** and execute it. It will take some time to complete.

The simulations should run without problems for this system. However, if you encounter extreme, non-stationary cell size fluctuations, or the formation of pronounced vacuum pores during the NPT runs at high temperatures, you can consider switching on the barostat coupling after reaching lower temperatures, e.g. roughly in the region of the suspected glass temperature. You could, for example, use the *NVT Nose Hoover* thermostat to cool the system from 5000 K to 2000 K at constant volume, and the *NPT Martyna Tobias Klein* barostat to cool it from 2000 K to 300 K.

Analyzing the Structure

After the simulations have finished, you can take a look at the trajectories using the **Movie Tool** or the **Viewer**.

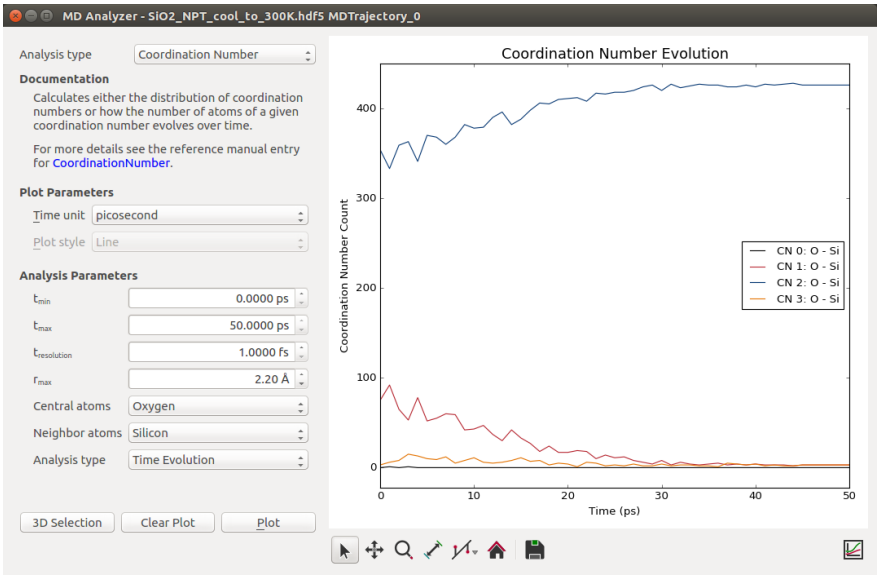


If you have a close look at the local atomic arrangements, you will notice that almost the entire structure is composed of slightly distorted, vertex- sharing tetrahedra formed by SiO_4 units. Additionally, you may encounter some few coordination faults.

For a quantitative assessment, select the `SiO2_300K_NPT_traj.hdf5` file on the **Lab Floor** and open it with the **MD Analyzer tool**. Here, you can perform various kinds of analyses of the MD trajectory. For amorphous systems, we are particularly interested in the *radial distribution function* (RDF). To perform such an analysis, increase the cutoff radius r:sub:*max* to 8.0 Å, select *Silicon* as `Element 1`, select *Oxygen* as `Element 2`, and click `Plot` to display the RDF between these two elements. To discard the high temperature part of the trajectory, you can set the t:sub:*min* parameter to 40 ps to analyze only the last 10 ps of the trajectory.

Instead of sharp single lines, as in a crystal structure, you will find a distribution of broadened peaks, which is characteristic for an amorphous structure. You can plot the RDF for different element pairs or between all elements.

The number of structural defects can be investigated by selecting the *Coordination number* analysis. Select, for example *Silicon* and *Oxygen* as `Element 1`, respectively `Element 2`, to calculate the coordination of silicon with oxygen atoms. Set the cutoff radius to 2.5 Å, according to the first minima in the RDF curve. Click `Plot` to create the distribution of coordination numbers. You will see that most of the silicon atoms have a coordination number of four, and only a tiny fraction have a lower coordination. Now switch the elements to calculate the coordination number of the oxygen atoms. Click `Plot` to add the distribution to the existing plot. Again, the majority of oxygen atoms exhibit its regular coordination number of two, whereas only few atoms are undercoordinated. Switch the `Analysis Type` to *Time Evolution* to plot how the number of atoms with a given coordination number changes during the cooling simulation. The following example shows that the number of one-fold coordinated oxygen atoms decreases during the simulation, while the number of two-fold coordinated atoms increase. This reduction of coordination defects could possibly be enhanced further by choosing a slower cooling rate (i.e. longer simulation time).



The **MD Analyzer** provides a large number of different analysis quantities that can be invoked with a few clicks. Feel free to explore its functions. For example, take a look at the *Angular distribution function* for *Silicon-Oxygen-Silicon* angles, or at the *Neutron scattering function*.

The density of the generated amorphous silica cell can be calculated from the volume of the cell, which can be found in the **Builder** under *Bulk Tools* → *Lattice Parameters*, and the numbers of the elements and their respective masses. For the present example, you should obtain a value around 2.6 g/cm^3. This value is a little higher than the experimental value of 2.2 g/cm^3, which must be considered a small shortcoming of the potential. To obtain exactly the experimental value, you may repeat the cooling simulation with a fixed volume, adjusted to reproduce the desired density. The *NVT Nose-Hoover* thermostat with a linear decrease in temperature might be the right method for such simulations.

The final result can be used as an input configuration for subsequent static calculations or MD simulations to calculate

additional properties of interest. However, you should keep in mind that the generated configuration represents only one possible snapshot out of the amorphous ensemble. This means that in order to obtain meaningful results, you should average over several different samples.

Refining Amorphous Structures

You can refine the structure obtained via classical MD to compensate some of the possible shortcomings of the force field. This becomes particularly beneficial if you intend to calculate additional properties of the amorphous material based on semi-empirical or quantum mechanical calculations, e.g. tight-binding (TB) or density-functional-theory (DFT).

The fastest and easiest way is to perform only a TB or DFT geometry optimization to bring the configuration to the nearest energy minimum. This will primarily improve locally distorted geometries, but is not expected to fix connectivity defects.

A more profound refinement can be achieved by a short TB/DFT MD annealing and cooling procedure[Page 1202, 1]. As these simulation are quite time-consuming they are suited predominantly for smaller systems comprising around 100-200 atoms.

In the following you will be guided through a brief example considering a small silica system with the ATK-DFT calculator. Since the accessible time in DFT-MD simulations is very limited, which makes a reliable constant pressure equilibration difficult and computationally expensive, you will perform the classical and DFT-MD simulations in this particular example at constant volume. The density will remain at the value of the cristobalite crystal, which is very close to the experimental density of amorphous silica.

Setting up the classical simulation

Before running the DFT simulation, you first have to prepare an amorphous cell using a classical MD simulation. These steps essentially follow the protocol outlined in the previous section.

Prepare a cristobalite cell in the same way as described in the previous section, but use only 2x2x1 repetitions in the *Repeat* tool of the **Builder**. This will create a cell containing 96 atoms. Due to this repetition the cell the box size is 14.33 x 14.33 x 7.17 Å3, i.e. the z-direction is thinner compared to the other directions, which might introduce an increased ordering in this direction. To avoid such effects, we will transform the cell to a cubic shape, which has the same volume as the original cell. The final cell size shall therefore be 11.375 x 11.375 x 11.375 $Å^3$. You will perform this shape transformation in two steps during the high temperature simulations where the system is in a liquid state.

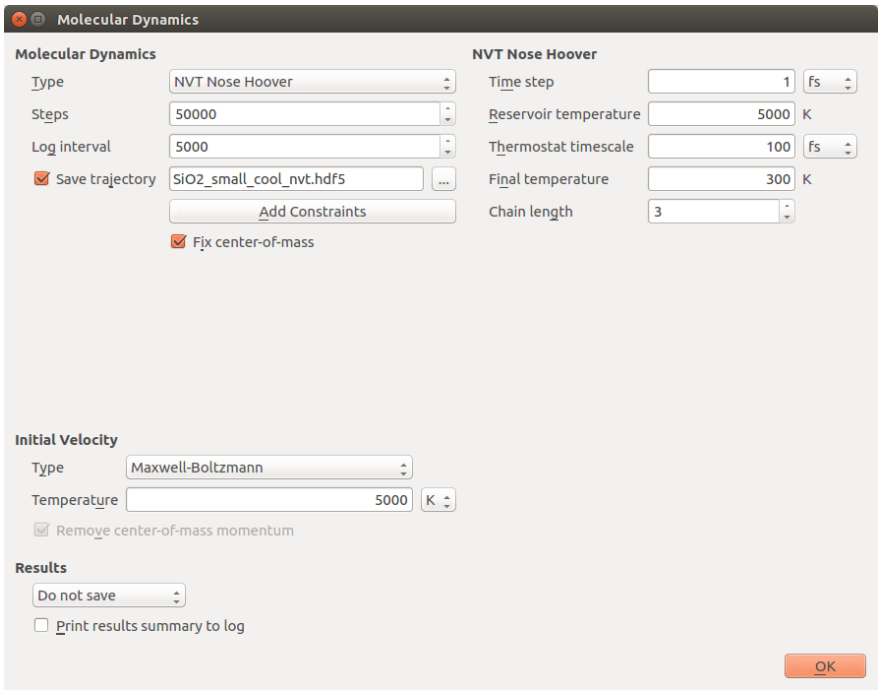
The first step comprises setting up a simulation, in exactly the same way as described above, i.e., adding the **ATK-ForceField** calculator with the *Pedone_Fe3_2006* potential and a **MolecularDyncamics** block with the *Langevin* type, a step number of 20 000, and a temperature of 5000 K. Send the resulting script to the **Editor**. To achieve a lower density and therefore facilitate the melting, increase the length of the *C*-vector of the box to its final value of 11.375 Å:

```
# Set up lattice
vector_a = [14.332, 0.0, 0.0]*Angstrom
vector_b = [0.0, 14.332, 0.0]*Angstrom
# Previous C-vector:
# vector_c = [0.0, 0.0, 7.166]*Angstrom
# New C-vector:
vector_c = [0.0, 0.0, 11.375]*Angstrom
lattice = UnitCell(vector_a, vector_b, vector_c)
```

Run the simulation and send the final snapshot from the **Movie Tool** to the **Builder**. Wrap the configuration, set up exactly the same simulation script as in the previous simulation, and send it again to the **Editor**.

The cell volume has to be reduced to restore the original cristobalite density. Instead of resetting the C-vector to the original value, you can now set the lengths of the A- and B-vectors to 11.375 Å, too, in order to obtain a cubic cell. Run the simulation.

Send the final snapshot to the **ScriptGenerator**, add the same **ATK- Classical** calculator as described above, and an *Optimize* → *MolecularDynamics* block. In the **MolecularDynamics** settings, select the *NVT Nose-Hoover* type, which allows to use a linear decrease in temperature. Adjust the settings as shown in the following screenshot.



These thermostat settings will invoke a linear decrease of the reservoir temperature from 5000 K to 300 K over 50 picoseconds.

Run the simulation. Send the final snapshot via *Movie Tool* → *Send To* → *Builder* → *Wrap* → *Send To* to the **ScriptGenerator**.

Setting up the DFT simulation

In the following you will perform an MD simulation using the **ATK-DFT** calculator in **ATK** to anneal the structure and cool it down to room temperature. MD simulations are rather expensive in terms of computational time. In order to generate amorphous structures, it is not absolutely crucial to obtain accurately converged energies. The suggested settings in the present example will therefore employ parameters, whose accuracy is slightly decreased with respect to the default values to accelerate the calculations. However, before you start the DFT simulations, be aware that these simulations can take very long time, up to several days, so it is recommended to run them on a cluster.

To set up the simulation script, add a *NewCalculator* and two *Optimize* > *MolecularDynamics* blocks. In the **NewCalculator** settings select **ATK-DFT** calculator. Open the calculator widget to adjust some of the settings. In the **Iteration control parameters** increase the `Tolerance` to 0.001 Hartree. In the **Basis set/exchange correlation** settings, change the exchange correlation `Type` to *GGA*. Next, change the basis sets from *DoubleZetaPolarized* to *SingleZetaPolarized*.

Depending on your computational resources you may of course choose more accurate settings here, in particular when aiming at production simulations.

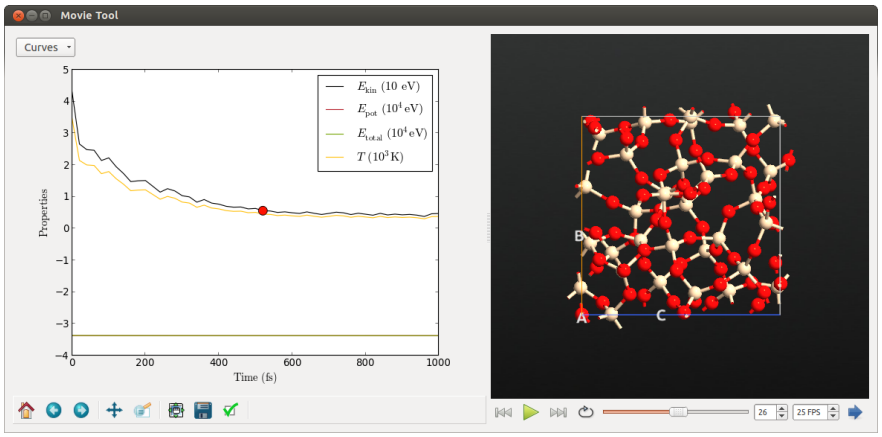
Close the **NewCalculator** settings by clicking `Ok`.

Add two *Optimize* → *MolecularDynamics* blocks to the script. Open the first block. Here, you will set up a short

annealing simulation at 3000 K. Therefore, select the Langevin type, set the number of steps to 500 and the log interval to 20. Choose an appropriate trajectory filename, e.g. `traj-sio2-DFT-MD-3000K.hdf5`, select *Maxwell-Boltzmann* initial velocities at 3000 K and a reservoir temperature of 3000 K, as well. Finally, uncheck `Save` and `Print` and close the settings.

Open the second **MolecularDynamics** block. In this simulation you will rapidly quench the system from 3000 K to 300 K. Use again the Langevin Type, set the number of steps to 1000 and the log interval to 20. Select again Maxwell-Boltzmann initial velocities at 3000 K. To cool the system during the simulation set the reservoir temperature to 300 K now, as if the system was transferred from a very hot reservoir to a heat bath at room temperature. Regarding the short simulation time this method is more efficient than using a linear decrease in the reservoir temperature via the NVT Nose-Hoover chain thermostat. Close the widget and run the simulation.

After the simulations have finished, the movie of the second phase, i.e. the quenching simulation, should look similar to the following.



The temperature decays from the initial value of 3000 K to room temperature. Of course, this rapid quenching within 1 ps is only a rough approximation to the experimental procedure.

Depending on the properties one is interested in calculating, one can continue from the final configuration and perform a DFT geometry optimization.

Creating Crystal/Amorphous Interfaces

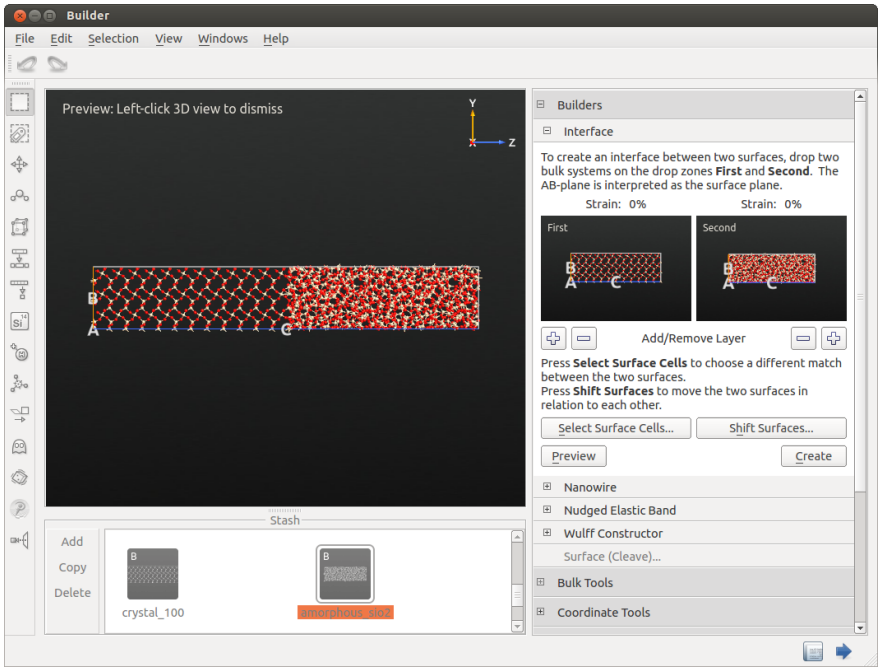
A particularly interesting application is given by interfaces between crystal and amorphous structures, as the local properties in proximity of the interface are largely unknown. Such systems can easily be created in the *QuantumATK*-Builder.

If the crystal is of the same material as the amorphous region, you can start by preparing the crystal configuration. The desired interface plane can be created using the *Surface (Cleaver)* tool in the Builder. Make a copy of the configuration. The latter system will serve as the basis to create the amorphous structure, as their surface areas already match exactly.

The following example considers the interface between quartz and amorphous silica. The initial structure is built in the *Surface (Cleaver)* tool by selecting the (10-10) surface and a 4x3 surface cell. Create a *Periodic (bulk-like)* supercell with a thickness of 12 layers. Perform a geometry optimization of the structure and the cell vectors, using again the **ATK-ForceField** *Pedone_2006_Fe3* calculator, and save the final configuration to a HDF5 file. Drag and drop the file to the **Builder**, and use it as the initial structure for the amorphous cell.

Prepare the amorphous cell via the same simulation protocol as described above, but apply the pressure coupling only to the Z-axis to preserve the lateral cell dimensions. Unidirectional pressure coupling can be selected in the **MolecularDynamics** settings, using *NPT Martyna Tobias Klein*. To couple the barostat only to the Z-component, first uncheck *Isotropic pressure* and then uncheck all boxes in the *Pressure coupling* group box, apart from the `zz` box.

After creating the amorphous supercell, you can join the optimized crystal and amorphous cell using the *Builders* → *Interface* tool in the **Builder** panel. Therefore, you can simply drag and drop the configurations from the **Stash** to *First* and *Second* field in the *Interface builder*. The builder should automatically detect suitable separations of both cells.



Click `Create` to finalize the build process and send the interface configuration to the **ScriptGenerator**.

Tip: You can learn more about the Interface Builder in the Technical Notes on *Interface Builder*.

If you zoom into the interface, you will find many defects, such as dangling bonds. Most of these defects can often be healed by an annealing simulation using classical potentials, even if such potentials are not explicitly designed to include chemical reactions.

Add a *NewCalculator*, an *Optimize* → *OptimizeGeometry*, and an *Optimize* → *MolecularDynamics* block. After selecting the desired calculator settings, in this case the *Pedone_2006_Fe3*-potential, open the **OptimizeGeometry** widget.

After the interface creation there will probably be many artificially close atomic distances, which will cause a subsequent MD simulation to be unstable. To remove these large forces from the interface, you will first run a geometry optimization. The `Force tolerance` does not need to be extremely low, so you can set a value of 0.5 eV/Å. Increase the `Maximum number of steps` to 1000. Uncheck the `Print` box, rename the output file to `interface_optimized.hdf5`, and close the **OptimizeGeometry** settings.

Open the first **MolecularDynamics** settings. During the MD annealing you should fix the atoms in the central crystal region to prevent the crystal region from melting. To this aim, click on `Add constraints` to open the **Constraints Editor**. In the presenter window, draw a rectangle around the central atoms of the crystal region to select them, click `Add tag from selection`, and select `Fixed` atoms constraints for this group in the table on the side of the widget.

Close the **Constraints Editor**.

In the **MolecularDynamics** widget, select *NVT Nose-Hoover Chain*, set the number of steps to 50 000 and the log interval to 2000 steps. First, you should anneal your structure at a temperature high enough to allow for local rearrangements of atoms, thus facilitating the healing of interfacial coordination defects, but not too high, to prevent melting of the global structure. A temperature of 1500 K is suitable for this purpose. Enter this temperature into the initial velocity temperature and the reservoir temperature fields.

Now add another *Optimize* → *MolecularDynamics* block to the script for the cooling simulation. Double-click it and open the **Constraints Editor**. The previously selected group *Selection 0* should already be present in the table. Select `Fixed` atom constraints for this group and close the widget. In the **MolecularDynamics** widget, select the *NVT Nose-Hoover Chain* thermostat, 50 000 steps, a log interval of 2000 steps, and *Configuration velocities* as initial velocities. In the thermostat settings set a `Reservoir temperature` of 1500 K and a `Final temperature` of 300 K to achieve a temperature decrease during the simulation.

Run the simulation by sending the script to the Job Manager.

To finalize the structure, you should run another *NPT* simulation, this time without any constraints. Use the *NPT Martyna Tobias Klein* barostat and uncheck *Isotropic pressure* as well as all stress coupling boxes except for the `zz`-box to equilibrate only the cell height perpendicular to the interface plane. Run the simulation for 50 000 steps at 300 K to obtain a room temperature amorphous/crystal interface structure.

Further Examples

Finally, this section provides some further examples of generating amorphous structures of the technologically relevant materials *alumina*, *titania*, and *hafnia*.

Al_2O_3

For the creation of an amorphous alumina sample, you can essentially follow the protocol outlined in Refs.[Page 1203, 3] and[4]. To use the same classical potential[5], you can either select *Matsui_CaMgAlSiO_1994*, or, if you use an older version of QuantumATK where this potential is not available, download the Python script attached to this tutorial. If you copy and paste its contents to the top of your simulation script, the potential will be available in the simulation.

To set up the system, you need to import the crystal structure of α-Al_2O_3 into the **Builder**. To this aim, download the `Al2O3_corundum_AMS_DATA.cif` file. In the **Builder**, click *Add* → *From Files* and open the file. For a more convenient handling in MD simulations the trigonal cell should be converted into an orthogonal cell. The are several

[4] G.ăGutierrez and B.ăJohansson. Molecular dynamics study of structural properties of amorphous Al2O3. *Phys. Rev. B*, 65:104202, Feb 2002. doi:10.1103/PhysRevB.65.104202.

[5] M.ăMatsui. A transferable interatomic potential model for crystals and melts in the system CaO-MgO-Al2O3-SiO2. *Miner. Mag.*, 58A:571, 1994. URL: http://rruff.info/doclib/MinMag/Volume_58A/58A-2-571.pdf.

ways to achieve this. One possibility is to open the *Builders* → *Surface(Cleave)* tool. Select (10-10) Miller indices, click `Next` and select a 3x1 surface lattice. Click `Next` and select a *Periodic (bulk-like)* cell with a thickness of 4. Click `Finish` to obtain an orthogonal supercell containing 360 atoms.

Now, you should proceed similar to the protocol outlined above, with the exception that the density will be fixed to 3.175 g/cm^3 (as proposed in Ref.[4]) during the cooling simulations. The entire protocol reads as follows:

1. Run a high temperature MD simulation at 5000 K and artificially reduced density.
2. Cool the system to 3000 K using the *NVT Nose-Hoover* thermostat.
3. Compress the system to the desired amorphous density.
4. Anneal at 3000 K.
5. Slowly cool the system to room temperature.
6. Run a final simulation at room temperature to calculate observables.

Send the orthogonal cell to the ScriptGenerator to set up a basic molecular dynamics script. Add a *NewCalculator* and two *Optimize* → *MolecularDynamics* block.

In the **NewCalculator** block, select **ATK-ForceField** and the *Matsui_CaMgAlSiO_1994* potential.

In the first **MolecularDynamics** block select the *NVT Nose-Hoover* thermostat, 150 000 steps, a log interval of 5000 steps and uncheck the `Save trajectory` box. Set the initial velocities to a *Maxwell-Boltzmann- distribution* at 5000 K. Set the reservoir temperature to 5000 K and the final temperature to 3000 K. The remaining parameters should be kept at the default values. Finally, uncheck `Save` and `Print`, close the calculator widget, and send the script to the **Editor**.

The second **MolecularDynamics** block should have similar settings, but 300 000 steps, a reservoir temperature of 3000 K and a final temperature of 300 K.

To obtain an artificially reduced density you should again multiply all three lattice vectors with 1.1, as explained above.

This first **MolecularDynamics** sequence yields a liquid system at 3000 K and lowered density. Based on this system, the density should be adjusted to achieve the target density of 3.175 g/cm^3. As it is often cumbersome to calculate the macroscopic density of an atomic cell and to obtain the exact scaling factors for the cell vectors by hand, this can conveniently be achieved using the QuantumATK unit engine by inserting the following piece of code in the simulation script, right before the second **MolecularDynamics** block (i.e. after the line `bulk_configuration = md_trajectory.lastImage()`):

```
# Get the volume and the lattice vectors of the cell.
V = bulk_configuration.bravaisLattice().unitCellVolume()
lattice_vectors = bulk_configuration.bravaisLattice().primitiveVectors()
# Get the coordinates and the elements.
fractional_coordinates = bulk_configuration.fractionalCoordinates()
elements = bulk_configuration.elements()
# The total and species-resolved number of atoms.
N = len(elements)
N_Al = len(numpy.where(numpy.array(elements)==Aluminum)[0])
N_O  = len(numpy.where(numpy.array(elements)==Oxygen)[0])
# Calculate the current density
density = (N_Al*Aluminium.atomicMass() + N_O*Oxygen.atomicMass())/V
# Get the density in g/cm**3
density = density.inUnitsOf(kiloGram/Meter**3)/1000.0
target_density = 3.175
# Calculate the scaling factor for the lattice vectors.
scale_factor = (density/target_density)**(1.0/3)
# Scale the lattice vectors.
```

(continues on next page)

(continued from previous page)

```
lattice_vectors = lattice_vectors*scale_factor
# Define a new cell.
new_lattice = UnitCell(lattice_vectors[0], lattice_vectors[1], lattice_vectors[2])
# Set up configuration
bulk_configuration = BulkConfiguration(
    bravais_lattice=new_lattice,
    elements=elements,
    fractional_coordinates=fractional_coordinates
    )
# The calculator is still defined and can readily be attached.
bulk_configuration.setCalculator(calculator)
```

These lines will extract the volume, calculate the density and the scaling factor required to obtain the desired target density of 3.175 g/cm^3. Finally, the lattice vectors are scaled accordingly and a new configuration is created, on which the second cooling sequence is performed.

Save the entire script to a Python file (an example for the final script can be found in the attachment), and run it via the **JobManager** or in a terminal using `atkpython`. It will take a couple of hours to complete. After the simulations have finished you can analyze the structure, as usual.

The complete script can be found in the file `script_al2o3_amorphous.py`.

TiO_2

To simulate amorphous titanium oxide, you will the use the potential of Matsui and Akaogi[6]. This potential has been used in many simulation studies of crystalline and amorphous titania systems, and yields properties in very good agreement with DFT-MD simulations. This potential is not yet available as a predefined potential in QuantumATK, but it can easily be set up in a script. Simply download the file `Matsui_TiO.py`, which is supplied as an attachment to this tutorial. Copy and paste its contents to the top of the script the you will create in the following.

To set up the system open the Builder and use *Add* → *From Database* to add the TiO_2 rutile crystal structure. Use the *Bulk tools* → *Repeat* function to create a 4x4x6 repetition of the system, which contains 576 atoms. Send the configuration to the **ScriptGenerator** and set up the same basic molecular dynamics script as in the alumina example. Send the final script to the **Editor**.

Locate the calculator definition as shown below:

```
potentialSet = Matsui_TiO_1991() # or any other potential class.
calculator = TremoloXCalculator(parameters=potentialSet)
```

Replace the line starting with `potentialSet = ...` with the entire content of the attached file `Matsui_TiO.py`.

When you adjust the volume to obtain the desired density, make sure that you adapt the script using the correct stoichiometry of TiO_2, the right element masses, and the right target density. For amorphous titania a density of 3.80 g/cm^3, as reported in Ref.[7], can be used.

The complete script can be found in the file `script_tio2_amorphous.py`.

[6] MăMatsui and M.ăAkaogi. Molecular dynamics simulations of the structural and physical properties of the four polymorphs of TiO2. *Mol. Sim.*, 6:239, 1991. URL: http://dx.doi.org/10.1080/08927029108022432.

[7] DăMergel, DăBuschendorf, SăEggert, RăGrammes, and BăSamset. Density and refractive index of TiO2 films prepared by reactive evaporation. *Thin Solid Films*, 371(1):218–224, 2000. URL: http://www.sciencedirect.com/science/article/pii/S0040609000010154.

HfO_2

For hafnia you can use the potential of Wang et al.[8], which is available in **QuantumATK** as *Wang_HfOZr_2012*.

To set up the system add the HfO_2 crystal structure from the database. Transform the *FCC* cell into a conventional unit cell, by opening the *Bulk tools* → *Supercell* plugin, and clicking `Conventional` and `Transform`. Repeat the system 3x3x3 times to obtain a supercell of suitable size.

Set up the same script as in the previous two examples. Make sure to adapt the system and element specific parameters accordingly and use an amorphous density of 7.97 g/cm^3 as suggested in[Page 1216, 8].

The complete script can be found in the file `script_hfo2_amorphous.py`.

3.8.7 Youngs modulus of a CNT with a defect

Modulus of elasticity

Youngs modulus is the relationship between stress, σ, and strain, ε, in a material in the elastic regime, where Hookes law applies: $E = \sigma/\varepsilon$

Carbon nanotubes are well known for their exceptional mechanical properties; Youngs moduli in the 1 TPa range have been measured[1], which is higher than any other known material. The theoretical Youngs modulus is fairly simple to calculate for a defect-free carbon nanotube, but this is not the case when defects are present. In that case, **molecular dynamics** (MD) is a suitable tool for calculation of the mechanical properties.

In this tutorial you will build a carbon nanotube (CNT) with a Stone–Wales defect, and use the **ATK-ForceField** engine to calculate the Youngs modulus.

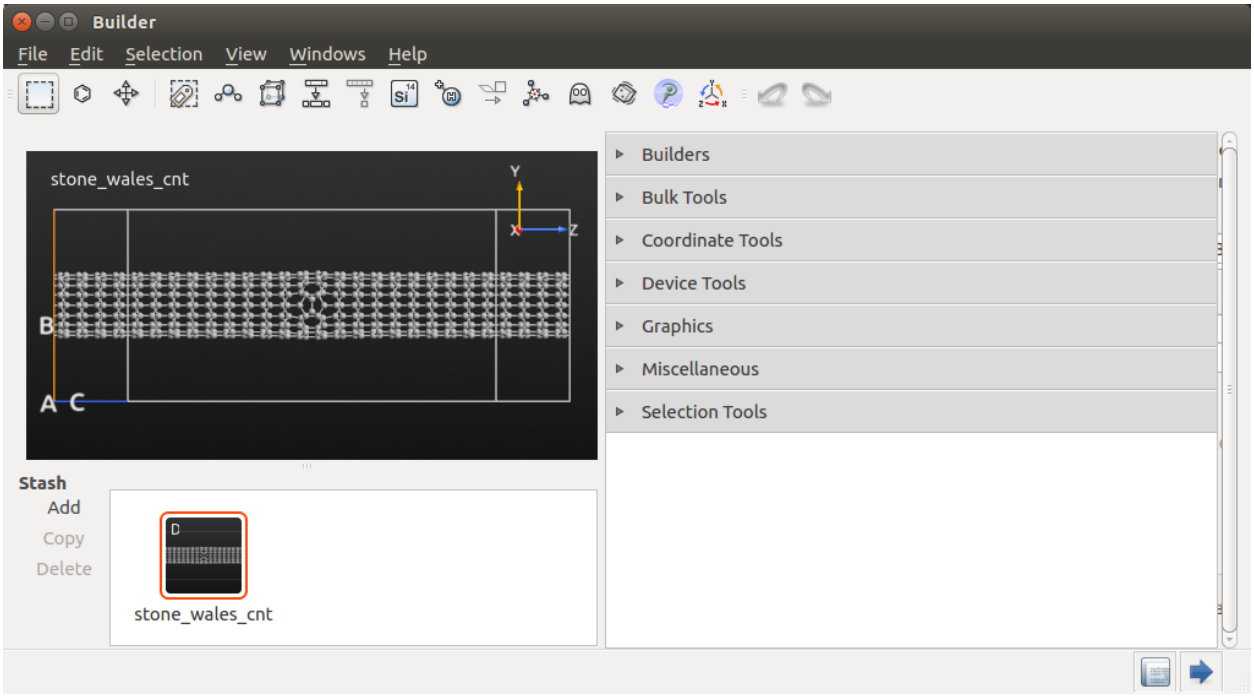
Important: This tutorial uses a CNT structure that is built in the tutorial *Stone–Wales Defects in Nanotubes*. If you have not already done so, please go that tutorial first and build the CNT device configuration, or simply download it as a Python script: `stone_wales_cnt.py`.

CNT bulk configuration

Open the QuantumATK **Builder** , and use *File* → *Add* → *From Files* to import the previously saved CNT configuration to the Stash. Note that the structure is a device configuration with the Stone–Wales defect in the middle of the central region.

[8] Y.ăWang, F.ăZahid, J.ăWang, and H.ăGuo. Structure and dielectric properties of amorphous high-k oxides: HfO2, ZrO2, and their alloys. *Phys. Rev. B*, 85:224110, 2012. URL: http://dx.doi.org/10.1103/PhysRevB.85.224110.

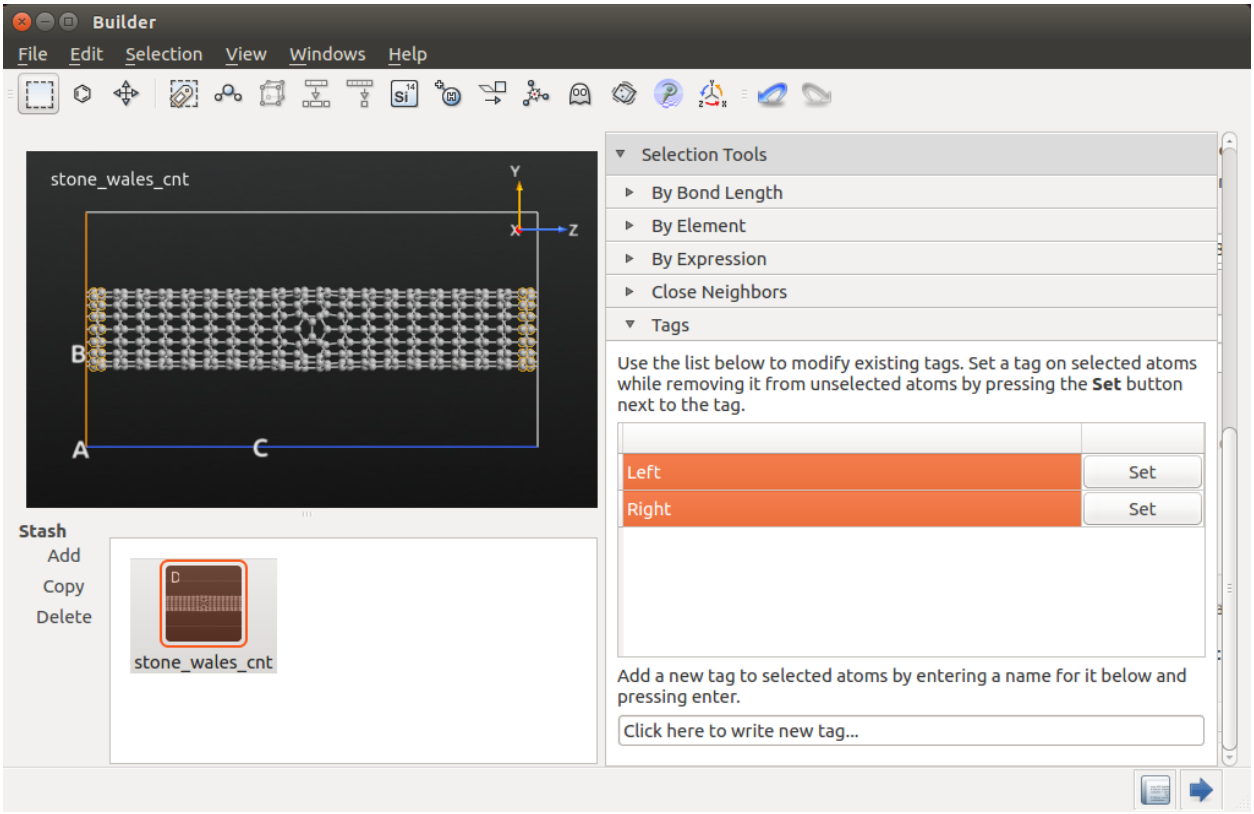
[1] A.ăKrishnan, E.ăDujardin, T.ăW. Ebbesen, P.ăN. Yianilos, and M.ăM.ăJ. Treacy. Youngs modulus of single-walled nanotubes. *Phys. Rev. B*, 58:14013–14019, Nov 1998. doi:10.1103/PhysRevB.58.14013.



Next, highlight the device Stash item, and click the icon to convert it to a bulk configuration (the device electrodes are simply removed), and use the *Selection Tools* → *Tags* tool to add tags to the atoms at both ends of the nanotube:

- Use the mouse to highlight the left-most carbon atoms and set the tag Left on them.
- Do the same for the right-most carbon atoms, as illustrated below.

These tags will be used to impose constraints on the structure during the MD simulation.



Configuring the MD simulation

Send the CNT bulk configuration with the Stone–Wales defect to the Script Generator and add the New Calculator and *Optimization* → *MolecularDynamics* blocks. Then edit both blocks to configure the calculation:

- First, change the default output file to `mdtrajectory_cnt.hdf5`.
- In the **New Calculation** block, select the *ATK-ForceField calculator*, and make sure to use the *Tersoff_C_2010* classical potential, which is designed for simulating lattice dynamics of graphene and nanotubes.

Note: For QuantumATK-versions older than 2017, the **ATK-ForceField** calculator can be found under the name **ATK-Classical**.

- Make the following changes to the **MolecularDynamics** block:

–Molecular Dynamics options:

∗Set the Type to *NVT Berendsen*.

∗Set Steps to *20000*.

∗Set the Log interval to *200*.

–Initial Velocity options:

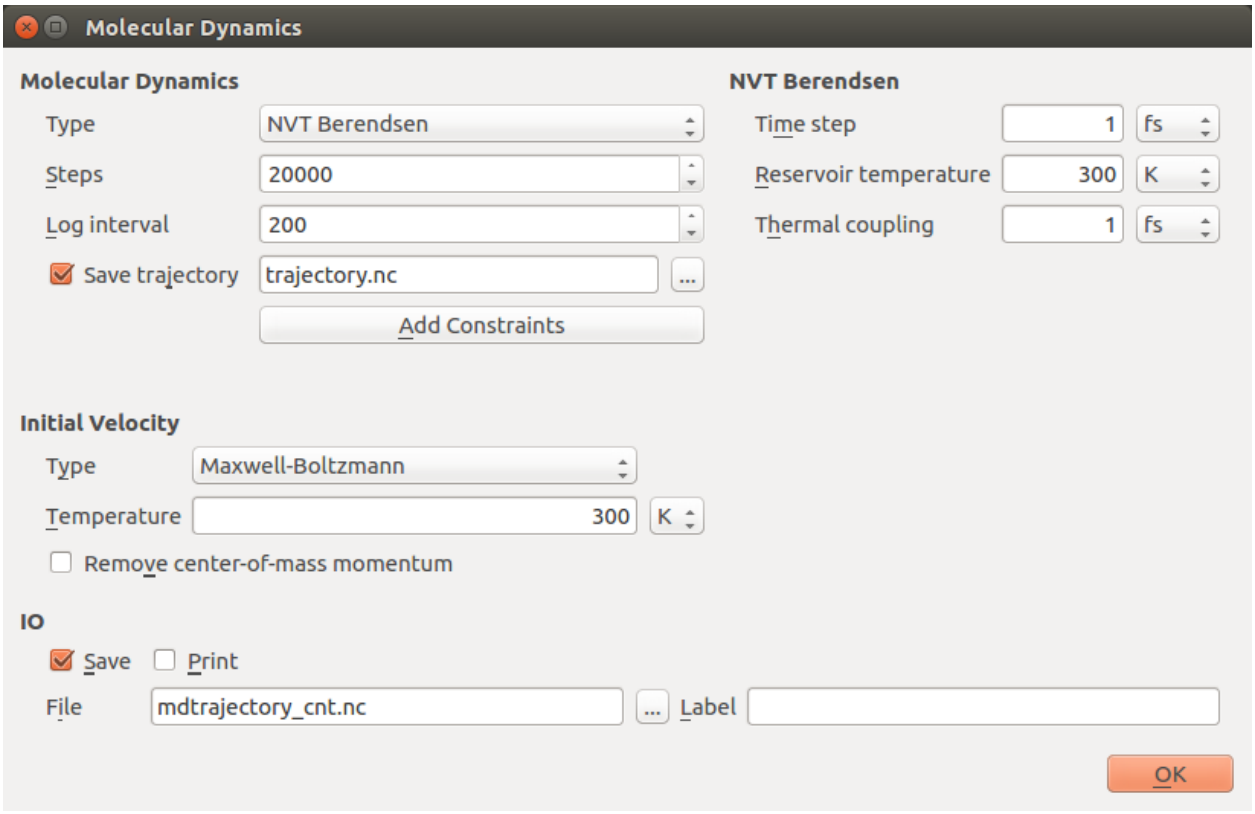
∗Set Type to *Maxwell-Boltzmann*.

∗Set Temperature to *300 K*.

∗Untick the *Remove center-of-mass momentum* option.

–**NVT Berendsen** options:

∗Set the Thermal coupling to *1 fs*.



Leave the remaining settings at defaults, like in the image above.

Save the script as `mdtrajectory_cnt.py` and send it to the **Editor** by using the icon.

Adding Python hooks

It is possible in QuantumATK to define hooks; Python functions or classes that are called before or after each MD step. These hooks can be used to provide customized on-the-fly analysis or monitoring of the system, or – as in this case – to modify the structure dynamically during the simulation.

You will now define a pre-step hook that will be used to strain the nanotube slightly for each step of the MD run:

•With the Python script open in the Editor, scroll down to the bottom of the script and locate the block defining the `md_trajectory`. The predefined tags Left and Right can now be used to apply constraints to the system. Change the line

```
constraints=[]
```

to

```
constraints=bulk_configuration.indicesFromTags(["Left","Right"])
```

•In the `md_trajectory` block, add the lines

```
pre_step_hook=strainer,
write_stresses=True,
```

and add a comma to the line immediately above it (`method=method,`). The first line will invoke the strainer hook function (defined below), and the second line will ensure that stresses are calculated and stored in the trajectory.

•You should also define what strainer is: Add the following line immediately before the `md_trajectory` block:

```
strainer = StressStrainUtility()
```

•The bottom of the script should now look like this:

```
# ------------------------------------------------------------
# Molecular Dynamics
# ------------------------------------------------------------

initial_velocity = MaxwellBoltzmannDistribution(
    temperature=300.0*Kelvin,
    remove_center_of_mass_momentum=False
)

method = NVTBerendsen(
    time_step=1*femtoSecond,
    reservoir_temperature=300*Kelvin,
    thermostat_timescale=100*femtoSecond,
    initial_velocity=initial_velocity
)

strainer = StressStrainUtility()

md_trajectory = MolecularDynamics(
    bulk_configuration,
    constraints=bulk_configuration.indicesFromTags(["Left","Right"]),
    trajectory_filename='mdtrajectory_cnt.hdf5',
    steps=20000,
    log_interval=200,
    method=method,
    pre_step_hook=strainer,
    write_stresses=True
)
```

•Line 17 above initializes an instance of the class `StressStrainUtility`, which is a Python class that you now will define. Insert the following at the very top of the script:

```
# Define a prestep function which can expand the system

class StressStrainUtility:
    """ Perform a strain of a configuration over time. """
    def __init__(self, delta=0.0001, skip=0):
        """
        @param delta The strain to apply in each step
        @param  first steps to "skip" strain
        """
        self.__delta = [0.0,0.0,delta]*Angstrom
```

(continues on next page)

(continued from previous page)

```
11          self.__skip = skip
12          self.stresses = []
13          self.lengths = []
14
15      def __call__(self, step, time, configuration, forces, stress):
16          """
17          Strainer call.
18          """
19          # Get the lattice vectors.
20          u1, u2, u3 = configuration.primitiveVectors()
21
22          # Don't apply strain in the earliest MD steps
23          if step < self.__skip:
24              return
25
26          # Store the history
27          self.stresses.append( stress[2,2].inUnitsOf(eV/Angstrom**3) )
28          self.lengths.append( u3[2].inUnitsOf(Angstrom) )
29
30          # Increase the lattice vectors.
31          u3 = u3 + self.__delta
32
33          # Set the new lattice.
34          configuration.setBravaisLattice(UnitCell(u1,u2,u3))
35
36          # Move all the atoms that are constrained on the right side.
37          constraints = configuration.indicesFromTags("Right")
38          for c in constraints:
39              xyz = numpy.array(configuration.cartesianCoordinates()[c]) + numpy.
↪array(self.__delta)
40              configuration.setCartesianCoordinates(indices=[c], cartesian_
↪coordinates=[xyz]*Angstrom)
41
42      def length(self):
43          return numpy.array(self.lengths)*Angstrom
44
45      def stress(self):
46          return numpy.array(self.stresses)*eV/Angstrom**3
47
```

This class defines a method to enable straining of a unit cell along the z-direction. You will use it to study how a CNT with a defect responds to strain.

As you can see from the script, the class has two inputs, `delta` and `skip`:

delta
defines how much the u3 vector (the z-direction) is expanded on every step in the MD calculation.

skip
defines how many steps should pass before the configuration will be strained.

The actual straining is done in the for-loop beginning at line 38, by increasing the coordinates of the atoms tagged Right by the amount `delta` along the z-direction. On lines 27 and 28, the stress and total length of the configuration are calculated and appended to two separate lists. These will be used later for plotting.

Tip: By writing `pre_strain_hook=strainer` in the `md_trajectory` block, the class (technically, the method `__call__`) is called *before* the force and energy calculation in every MD step (for more details about hook functions see *MolecularDynamics()*).

Computing Youngs modulus

To properly calculate the Youngs modulus, it is necessary to take the total volume of the simulation domain into account. The stress reported by QuantumATK therefore has to be multiplied by the total volume of the cell and then divided by the volume of the nanotube.

Several definitions of the volume of a CNT. A common way of defining it is to say that the wall of the nanotube extends for half a π-bond in and out of the wall, so that it becomes a cylindrical shell with thickness equal to that of a π-bond, approximately 1.35 Å, so that the total cross-sectional area is 1.35 Å times the circumference of the nanotube. The circumference for a (5,5)-armchair nanotube is $5 \times (3 \times x)$, where x=1.42 Å is the carbon-carbon bond length. Finally, for the volume, you need the length of the tube, which is given in the `.hdf5` file saved by QuantumATK.

- At the bottom of the script, delete the line `nlsave('mdtrajectory_cnt.hdf5', md_trajectory)`.
- Add instead the following lines of code in order to invoke the proper stress calculation:

```
# ------------------------------------------------------------
# Finding Young's Modulus
# ------------------------------------------------------------

# Find center of cnt from mean x- and y-coordinates
coords = bulk_configuration.cartesianCoordinates()
x_coords = coords[:,0]
y_coords = coords[:,1]
x_0 = numpy.sum(x_coords)/len(x_coords)
y_0 = numpy.sum(y_coords)/len(y_coords)

# Find radius by mean distance from center to atoms' x- and y-coordinates
radius = numpy.sum( ( (x_coords - x_0)**2 + (y_coords - y_0)**2 )**(1/2.0) ) / len(x_
↪coords)

# Find cross-sectional area by multiplying circumference with length of a pi-bond
pi_bond = 1.35
circumference = radius * 2 * numpy.pi
area = circumference * pi_bond

# Find volumes of CNT and of whole cell
volume_cnt = area * strainer.lengths[-1]

u1, u2, u3 = bulk_configuration.bravaisLattice().primitiveVectors()
volume_cell = u1[0] * u2[1] * u3[2]

# Factor the stresses to the volume of the CNT
stresses_factored = numpy.array(strainer.stresses * (volume_cell / volume_cnt) )*eV/
↪Angstrom**3

# Calculate the strain
strain = (strainer.length() - strainer.length()[0] ) / strainer.length()[0]
```

(continues on next page)

(continued from previous page)

```
# Calculate Young's modulus in TPa
modulus = (stresses_factored[-1].inUnitsOf(Pa) - stresses_factored[0].inUnitsOf(Pa) ) /␣
↪float(strain[-1]) / 1e12
print("Young's Modulus: {} TPa".format(modulus))
```

•Finally, add a few lines of code that will save different parts of the calculation and plot the results using pylab.

```
# Save the result to a file.
print(strainer.length())
nlsave("mdtrajectory_cnt.hdf5", md_trajectory, "MD")
nlsave("mdtrajectory_cnt.hdf5",strainer.length(), "C length")
nlsave("mdtrajectory_cnt.hdf5",strainer.stress(), "C stress")
nlsave("mdtrajectory_cnt.hdf5",stresses_factored, "C stresses factored")

# Plot stress-strain curve.
import pylab
pylab.figure()
pylab.plot(strain * 100, stresses_factored.inUnitsOf(GPa))
pylab.title('CNT with Stone-Wales defect')
pylab.xlabel('Strain (%)')
pylab.ylabel('Stress (GPa)')
pylab.grid(True)
pylab.savefig("mdtrajectory_cnt_fig.png")
```

The script is now ready to be executed. You may download the script to make sure you did the manual editing correctly: `mdtrajectory_cnt.py`.

Send the script to the **Job Manager** by clicking the icon, then save it, and run it. The job should take around 3 minutes on a laptop.

Visualize and analyse the results

The nanotube lengths and stresses that occur during the MD simulation run are saved in the `.hdf5` file with different IDs (C length, C stress, and C stresses factored). These are used to produce the plot titled `mdtrajectory_cnt_fig.png`, which is automatically saved in the project folder. It shows the stress vs. strain relationship for the nanotube, which is also shown below. The linear (elastic) behavior for small strains make it possible to calculate Youngs modulus E for the nanotube, defined as $E = stress/strain$.

With this procedure, the calculated Youngs modulus of the carbon nanotube with one Stone–Wales defect is around 2.3 TPa (it may vary across different MD runs). This is pretty far from the calculated value of 1.28 TPa for defect-free nanotubes[2]. However, as shown in[1], nanotubes with defects have in general a higher Youngs modulus.

Note: The figure above shows that the stress is negative for small stress levels, which means that the nanotube is actually under compressive stress until around 1.1% strain.

This could be avoided by running a **geometry optimization** step before running the MD calculation, which can be done using the Optimization block available in the Script Generator. However, for the strains investigated here, the CNT

shows a linear stress–strain behavior, so the obtained Youngs modulus should not change significantly if a geometry optimization is performed first.

The data file `mdtrajectory_cnt.hdf5` should be shown on the **LabFloor**. Select the file and click the **Movie Tool** in the right-hand plugins panel. The Movie Tool can be used to inspect MD trajectories; it will show a movie of the simulation and data about energies and temperatures. The tool looks like illustrated below.

Tip: Right click the mouse and select *Show bonds* to visualize the bond connection between the carbon atoms.

Another useful plugin is the **MD Analyzer**, which can show the radial distribution, velocity distribution, and the kinetic energy distribution of the atoms in the system. A screenshot of the velocity distribution is shown below.

3.8.8 Diffusion in Liquids from Molecular Dynamics Simulations

Version: P-2019.03

In this tutorial, you will learn how to calculate the atomic diffusion coefficient in liquid metals using molecular dynamics (MD) simulations. In general, an accurate measurement of the diffusion coefficient in liquids is a challenging task. The present tutorial demonstrates how the **QuantumATK** tools allow you to efficiently study this fundamental phenomenon in a straightforward manner on a computer instead.

We adopt **classical molecular dynamics** to be able to generate rather long MD trajectories of liquid copper. This is a computationally efficient approach to obtain statistically meaningful averages of the physical quantities needed for calculating the diffusion coefficient of a single Cu atom in this liquid metal. The entire MD procedure is divided into three major steps:

1. *heating crystalline copper* to above its melting point,

2. *annealing liquid copper* at high temperature to bring the system to equilibrium,
3. *further annealing of this equilibrated liquid copper* to get more statistical data for accurate calculation of the atomic diffusion coefficient, using the time-dependent mean-square displacement derived from the corresponding MD trajectory.

Theory

Diffusion in liquid metals differs from atomic diffusion in solids, as it takes place at a much shorter time scale, allowing for a brute force approach based on molecular dynamics simulations to calculate an atomic diffusion coefficient, denoted D. Knowing this fundamental physical quantity is needed to understand liquid dynamics, as well as many other related phenomena, such as nucleation and crystal growth. Unfortunately, experimental diffusion data for liquids are often rather inaccurate for various reasons[1]. Instead, liquid diffusion can be rather accurately studied theoretically as demonstrated in this tutorial.

Tip: If you are interested in atomic diffusion in solids, please refer to the following two tutorials on *Boron diffusion in bulk silicon* and *Modeling Vacancy Diffusion in Si0.5 Ge0.5 with AKMC* as studying diffusion in solids usually requires a more sophisticated computational approach compared to the molecular dynamics approach.

Given that the MD simulation of the equilibrated liquid has been run for time T_{MD}, the diffusion coefficient, D, can then be expressed in terms of the mean-square displacement of atoms in this MD run

$$6tD = \left\langle X^2(t) \right\rangle ,$$

where $\left\langle X^2(t) \right\rangle$ is the mean-square displacement of Cu atoms in liquid copper, calculated at the observation time t

$$\left\langle X^2(t) \right\rangle = \lim_{T\to\infty} \frac{1}{T} \int_0^T dt' \frac{1}{N_{\mathrm{at}}} \sum_{j=1}^{N_{\mathrm{at}}} \left[\mathbf{r}_j(t'+t) - \mathbf{r}_j(t') \right]^2 \approx \frac{1}{T_{\mathrm{MD}} - t} \int_0^{T_{\mathrm{MD}}-t} dt' \frac{1}{N_{\mathrm{at}}} \sum_{j=1}^{N_{\mathrm{at}}} \left[\mathbf{r}_j(t'+t) - \mathbf{r}_j(t') \right]^2 ,$$

and N_{at} is the total number of Cu atoms in the supercell, and $\mathbf{r}_j(t'+t)$ and $\mathbf{r}_j(t')$, where $j \in [1, \ldots, N_{\mathrm{at}}]$, are atomic position coordinates at time $t'+t$ and t', respectively. In this tutorial, t is the time interval of observation that is adopted to extract the atomic diffusion coefficient from the time-dependent mean-square displacement, $\left\langle X^2(t) \right\rangle$, assuming that $\left\langle X^2(t) \right\rangle$ shows a linear behavior with respect to t. This observation time t cannot exceed the total time T_{MD} of the MD simulation of liquid. The mean-square displacement may become quite noisy, not showing a linear dependence with respect to the time interval t for the values of t close to T_{MD}. In some cases, only those values of t that are much smaller than the simulation time, i.e., when $t \ll T_{\mathrm{MD}}$, allow for accurate estimates of the diffusion coefficient from the linear fit of $\left\langle X^2(t) \right\rangle$.

Strictly speaking, the formula given in the previous paragraph defines the self-diffusion coefficient of liquid copper. That is the atomic diffusion coefficient averaged over all the copper atoms in the liquid. This ensemble averaging is possible in this case because all these copper atoms are assumed to be identical, having the same atomic mass and

[1] A.ăMeyer. Self-diffusion in liquid copper as seen by quasielastic neutron scattering. *Phys. Rev. B*, 81:012102, Jan 2010. doi:10.1103/PhysRevB.81.012102.

other physical characteristics that may affect diffusion of atoms. If a foreign (impurity) atom or a copper isotope with a different atomic mass was introduced in liquid copper, we would then have an additional diffusion process, which is diffusion of this foreign atom in liquid copper. To quantify this process, we can calculate the atomic diffusion coefficient, D_{imp}, of this single atom as follows

$$6tD_{\mathrm{imp}} = \left\langle X^2(t) \right\rangle \approx \frac{1}{T_{\mathrm{MD}} - t} \int_0^{T_{\mathrm{MD}}-t} dt' \left[\mathbf{r}_{\mathrm{imp}}(t'+t) - \mathbf{r}_{\mathrm{imp}}(t') \right]^2 ,$$

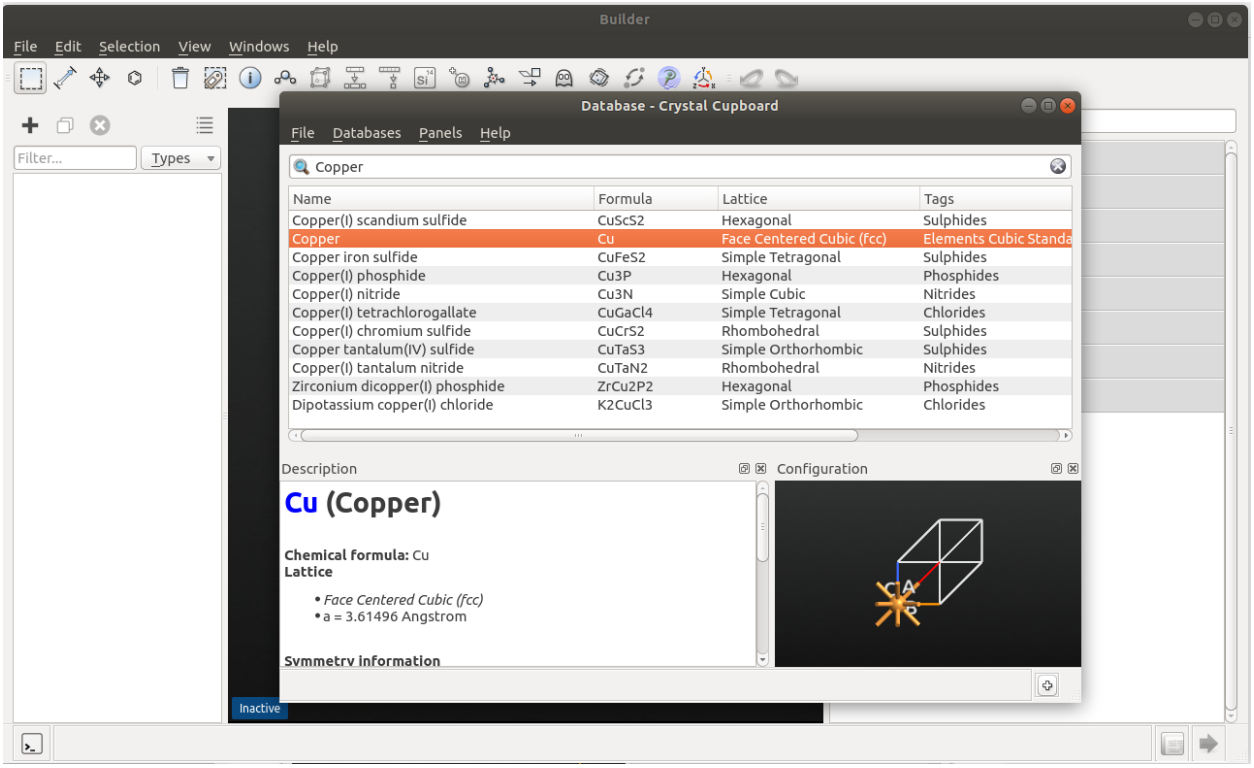
where the individual atom trajectory $r_{\mathrm{imp}}(t)$ is taken from the MD trajectory of the entire system of many atoms.

One should bear in mind that diffusion properties of materials depend on the temperature, and that also holds true for the atomic diffusion coefficient. In this tutorial, we will study liquid copper at T=2000 K, which is a temperature well above the melting point of crystalline copper.

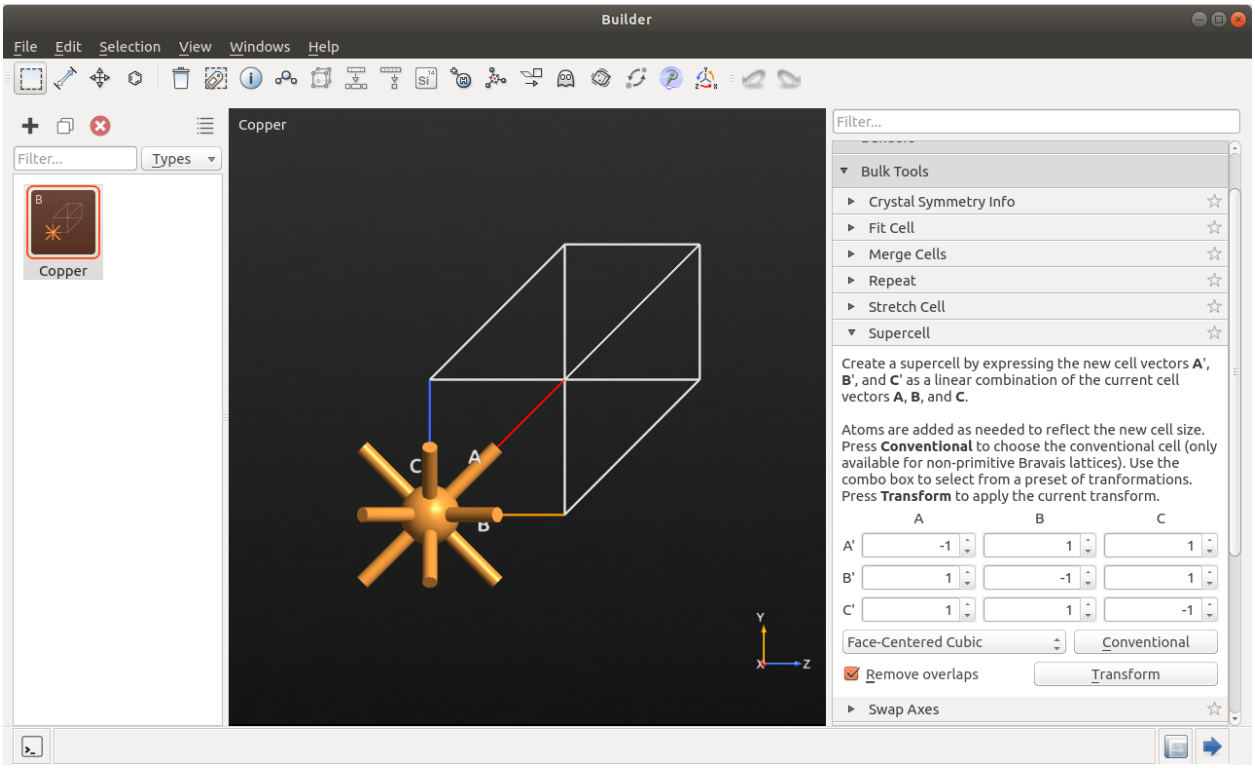
Computational Procedure

Building a Copper Supercell Structure

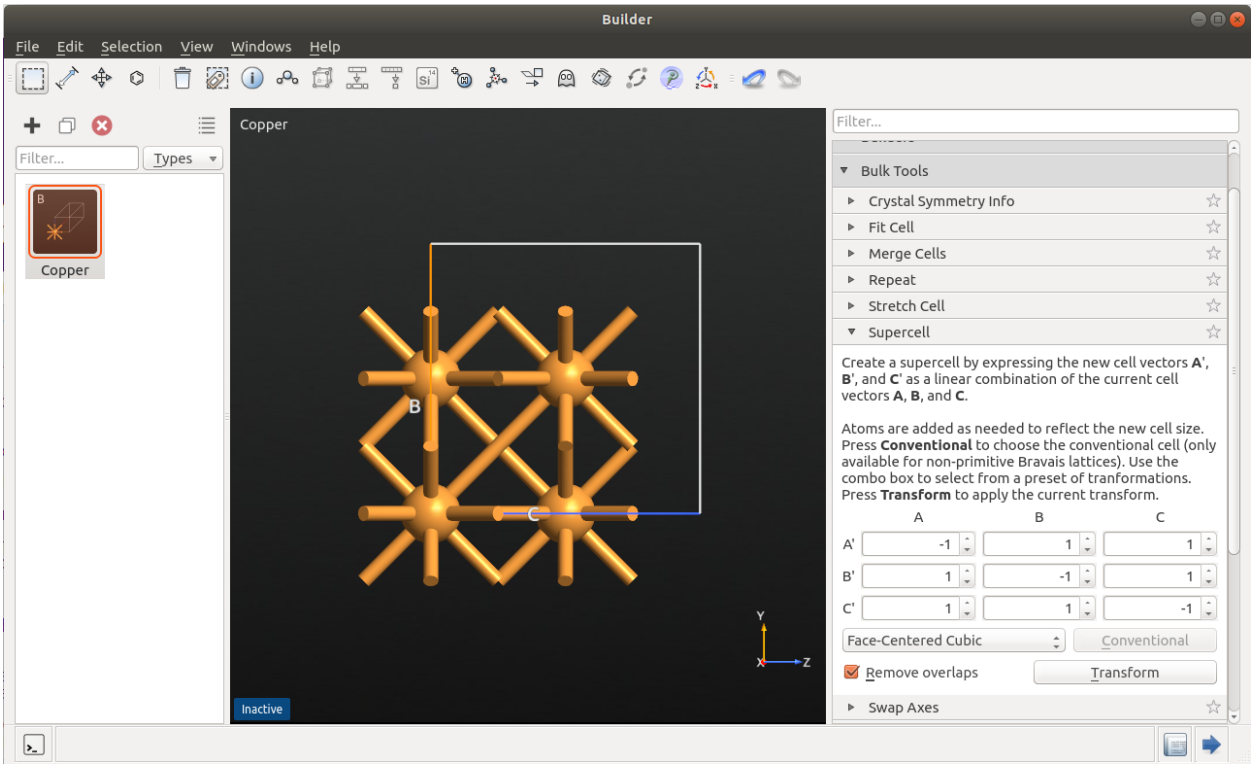
•Open the **Builder** and add a face-centered crystal structure of Copper from Database to the **Stash**.



•In **Bulk Tools**, choose *Supercell* and click on *Conventional*.



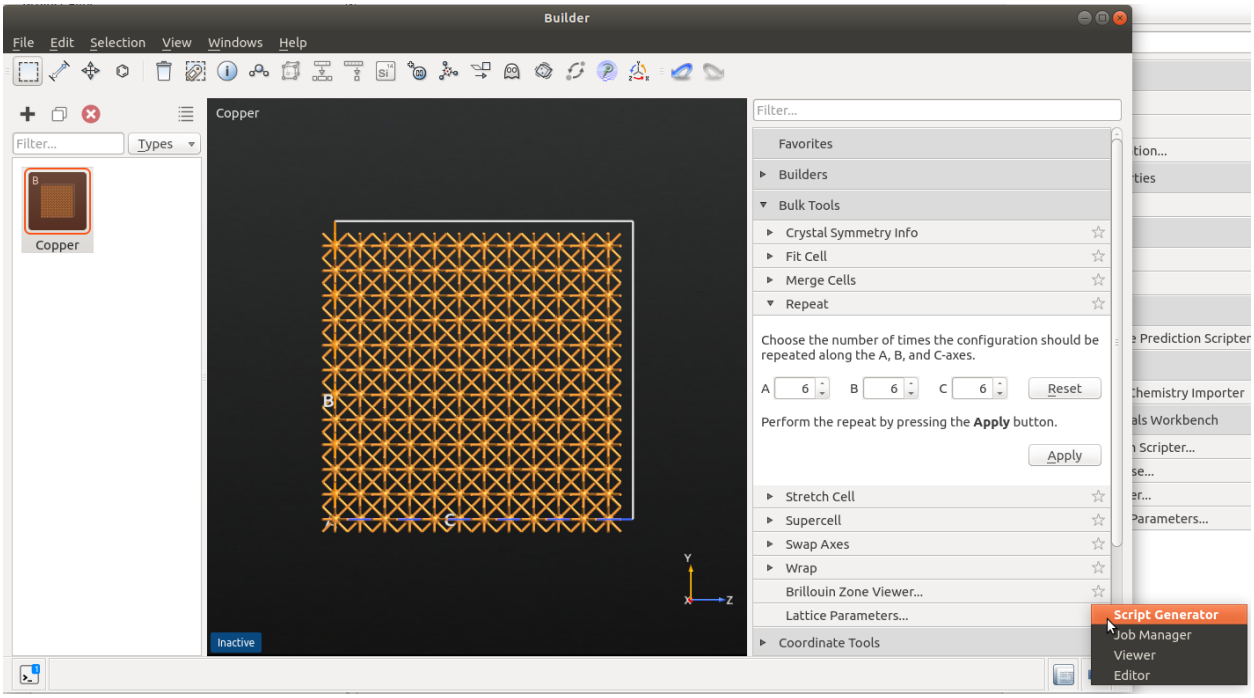
•Then click on *Transform* to convert the primitive cell of bulk copper with 1 Cu atom to the conventional unit cell with 4 Cu atoms.



•In **Bulk Tools**, choose *Repeat* and set the repetition of the conventional unit cell along the A, B, and C axes to 6.

•Click on *Apply* to create a 6x6x6 cubic supercell of bulk copper, which is the initial structure for MD simulations.

•Send the copper supercell structure to the **Script Generator** with the **Send To** icon .



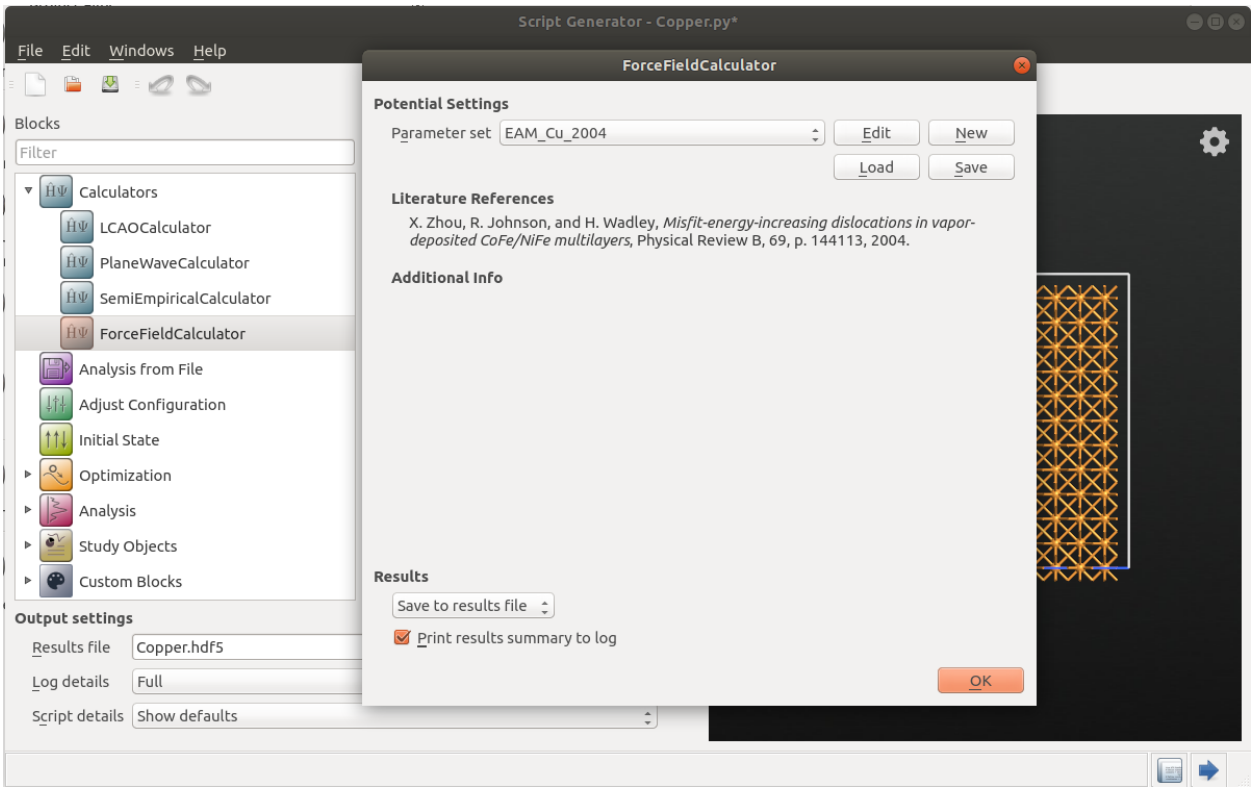
Setting up MD Simulations in the Scripter

•Add a *Calculators* → *ForceFieldCalculator* .

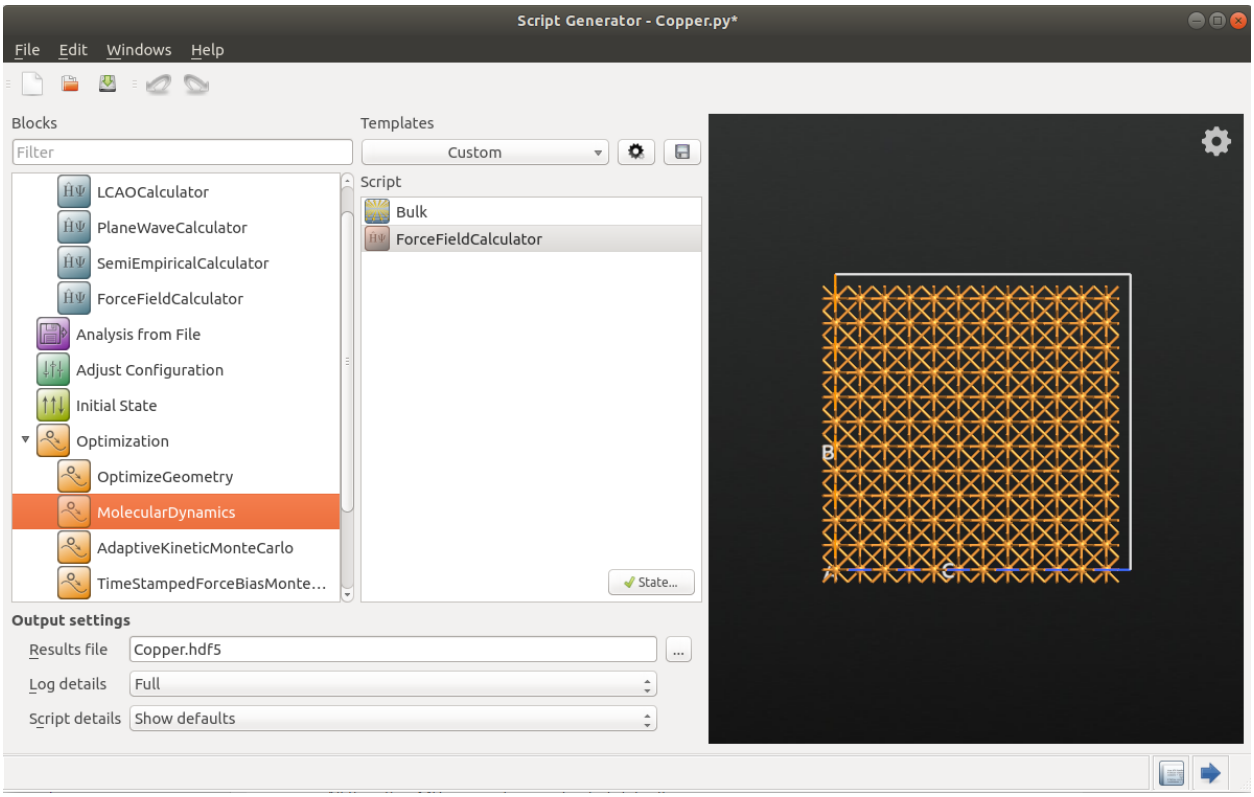
Note: For QuantumATK-versions older than 2017, the **ATK-ForceField** calculator can be found under the name **ATK-Classical**.

•In the Potential Settings, set the classical potential in Parameter set to EAM_Cu_2004[2].

[2] X.ăW. Zhou, R.ăA. Johnson, and H.ăN.ăG. Wadley. Misfit-energy-increasing dislocations in vapor-deposited CoFe/NiFe multilayers. *Phys. Rev. B*, 69:144113, Apr 2004. doi:10.1103/PhysRevB.69.144113.



•Add an *Optimization → MolecularDynamics* object to the Script to set up the first step of the MD procedure, which is *heating crystalline copper* above its melting point.



Set the computational parameters for MolecularDynamics to heat up the supercell structure of crystalline copper from

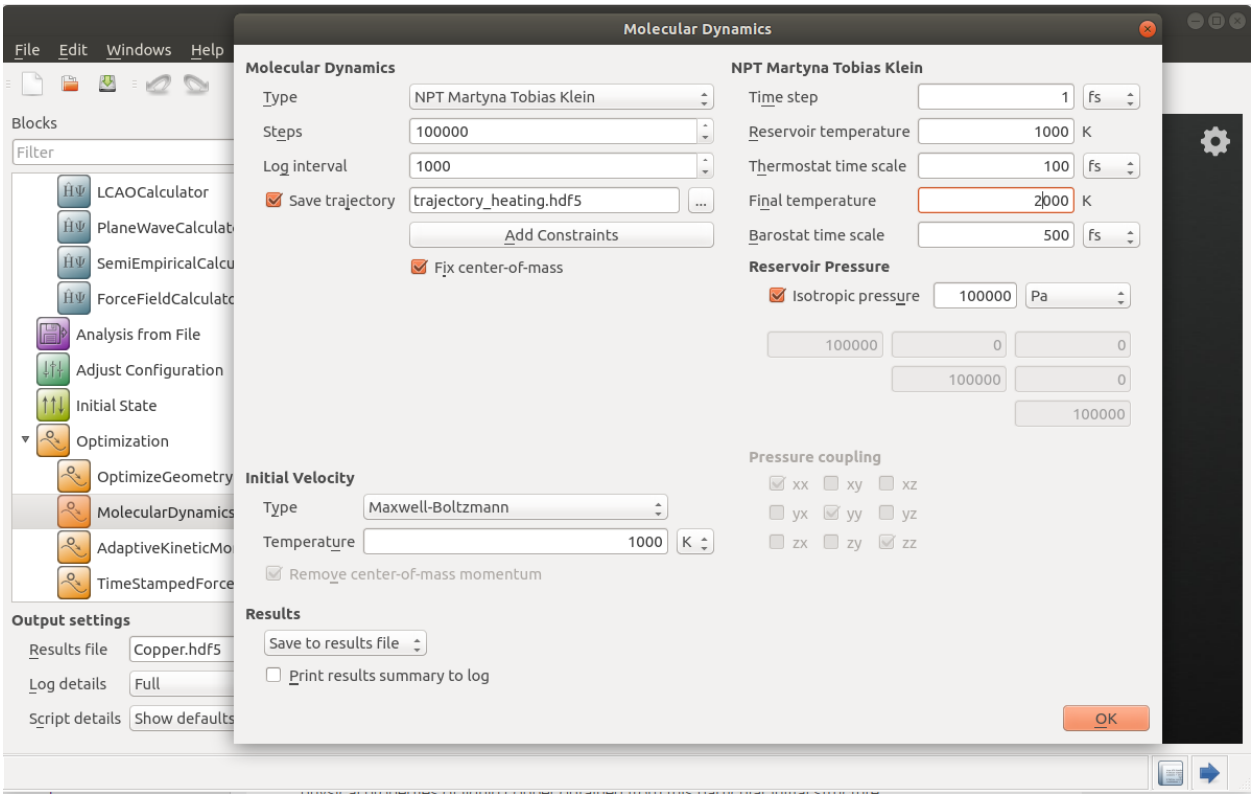
1000 to 2000 K, using an NPT barostat. This procedure allows us to increase the temperature of the system gradually above its melting point. It means that the ordered solid will eventually become a liquid, which only exhibits a short-range order as demonstrated using the radial distribution function (RDF) in the Analysis section.

•Set Molecular Dynamics Type to NPT Martyna Tobias Klein, Steps to 100000, Log interval to 1000, and Save trajectory to the `trajectory_heating.hdf5` file.

•Set Initial Velocity Type to Maxwell-Boltzmann, and Temperature to 1000 K.

•In the NPT Martyna Tobias Klein barostat settings, set Reservoir temperature to 1000 K, and Final temperature to 2000 K.

•All the other MD parameters are kept at default.



•Add a second *Optimization* → *MolecularDynamics* object to the script to set up the second step of the MD procedure, which is *annealing liquid copper* to bring the system to equilibrium.

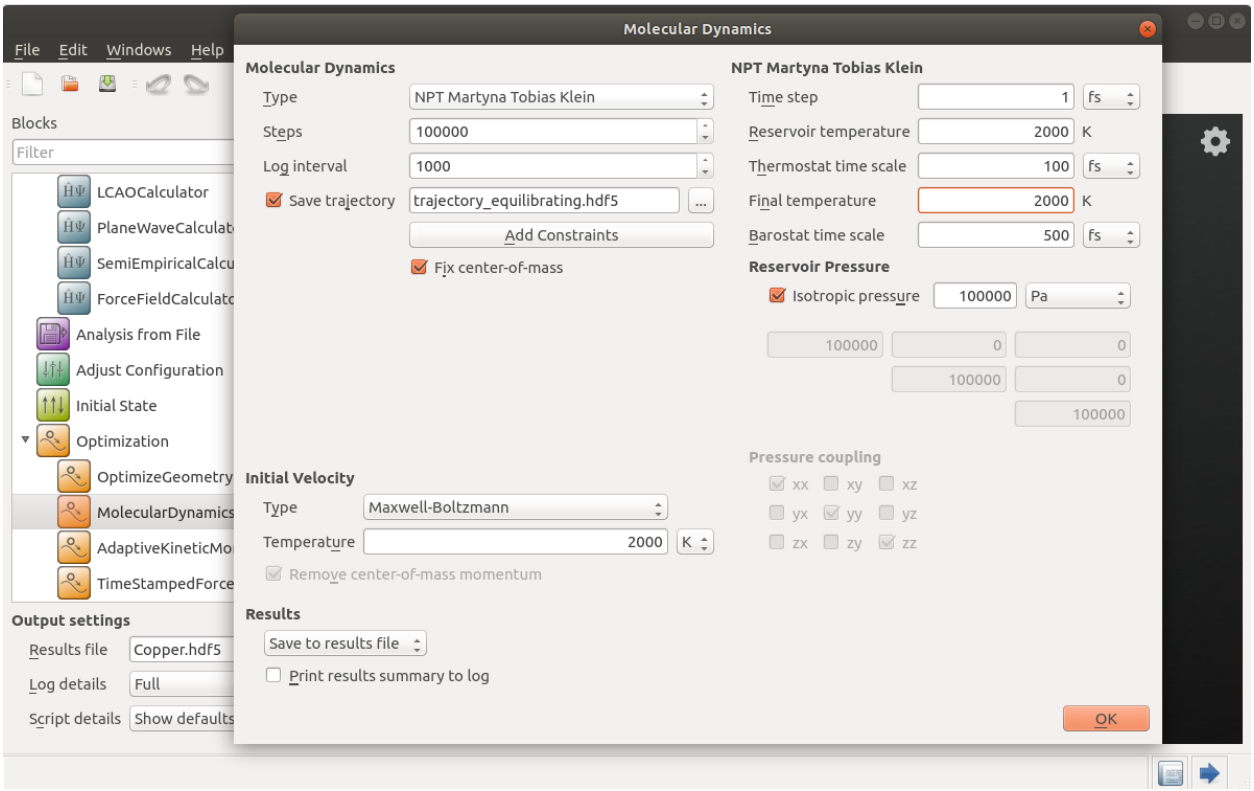
We should set the computational parameters for MolecularDynamics to equilibrate the supercell structure of liquid copper at the constant temperature 2000 K, using an NPT barostat. This step is needed to eliminate any memory effect of the initial copper structure (solid copper) on the physical properties of liquid copper obtained from this particular initial structure.

•Set Molecular Dynamics Type to NPT Martyna Tobias Klein, Steps to 100000, Log interval to 1000, and Save trajectory to the `trajectory_equilibrating.hdf5` file.

•Set Initial Velocity Type to Maxwell-Boltzmann, and Temperature to 2000 K.

•In the NPT Martyna Tobias Klein barostat settings, set Reservoir temperature and Final temperature to 2000 K.

•All the other MD parameters are kept at default.



•Add a third *Optimization* → *MolecularDynamics* object to the script to set up the third step of the MD procedure to collect sufficient statistical data for calculating the self-diffusion coefficient of liquid copper.

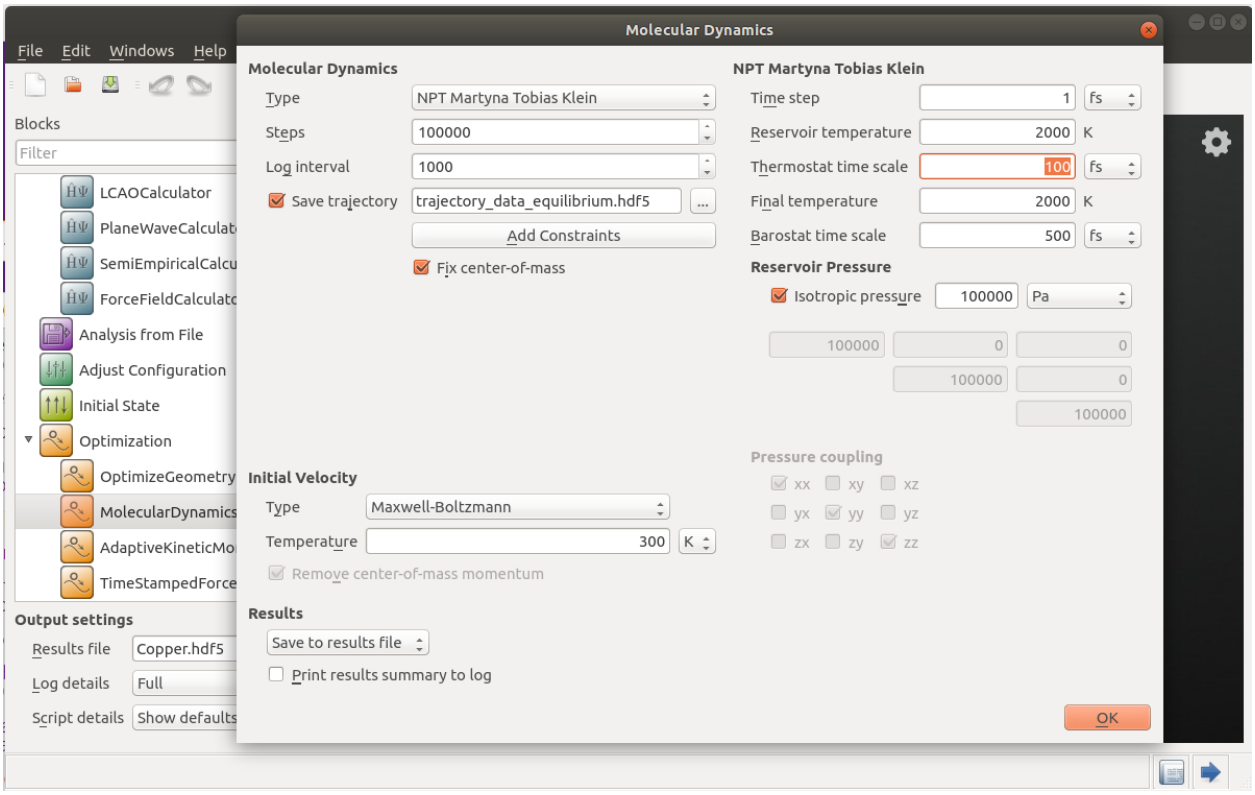
Set the computational parameters for MolecularDynamics to run the MD simulation for the supercell structure of equilibrated liquid copper at the constant temperature 2000 K, using an NPT barostat. In this step, we aim at collecting a good statistical data (a set of MD frames) for calculating atomic diffusion coefficient of liquid copper.

•Set Molecular Dynamics Type to NPT Martyna Tobias Klein, Steps to 100000, Log interval to 1000, and Save trajectory to the `trajectory_data_equilibrium.hdf5` file.

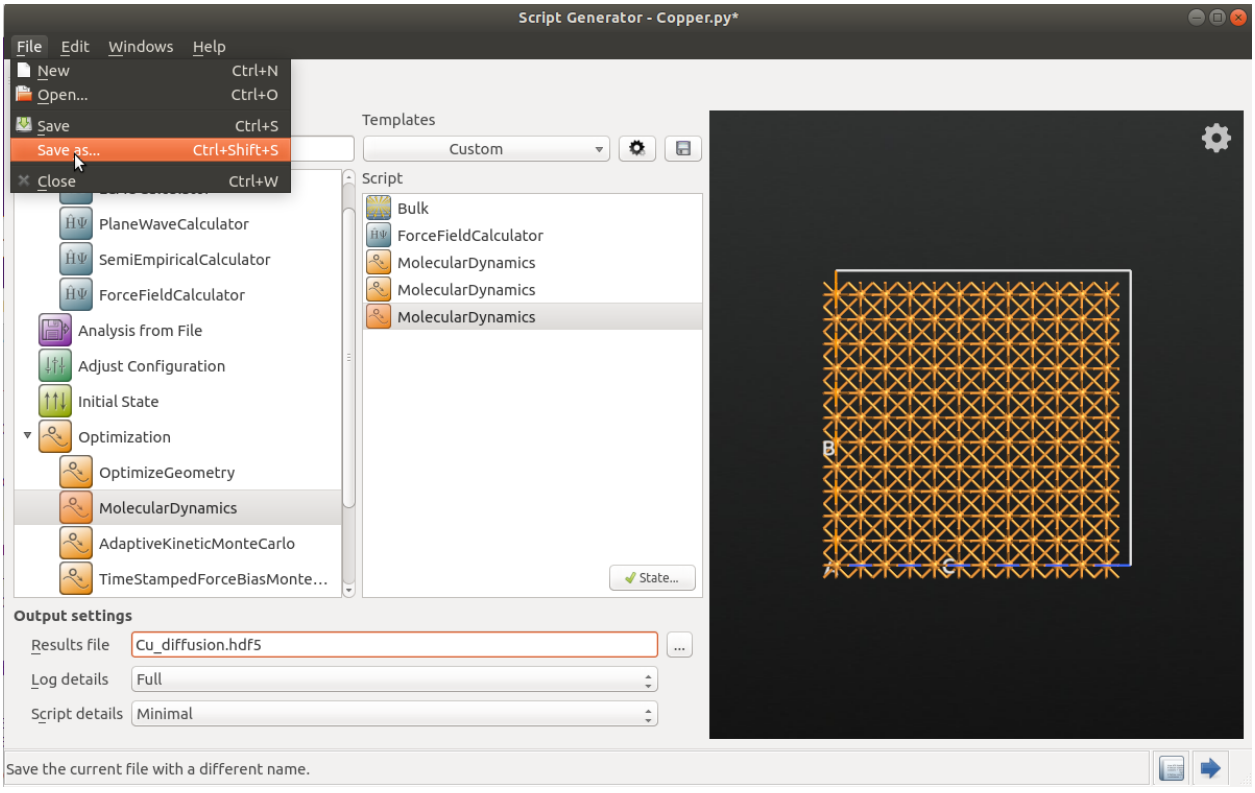
•Set Initial Velocity Type to ConfigurationVelocities, so that the velocities from the previous (second) MD run will be used as initial velocities for this (third) MD simulation.

•In the NPT Martyna Tobias Klein barostat settings, set Reservoir temperature and Final temperature to 2000 K.

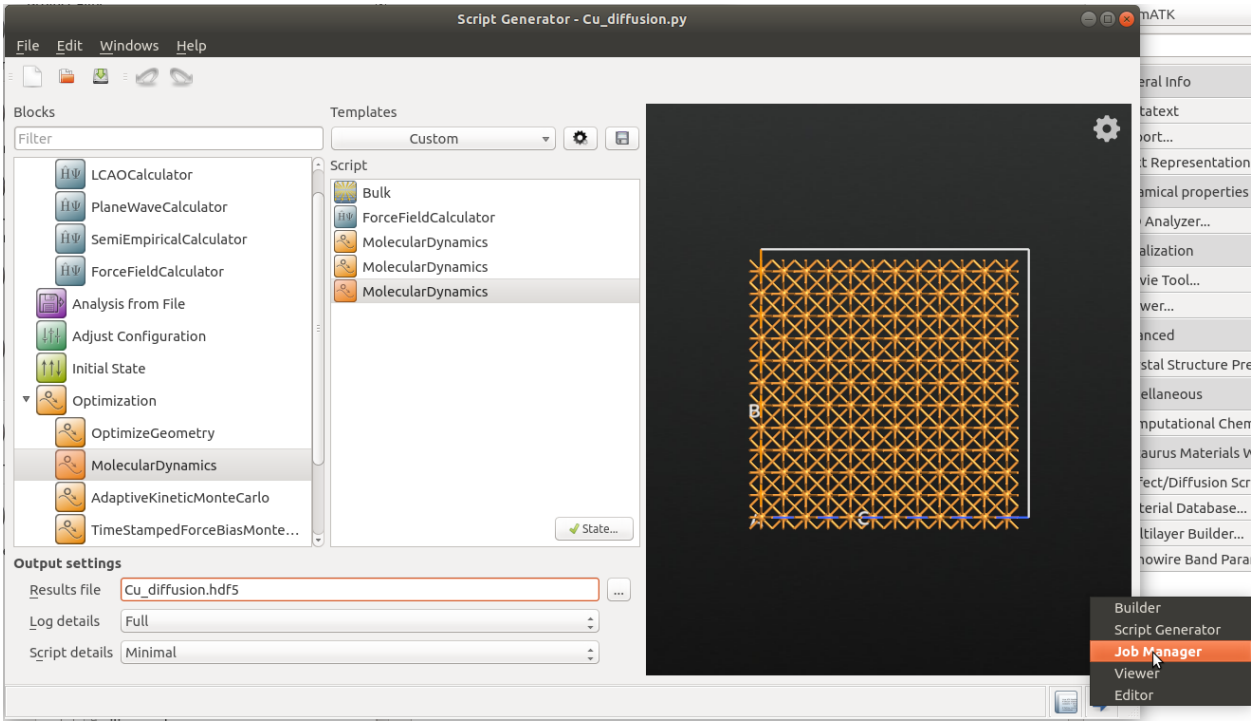
•All the other MD parameters are kept at default.



•In Output settings, rename Results file to `Cu_diffusion.hdf5`, and save the Script to *File* → *Save as* `Cu_diffusion.py`.



•Send the job to the **Job Manager** .



•Depending on your machine, it will take about half an hour to do the classical MD simulations for the supercell structure with 864 copper atoms adopted in this tutorial.

Download the scripts here: `Cu_diffusion.py` and `analysis.py`.

Analysis

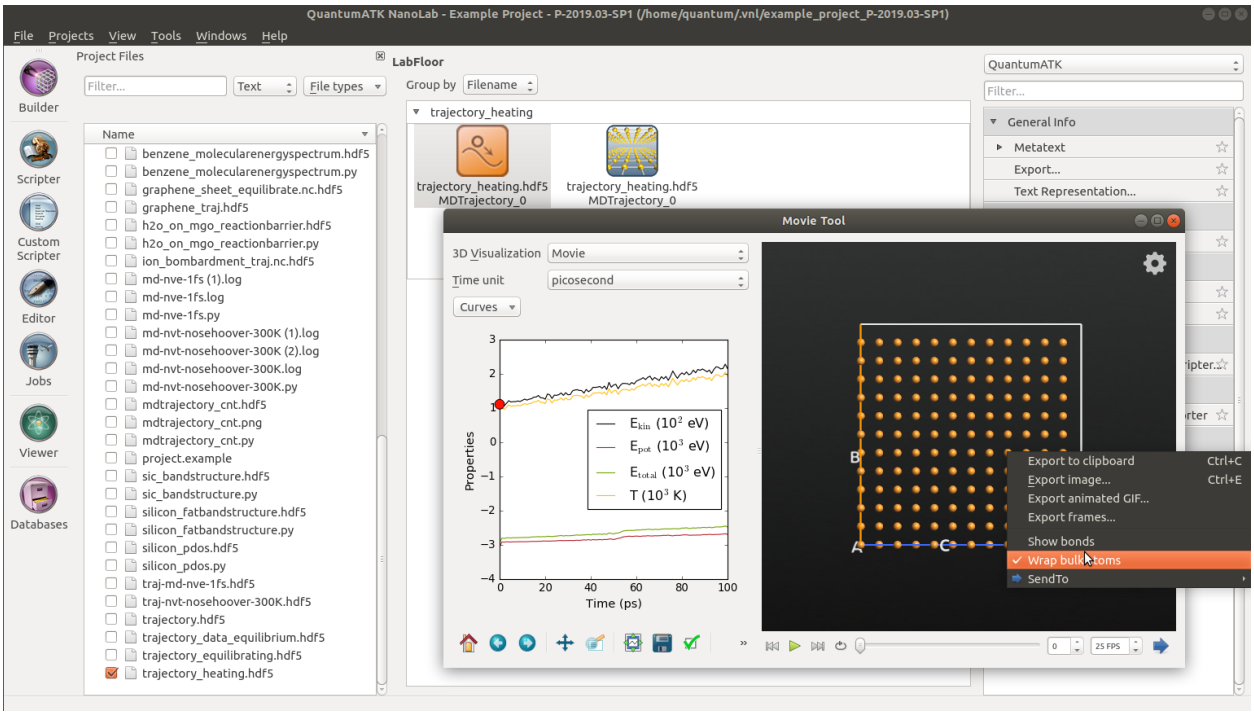
Self-diffusion of Liquid Copper

Once the calculations are done, the requested HDF5 data files should appear in the QuantumATK Project Files list, and their contents should be visible on the LabFloor.

•Select the trajectory named `trajectory_heating.hdf5` and open the **Movie Tool** from the right-hand plugins bar.

The left-hand plot shows the time-evolution of the MD quantities: kinetic energy, potential energy, total energy, and temperature, all as a function of MD simulation time. On the right you can see a movie of the MD trajectory.

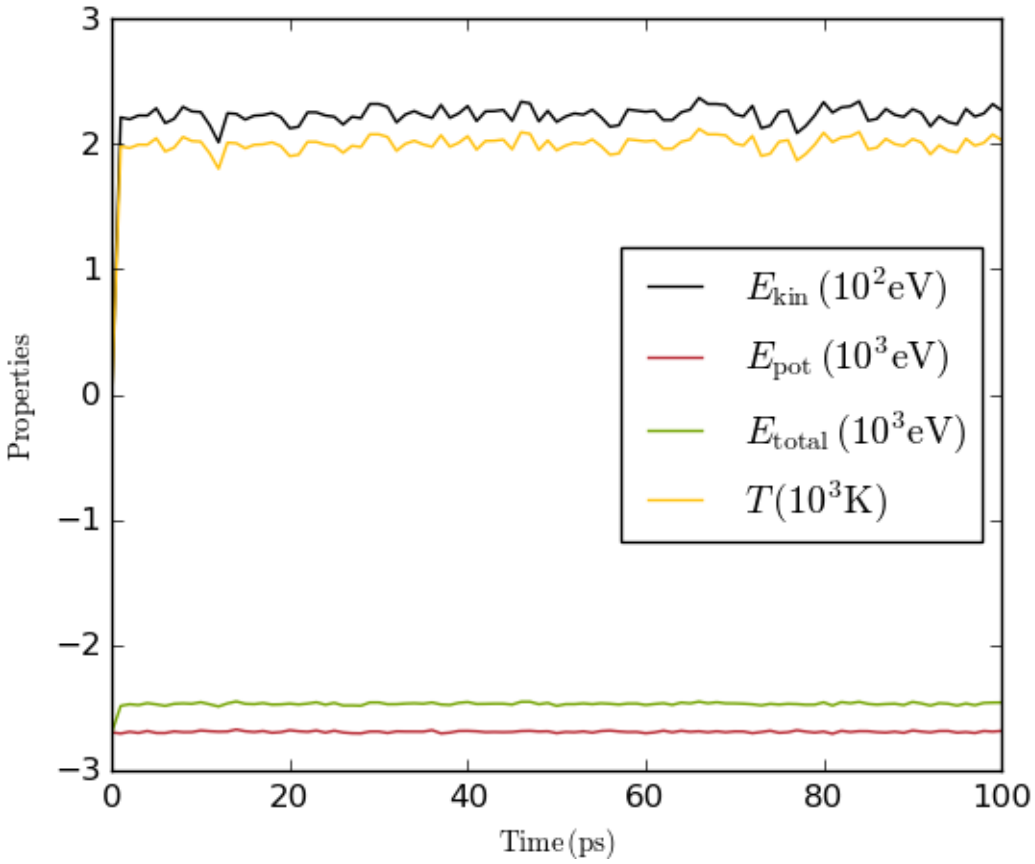
•Use mouse right-click to tick the option **Wrap bulk atoms**, and then click on the ▶ icon to start the movie.



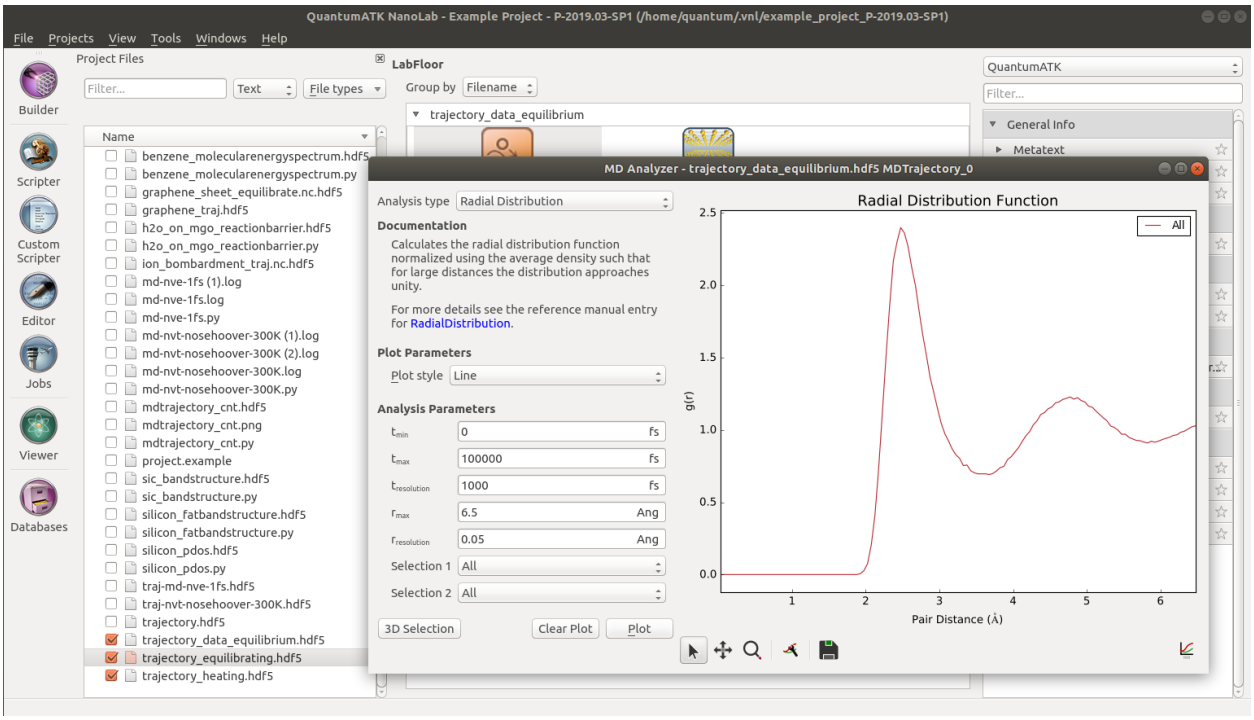
As shown in the animation of the MD trajectory, the average velocity of the copper atoms increases at elevated temperatures, and then the phase transition from the crystalline to liquid copper occurs about half-way through the heating MD run.

Tip: You can easily save such an animated GIF file yourself: Right-click the movie and select **Export animated GIF**.

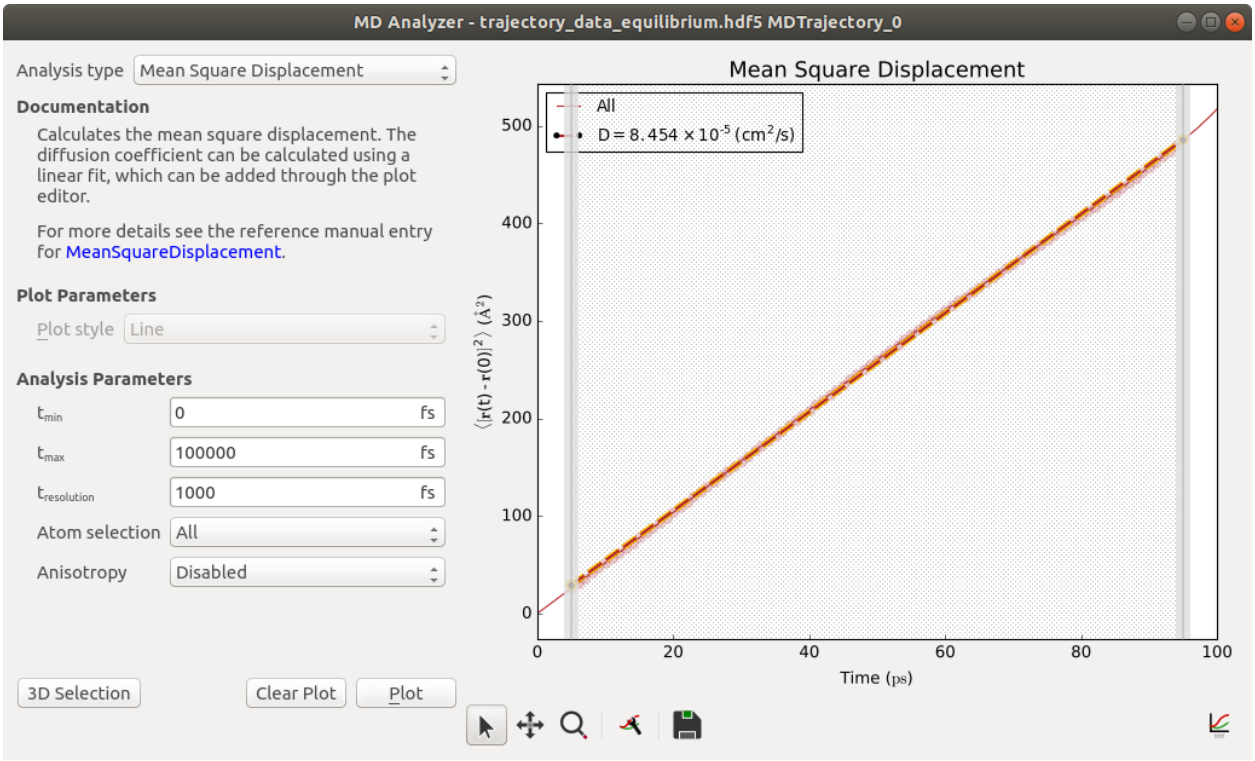
You can also use the Movie Tool to inspect the trajectory for the equilibration MD run, `trajectory_equilibrating.hdf5`. Note that the temperature and energy are fairly constant throughout the equilibration of the system:



As mentioned in the Computational procedure section, an ordered solid transforms into a liquid phase with a short-range order preserved upon melting. To demonstrate that liquid copper exhibits some structural ordering, select the final MD trajectory, `trajectory_data_equilibrium.hdf5`, and open the **MD Analyzer** from the right-hand plugins bar. Select *Radial Distribution* in the drop-down menu, and click on *Plot* to generate a plot of the radial distribution function $g(r)$ for the liquid copper. The distribution function shows a pronounced peak at 2.5 Å, indicating that this is the dominant nearest-neighbor distance between atoms in the liquid copper. This value is comparable to the nearest-neighbor bond distance of 2.55 Å in crystalline copper at room temperature, suggesting that there still exists some short-range order in the liquid phase of copper.



As described in the Theory section, the diffusion coefficient is related to the mean-square displacement (MSD) of the Cu atoms as the final MD simulation progresses. You can plot the MSD using the MD Analyzer: Select *Mean Square Displacement* as the quantity to be plotted, and then click on *Plot*.



The MSD increases linearly with simulation time, and all you need to compute the diffusion coefficient is the slope of the line. Right-click on the line, select Add fit, and click Polynomial fit. Close the Plot editor.

The atomic diffusion coefficient in liquid copper calculated at 2000 K is 0.85 Å^2/ps.

Diffusion of a Single Atom in Liquid Copper

To demonstrate how the diffusion coefficient, D_{imp}, of an individual atom in liquid can be obtained within the framework of the MD approach, we will look at the diffusion of a single copper atom in the liquid copper, pretending that this (randomly-chosen) atom differs from all the other copper atoms in the system. In this particular case, one would expect that the value of the atomic diffusion coefficient for this individual atom should be close to the self-diffusion coefficient value of liquid copper.

The MD trajectory that has already been obtained for liquid copper can be directly adopted for calculating atomic diffusion of a single copper atom. The MSD of a single atom also increases linearly with simulation time, at least on the short-time scale as seen in the figure given below, and all you need to compute the diffusion coefficient is the slope of the line.

Use the script `analysis_single_atom.py` for computing the diffusion coefficient. The content of the script is shown below. The script takes as an argument the name of the HDF5 file `trajectory_data_equilibrium.hdf5` from which it extracts the MD trajectory of a **single copper atom** (atom #7 as chosen in the script) in the equilibrated liquid copper, then uses the built-in function `MeanSquareDisplacement()` to calculate the MSD of the copper atom #7, and uses *NumPy* to do the linear fitting. Finally, a plot is produced using *pylab*.

```
# Get the name of the MD trajectory (hdf5) file given in the system arguments
filename = sys.argv[1]
#filename = 'trajectory_data_equilibrium.hdf5'

# Get the frames of the MD trajectory from the file
md_trajectory = nlread(filename)[-1]

# Get Mean Square Displacement (MSD) for a single Cu atom (#7) from the MD trajectory
msd = MeanSquareDisplacement(md_trajectory,atom_selection=[7])

# Get the times in ps and the MSD values in Ang**2.
t        = msd.times().inUnitsOf(ps)
msd_data = msd.data().inUnitsOf(Angstrom**2)

# Fit the slope of the MSD to estimate the diffusion coefficient.
# If you discover non-linear behavior at small times, you should then discard this␣
↪initial part in the fit.
for i in range(10,110,10):
  first_image = 0
  a = numpy.polyfit(t[first_image:i], msd_data[first_image:i], deg=1)
  print(i, a[0]/6)

# Setting the endpoint to 25 is based on a visual inspection of the plot for MSD(t).
# Note that this kind of plots may have some noise for large time-values.
endpoint = 25
a = numpy.polyfit(t[first_image:endpoint], msd_data[first_image:endpoint], deg=1)
line_fit = numpy.poly1d(a)

# Calculate the diffusion coefficient of the copper atom #7 in Ang**2/ps.
diffusion_coefficient = a[0]/6.0
print('Diffusion coefficient for a single atom in liquid copper at T=2000K is: ',
↪diffusion_coefficient, ' Ang**2/ps')
```

(continues on next page)

(continued from previous page)

```
# Plot the data using pylab.
import pylab

pylab.plot(t, msd_data, linewidth=2,label='MSD of a copper atom')
pylab.plot(t[first_image:endpoint], line_fit(t[first_image:endpoint]), linewidth=4,color=
↪'k', linestyle='--', label='Linear fit of MSD of a copper atom')
pylab.xlabel('t (ps)')
pylab.ylabel('MSD(t) ($\AA^{2}$)')
pylab.ylim(0,600)
pylab.legend(loc='upper left')

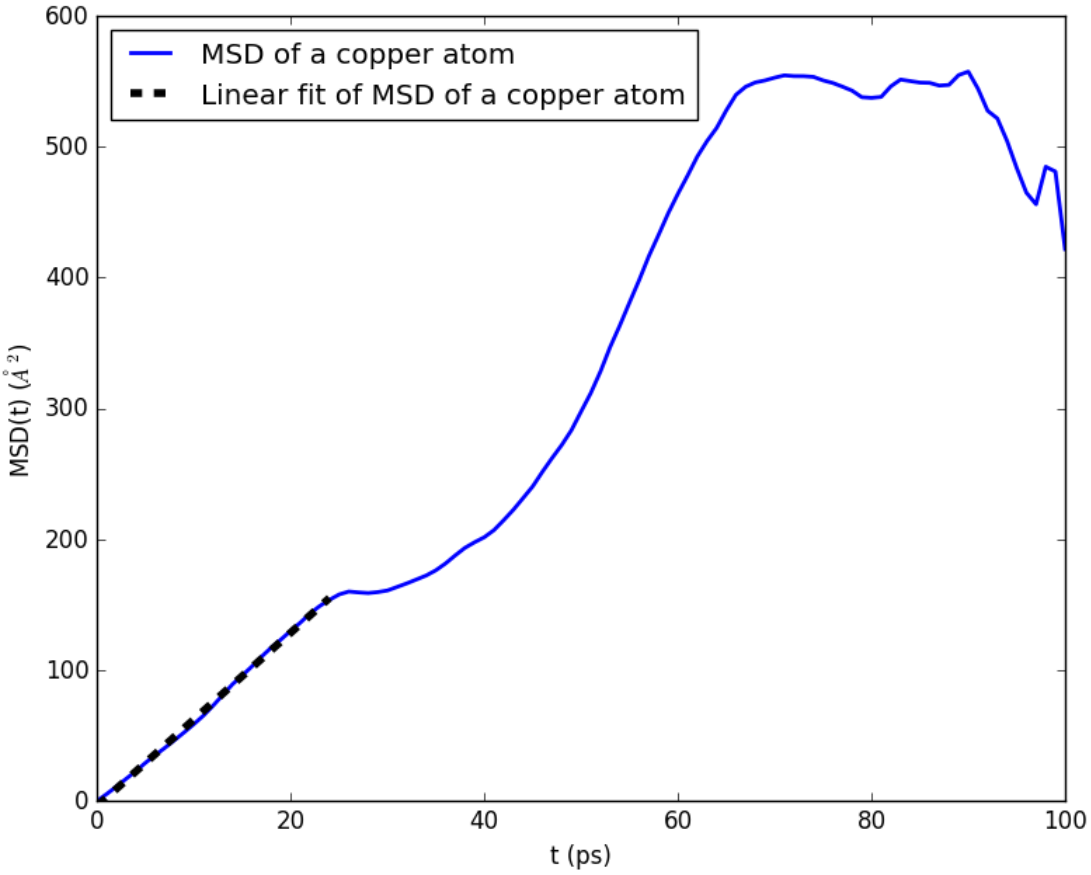
pylab.show()
```

Download the script and execute it from the command line. The calculated diffusion coefficient of a single atom will be printed at the end of the logging output:

```
$ atkpython analysis_single_atom.py trajectory_data_equilium.hdf5
...
...
...
Diffusion coefficient for a single atom in liquid copper at T=2000K: 1.10459718032␣
↪Ang**2/ps
```

Tip: This python script used for the analysis can also be executed from the Job Manager, i.e., without using the command line. For that, replace filename = sysargv[1] with filename = trajectory_data_equilibrium.hdf5 in the downloaded *analysis_single_atom.py* script, save it, and send it to the Job Manager to execute it as a regular QuantumATK job.

The diffusion coefficient of a single atom in liquid copper calculated at 2000 K is found to be 1.10 Å^2/ps in this case. As expected, this value is comparable to that of the self-diffusion coefficient of liquid copper, 0.89 Å^2/ps. The difference between these two calculated coefficients originates from the fact that we have done ensemble-averaging over all the copper atoms in liquid to calculate the self-diffusion coefficient, D, whereas there is only one data point at a given time, t, for calculation of the atomic diffusion coefficient, D_{imp}. So, we may need to run MD simulations for much longer time (T_{MD}) to more accurately calculate the self-diffusion coefficient of liquid copper from the MD trajectory of a single copper atom. This longer MD trajectory should allow us to get better statistics and increase the observation time interval (t) where the mean-square displacement exhibits a linear time dependence. The linear region in the following figure, which shows the time-dependent mean-square displacement, is then expected to increase from $t = 25$ ps to a larger observation time value.



Note: When analyzing only a single atom for this amount of time, the statistics are not sufficient for obtaining the diffusion constant. If you want the diffusion constant from a single atom, the simulation needs to run much longer than if the averaging is done over many atoms.

Temperature Dependence of Diffusion Coefficient

As an exercise, you may repeat all the steps of the MD procedure to obtain the MD trajectory of liquid copper equilibrated at T=1620 K, and then calculate the self-diffusion coefficient from this MD trajectory. You will find that this physical quantity calculated without any adjustable parameters, i.e., calculated from first-principles, agrees very well with the experimental value of 0.52 Å^2/ps measured for liquid copper at T=1620 K. The smaller diffusion coefficient value at 1620 K compared to that at 2000 K suggests that the self-diffusion coefficient decreases upon lowering the temperature of liquid, as expected.

3.8.9 Simulating a creep experiment of polycrystalline copper

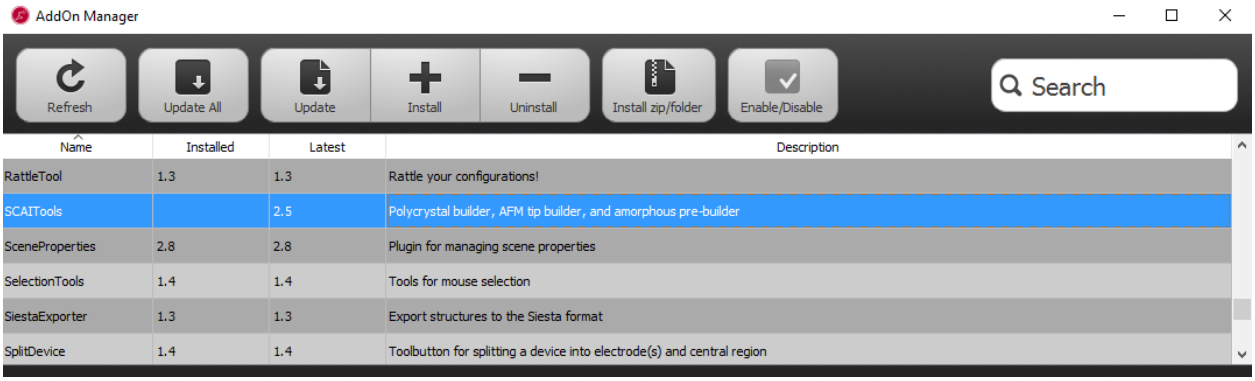
Version: 2016.3

This tutorial will show how to set up, run, and analyze a molecular dynamics (MD) simulation of a microscopic creep experiment using polycrystalline copper, *i.e.* the strain response to an externally imposed uniaxial stress[1]. You will get to know the **Polycrystal Builder** and the **Local Structure** analysis tool, and you will learn how to run **advanced MD simulations** at constant external stress.

Although the construction of realistic grain sizes of several nanometers is in principal possible, the computational cost of such simulations is relatively large, as the required system size can easily exceed a million atoms. Such calculations are certainly possible with QuantumATK, but for demonstration purposes you will here simulate only a small model system, to reduce the calculation time. Still, the presented methodology can be transferred in a straightforward manner to larger systems.

Installing the polycrystal builder plugin

First, make sure that the Polycrystal plugin is installed and available in the **Builder** – it should appear in the Builder panel under *Builders* → *Polycrystal (Voronoi)*. If the plugin is not listed, you have to install it via *Help* → *AddOn Manager*. Select the **SCAITools** package and install it.



You may have to restart QuantumATK to activate the plugin in the Builder.

Building the polycrystalline cell

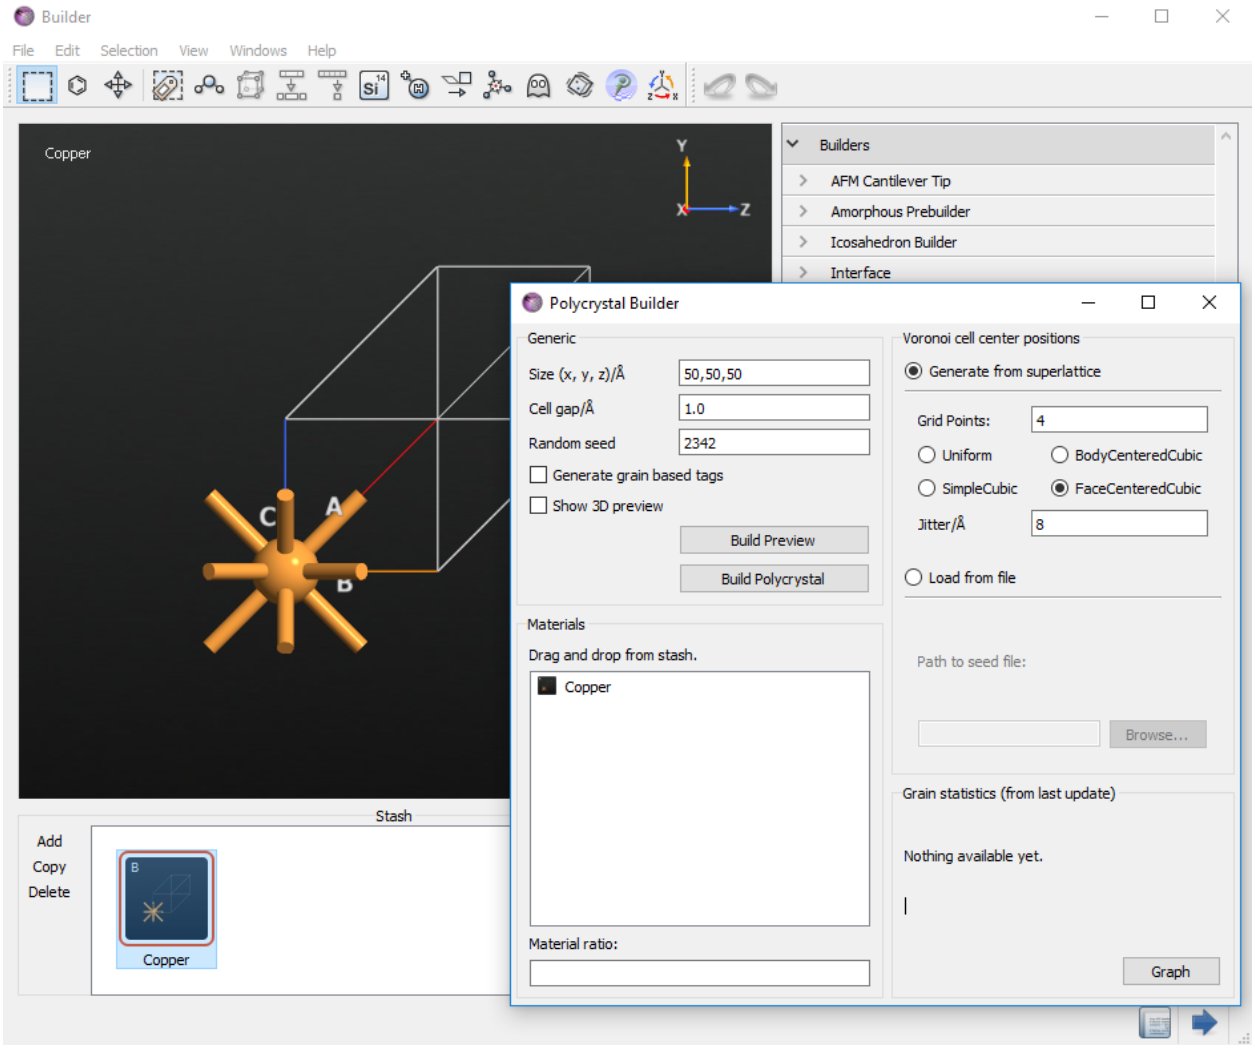
Create a new project in QuantumATK, call it for instance Polycrystalline Copper.

Open the **Builder** and add the fcc copper single crystal material to the **Stash** using *Add* → *From Database*.

To start building the polycrystalline structure, select *Bulk Tools* → *Polycrystal (Voronoi)*. Set the crystal size to 50, 50, 50 Å to obtain an cubic supercell. Set the gap between grains to a small value, like 0.1 Å, to allow for a compact packing of the grains. Drag and drop the cubic copper cell from the Stash to the **Materials** field. Make sure the *Generate grain based tags* option is unticked. As an advanced analysis feature, this option allows you to mark the atoms within each grain by different tags, so that the transformation of the grains during the simulation can be monitored. We will not use this feature in this tutorial.

[1] Yun-Jiang Wang, Akio Ishii, and Shigenobu Ogata. Grain Size Dependence of Creep in Nanocrystalline Copper by Molecular Dynamics. *MATERIALS TRANSACTIONS*, 53(1):156–160, 2012. doi:10.2320/matertrans.MD201122.

You can choose how the seeds for the grains are created. Select **Generate from superlattice** and set the number of grid points to 4. Select *FaceCenteredCubic* as the superlattice of the grain structure, and set the value of *Jitter* to 8 Å. These settings will create four initial grains on a distorted fcc lattice, with a distortion variance of 8 Å.



You can preview the grain structure by clicking **Build Preview**. Now, the 3D-window will show the only the seeds of the grains. You can additionally switch on the visualization of the grain boundaries by checking **Show 3D preview** box.

Click **Build Polycrystal** to initiate the structure generation.

After a few seconds the final polycrystalline cell will appear on the Stash.

Analyzing the grain structure

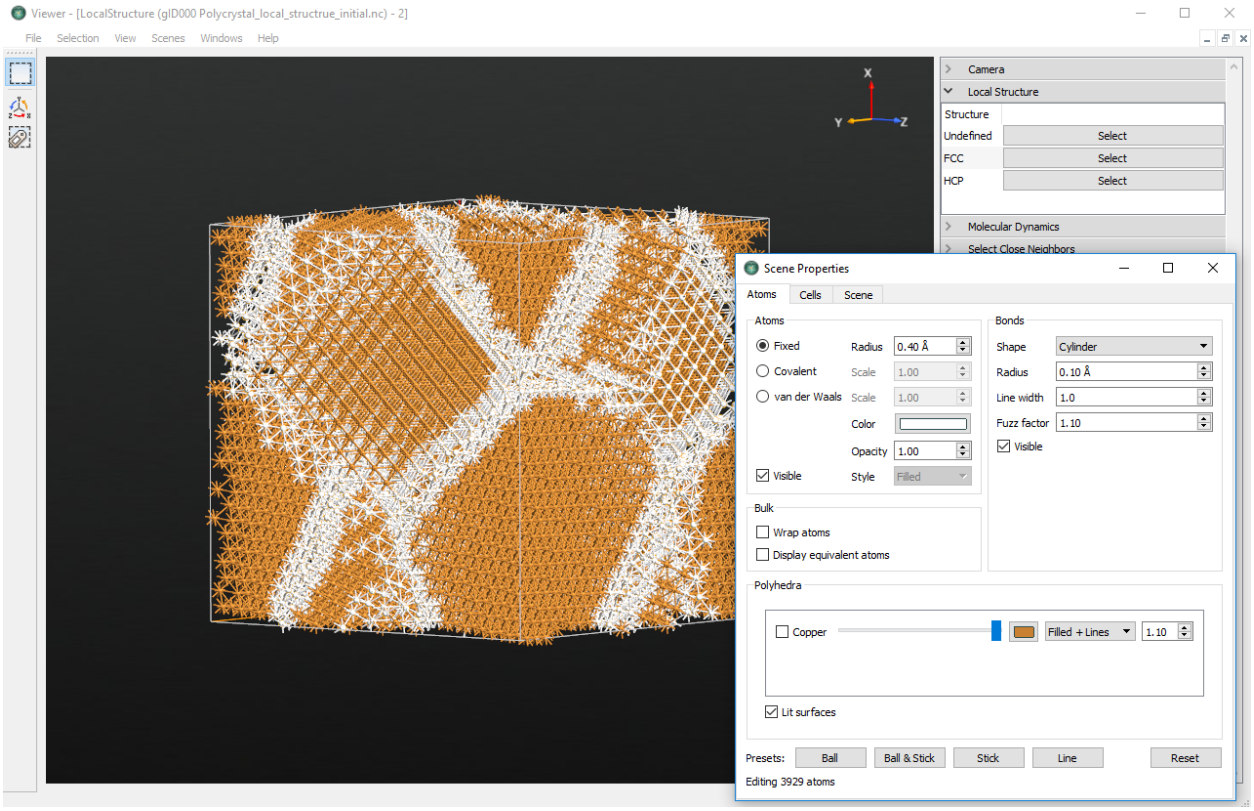
By rotating the cell in the Builder window, you can already see part of the grain structure. A better visualization in terms of the local crystal structure can be performed by using the **LocalStructure** analyzer.

For this, send the polycrystalline cell to **Scripter**, and just left double-click **Analysis** and add the **LocalStructure** (do not add any New Calculator, as you may be used to – we are not going to run any simulation, only analyze the real-space geometry). Change the output filename to something suitable, e.g. `local_structure_init.hdf5`.

Send the script to the **Job Manager** and run it.

After a few seconds, the results will appear on the **LabFloor**. Select the LocalStructure item and click the **Viewer**.

You can now use the **Local Structure** plugin in the Viewer to analyze the crystal structure. You will there find a list of the crystal structure types which have been detected in the polycrystalline cell.



In this example, the cell contains atoms in a local FCC, as well as HCP, or Undefined environment. Since the underlying basic copper crystal forms a fcc strucure, the grains will be of such struture, too. To identify the grain boundaries, click to select all Undefined and HCP atoms (the latter will be only a tiny fraction). Then open the **Properties** plugin and change the color of the selected atoms to e.g. white. Grains as well as grain boundaries will now be clearly visible, as illustrated above.

Tip: Alternatively, you could uncheck the *Visible* box to hide the selected grain-boundary atoms, or perform any other customized graphical modification of the scene.

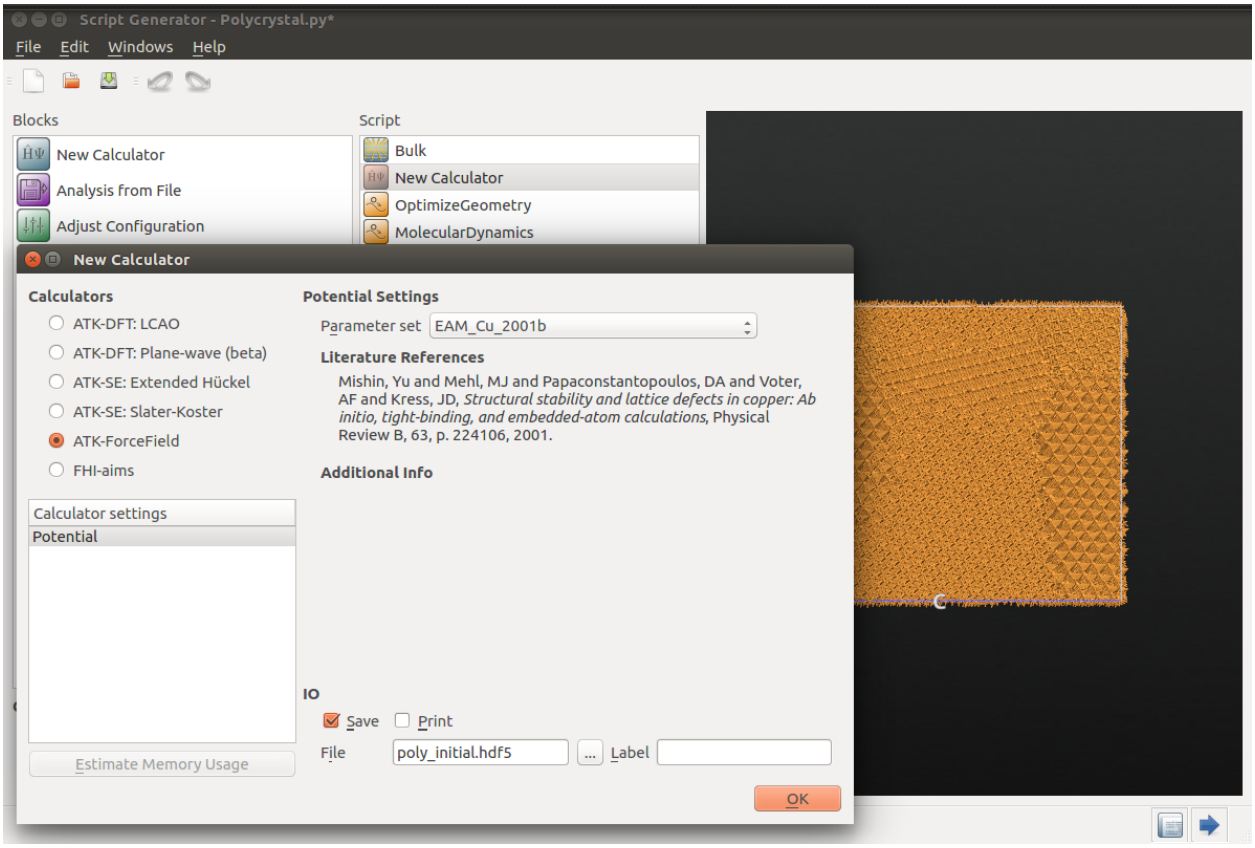
Note: The exact grain structure has been generated randomly and might be different from case to case.

Setting up the creep simulation

You will now set up the MD simulations; first equilibration and then the actual creep simulation. Send the bulk configuration from the **Builder** to the **Scripter**.

Add a **New Calculator** and open it (double-click). Select **ATK-ForceField** in the left panel; the suggested Embedded Atom Model (EAM) potential named *EAM_Cu_2001b*[2] is a suitable choice. Set the filename to `poly_initial.hdf5` to save the initial supercell in a separate HDF5 file – using separate data files can help organize the data. Uncheck the *Print* tick box at the bottom to not clutter the log file too much. Click *OK* to close the Calculator dialog.

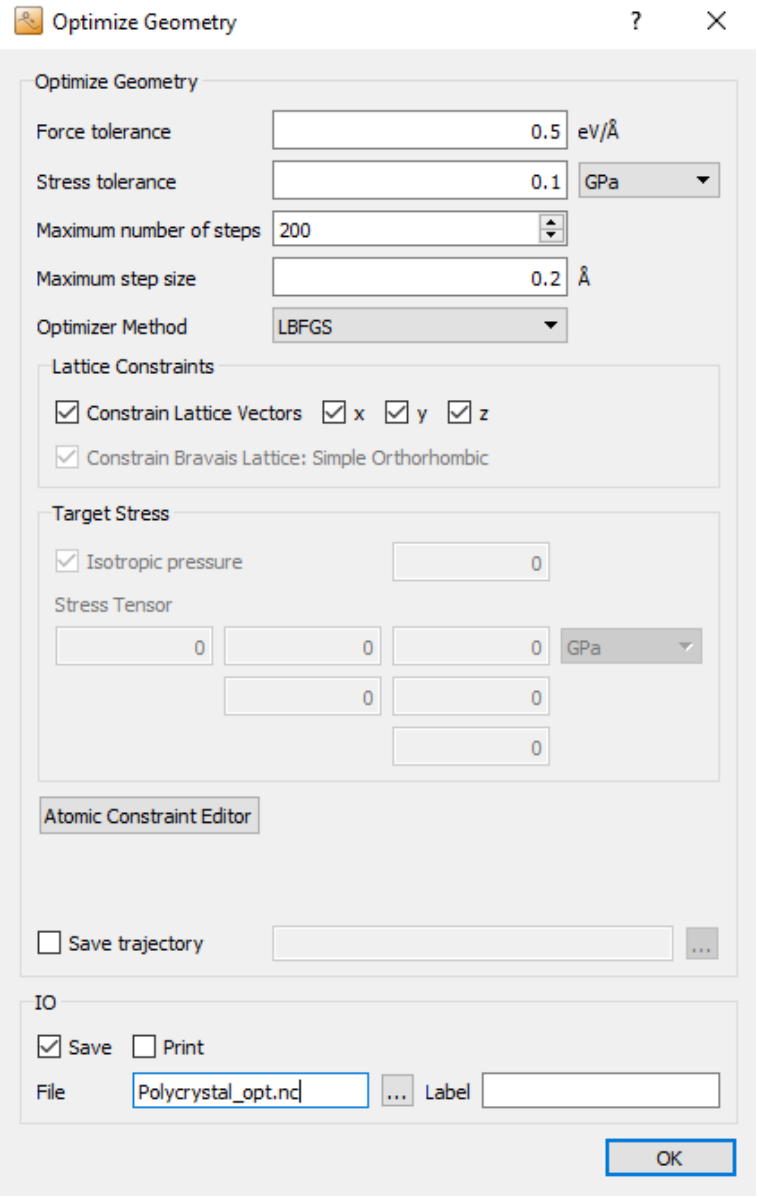
Note: For QuantumATK-versions older than 2017, the **ATK-ForceField** calculator can be found under the name **ATK-Classical**.



Next, add the **OptimizeGeometry** block (click *Optimize* → *OptimizeGeometry*). This step will remove possibly large inter-atomic forces due to the building procedure, before running the actual MD simulation. Double-click to open its settings. As we do not require a perfectly force-free structure, the force tolerance can be increased to 0.5 eV/Å, in

[2] Y.ăMishin, M.ăJ. Mehl, D.ăA. Papaconstantopoulos, A.ăF. Voter, and J.ăD. Kress. Structural stability and lattice defects in copper: Ab-initio, tight-binding, and embedded-atom calculations. *Phys. Rev. B*, 63:224106, May 2001. doi:10.1103/PhysRevB.63.224106.

order to speed up the calculation. The remaining parameters can be kept at their default values, although you could remove the checkmarks for *Save* and *Print*.

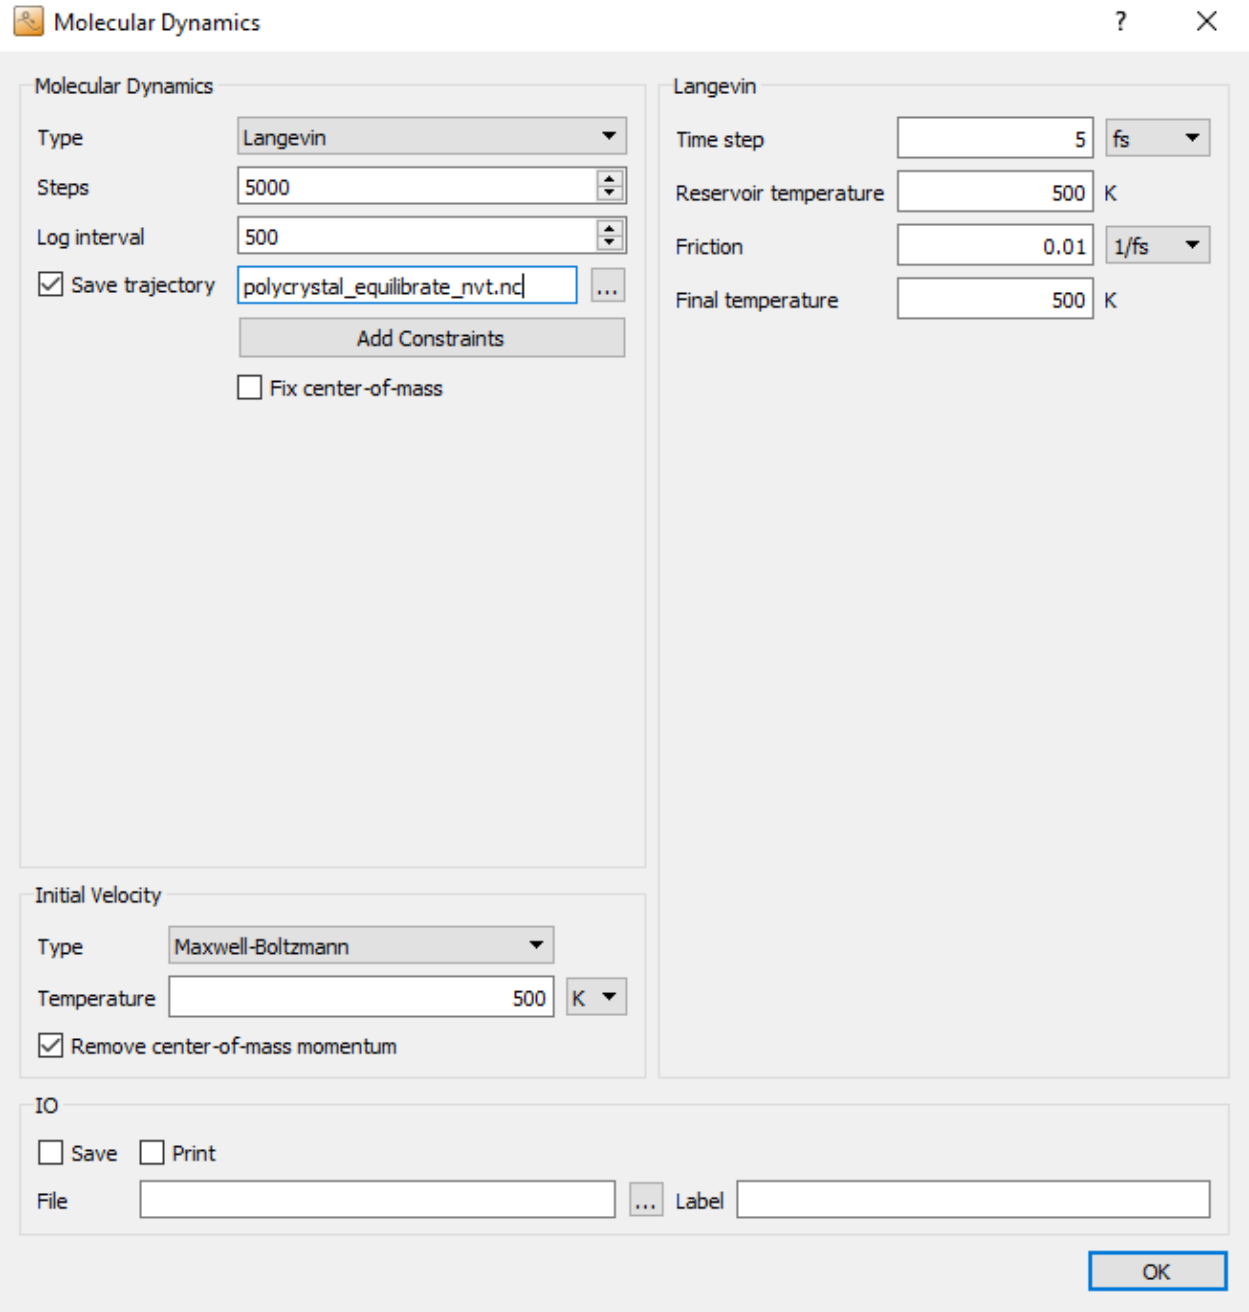


After the geometry optimization, you will want to run two short NVT (constant volume) and NPT (constant pressure) molecular dynamics simulations to get an equilibrated configuration. Therefore, add two **MolecularDynamics** blocks (click *Optimize* → *MolecularDynamics*). Later on, you will add one more MD block for the creep simulation.

In some cases, in particular if the initial configuration is far from equilibrium, directly starting with a constant pressure simulation can make the system to unstable and lead to unreasonable results. A safer approach is to equilibrate the system at constant volume first, before switching on the pressure coupling. To this aim, select Langevin for NVT simulation in the setting of the first MolecularDynamics block, choose the *Maxwell-Boltzmann* initial velocities at a *temperature* of 500 K. You can use a large *time step* of 5 fs for copper, as the atoms are quite heavy and thus the vibrational frequencies are small enough. Be aware, however, that a time step this large might in other cases affect the accuracy of the integration algorithms, so before simulating a new system one should carefully assess the chosen time step by monitoring the energy conservation in an NVE simulation at the desired temperature.

Set both the *reservoir temperature* and the *final temperature* to 500 K. We run the simulation at a slightly elevated temperature to accelerate possible thermally activated processes, to see at least the onset of the creep behaviour in a relatively short simulation time.

Save the trajectory to the file `polycrystal_equilibrate_nvt.hdf5`. Uncheck the *Save* and *Print* boxes at the bottom, as the trajectory is already being saved.

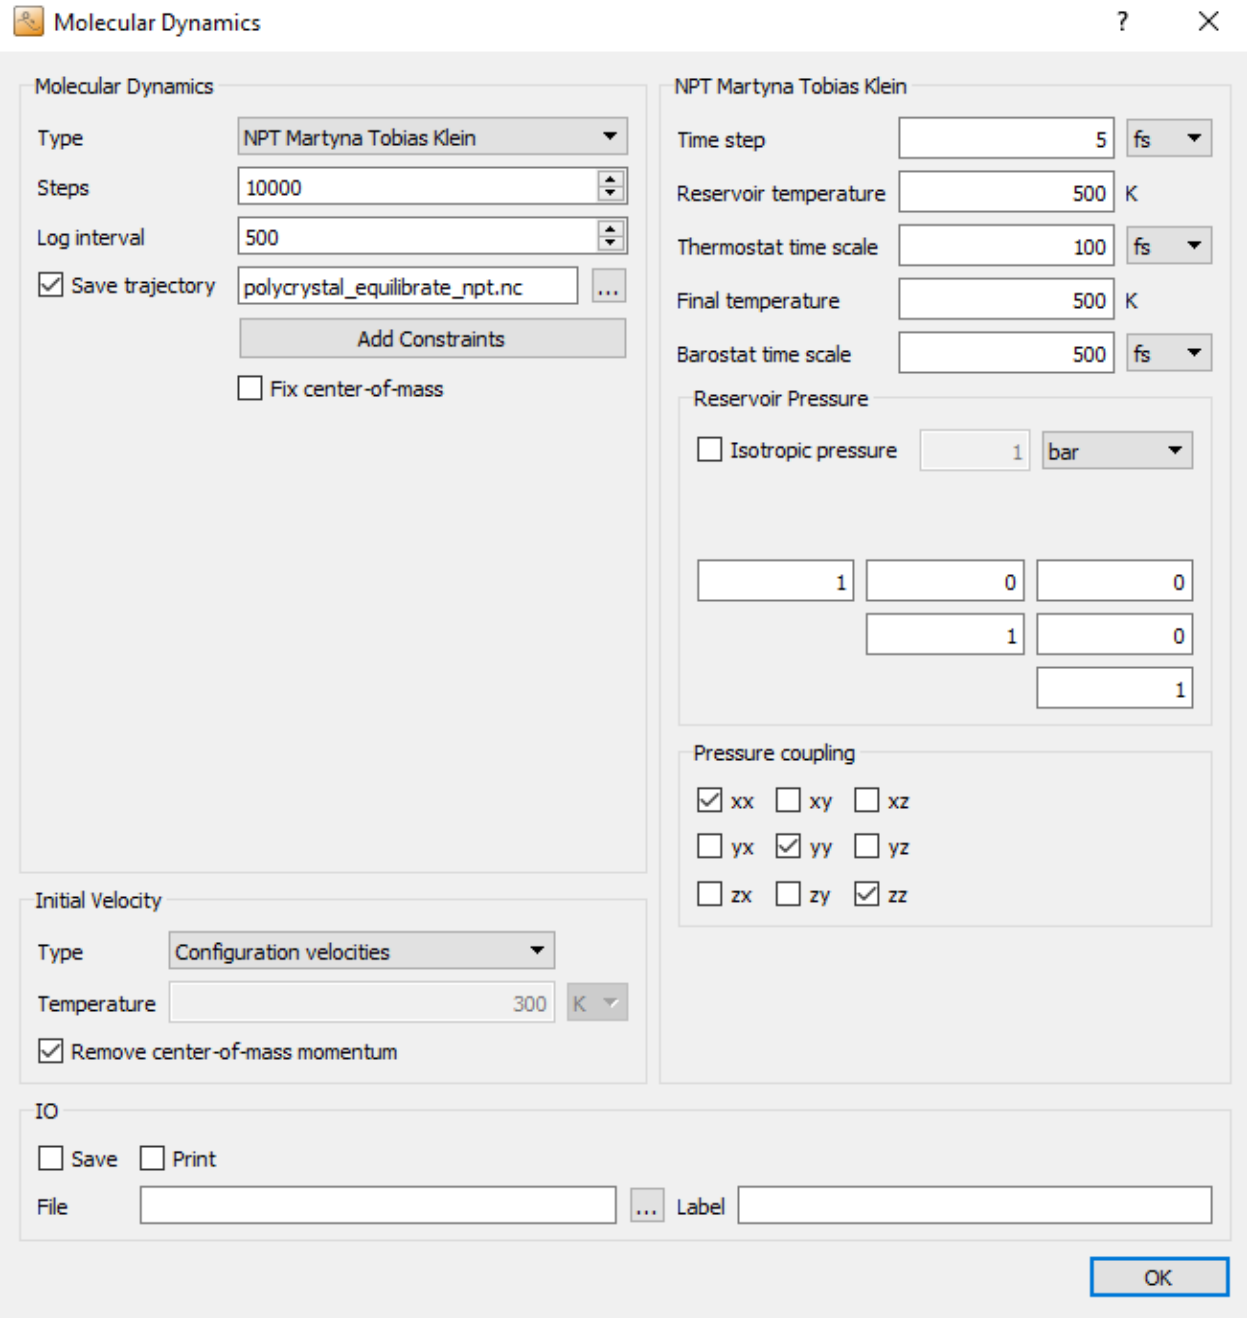


In the next **MolecularDynamics** block, you will perform another equilibration simulation, this time at constant pressure. Therefore, select *NPT Martyna Tobias Klein* MD type, as this method allows to impose an independent pressure coupling to each component of the stress tensor. Set the number of *steps* to 10,000 and the *log interval* to 500. Select an appropriate filename for the trajectory file, e.g. `polycrystal_equilibrate_npt.hdf5`.

Choose *Configuration velocities* as initial velocities.

Choose again a fairly large *time step* of 5 fs and 500 K for the *reservoir* and *final* temperatures. Moreover, make sure that the reservoir pressure is 1 bar.

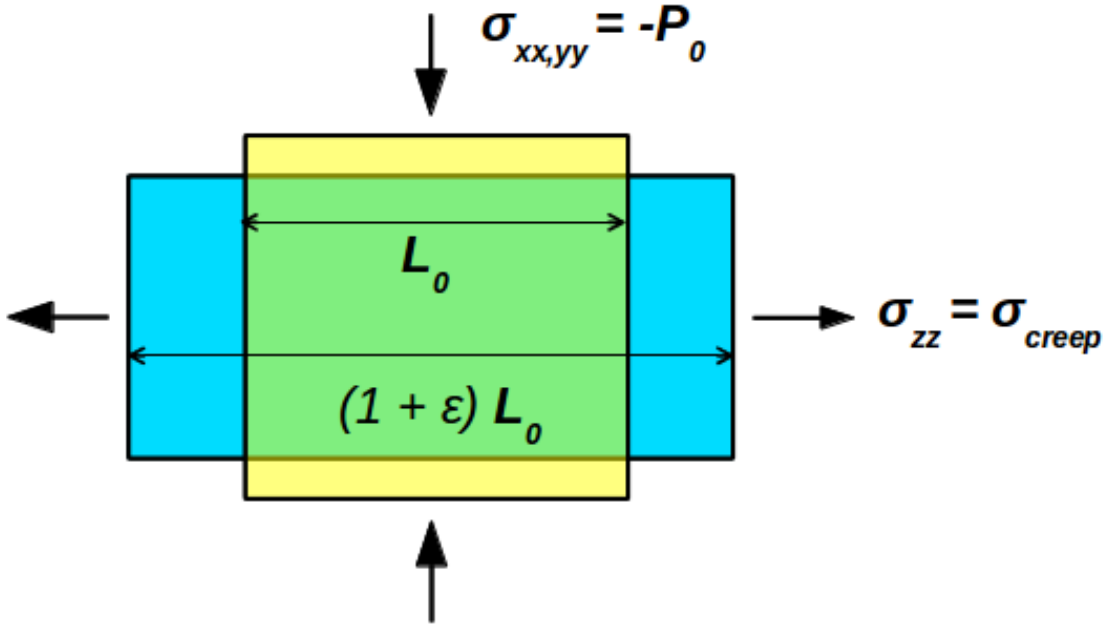
Uncheck **Isotropic pressure** to couple each cell vector independently to the barostat. In the field named *Pressure coupling* you can select which components of the stress tensor the barostat should couple to. Here, you should stick to the default settings, which activate only the hydrostatic stress, without any shear stress components.



Now, for the actual creep simulation, add a third **MolecularDynamics** block. Choose the same settings as in the previous (NPT) MD block, except for the *number of steps* and the *log interval*, which should be set to 40,000 and 250, respectively.

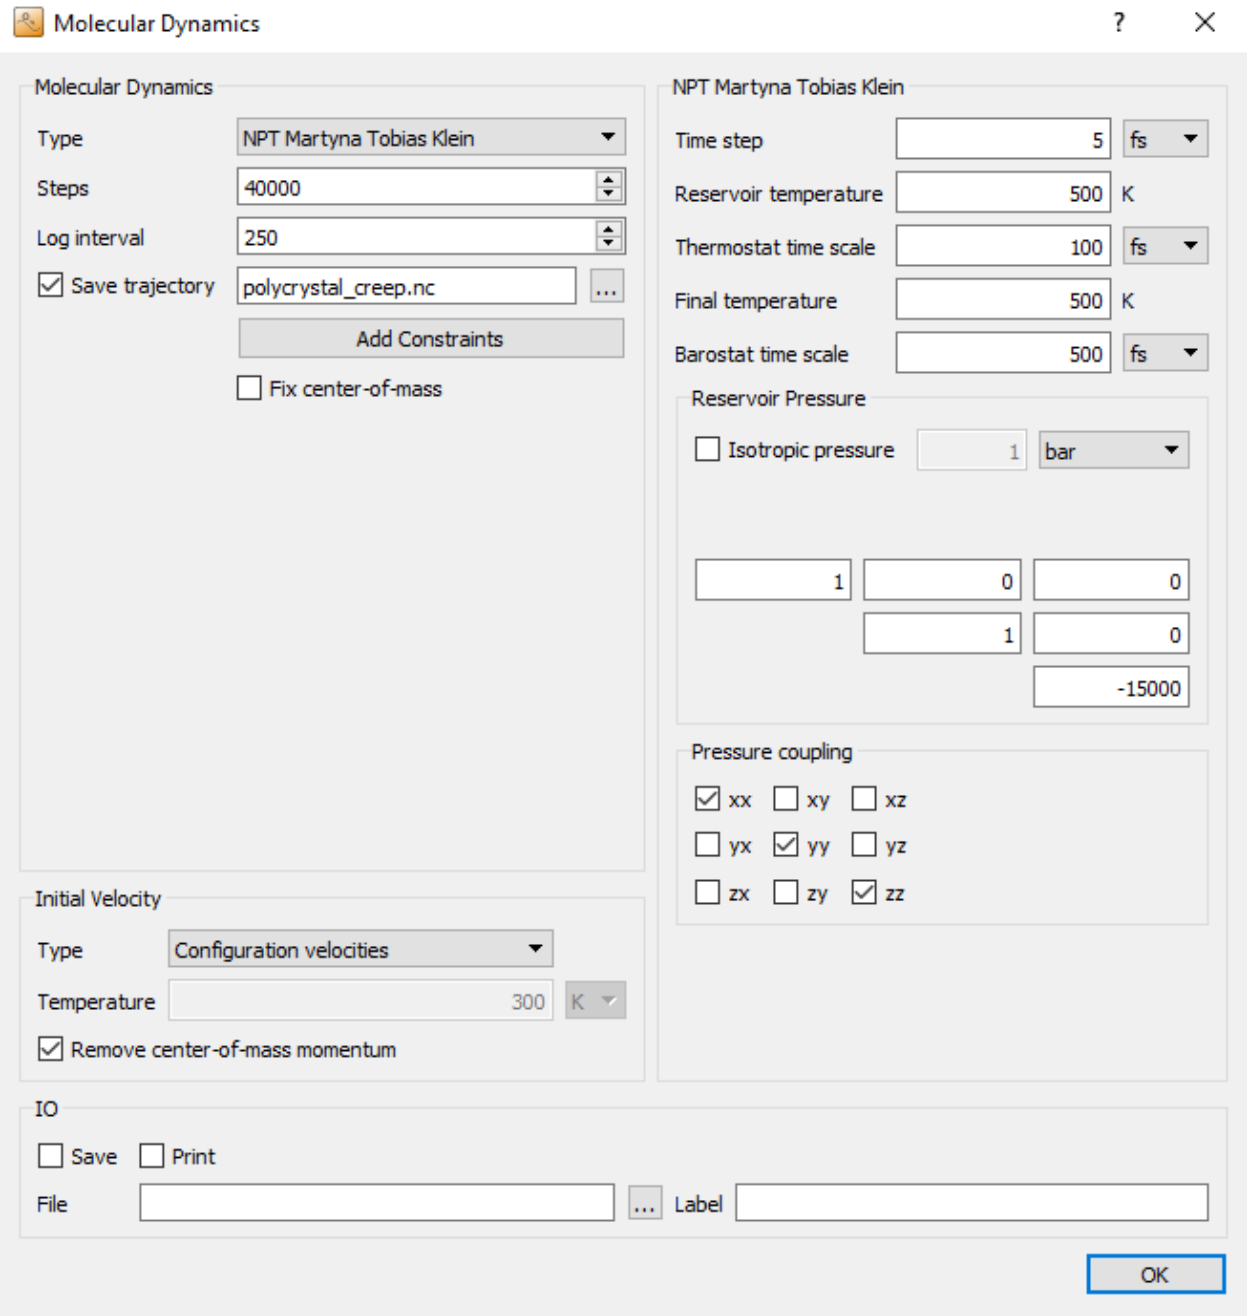
The essential point of a creep simulation is exposing the system to a large uniaxial stress σ_{creep} and monitoring the

strain response, as illustrated below:



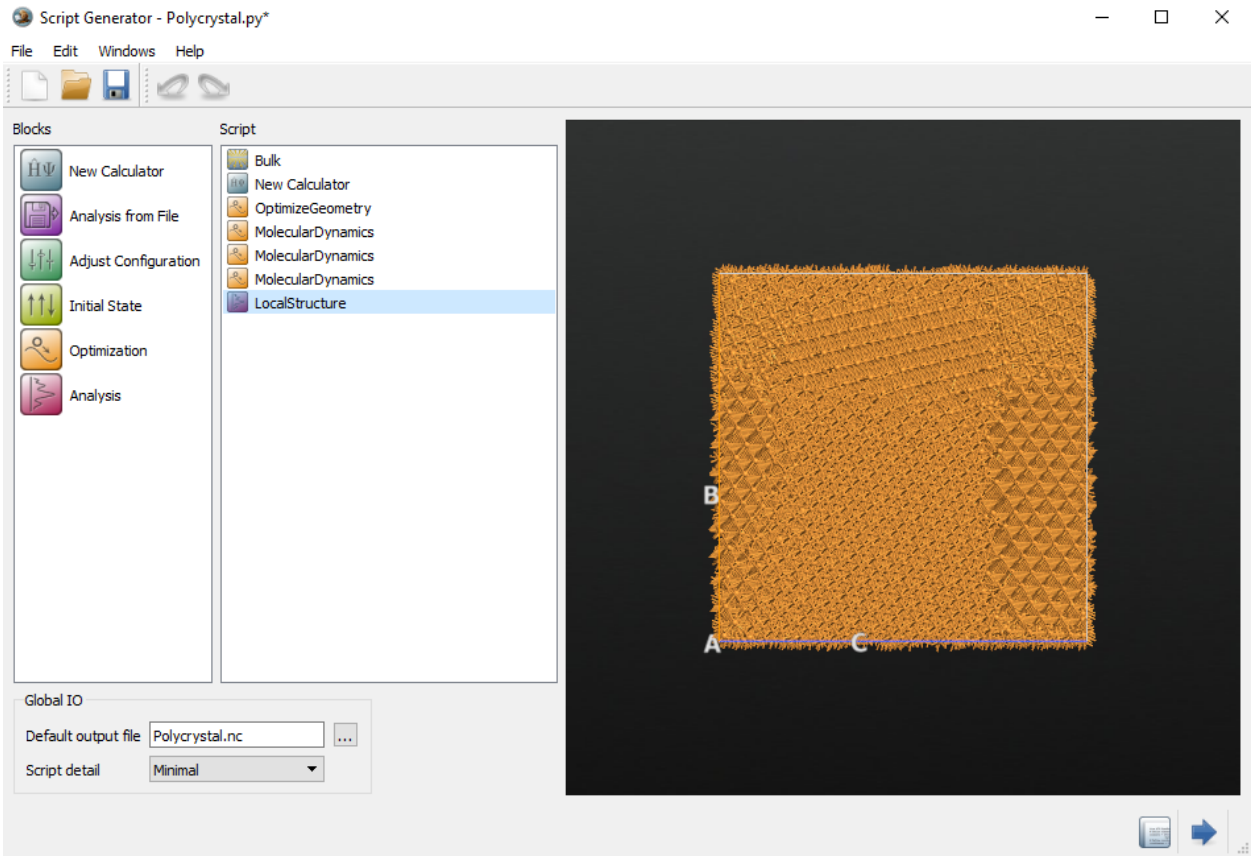
To this aim, you first need to uncheck the **Isotropic pressure** box, to achieve an independent pressure-coupling of the cell vectors. Then, you need to modfiy the Reservoir pressure tensor. The first two diagonal entries (xx and yy) define the ambient pressure perpendicular to the creep direction to allow for lateral relaxation, according the the poisson ratio of the material. For the actual creep stress, which is specified as the third diagonal entry (zz), we set a value of -15,000 bar, corresponding to -1.5 GPa. Note, that negative pressure values are interpreted as tensile external stress.

The off-diagonal entries denote the shear stresses (yz, zx, xy), which do not play a role here as we have de-ativated the coupling to these contributions.



Finally, add another **LocalStructure** analysis block in order to be able to analyze and visualize the final grain structure. Open the block and change the output filename to `local_structure_final.hdf5`.

The **Script Generator** should now look like below. Send the script to the **Editor** by using the botton.



Strain vs. time

A creep simulation is commonly analyzed in terms of the strain as a function of time, to measure the response to the imposed stress. To perform a similar analysis for our model simulation you have to add some more lines to bottom of the script you just produced.

These extra QuantumATK Python script lines are shown below and can be downloaded as a separate script: `analysis.py`. The relevant data (i.e. cell vectors, stress, potential energy) are extracted from the **md_trajectory** object by using the corresponding class methods. Plots of strain, stress and potential energy are then plotted using the pylab module, and saved as PNG files. This analysis can also be carried out separately, after loading a saved HDF5 trajectory using the **nlread()** function.

In the **Editor**, copy the analysis script lines into the bottom on the simulation script.

```
# ------------------------------------------------------------
# Custom Analysis
# ------------------------------------------------------------
md_trajectory = nlread('polycrystal_creep.nc')[-1]
# Extract the times, cell vectors, potential energies, and pressure tensors
times        = md_trajectory.times().inUnitsOf(picoSecond)
cell_vectors = md_trajectory.cells()
e_pot        = md_trajectory.potentialEnergies().inUnitsOf(eV)
pressure       = md_trajectory.pressureTensors().inUnitsOf(GPa)
# Convert the tensor elements into lists
strain_xx = cell_vectors[:, 0, 0]/cell_vectors[0, 0, 0] - 1.0
```

(continues on next page)

(continued from previous page)

```
strain_zz = cell_vectors[:, 2, 2]/cell_vectors[0, 2, 2] - 1.0
pressure_zz = pressure[:, 2, 2]
# Plot the data usig pylab
import pylab
# Plot the strain
pylab.figure()
pylab.plot(times,strain_zz,'b')
pylab.plot(times,strain_xx,'g')
pylab.title('Creep strain in Copper Polycrystal at 500K and a load of 1.5 GPa')
pylab.xlabel('MD time (ps)')
pylab.ylabel('Strain')
pylab.grid(True)
pylab.savefig("CreepStrain.png")
# Plot the pressure
pylab.figure()
pylab.plot(times,pressure_zz,'b')
pylab.title('Stress in Copper Polycrystal')
pylab.xlabel('MD time (ps)')
pylab.ylabel('Stress (GPa,bar)')
pylab.grid(True)
pylab.savefig("CreepStress.png")
# Plot the potential energy
pylab.figure()
pylab.plot(times,e_pot)
pylab.title('Potential energy during creep in copper polycrystal')
pylab.xlabel('MD time (ps)')
pylab.ylabel('Potential energy (eV)')
pylab.grid(True)
pylab.savefig("CreepEPot.png" )
```

Running the simulation

After editing the simulation script as desribed above, use the button to transfer the script to the **Job Manager**, then save the script as `run_polycrystal.py` and run it. The whole simulation takes approximately an hour, depending on your computing infrastructure, since the system is quite large (and yet small compared to the geometries studied in[Page 1241, 1]).

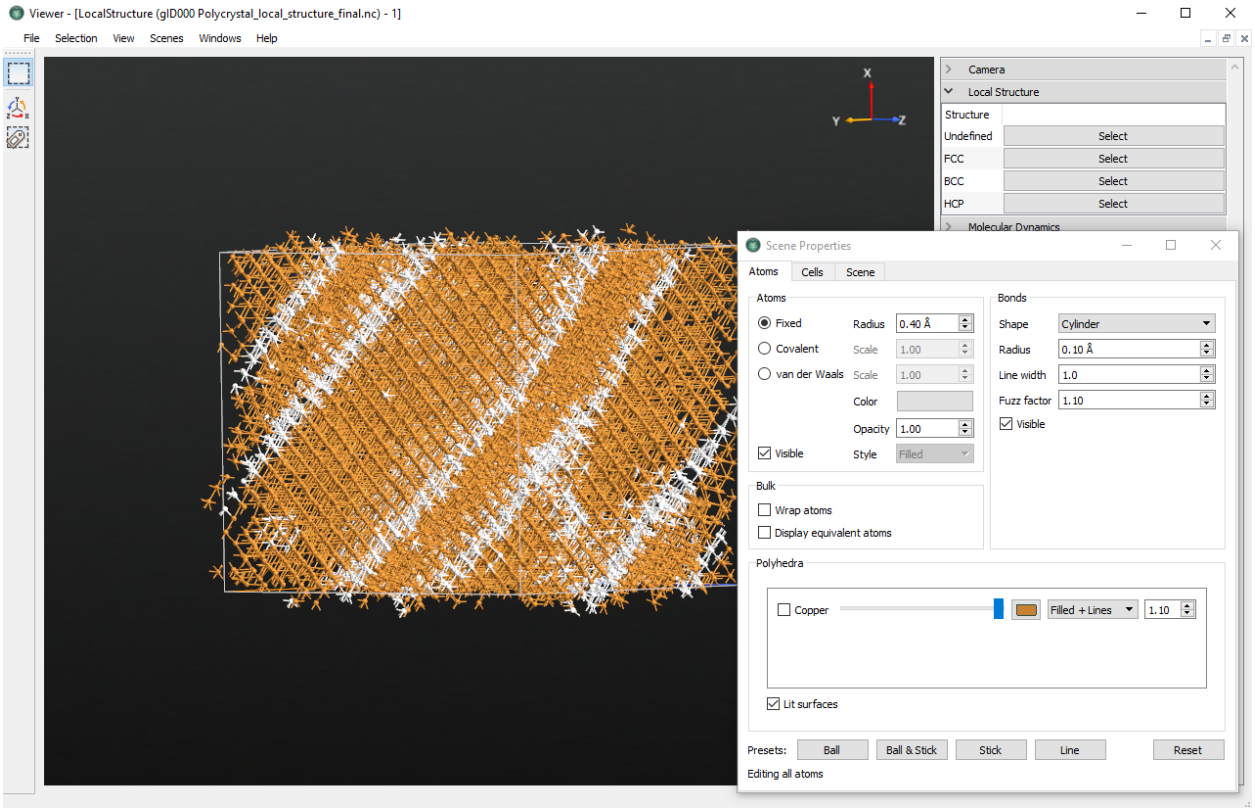
Analyzing the results

After the simulation has finished, let us at first take a look at the trajectory. Select the trajectory named `polycrystal_creep` on the **LabFloor** and open it using the **Movie Tool**. Start the movie by clicking the *Play* button.

You will immediately see an elongation of the simulation cell in the z-direction, accompanied by a slight compression in the perpendicular directions. The elongation proceeds as the simulation continues, but slows down. By rotating the cell with the right mouse button, you can identify the lattice planes of the grains – this allows you to get a visual impression of the grain dynamics.

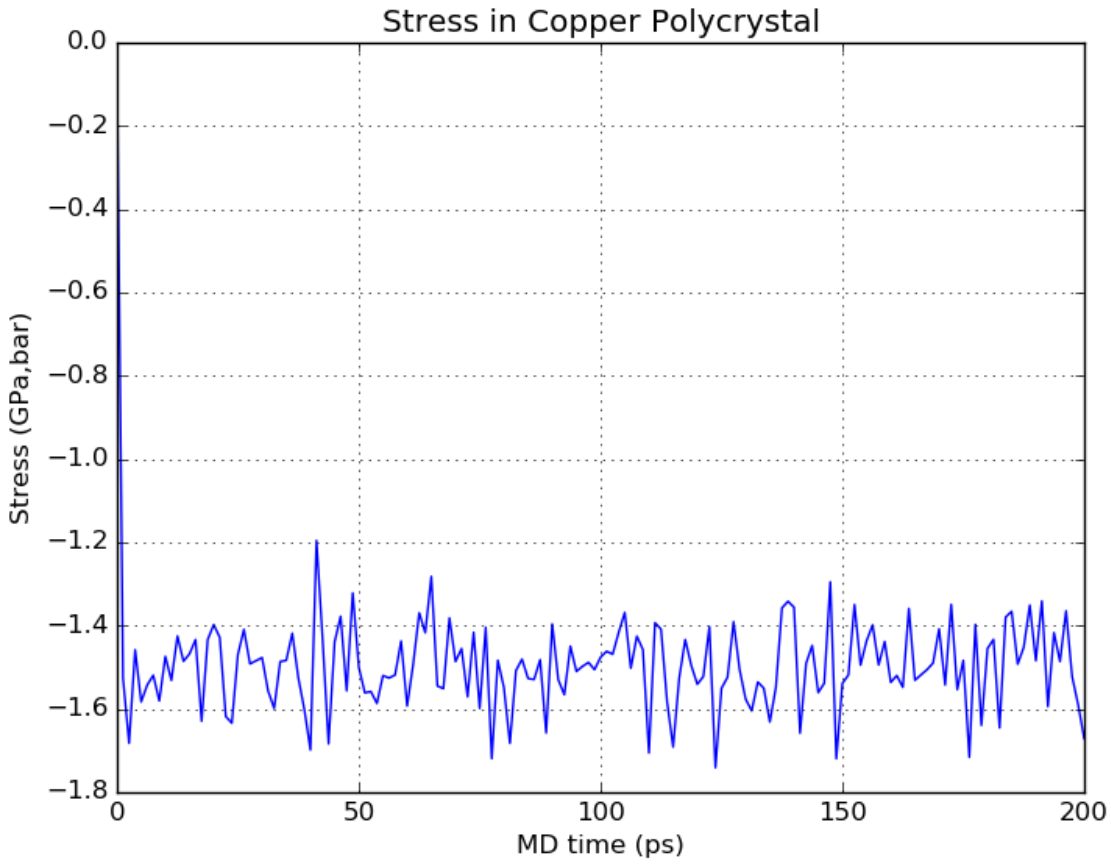
The final grain structure can be be analyzed in a more quantitative manner by using the **Viewer** to visualize the **LocalStructure** analysis item saved in the `local_structure_final.hdf5` file. Edit the coloring scheme just like

you did in the beginning of the tutorial. Probably (although it may depend on the initial structure) the major part of the cell has transformed into a planar grain, which extends across the periodic boundaries.



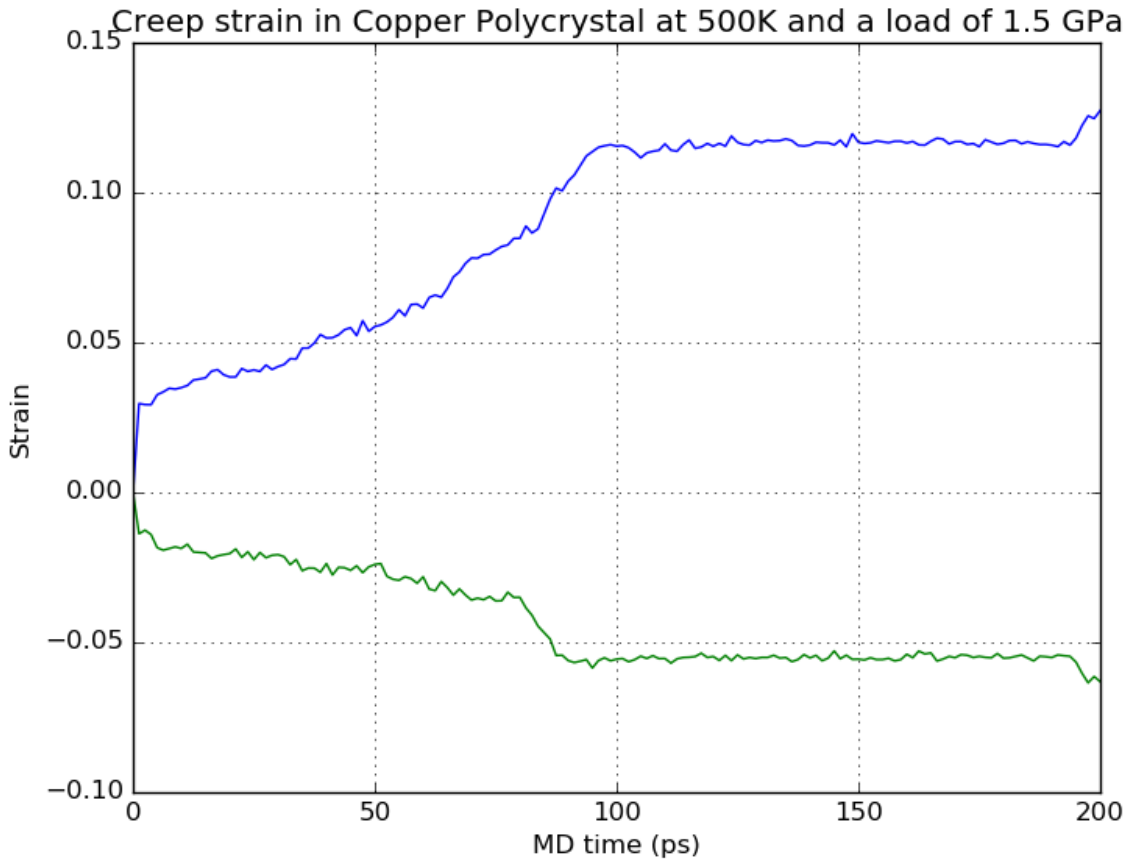
By rotating the cell, you will still see some grey regions, which are the remainders of the grain boundaries. The fast sliding and merging of the grains must be attributed to the small initial grain size, as this reduces the energy barrier upon changing their structure. The final structure appears locked by the periodic boundary conditions of the small cell, and little additional sliding to release energy is possible.

After the structural inspection you may want to have a look at the output observables, starting with the stress in the z-direction. The stress curve has been saved to the file `CreepStress.png`:



The graph shows that the stress oscillates at high frequency and stabilizes around the target value of -1.5 GPa. Generally, as long as the oscillations remain within reasonable bounds and do not increase in magnitude you dont have to worry about this behavior.

The time-dependent creep strain is plotted in the file `CreepStrain.png`. The curves denote the strain in the x (green) and z (blue) directions, respectively:

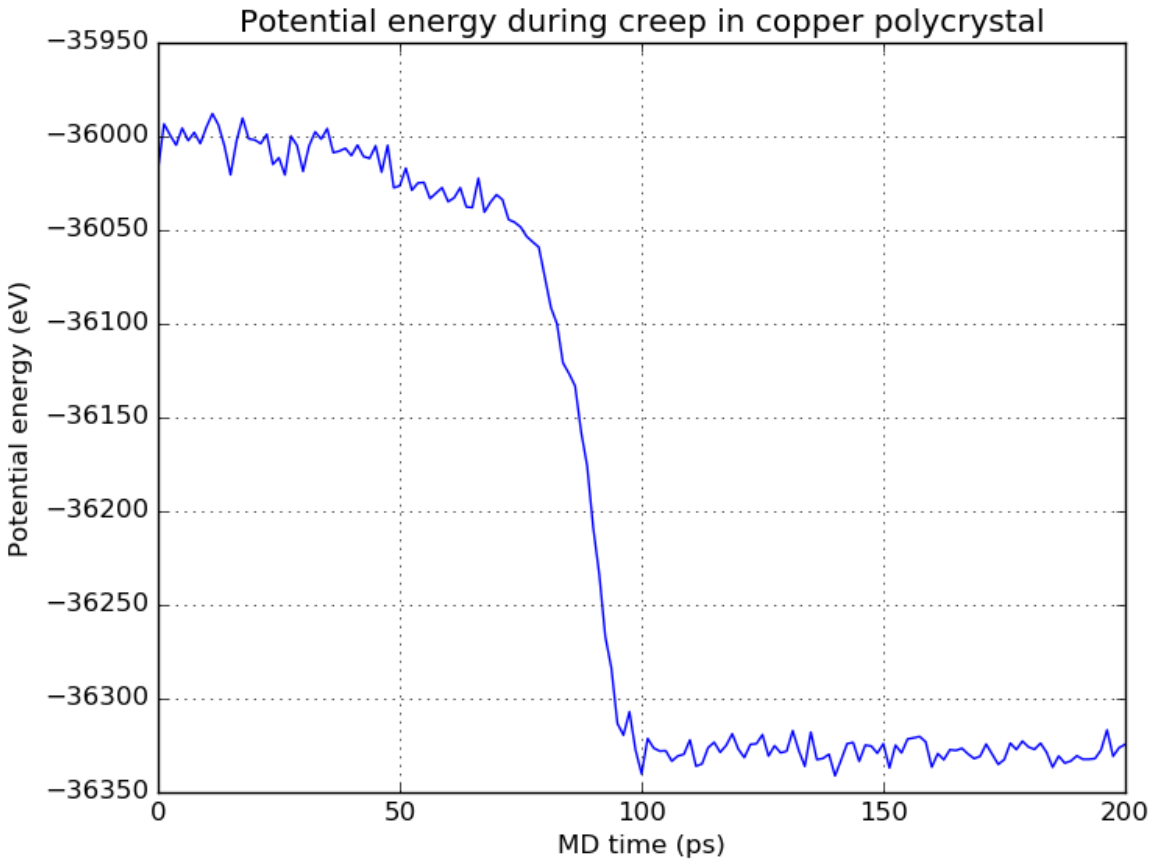


Although your example may look different from the results shown here (due to the random nature of the polycrystalline supercell building process) it should have some common features. In the beginning of the simulation a rapid increase of z-axis strain to about 2% is visible. This contribution arises from the immediate elastic deformation of the solid and it should be to a large extent reversible. Following that, a continuous – but much slower – increase in strain takes place. Here, the grain structure relaxes irreversibly by sliding and diffusion, or even structural transformation. Note that at around 90 ps a jump in the creep curve becomes visible, which must be attributed to a major (inelastic) structural rearrangement.

Important: Be aware that we are considering only the initial onset of creep behavior in a very small model system with very few grains and grain sizes in the order of less than one nanometer! The observed behavior might thus not be transferable in a straightforward way to real polycrystals with considerably larger grain sizes.

The elongation is accompanied by a transverse shrinking of the simulation box, as visualized by the x-strain, from which one can calculate the Poisson ratio of the polycrystal.

Finally, take a look at the time-dependent potential energy:



After the initial elastic deformation, which is of course accompanied by an increase of energy (it can be hard to see in the plot, it is very sudden), the creep process leads to a continuous decrease of potential energy caused by relaxation processes within the grain structure. As already observed in the creep strain, the same pronounced jump at 90 ps appears in the potential energy curve as well. From its magnitude, you can see that the corresponding relaxation process is accompanied by a large release of energy.

Outlook

Using the **Polycrystal Builder**, you can easily build huge polycrystal systems with a large number of grains. The following example shows a copper polycrystal of 300 x 300 x 300 $Å^3$. The system contains around 2.3 million atoms.

Simulations of such huge systems are perfectly possible with the **ATK- Classical** simulation engine, but will naturally take longer time, and one has to be careful with the size of the output files. The picture also nicely demonstrates the great graphical performance of QuantumATK – rotating and manipulating this crystal in 3D can be done completely fluently.

3.8.10 Metadynamics Simulation of Cu Vacancy Diffusion on Cu(111) - Using PLUMED

Version: W-2024.09

In this tutorial you will learn how to setup and run metadynamics simulations in **QuantumATK** using the `PlumedMetadynamics` class and the PLUMED plugin. It will cover setting up a simulation to explore the free-energy landscape associated with the diffusion of a Cu vacancy on Cu(111), how to set up a metadynamics calculation, and how to analyze the results.

Introduction

Metadynamics[1] is a powerful method based on molecular dynamics to explore multidimensional free energy surfaces (FESs). It allows one to reconstruct the FES of a system as a function of a number of collective variables (CVs) which are based on the microscopic coordinates of the system.

In metadynamics, an additional bias potential is added to the system at regular intervals during the simulation time. This allows the system to escape deep free-energy minima and overcome high-energy barriers, thereby exploring efficiently the entire free-energy surface. Within materials science, the method has been used to investigate crystal polymorphism, solid-liquid interfaces, and chemical reactions in solids and surfaces. Here, you will apply it to investigate the diffusion of a Cu vacancy on Cu(111).

QuantumATK implements metadynamics via the PLUMED plugin. In this tutorial, we will introduce the method briefly, explain how to setup a metadynamics script for the vacancy diffusion on Cu(111), and how to analyze the resulting free-energy surface.

For more information on the metadynamics method, you may look at Refs.[2] and[3].

Theoretical Background

In metadynamics, an external bias potential is constructed in the phase space of a few selected degrees of freedom, S, generally called collective variables (CVs)[Page 1257, 1]. S is a set of d functions of the microscopic coordinates R of the system.

$$S(R) = (S_1(R), ..., S_d(R)).$$

This potential is built as a sum of Gaussians deposited along the trajectory in the CVs space at time t. In its simplest version, the potential takes the form[2]

$$V(S,t) = \int_0^t dt' \frac{W}{\tau} \exp\left(-\sum_{i=1}^{d} \frac{(S_i(R) - S_i(R(t')))^2}{2\sigma_i^2} \right),$$

where τ is the Gaussian deposition stride, σ_i is the width of the Gaussian for the i-th CV, and W is the height of the Gaussian. The effect of the bias potential is to push the system away from local minima and allow it to visit new regions of the phase space.

Metadynamics Simulation of Cu Vacancy on Cu(111)

Creating a Vacancy on Cu(111)

To create the Cu vacancy on Cu(111), you first need to make a Cu(111) surface.

In the **Builder**, click on the in the **Stash** and select *From Database*. In the database dialog, ensure you are on the **Crystals** tab and search for *Copper*. Add Copper to the Builder stash by double-clicking on the row. Next, find the **Surface (Cleave)** plugin in the plugins panel, either by using the filter or manually finding it under the **Builders** category. To create the Cu(111) surface, open the plugin and use the following settings:

a. Set the Miller indices to $\langle 111 \rangle$.

b. Set the surface indices to $v_1 = (4, 0)$ and $v_2 = (2, 4)$.
