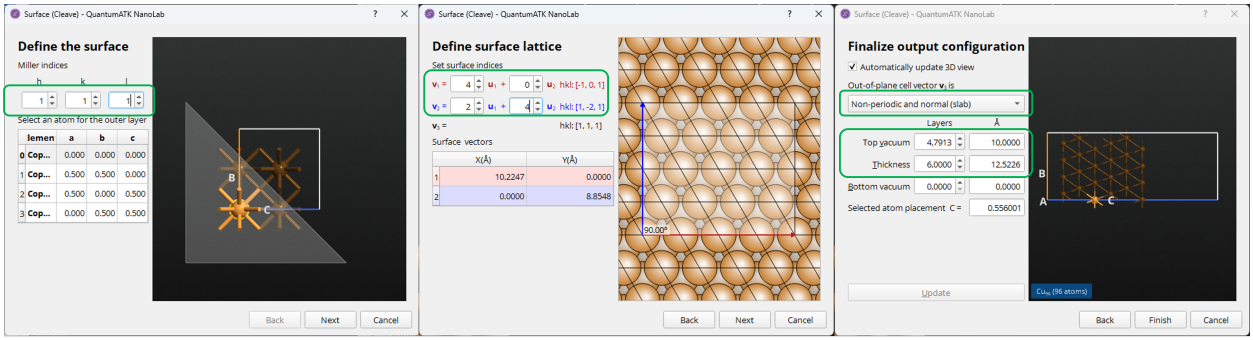
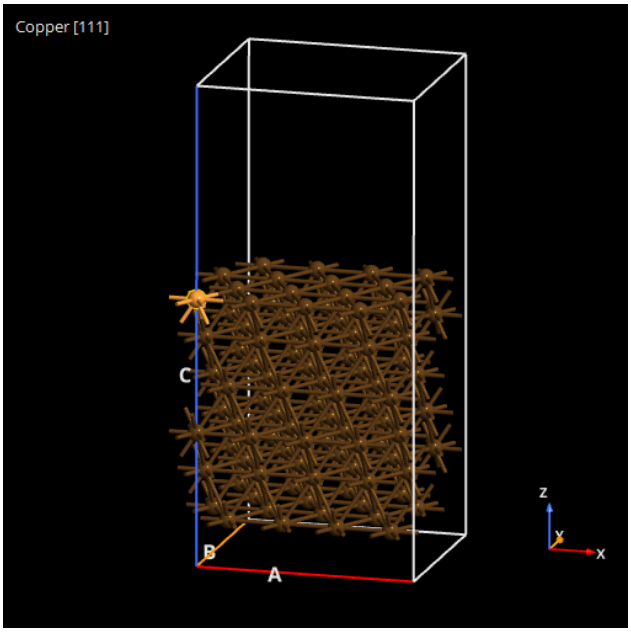
c. Set the out-of-plane cell vector as *Non-periodic and normal (slab)*, the thickness to six layers and the (top) vacuum gap to 10 Å.

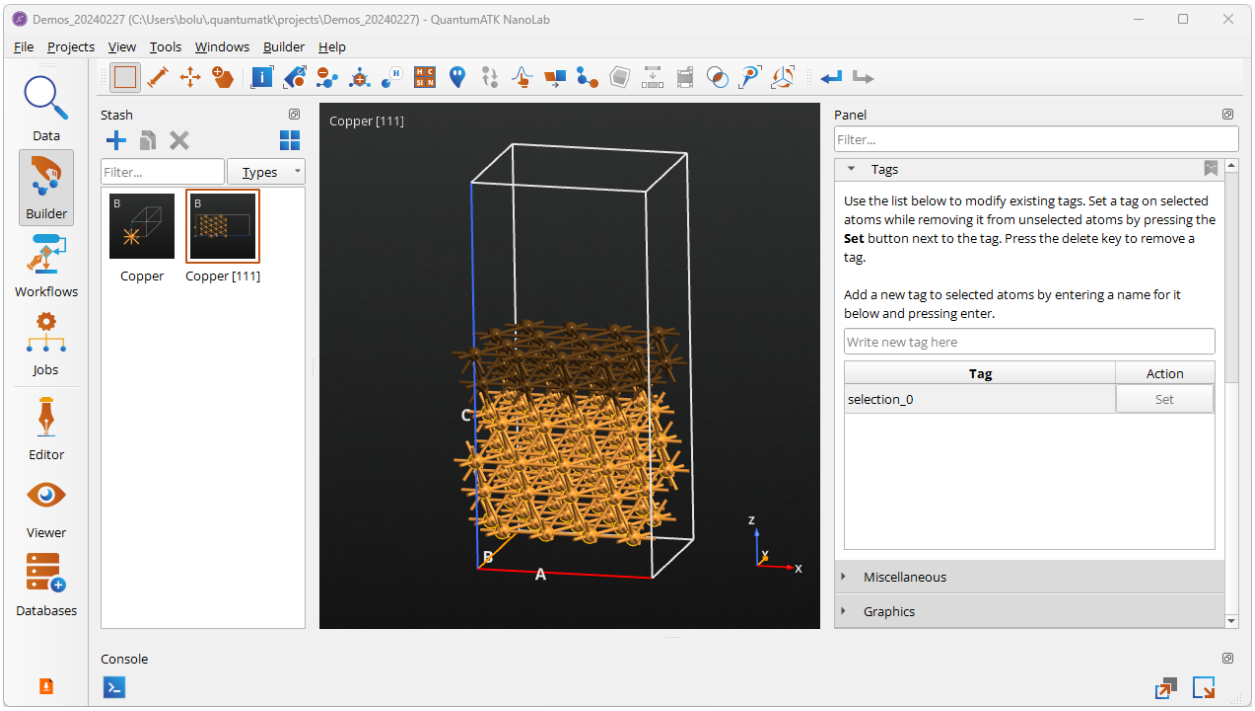


Next, create a vacancy by deleting the atom of the topmost layer with position $(x, y) = (0, 0)$ (shown highlighted in the figure below):



Finally, find the **Tags** plugin (**Selection Tools** category) and select the 4 lower-most Cu(111) layers. Add a new tag by entering a name, selection_0 or another name of your choosing, and hitting Enter. A successfully added tag will show

up in the list in the plugin and also be displayed in the tool-tip of any tagged atom. This tag will be used to fix them during the metadynamics simulation.



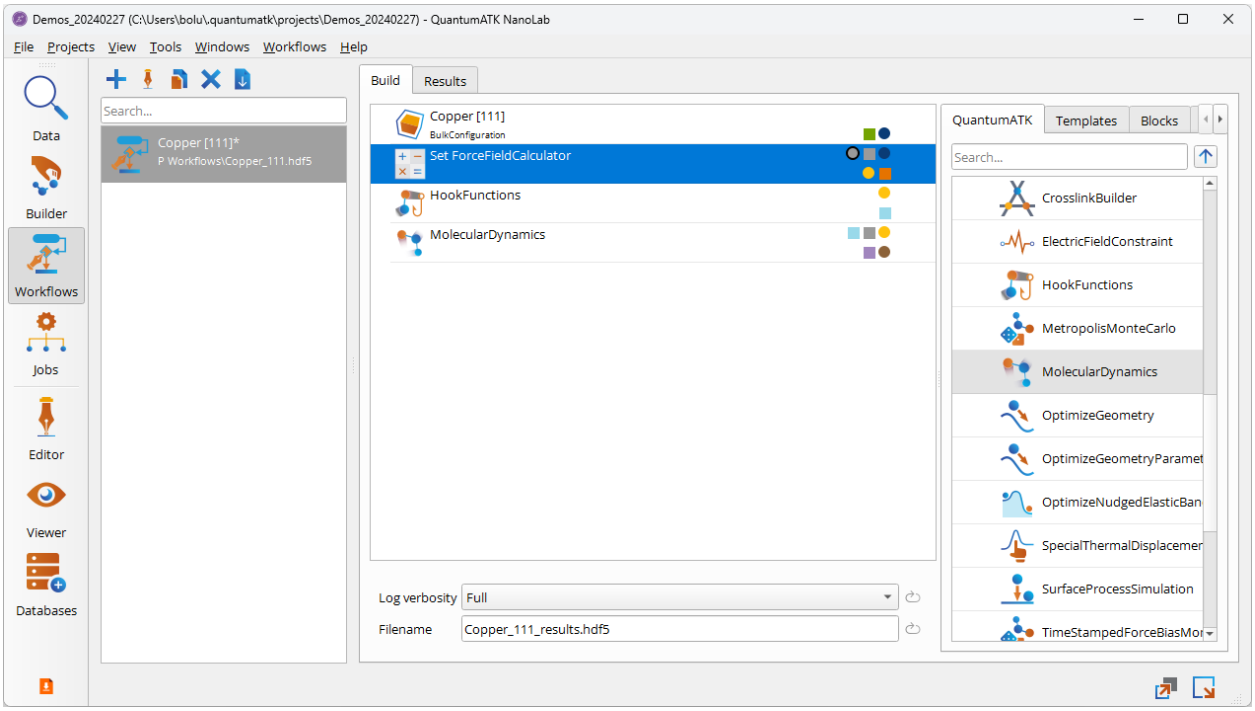
Now you are ready to create the workflow to perform the metadynamics simulation. Use the Send-to menu to send the structure to **Workflows**.

Creating the Metadynamics Workflow

Sending the configuration automatically creates a new workflow with the name of the configuration, and the configuration itself added in a Configurations block. To set up the remainder of the workflow, add the following blocks:

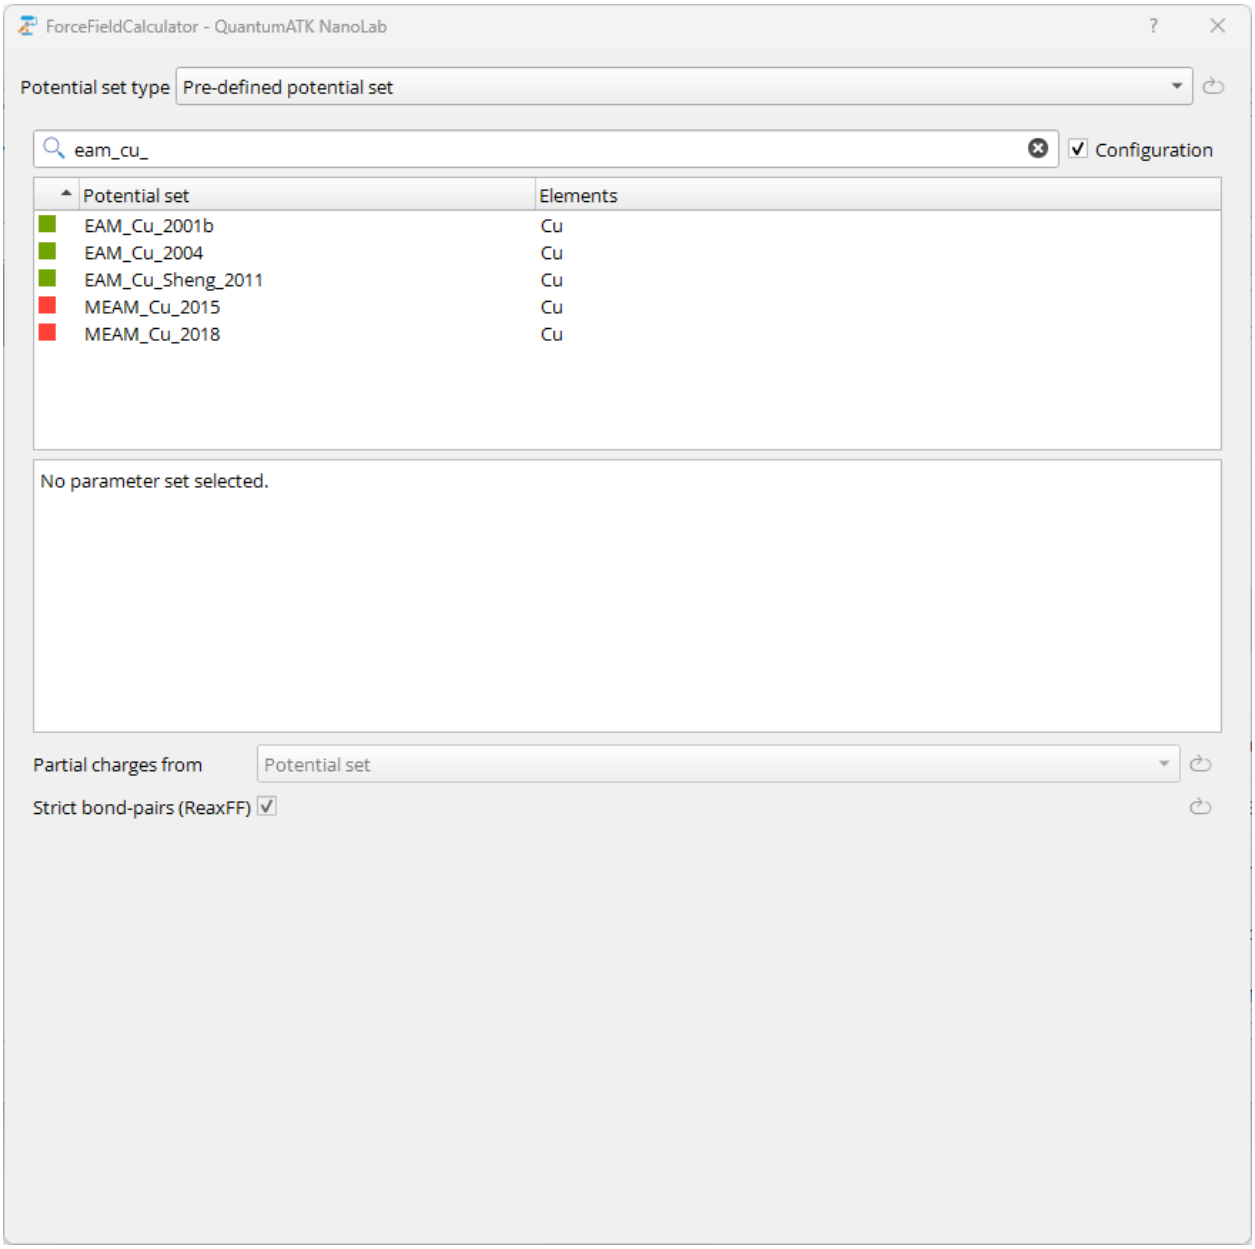
- *Calculators → Set ForceFieldCalculator*
- *Optimization and Dynamics → HookFunctions*
- *Optimization and Dynamics → MolecularDynamics*

Your workflow should now look like this:



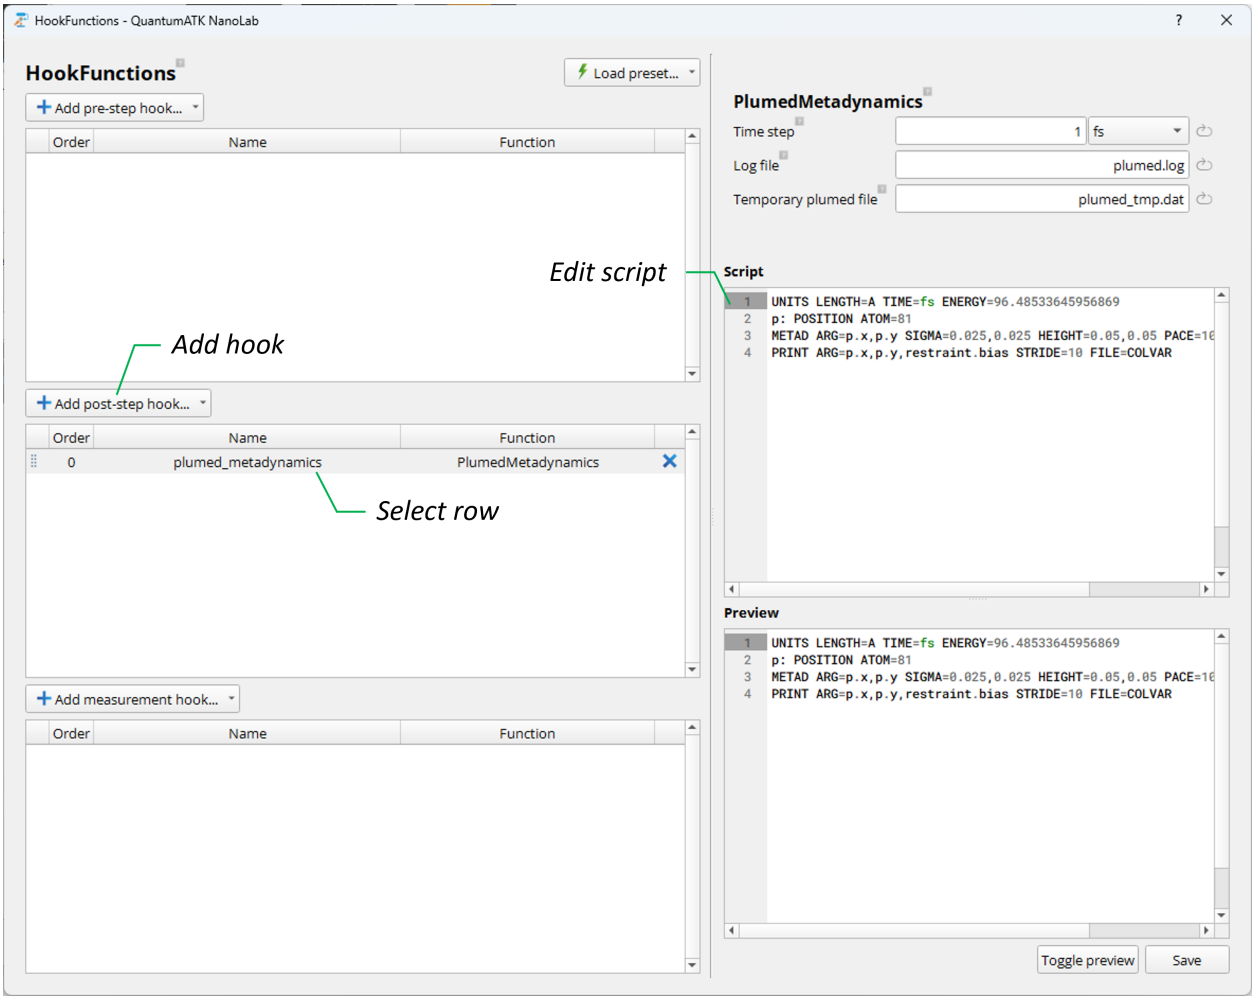
Next, double-click on each of the added blocks to edit them:

1. In the **Set ForceFieldCalculator** block, ensure that the **Potential set type** is set to Pre-defined potential set. Find and select EAM_Cu_2001b in the list of potential sets. To make it easier to find, use the search field to narrow down the list.



2. In the **HookFunctions** block, add a **PlumedMetadynamics** post-step hook. Click on the added row in the table to edit the hook settings. In the **Script** textbox, one can add any PLUMED[2] command. In this example we would like to add the following command:

```
UNITS LENGTH=A TIME=fs ENERGY=96.48533645956869
p: POSITION ATOM=81
METAD ARG=p.x,p.y SIGMA=0.025,0.025 HEIGHT=0.05,0.05 PACE=1000 LABEL=restraint
PRINT ARG=p.x,p.y,restraint.bias STRIDE=10 FILE=COLVAR
```



There are four command lines:

•`UNITS`: this line controls the units that will be used by PLUMED. Edit the lines as above, and the units of *Å*, *femtoseconds*, and *eV* will be used.

•p: This line is used to define the atoms, whose cartesian position should be used as collective variable. In this case, the atom with index 81.

Note: This value should be set according to the indexing used by PLUMED, where atom indexing starts from 1, and not from 0 as in **QuantumATK**. This value should therefore be set to *atom index* $+1$, where *atom index* is the index of the atom, which should be used in the collective variable.

We will look at the potential energy surface in the x- and y- axis using the Gaussian function of the *width* (0.025) and *height* (0.05) on each axis.

•`METAD`: This line controls the type of metadynamics and the shape of Gaussians functions that will be used during the simulations:

–`ARG`: this flag is used to set the collective variables. In this case, we will use as collective variables the position of the atom p along the Cartesian direction x $(p.x)$ and y $(p.y)$.

–`SIGMA`: this flag is used to set the value of the width of the Gaussian functions σ used for each collective variable. In this case, we will use $\sigma = 0.025$ for both collective variables.

–`HEIGHT`: this flag is used to set the height of the Gaussian functions used for each collective variable. In this case, we will use a height of 0.05 eV for both collective variables.

–`PACE`: this flag is used to set the intervals at which a new Gaussian function will be added. In this case, we will add a new Gaussian function every 1000 MD steps.

–`LABEL`: this flag is used to set the name of the collective variables.

•`PRINT`: This line controls the format of the PLUMED output.

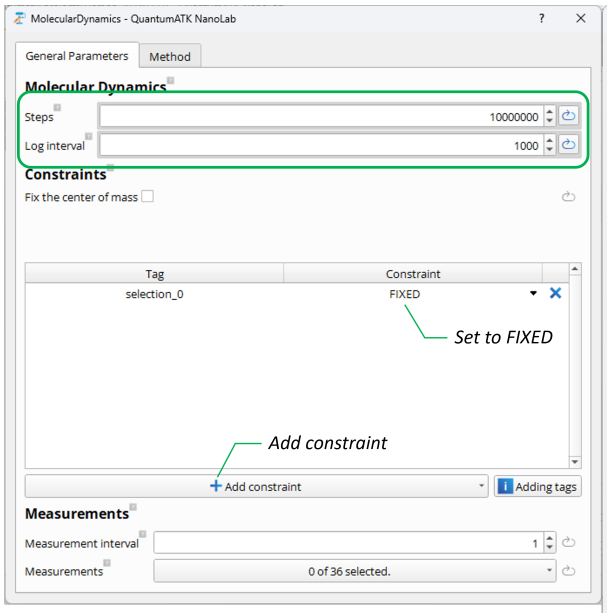
–`ARG`: this flag controls the variables that will be printed, in the present case $p.x$, $p.y$, and the bias.

–`STRIDE`: this indicates the printing interval. In the present case, 10 MD steps.

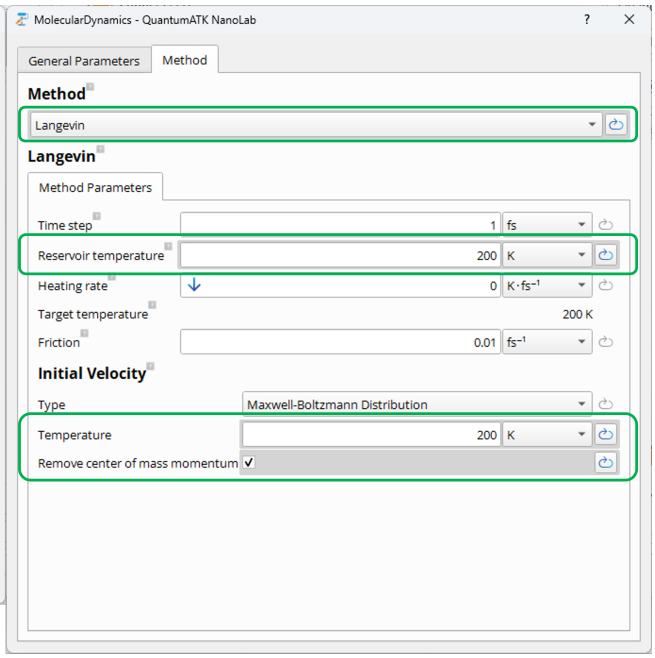
–`FILE`: this line indicates the name of the output file.

If you would like to know more detailed information, we recommend you to look in the PLUMED documentation. These commands are passed to the *`PlumedMetadynamics`* class. The latter is passed to the `MolecularDynamics` class using a **hook function**.

3. Open the **MolecularDynamics** block and set the simulation parameters on the two tabs as shown in the figures below. Also click on **Add constraint** and select for the previously added tag (by default, the tag is selection_0). Set the constraint type to *FIXED*.



a)



b)

For reference, the input files can be downloaded here:

•Worfklow `Cu111_vacancy_hopping.hdf5`

•Script `Cu111_vacancy_hopping.py`

Once you are done, send it to **Jobs** to run the simulation, which should take about 8 hours on 8 CPUs.

Analyzing the Results

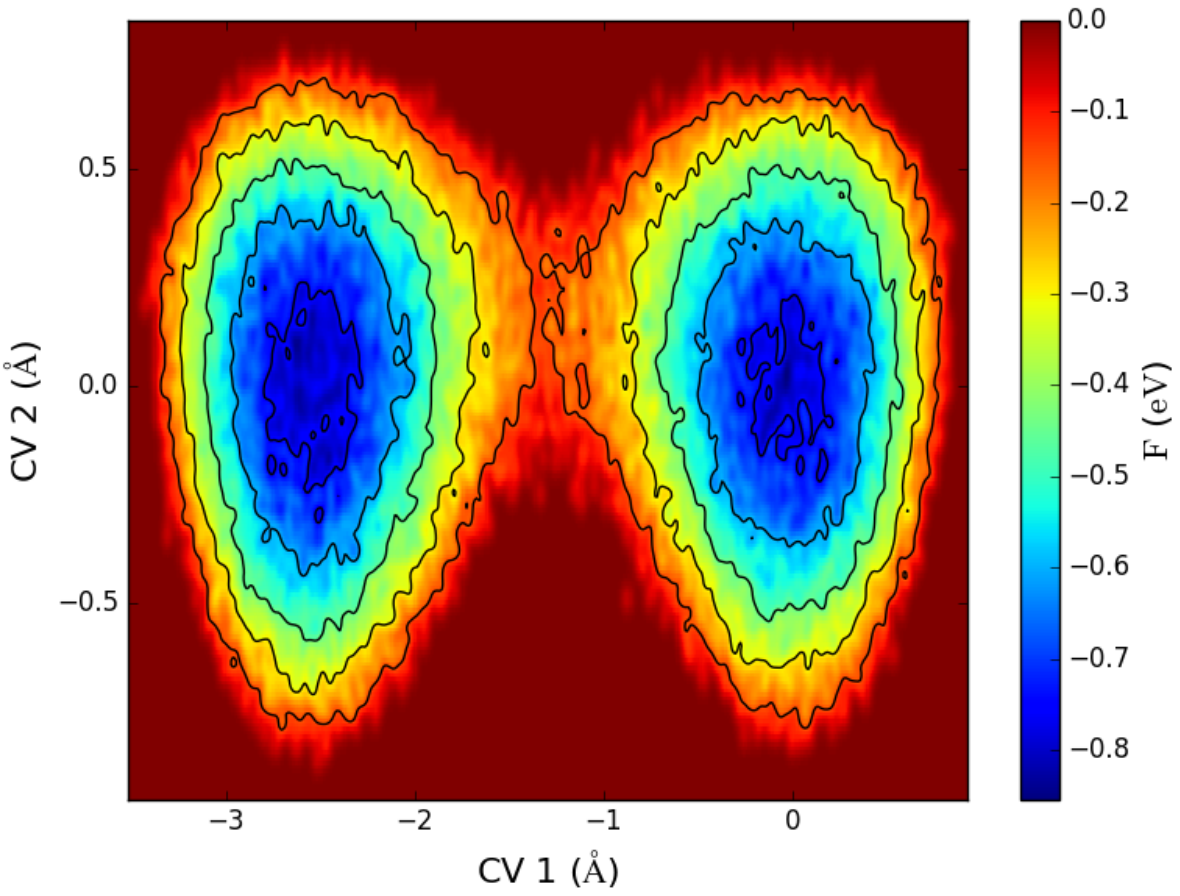
In addition to the standard **QuantumATK** output, at the end of the job you will obtain the files `COLVAR` and `HILLS`. These two files are the output of PLUMED and will be used to analyze the metadynamics simulation.

To plot the profile of the free energy F as a function of the collective variables CV 1 and CV 2, you first have to run the script `extract_F.py` as `atkpython extract_F.py`. Three output files will be produced:

- `F_vs_cv1.dat` contains the data for F vs. CV 1.
- `F_vs_cv2.dat` contains the data for F vs. CV 2.
- `F_vs_cv1_cv2.dat` contains the data for F vs. CV 1 and CV 2.

The map of the free energy profile F can be obtained by running the script `plot_F_vs_cv1_cv2.py` as:

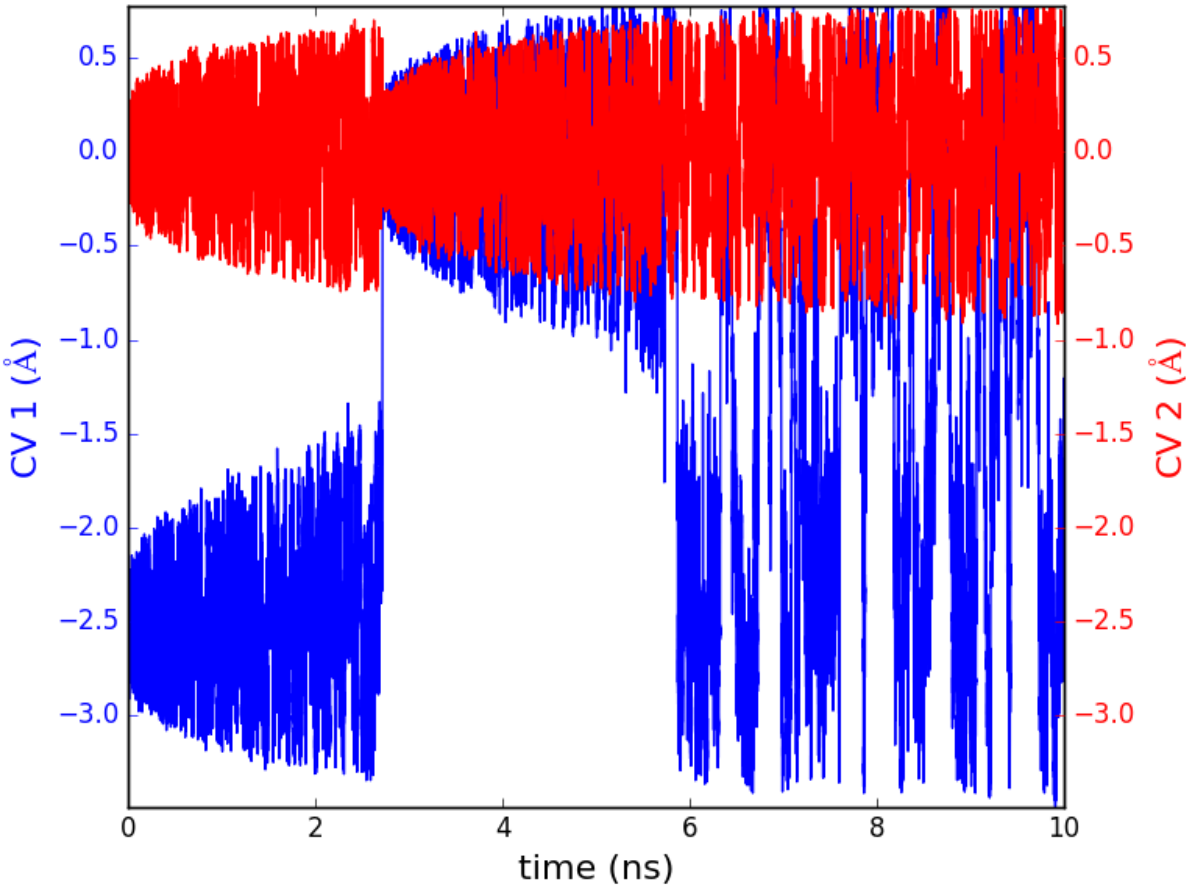
```
atkpython F_vs_cv1_cv2.py
```



The above plot shows a heat map of the free energy profile as a function of the collective variables CV 1 and CV 2. It can be seen that there are two minima on the free-energy surface, corresponding to the diffusion of the vacancy from one site to the neighboring one.

The evolution of the collective variables over the simulation time can be obtained by running the script `cv1_cv2_vs_time.py` as:

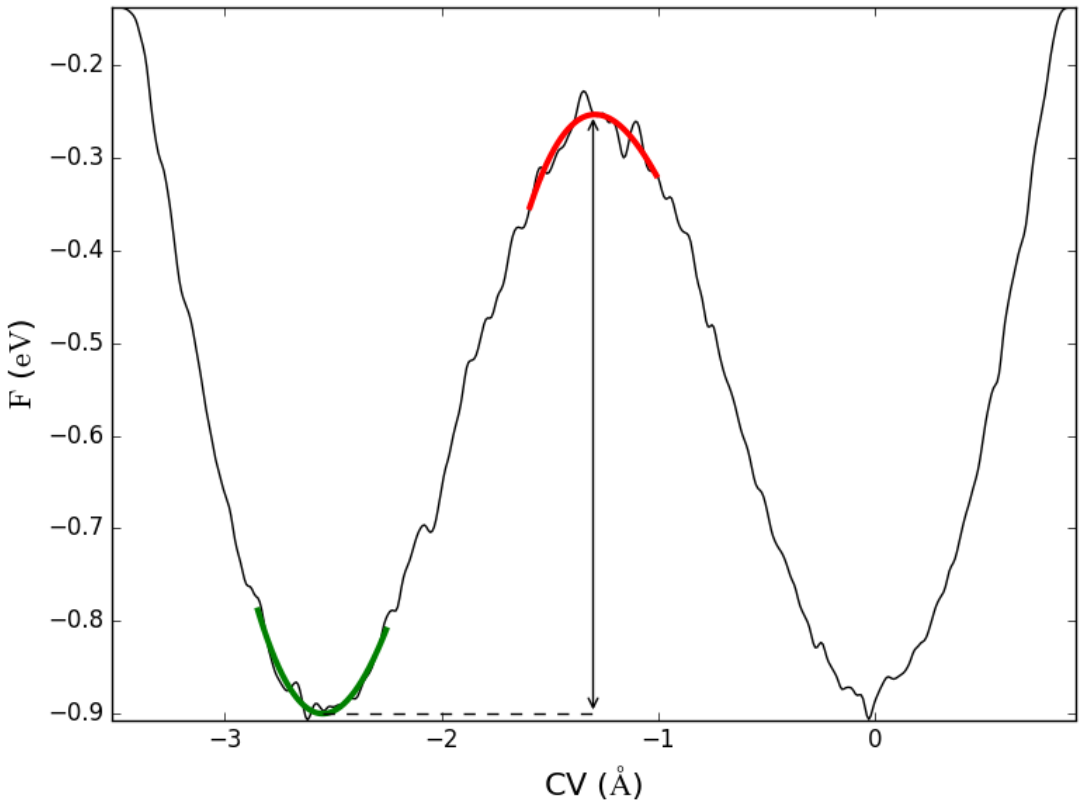
```
atkpython cv1_cv2_vs_time.py
```



The resulting plot shows the evolution of CV 1 (*red*) and CV 2 (*blue*) as a function of the simulation time. It can be seen that CV 2, which corresponds to the y Cartesian coordinate, oscillates around a constant value (CV 2 $= 0$), because both free energy minima occur at the same value of y. Conversely, the evolution of CV 1, which corresponds to the x Cartesian coordinate, indicates that the simulation starts in the minimum on the left (CV 1 $= -2.5$). The first minimum is filled until at approx. 2.2 *ns*, and then the system moves to the second minimum (CV 1$= 0$). After the second minimum is also filled, at around 6 *ns* the system oscillates with equivalent probabilities between the two minima, until the simulation is completed.

The free energy barrier can also be analyzed by running the script `barrier.py` as:

```
atkpython barrier.py
```



The results show that the barrier has a height of 0.647 *eV*, in good agreement with the results in[4].

3.8.11 Viscosity in liquids from molecular dynamics simulations

Version: P-2019.03

In this tutorial you will learn how to calculate the viscosity of different liquids using molecular dynamics (MD) simulations using the example of liquid methanol. Understanding viscosity is critical in designing a number of industrial chemical processes, as viscosity gives a description of how the liquid flows. This tutorial demonstrates how you can use the QuantumATK tools to simulate the viscosity of a simple fluid. This methodology can be applied to much more complicated fluids as well as mixtures.

To simulate the behavior of liquid methanol we use classical molecular dynamics to generate trajectories of the motion of molecules. These trajectories give the information necessary to statistically calculate the overall properties of the liquid. This tutorial also demonstrates how to set up and use specific bonded forcefields that have been created for these types of molecular problems.

Theory

Molecular viscosity

Viscosity is a measure of the friction between molecules passing each other in the fluid. There are a number of ways of estimating this friction[1], but one that is commonly used is the Einstein relationship where the viscosity η can be stated as[2]:

$$\eta = \lim_{t\to\infty} \frac{V}{2tk_BT} \left\langle \left(\int_0^t \tau_{\alpha\beta}(t')dt' \right)^2 \right\rangle$$

Here the quantities being integrated are the off-diagonal elements of the pressure tensor. The labels α and β refer to these elements. The other quanities represented here are time t, temperature T, volume V, and the Boltzmann constant k_B.

An alternative method for calculating the viscosity is through the Green-Kubo relation[3]:

$$\eta = \frac{V}{k_BT} \int_0^\infty \langle \tau_{\alpha\beta}(t_0)\tau_{\alpha\beta}(t) \rangle \, dt$$

Here the quantity in the angle brackets is the autocorrelation function of the pressure tensor. As this auto-correlation function decays to zero at long timescales, the integral converges to give the fluid viscosity.

[1] B. Hess: Determining the shear viscosity of model liquids from molecular dynamics simulations. J. Chem. Phys. 116, 209 (2016)

[2] S. H. Jamali, R. Hartkamp, C. Bardas, J. Sohl, T. J. H. Vlugt, O. A. Moultos: Shear viscosity computed from the finite-size effects of self-diffusivity in equilibrium molecular dynamics. J. Chem. Theory. Comput. 14, 5959 (2018)

[3] D. Gonzalez-Salgado, C. Vega: A new intermolecular potential for simulations of methanol: The OPLS/2016 model. J. Chem. Phys. 145, 034508 (2016)

Both of these equations may produce similar results. For a trajectory with a large number of data points, the Green-Kubo expression can become computationally expensive. Calculating the autocorrelation function scales as $O(N^2)$ where N is the number of data points. The Einstein relationship scales as only $O(N)$. As calculating viscosity requires looking at a large number of data points, the focus will be placed on the Einstein relationship.

The pressure tensor itself is made up of contributions both from the motion of the atoms and also from how the atoms interact with the boundary conditions in the simulation. The pressure tensor can be given as:

$$\tau_{\alpha\beta} = \sum_i m_i v_{i,\alpha} v_{i,\beta} - \frac{dE}{d\varepsilon_{\alpha\beta}}$$

Here m_i references the mass of atom i, $v_{i,\alpha}$ references the velocity of the atom i in the cartesian direction α and E is the energy of the system which is being differentiated with respect to the strain $\varepsilon_{\alpha\beta}$

Force fields

Classical force fields work by replacing the computationally expensive calculation of electronic structure with simple functions designed to approximate the overall energy. This approach enables the effective simulation of much larger systems, well beyond what is possible with electronic structure calculations. One of the main challenges in this approach is fitting parameters for the replacement functions so they can accurately predict the energy.

One approach is to divide molecules up into a number of chemical types. Specific parameters can then be found for different types of interactions using these types. As an example, an sp^3 carbon in ethane will have different associated potentials to an sp^2 carbon in a benzene ring. As several combinations will be excluded based on how the types are defined, this limits the number of parameters that need to be found. Because parameters are fitted for specific atomic types and functions, these types of potentials can often be more accurate. As a trade-off these potentials are often more difficult to set up, as the chemical types for each atom need to be assigned for the structure. Potentials of this type also cannot model reactions, as the atom connectivity is needed to determine the chemical type.

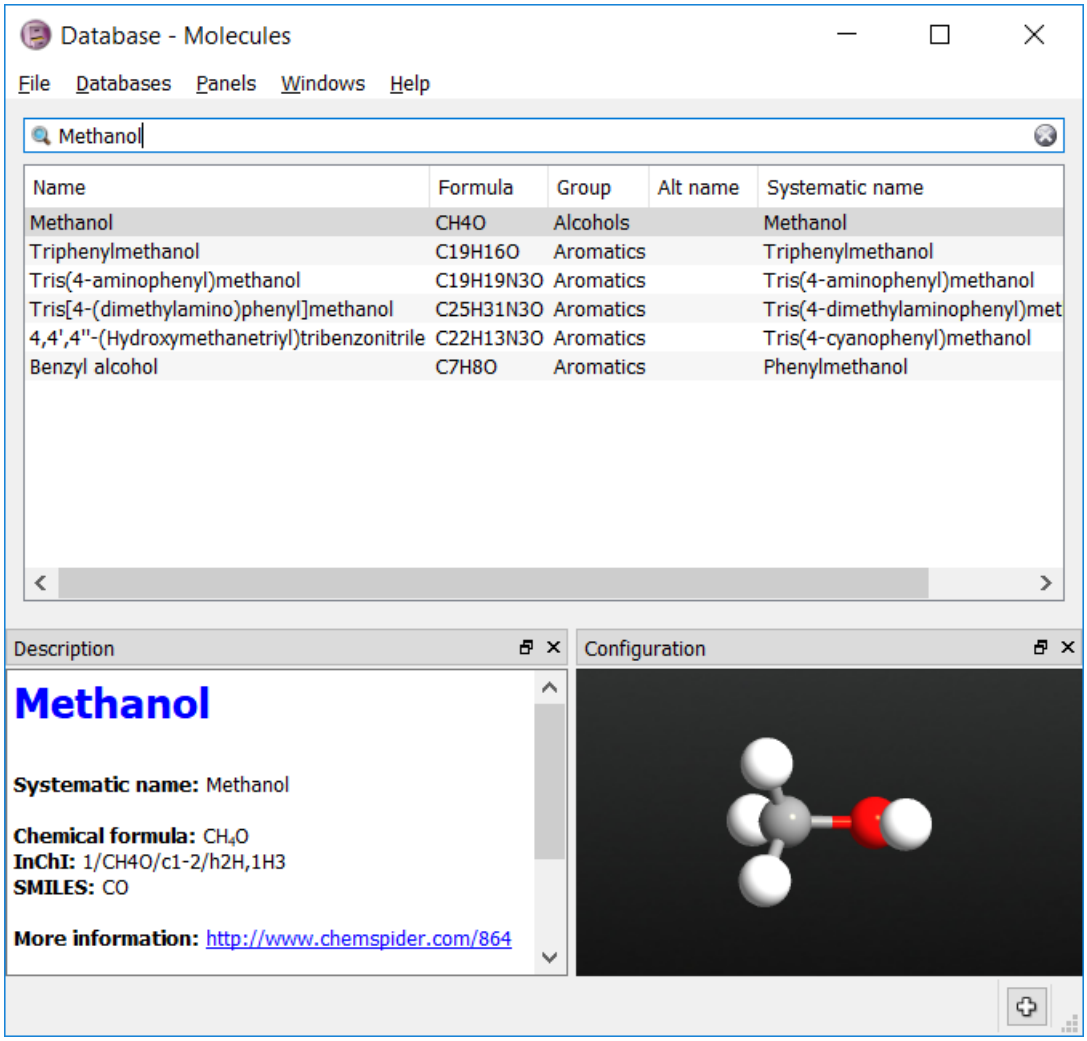
In this tutorial you will use the OPLS-AA forcefield to model methanol[4]. The OPLS-AA forcefield uses atom types with specifically fitted potentials for those types. This tutorial covers how to set up calculations using these types of forcefields.

Computational procedure

Building the initial methanol configuration

Open the **Builder** and select *Add* → *From Database*. Add the molecular structure of methanol from Database to the **Stash**, making sure to choose the molecule database by selecting *Databases* → *Molecules*.

[4] W. L. Jorgensen, D. S. Maxwell, J. Tirado-Rives: Development and Testing of the OPLS All-Atom Force Field on Conformational Energetics and Properties of Organic Liquids. J. Am. Chem. Soc. 118, 11225 (1996) 118,



Now the chemical types for each of the atoms needs to be assigned. OPLS methanol has 4 types:

•CT for the tetrahedral carbon

•HC for the hydrogens attached to the carbon

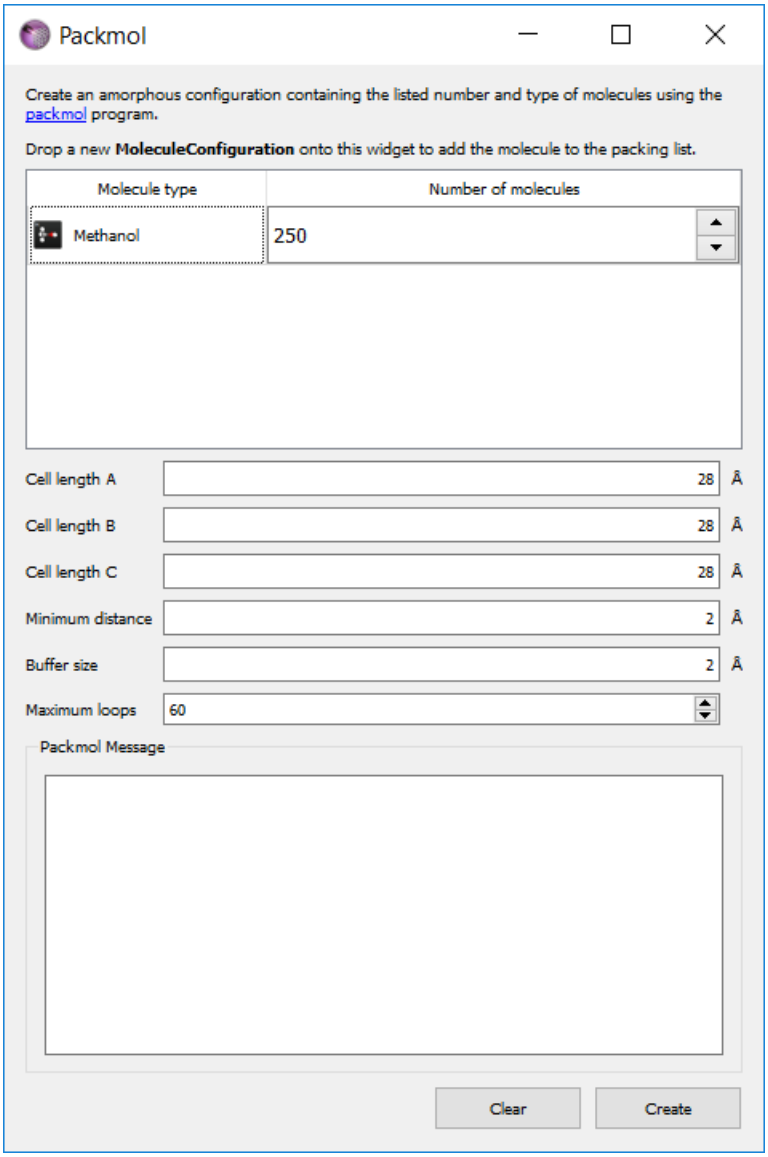
•OH for the alcohol oxygen

•HO for the alcohol hydrogen.

Select the three hydrogen atoms attached to the carbon. Set their types to HC by going to *Selection Tools* → *Tags* and typing in the tag HC. You should now be able to select these atoms by using the tag. Repeat the process for the other three atom types.

Tip: When selecting atoms, holding down the *Ctrl* key adds atoms to the current selection, while holding down the *Shift* key removes them.

Next create a bulk model of liquid methanol by selecting *Builders* → *Packmol*. Drag the molecule of methanol from the stash into the molecule type column, and select 250 molecules. Set each cell length to 28 Ångstroms. Click Create.

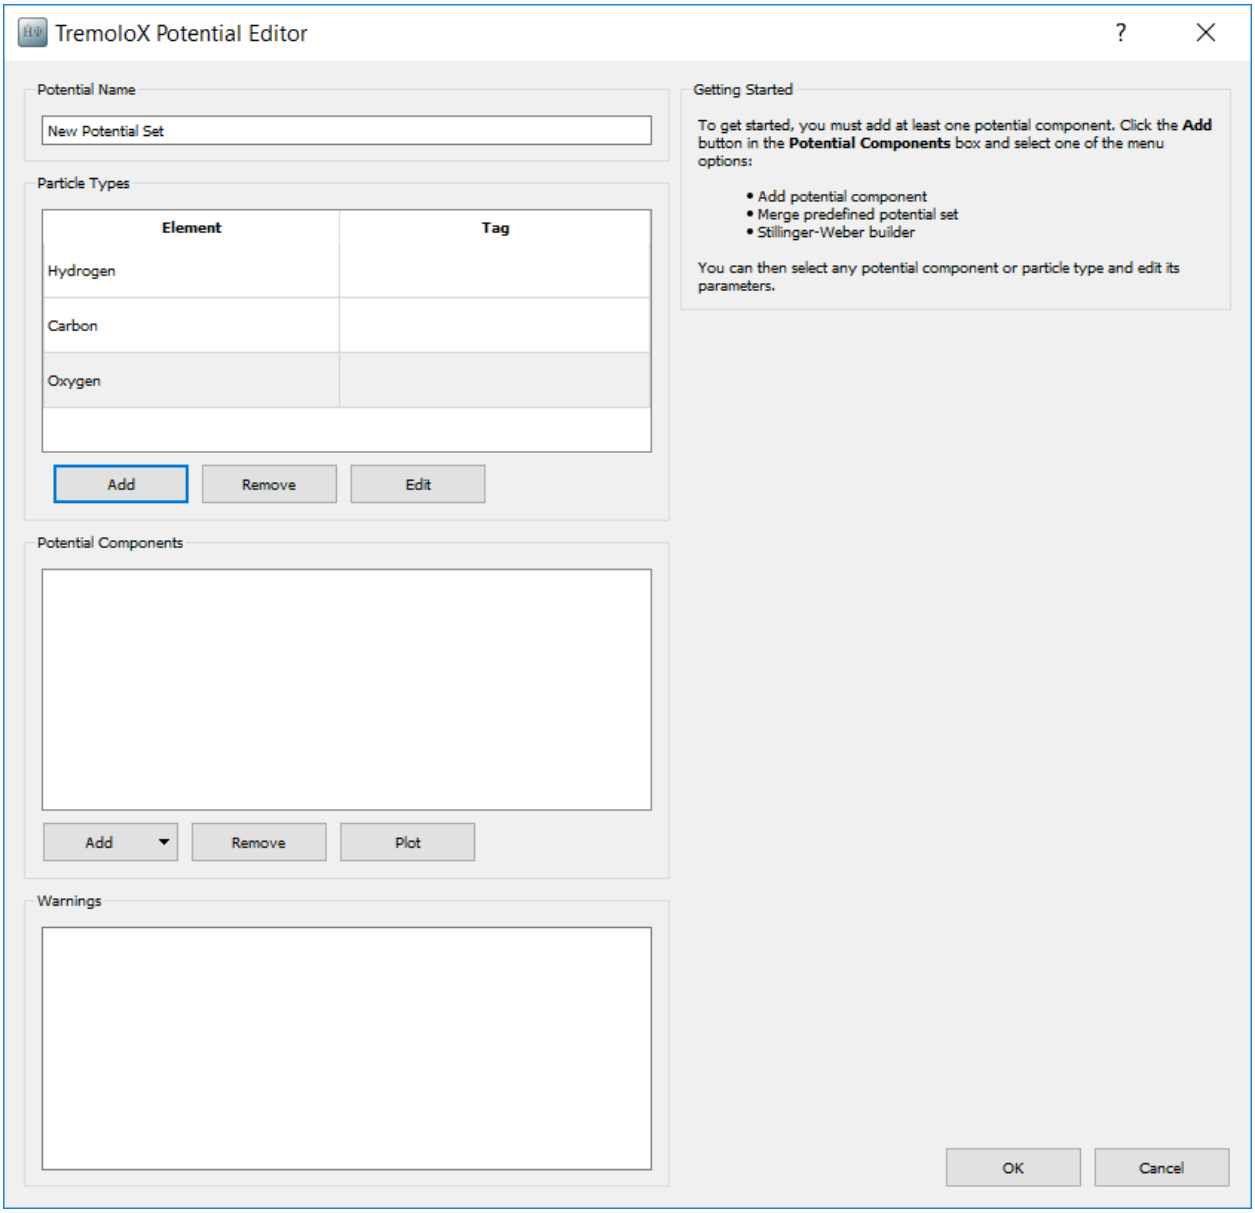


Mouse over the atoms in the new structure to check that the tags reflect the type of each atom.

Adding the forcefield to the calculation

One you are happy with the atom tag assignment, send the bulk methanol structure to the **Scripter** using the **Send To** icon .

In the **Scripter** first add in a **ForceFieldCalculator** block. In this block the forcefield needs to be defined. To do this a new forcefield definition needs to be added to the script. Open the **ForceFieldCalculator** and select *New*. This opens up the **Potential Editor** dialogue to enter in new forcefield terms.



Give the new potential the name `Methanol OPLS-AA`. When opening the **Potential Editor** particle types are added for each atom. These need to be deleted and replaced with particle types for the 4 atom tags. Select each element and press *Remove*. Then press *Add* to add each atom term.

Atom Tags

Pressing *Add* opens the **Particle Type Editor**. In this the type and basic information about the non-bonding parameters for the type are added.

The OPLS-AA forcefield used the expression for the non-bonding energy E_{nb}:

$$E_{nb} = \sum_{ij} 4\epsilon_{ij} \left[\left(\frac{\sigma_{ij}}{r_i j} \right)^{12} - \left(\frac{\sigma_{ij}}{r_{ij}} \right)^{6} \right] + \frac{q_i q_j}{4\pi\varepsilon_0 r_{ij}}$$

The terms ϵ_{ij} and σ_{ij} are calculed from the Lorentz-Berthelot combination rules:

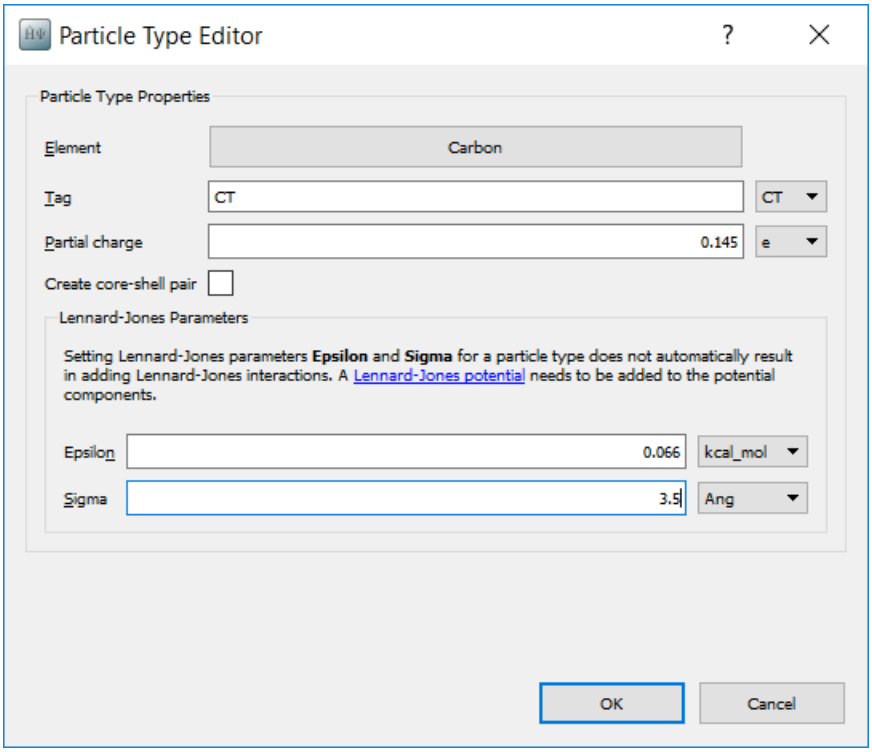
$$\epsilon_{ij} = \sqrt{\epsilon_i \epsilon_j}$$
$$\sigma_{ij} = \frac{\sigma_i + \sigma_j}{2}$$

The nonbonding parameters for the 4 atom types in methanol are:

Type	ϵ_i / kcal mol^{-1}	σ_i / Å	q_i / e
CT	0.066	3.50	0.145
OH	0.170	3.12	-0.683
HC	0.030	2.50	0.04
HO	0.000	0.00	0.418

Note: The HO type is not a van der Waals site in the OPLS-AA potential, and so the parameters for this atom are zero. It is however an electrostatic site, and so carries a charge.

Select the element from the pop-up periodic table, and then select the tag from the dropdown list. Add the corresponding nonbonding parameters. As an example, the input for the CT type is shown below.



Bonding Terms

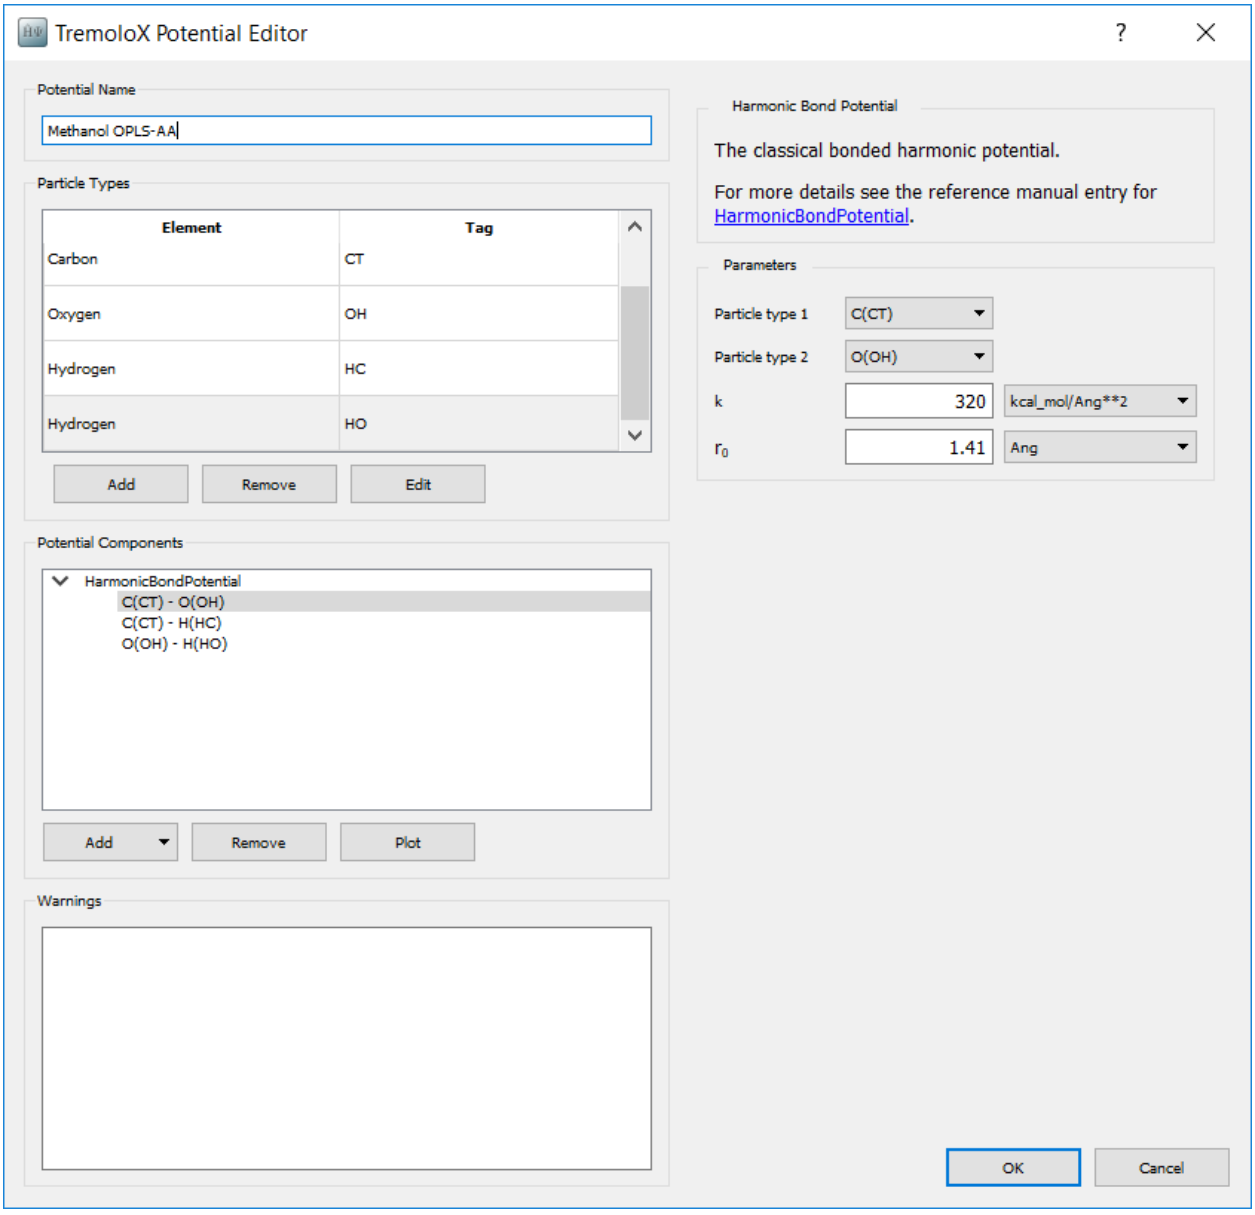
Bond stretching energy E_{bond} is approximated by a simple harmonic spring equation:

$$E_{bond} = \sum_{ij} K_{ij} \left(r_{ij} - r_0\right)^2$$

There are three different types of bonds in methanol. The parameters for these bonds are given in the following table:

Type I	Type J	K_{ij} / kcal mol^{-1} Å^{-2}	r_0 / Å
CT	OH	320.0	1.41
CT	HC	340.0	1.09
OH	HO	553.0	0.945

To add the bonding potentials, in the *Potential Components* box select *Add* → *Add potential component*. From the list of potential types select *HarmonicBondPotential*. Selecting a potential displays the parameters for it one the right hand side. Add three potentials and enter the parameters for each bond type. The input for the `CT - OH` bond type is shown below.



Angle Terms

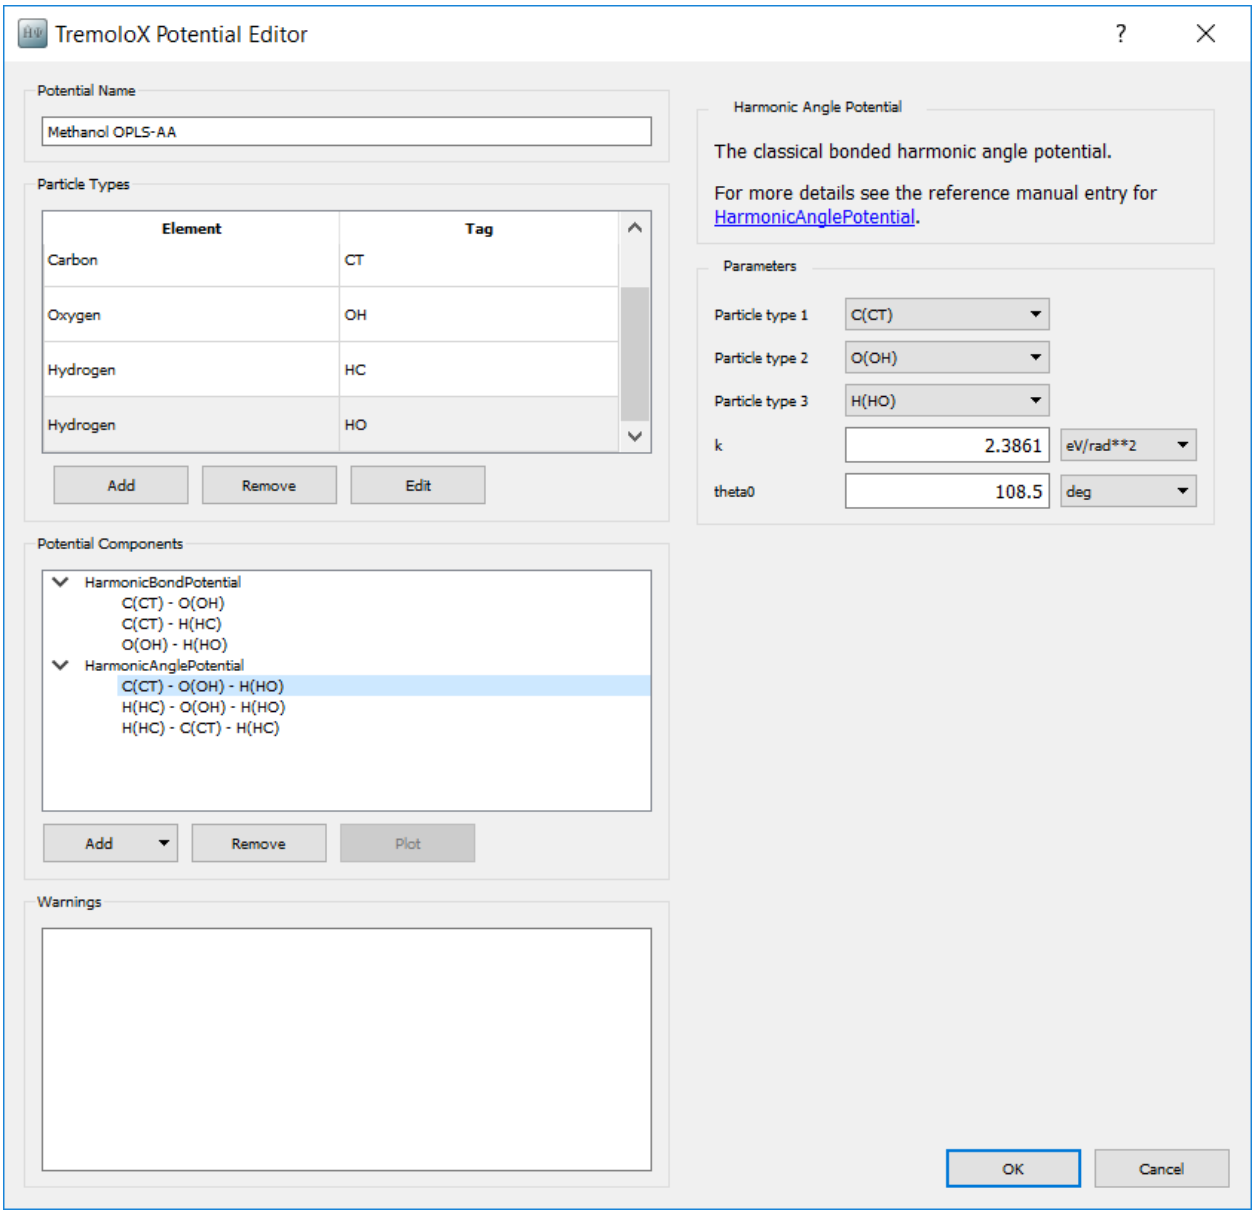
Angle stretching energy E_{angle} is approximated by another simple harmonic spring equation:

$$E_{angle} = \sum_{ijk} K_{ijk} \left(\theta_{ijk} - \theta_0\right)^2$$

There are three different types of angles in methanol. The parameters for these angles are given in the following table:

Type I	Type J	Type K	K_{ijk} / eV rad^{-2}	θ_0 / degree
CT	OH	HO	2.3861	108.5
HC	CT	OH	1.5184	109.5
HC	CT	HC	1.4317	107.8

To add the angle potentials, in the *Potential Components* box select *Add* → *Add potential component*. From the list of potential types select *HarmonicAnglePotential*. Selecting a potential displays the parameters for it one the right hand side. Add three potentials and enter the parameters for each bond type. The input for the `CT - OH - HO` angle type is shown below.



Torsion Terms

In methanol, there is only one bond torsion term. This extends across the type `HC - CT - OH - HO`. The bond twisting energy $E_{torsion}$ in this term is approximated by a Fourier expansion:

$$E_{torsion} = K(1 + \cos(3\phi))$$

The general torsion term in the OPLS-AA potential is actually a more complicated 3-term Fourier expansion. This potential cannot be added in directly in the interface, but can be easily set up with a small modification to the script. To create a place for the potential, in the *Potential Components* box select *Add* → *Add potential component*. From the list of potential types select *CosineTorsionPotential*. We will set the parameters later when editing the final script.

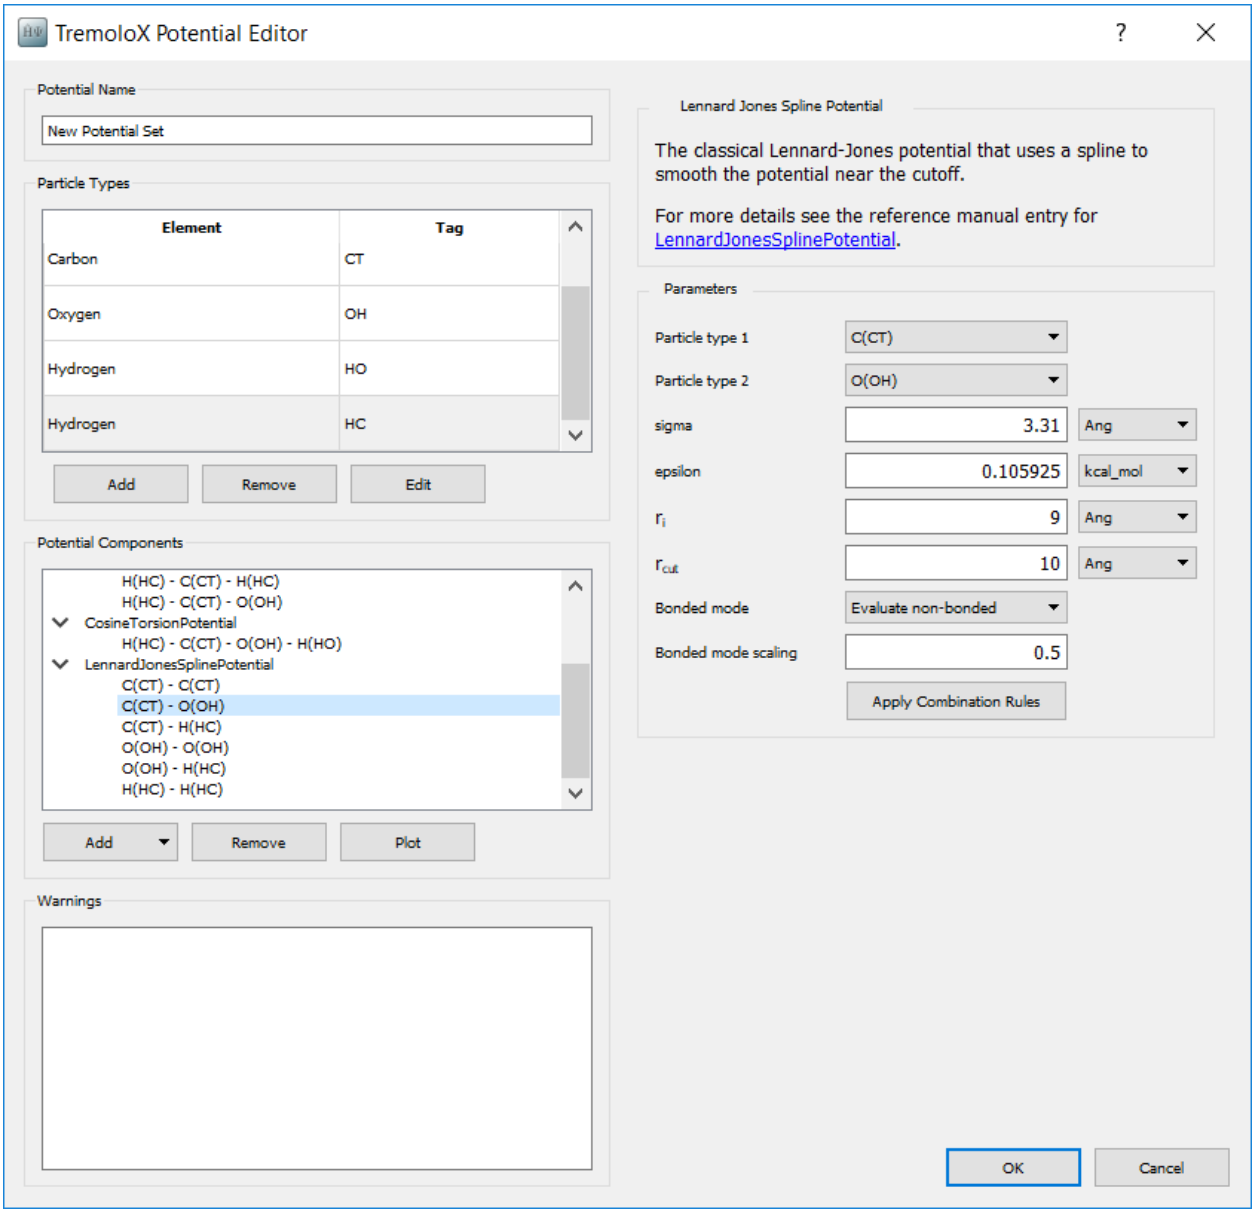
Van der Waals Terms

While parameters have been added for single atom types in the particle type definition, it is also necessary to add terms for pairs of types. As the atom type *HO* is not a van der Waals site, pair terms involving this atom do not need to be added. The remaining 3 types then gives 6 unique combinations.

For each combination in the *Potential Components* box, select *Add* → *Add potential component*. From the list of potential types select *LennardJonesSplinePotential*. The parameters for each can now be set on the right hand side.

- Sigma and epsilon can be filled in from the single atom type parmameters by pushing *Apply Combination Rules*
- Set r_{cut} to `10` Å. This sets the distance beyond which potential terms are ignored
- Set r_i to `9` Å. This sets the distance beyond which potential terms are scaled down by a spline function, so that they are zero at the cutoff. This is necessary so that there is not a sudden increase in forces as atoms come within range of each other.
- Set *Bonded mode scaling* to `0.5`. This scaling is for atoms connected through 3 bonds and is specified by the OPLS-AA potential.

An example for the `CT - OH` nonbonding potential is shown below.



Electrostatic Terms

Atomic charges were added to the model in the definition of particle types. A summation method for the electrostatic terms still needs to be added.

In the *Potential Components* box select *Add* → *Add potential component*. From the list of potential types select *CoulombSPME*. This selects *Smooth Particle Mesh Ewald* summation of electrostatic terms. This method uses Fourier transforms to correctly estimate the long-range electrostatic interactions.

In the parameters section on the right hand side:

- Set r_{cut} to 9 Å.
- Set Accuracy to `0.001`.

The other default parameters are suitable for the calculation.

Having added all of these potentials terms, click *OK* on the **Potential Editor** and on the **ForceFieldCalculator**

Relaxing the starting structure

Optimizing the structure

Now that the forcefield has been defined, calculations can be added to the script.

Note: This tutorial follows the general methodology for running molecular dynamics simulations. For more information on specifics of the method and settings see the tutorials:

- *How to Setup Basic Molecular Dynamics Simulations*
- *Diffusion in Liquids from Molecular Dynamics Simulations*

The first step is to optimise the geometry to remove any large forces from the starting configuration. Large initial forces can cause integration problems in the following molecular dynamics calculations. It is not important that the structure is completely optimised, only that any atom-atom overlaps are removed, which usually happens in the first few steps of a geometry optimisation.

In the **Scripter** add a *Optimization* → *OptimizeGeometry* block. The default parameters for this block are sufficient.

Obtaining the right density

When the structure was built, the density was too low to make it easier to add methanol molecules into the bulk structure. Now the cell needs to be contracted to approximately the right density. This can be done with a simple molecular dynamics calculation.

Add a molecular dynamics block using the *NPT Berendsen* barostat. This barostat is more stable but also less accurate than the MTK barostat, making it useful for creating relaxed structures from inital guesses. A run of 100ps is typically sufficient for the system to condense to the liquid density.

Equilibrating the structure

Add a molecular dynamics block using the *NPT Martyna Tobias Klein* barostat. In this calculation 100ps is an adequate time for the simulation to equilibrate. Equilibration time can vary greatly however depending on the system being investigated. The simulation should also be started using the velocities from the previous calculation, which can be done by setting the *Initial Velocity* type to `Configuration Velocities`.

Setting the production calculation

Add a molecular dynamics block using the *NPT Martyna Tobias Klein* barostat. Set the dynamics to run for 500ps. The appropriate length of the production simulation depends largely on the system being studied and also the desired accuracy of the final result. Two specific things to that should be set in this part are:

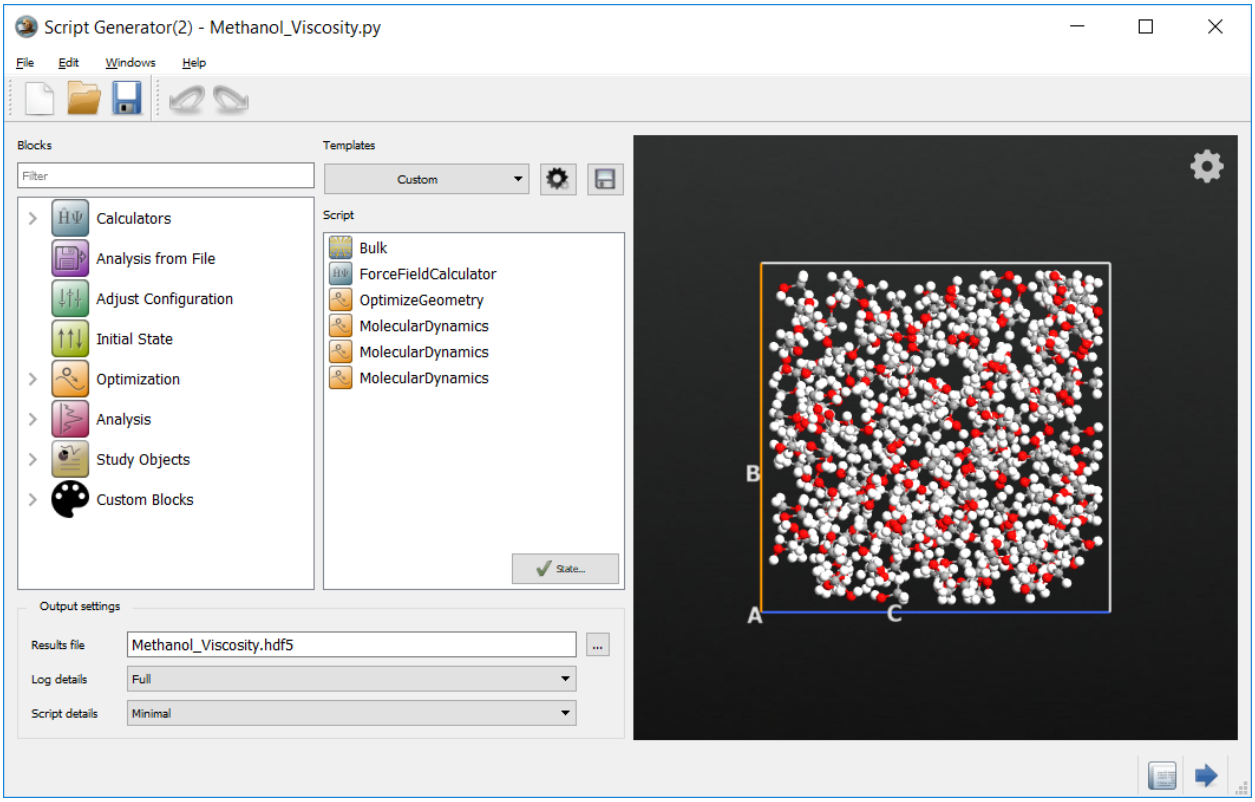
- Set the *Save Trajectory* box to `Production_Trajectory.hdf5`
- Set the *Log interval* box to 1000

Both of these details will be used in the analysis part of the tutorial.

Modifying the script

Adding the torsion terms

Now that the basic calculation is created, **Scripter** set the output file to `Methanol_Viscosity.hdf5`. The script generator should look like:



The script can now be sent to the **Editor** using the **Send To** icon . The torsion parameters can now be set. The torsion potential is defined in the section:

```
_potential = CosineTorsionPotential(
   particleType1 = ParticleIdentifier('H', ['HC']),
   particleType2 = ParticleIdentifier('C', ['CT']),
   particleType3 = ParticleIdentifier('O', ['OH']),
   particleType4 = ParticleIdentifier('H', ['HO']),
   k = [0.0*eV, ],
   n = [0, ],
   delta = [0.0*Radians, ],
)
potentialSet.addPotential(_potential)
```

Replace this block with the block

```
_potential = CosineTorsionPotential(
   particleType1 = ParticleIdentifier('H', ['HC']),
   particleType2 = ParticleIdentifier('C', ['CT']),
   particleType3 = ParticleIdentifier('O', ['OH']),
```

(continues on next page)

(continued from previous page)

```
    particleType4 = ParticleIdentifier('H', ['HO']),
    k = [0.176*kiloCaloriePerMol, ],
    n = [3, ],
    delta = [0.0*Radians, ],
)
potentialSet.addPotential(_potential)
```

Save the edited script.

Defining the hook function

To calculate the viscosity the values of the pressure tensor during the simulation are required. As the pressure changes rapidly during the simulation, a high resolution of data is necessary. While saving structures into the trajectory also saves the pressure tensor, saving trajectory files with short timesteps quickly results in unreasonably large files. What is required is a method to save just the pressure information at each step.

In **QuantumATK** this can be easily achieved with hook functions. These are functions that are run before or after each molecular dynamics integration. Hook functions are designed for either controlling the simulation, or as in this case, recording and analysing various quantities during the simulation.

Note: For an example on how to use hook functions to modify the simulation, see the tutorial: *Youngs modulus of a CNT with a defect*

To use a hook function a Python object that implements the __call__ function must first be added. The arguments passed to this function are:

- *step*: The step number that the simulation is up to when the function is called
- *time*: The amount of time that has elapsed in the simulation so far
- *configuration*: A *BulkConfiguration* object containing the current structure
- *forces*: An array of the forces on each atom
- *stress*: The stress tensor for the current structure

Using these values it is possible to create many custom analysis and data recording methods. In the present case the pressure tensor needs to be recorded. This can be done by the *PressureRecordingUtility* class defined in the script below.

```
# Define the class that does the analysis for the MD simulation
class PressureRecordingUtility:
    ''' Calculate and record the volume and pressure tensor at each step '''

    def __init__(self):
        ''' Initialse the arrays used to store the data '''
        self._time_list = []
        self._volume_list = []
        self._pressure_list = []

    def __call__(self, step, time, configuration, forces, stress):
        ''' Function called at each step that calculates and records the pressure tensor '''

        # Add the current time onto the list
```

(continues on next page)

(continued from previous page)

```
        self._time_list.append(time)

        # Get the cell volume and add that to the list too
        volume = configuration.bravaisLattice().unitCellVolume()
        self._volume_list.append(volume)

        # Get the velocity component of the pressure tensor
        velocity = configuration.velocities()
        masses = configuration.atomicMasses()
        velocity_tensor = ((velocity.reshape(-1,3,1) * velocity.reshape(-1,1,3)) *␣
↪masses.reshape(-1,1,1)).sum(axis=0)

        # Construct the pressure tensor
        pressure_tensor = (velocity_tensor/volume) - stress

        # Add the pressure tensor to the list
        self._pressure_list.append(pressure_tensor)

    def times(self):
        ''' Function that returns the list of times saved during the simulation '''
        return Units.PhysicalQuantity(self._time_list)

    def volumes(self):
        ''' Function that returns the list of volumes saved during the simulation '''
        return Units.PhysicalQuantity(self._volume_list)

    def pressure_tensors(self):
        ''' Function that returns the list of pressure tensors saved during the simulation '
↪'
        return Units.PhysicalQuantity(self._pressure_list)
```

Paste this code at the top of the simulation script and then save the edited script.

Using the hook function in the molecular dynamics simulation

Now that an appropriate hook function is defined, **QuantumATK** needs to be told how to use this function during the simulation.

Find the section of the script where the final production phase of the molecular dynamics calculation is carried out. At the top of this section add the following line:

```
pressureRecorder = PressureRecordingUtility()
```

This line declares an instance of the class used to record the pressure data, allocating a memory space in which to store it.

Now the **MolecularDynamics** call needs to be changed to add the hook function. Edit this function call to include the argument:

```
post_step_hook=pressureRecorder
```

This tells **QuantumATK** to use the *pressureRecorder* instance of the *PressureRecordingUtility* to run and store the data at each step.

Note: The **MolecularDynamics** function supports arguments *pre_step_hook* and *post_step_hook* for running the hook function before or after the molecular dynamics integration step respectively.

Finally the data collected by the *pressureRecorder* object needs to be written out to a file for later processing. This can be done by writing the data to a hdf5 file. To do this add the following code to the end of the script.

```
data_file = 'md_methanol_data.hdf5'
temperature = 300 * Kelvin

nlsave(data_file, pressureRecorder.times(), "Time")
nlsave(data_file, pressureRecorder.pressure_tensors(), "Pressure")
nlsave(data_file, pressureRecorder.volumes(), "Volume")
nlsave(data_file, pressureRecorder.volumes().mean(), "Volume_Average")
nlsave(data_file, temperature, "Temperature")
nlsave(data_file, md_trajectory.timeStep(), "Time_Step")
```

Save the edited script.

Running the calculation

All of the necessary parts of the script are now in place. The script can be sent to the **Job Manager** and run by using the icon.

Analyzing the results

Viewing the change in pressure

When using the NPT ensemble, it is important to check how the pressure was controlled during the simulation. Ideally the pressure should average out to the target value over the course of the simulation. If this does not happen a longer equilibration or simulation time may be needed.

When the NPT ensemble is used the pressure is written to the HDF5 file by default. To visualise this pressure a script can be used to read it from the HDF5 file and plot it. To do this open the **Editor** using the and paste in the following script.

```
import pylab

# Read in the existing trajectory to ge the data
trajectory_file = "Production_Trajectory.hdf5"
trajectory = nlread(trajectory_file, MDTrajectory)[-1]
time = trajectory.times()
pressure = trajectory.pressures()

# Set the average and target pressures
p_tot_avg = numpy.cumsum(pressure.inUnitsOf(GPa)) * GPa / (numpy.arange(pressure.
↪shape[0])+1)
p_target = numpy.ones(pressure.shape[0]) * Pa

# Plot the resulting pressure and average pressure
```

(continues on next page)

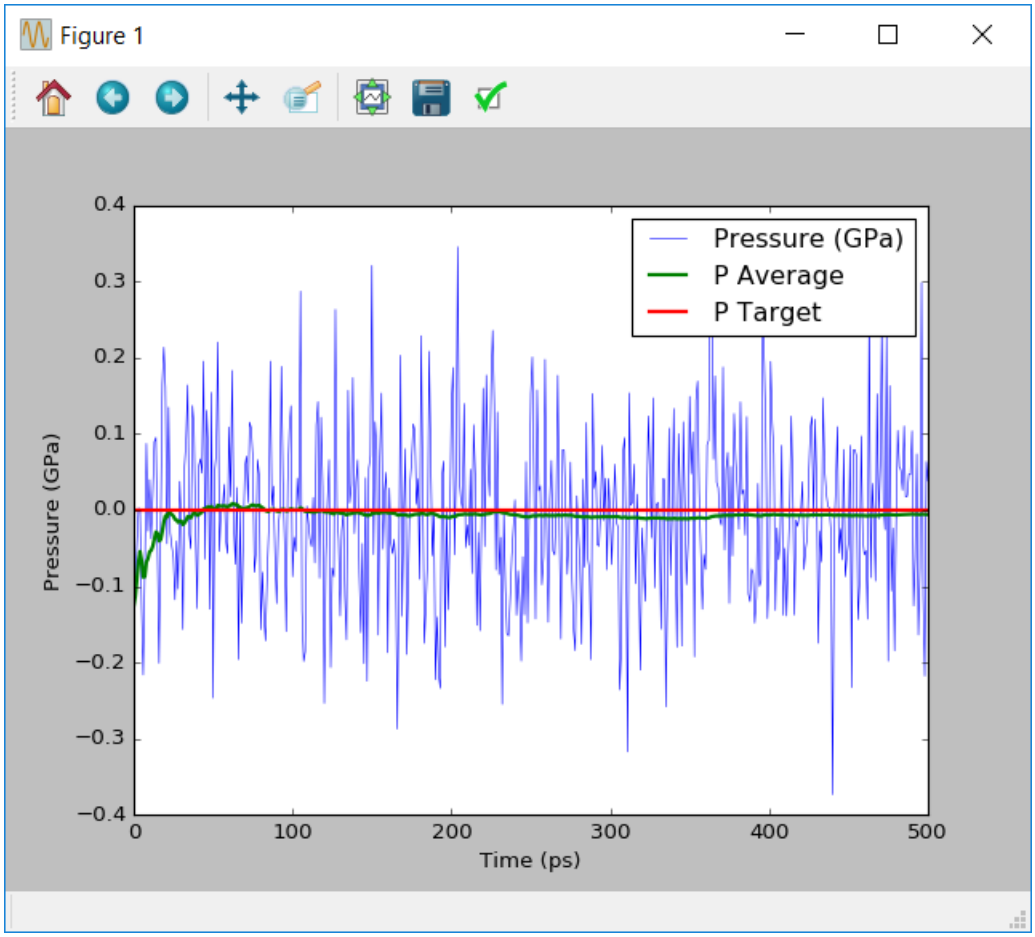
(continued from previous page)

```
pylab.figure()
pylab.plot(time.inUnitsOf(picosecond), pressure.inUnitsOf(GPa), label='Pressure (GPa)',␣
↪linewidth=0.5)
pylab.plot(time.inUnitsOf(picosecond), p_tot_avg.inUnitsOf(GPa), label='P Average',␣
↪linewidth=2.0)
pylab.plot(time.inUnitsOf(picosecond), p_target.inUnitsOf(GPa), label='P Target',␣
↪linewidth=2.0)
pylab.xlabel('Time (ps)')
pylab.ylabel('Pressure (GPa)')
pylab.legend()
pylab.show()
```

The script can also be directly downloaded here. `pressure_analysis.py`

Run this script by sending it to the **Job Manager**. The script should display a graph similar to the one below.

Tip: Analysis scripts like this can also be run from the command line using the **atkpython** command



Note that during the dynamics simulation the pressures swing by approximately 0.2GPa. These large pressure changes are typical for molecular dynamics simulations. What is important is that as the simultion runs the average pressure converges to the target pressure of 0.1MPa.

Calculating the viscosity from the Einstein relationship

Using the data collected by the hook function during the molecular dynamics simulation, it is possible to calculate and visualise an estimate of the viscosity.

This can be done by using an **ATKPython** script. Open a new script in the **Editor** and paste in the following script.

```
import pylab
import scipy

# Read the data that is stored in the HDF5 file from the simulation
data_file = 'md_methanol_data.hdf5'
time = nlread(data_file, object_id="Time_8")[-1]
pressure_tensor = nlread(data_file, object_id="Pressure_8")[-1]
volume_avg = nlread(data_file, object_id="Volume_Average_8")[-1]
temperature = nlread(data_file, object_id="Temperature_8")[-1]
time_step = nlread(data_file, object_id="Time_Step_8")[-1]

# Set up the calculation to create 100 time based estimates of the viscosity
N = pressure_tensor.shape[0]
N_steps = 101
skip = int(N/100)
time_skip = time[::skip]

# Calculate the off-diagonal elements of the pressure tensor
P_shear = numpy.zeros((5,N), dtype=float) * Joule / Meter**3
P_shear[0] = pressure_tensor[:,0,1]
P_shear[1] = pressure_tensor[:,0,2]
P_shear[2] = pressure_tensor[:,1,2]
P_shear[3] = (pressure_tensor[:,0,0] - pressure_tensor[:,1,1]) / 2
P_shear[4] = (pressure_tensor[:,1,1] - pressure_tensor[:,2,2]) / 2

# At increasing time lengths, calculate the viscosity based on that part of the␣
↪simulatino
pressure_integral = numpy.zeros(N_steps, dtype=numpy.float) * (Second * Joule /␣
↪Meter**3)**2
for t in range(1,N_steps):
    total_step = t*skip

    for i in range(5):
        integral = scipy.integrate.trapz(
            y = P_shear[i][:total_step].inUnitsOf(Joule/Meter**3),
            dx=time_step.inUnitsOf(Second)
        )
        integral *= Second * Joule / Meter**3
        pressure_integral[t] += integral**2 / 5

# Finally calculate the overall viscosity
# Note that here the first step is skipped to avoid divide by zero issues
kbT = boltzmann_constant * temperature
viscosity = pressure_integral[1:] * volume_avg / (2*kbT*time_skip[1:])

# Print the final viscosity
print("Viscosity is {} cP".format(viscosity[-1].inUnitsOf(millisecond*Pa)))
```

(continues on next page)

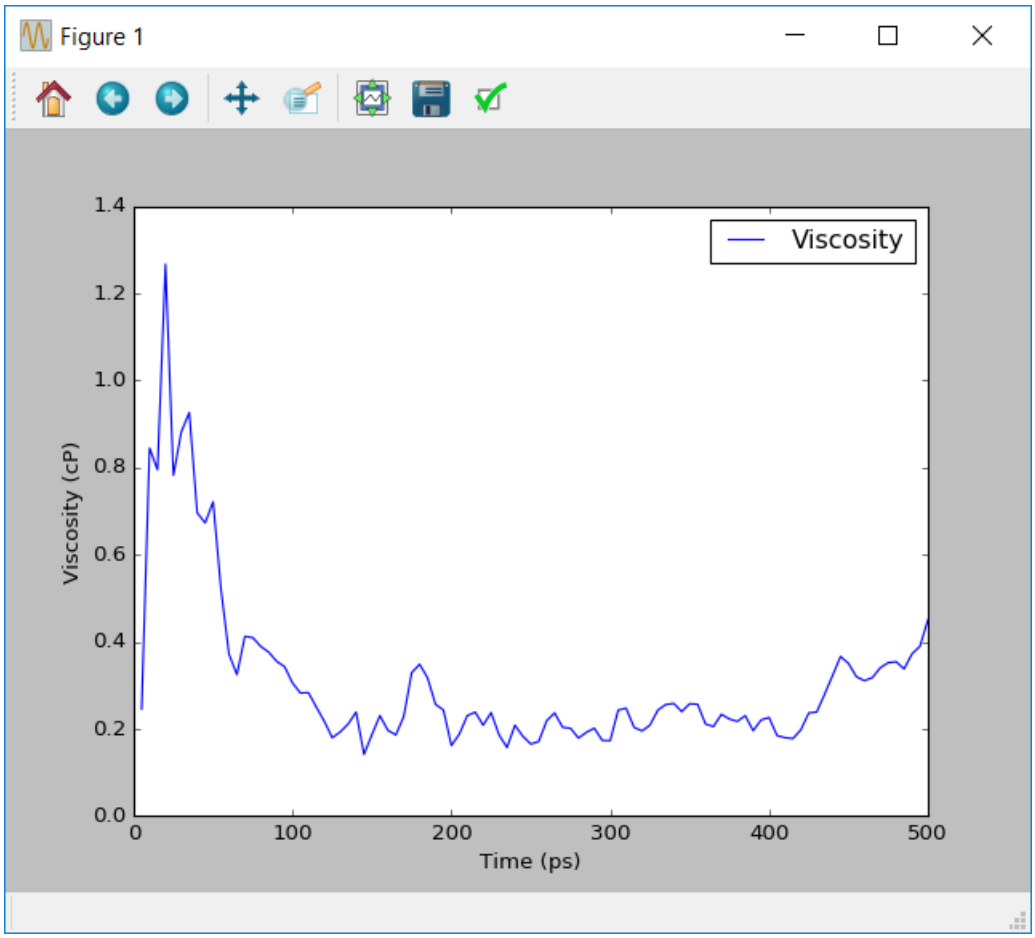
(continued from previous page)

```
# Display the evolution of the viscosity in time
pylab.figure()
pylab.plot(time_skip[1:].inUnitsOf(ps), viscosity.inUnitsOf(millisecond*Pa), label=
↪'Viscosity')
pylab.xlabel('Time (ps)')
pylab.ylabel('Viscosity (cP)')
pylab.legend()
pylab.show()
```

The script can also be directly downloaded here. `viscosity_analysis.py`

This script reads in the saved data from the HDF5 file saved from the hook function. It then calculates the viscosity using the Einstein relationship given in the theory section. Note that the integral is averaged over the 5 unique off-diagonal components of the pressure tensor, P_{xy}, P_{yz}, P_{xz}, $\frac{P_{xx}-P_{yy}}{2}$ and $\frac{P_{yy}-P_{zz}}{2}$. The script then prints the final viscosity at the simulation time limit, as well as showing how the estimate of the viscosity changed over the course of the simulation.

Below is a typical example of the viscosity calculated by the simulation. For comparison the experimental value of the density of methanol at 298K is 0.54cP. A rigid OPLS-AA model which only includes non-bonding interaction and keeps the configuration of each molecule fixed gives a viscosity of 0.43cP[Page 1267, 3]. Although the example gives similar results, there is still a reasonable amount of noise in the calcuated viscosity. Ideally this viscosity should converge to a distinct value. This indicates that more sampling of the pressure is required to improve the accuracy of the simulation.



Calculating the viscosity from the Green-Kubo relationship

Similar results for the viscosity can be obtained using the Green-Kubo relationship. A script outlining how this is achieved can be downloaded here. `green_kubo_analysis.py`

Advanced users of Python are encouraged to view and run the script to understand how it works. This script also demonstrates some of the power and flexibility of the **ATKPython** platform for not only running, but also analyzing simulations.

Extending the results

Running more independent trajectories

In the previous section it was seen that more simulations need to be done in order improve the accuracy of the estimated viscosity.

In **QuantumATK** simulations can be easily repeated by placing them within Python loops. In the case of methanol one strategy is to loop over both the equilibration and production phases of the simulation. As the velocities are re-randomised at the start of the equilibration phase this generates a series of independant trajectories. From these not only the average viscosity but also the error in the average viscosity can be easily estimated using standard statistical methods.

To loop over calculations in Python the code to be repeated can be placed in a *for* loop. To loop the viscosity calculation 30 times to produce different trajectories the simulation code needs to be placed in a *for* loop such as:

```
for loop in range(30):
    # Molecular dynamics simulation commands

# Futher commands outside the loop
```

Note: One of the important features of Python is that it uses indentation to determine the extent of code blocks. This determines which lines are inside or outside loops and logical statements. The indentation in the above example is how you distinguish code from inside or outside a Python loop.

The only other necessary change in the script to create several trajectories is to modify how the output is done. In HDF5, files writing data with the same text descriptor overwrites the previous data. Unique descriptors are therefore needed. This is simply done by including the looping variable (in the above case the variable *loop*) into the name. This is done by changing the file-writing code to

```
data_file = 'md_methanol_data.hdf5'
temperature = 300

nlsave(data_file, pressureRecorder.times(), "Time_"+str(loop))
nlsave(data_file, pressureRecorder.pressure_tensors(), "Pressure_"+str(loop))
nlsave(data_file, pressureRecorder.volumes(), "Volume_"+str(loop))
nlsave(data_file, pressureRecorder.volumes().mean(), "Volume_Average_"+str(loop))
nlsave(data_file, temperature, "Temperature_"+str(loop))
nlsave(data_file, md_trajectory.timeStep(), "Time_Step_"+str(loop))
```

To read in the data from each trajectory for analysis the names need to be changed in the `nlread` commands in the same way.

Improving the accuracy

To demonstrate how the accuracy of the simulation can be improved using multiple runs, the simulation was repeated 30 times. The average obtained from these simulations was 0.41cP, with a standard error of 0.05cP. The graph below shows the change in the average viscosity and the standard error with the number of simulations.

3.9 Molecular Electronics

3.9.1 Building molecule–surface systems: Benzene on Au(111)

Version: 2017.0

In this tutorial you will learn how to use **QuantumATK** (**QuantumATK**) to construct two different adsorption configurations of a benzene molecule adsorbed on the gold (111) surface, here denoted Bz@Au(111). In particular, you will:

- Create the structure of bulk Au using the value of the lattice constant reported by Lui *et al.* in Ref.[1];
- Construct a slab model for the Au(111) surface according to the parameters reported in[Page 1287, 1];
- Attach a benzene molecule to the Au(111) surface slab model;
- Modify the atomic coordinates of the Bz molecule to construct configurations of Bz@Au(111) using the advanced building tools in the QuantumATK **Builder**.

[1] Wei Liu, VictorăG Ruiz, Guo-Xu Zhang, Biswajit Santra, Xinguo Ren, Matthias Scheffler, and Alexandre Tkatchenko. Structure and energetics of benzene adsorbed on transition-metal surfaces: density-functional theory with van der Waals interactions including collective substrate response. *New Journal of Physics*, 15(5):53046, 2013. URL: http://stacks.iop.org/1367-2630/15/i=5/a=053046.

Tip: Once you have constructed these geometries, you can optimize them using one of the computational methods implemented in QuantumATK, and perform further analysis.

Note: Many of the QuantumATK functions described in this tutorial are rather general, and can be used to build complex geometries other than molecules on surfaces, see for example the tutorial on *Building a molecular junction*.

Summary of workflow

The following is a summary of the main steps needed for building the Bz@Au(111) configurations. These steps are also shown in the short **video** available below. If needed, more detailed instructions are given in the sections after the video.

1. Create a new QuantumATK project and open the **Builder**.
2. Use the **Builder Database** to import the bulk gold primitive unit cell.
3. Use the **Lattice Parameters** plugin to change the gold lattice parameter to $a = 4.159$ Å, as reported in Ref.[1] using DFT and the PBE density functional.
4. Open the **Surface (Cleave)** plugin, and create the 3×3 Au(111) slab with 6 metal layers and 20 Å vacuum above it.
5. Use the **Molecular Builder** tool to add the benzene molecule to the slab configuration.
6. Select the Bz atoms, and use the **Rotate** plugin to rotate the molecule 90° around the y-axis such that the molecule can adsorb parallel to the slab surface plane.
7. Click the icon to add a new atom in at the geometrical center of the molecule.
8. Use the **Move** tool to move the molecule into the hcp-30° adsorption site. The extra atom added in the previous step is used to snap the molecule into position, and is afterwards removed from the configuration.
9. **Rename** the configuration and create a **copy** of it in the Stash.
10. **Rename** the copy, and use the **Rotate** plugin to rotate the Bz 30° around the z-axis to create the hcp-0° adsorption geometry.

Many more **video tutorials** are available on the QuantumATK YouTube channel.

Detailed instructions

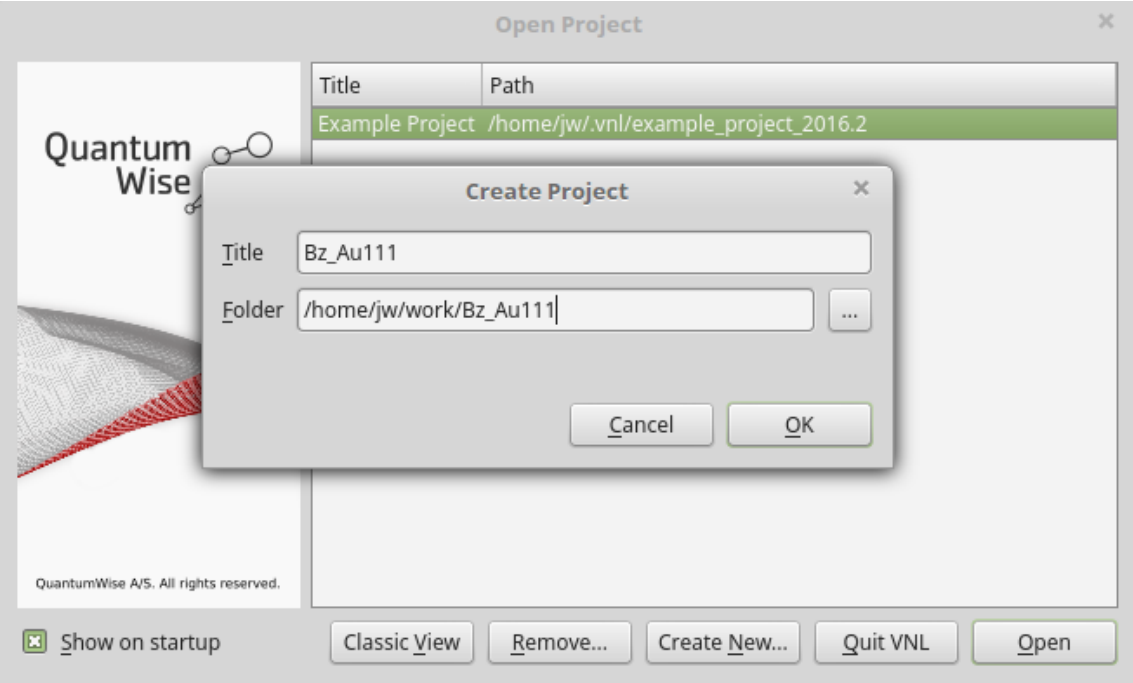
Building the Au(111) surface

You will here construct a slab model for the Au(111) surface starting from the gold primitive unitcell.

Bulk gold

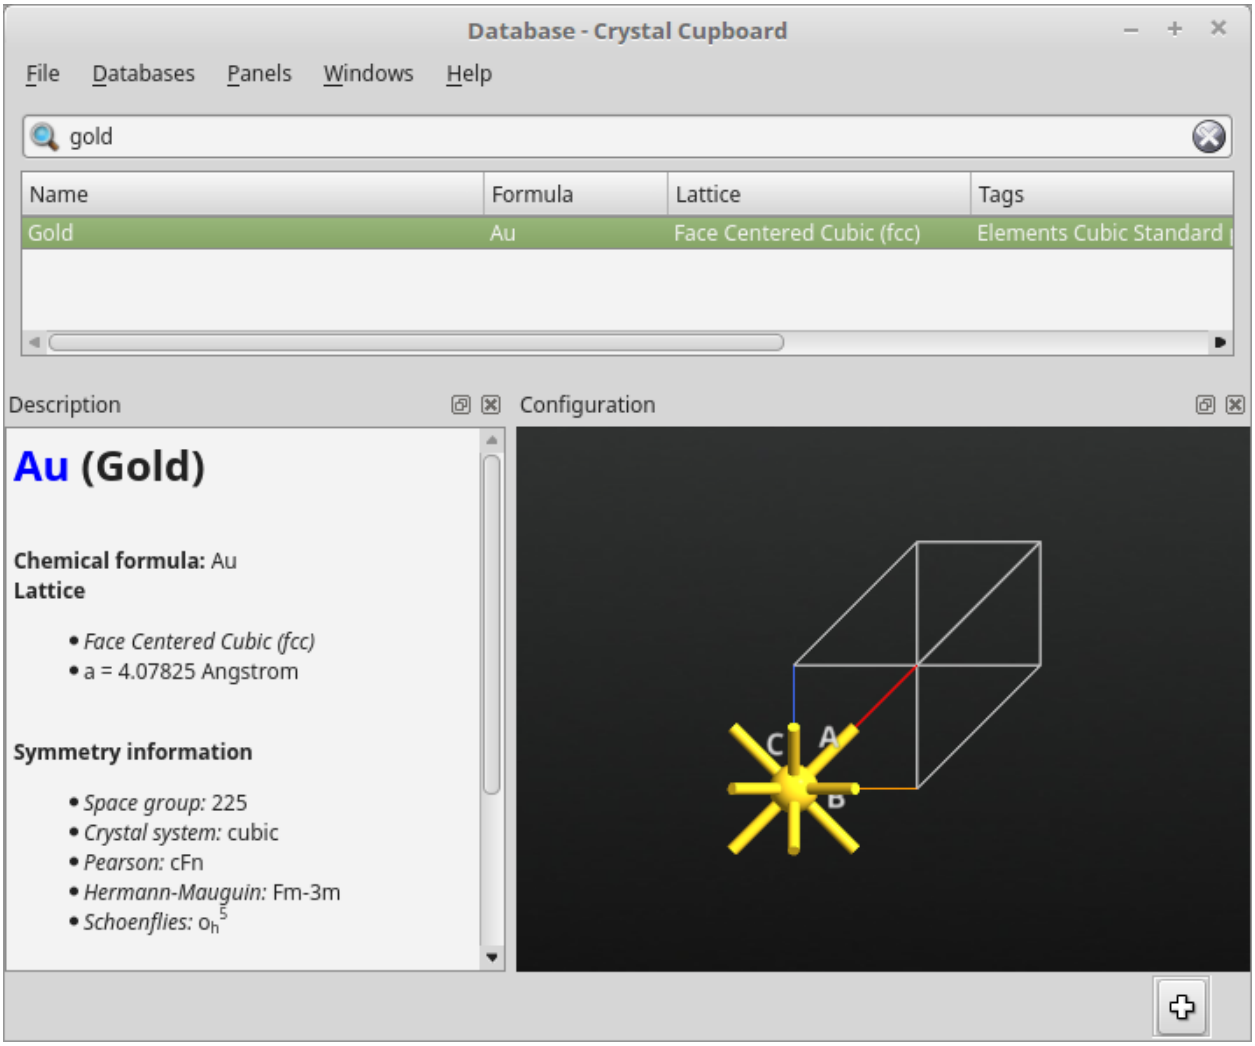
Open **QuantumATK** and create a new project. Give the project a title (here: *Bz_Au111*), select the folder where the project files should be stored (scripts, data files, etc.), and click **OK** to create the project.

click **Open** to open the project and start your QuantumATK session.



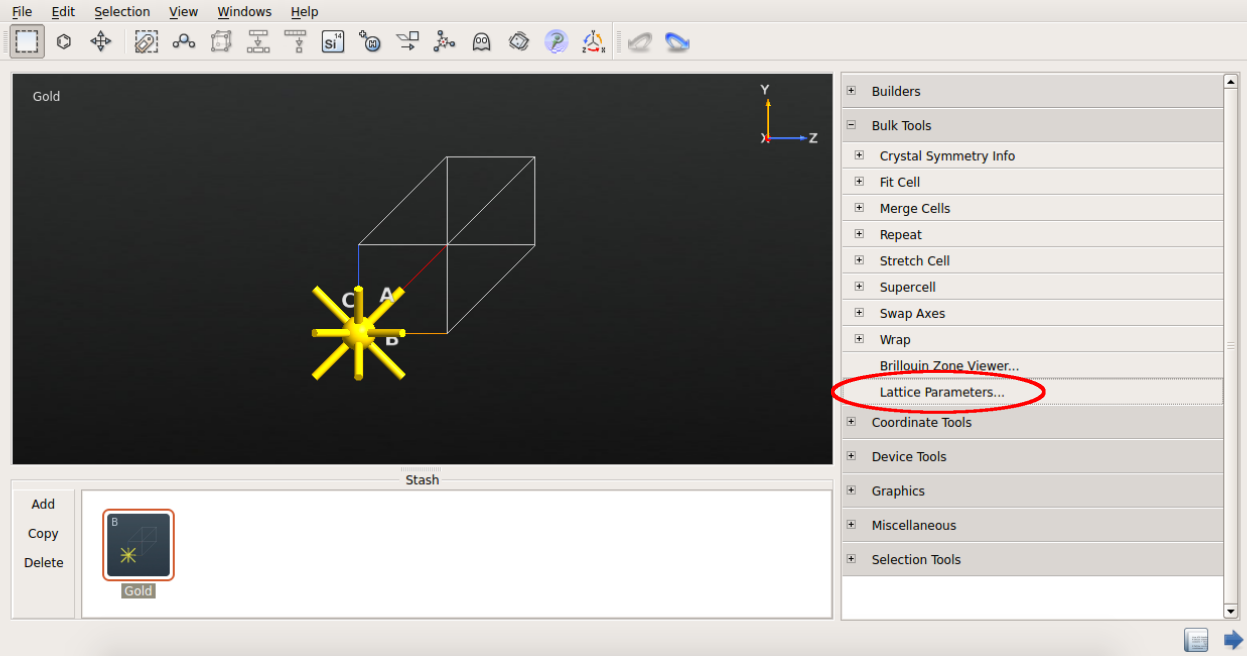
In the QuantumATK main window, open the **Builder**, and click *Add* → *From Database* next to the **Stash** to open a database of common materials in their experimental structures.

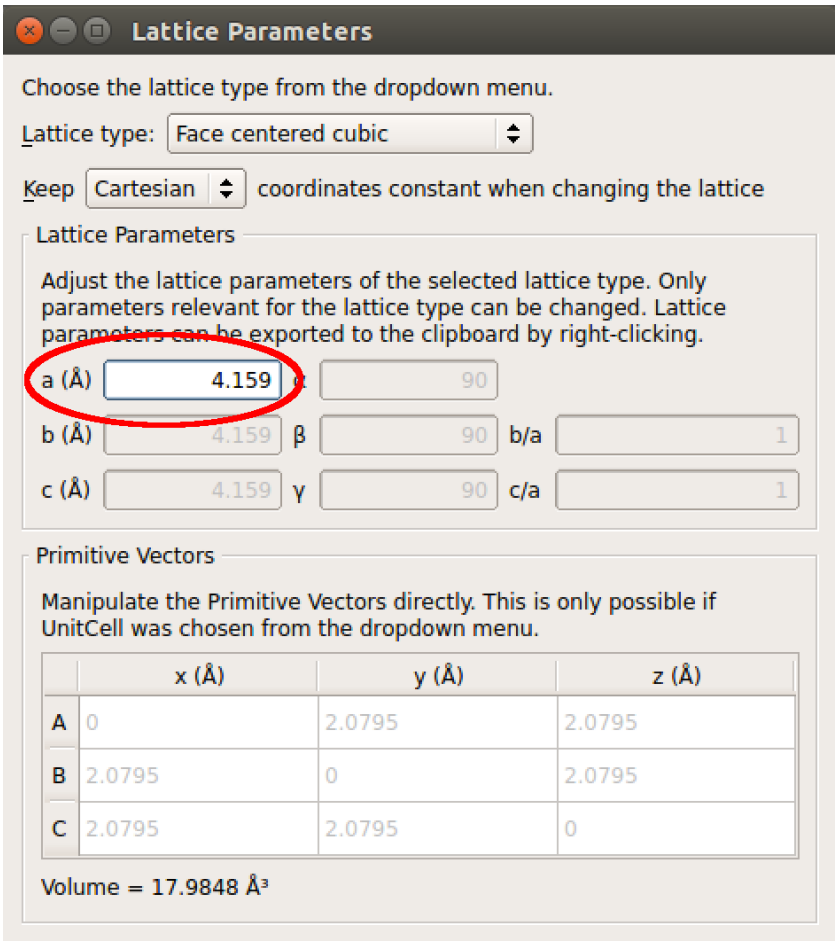
Search for gold using the search bar, and import the structure to the **Stash** by clicking the search result and then clicking the icon:



The gold primitive cell has been added as a **Stash** item, and may now be modified using the **Builder plugins**.

In this case, use the *Bulk Tools* → *Lattice Parameters* plugin to change the lattice parameter to that reported in Ref.[Page 1287, 1] using DFT and the PBE functional, $a = 4.159$ Å.



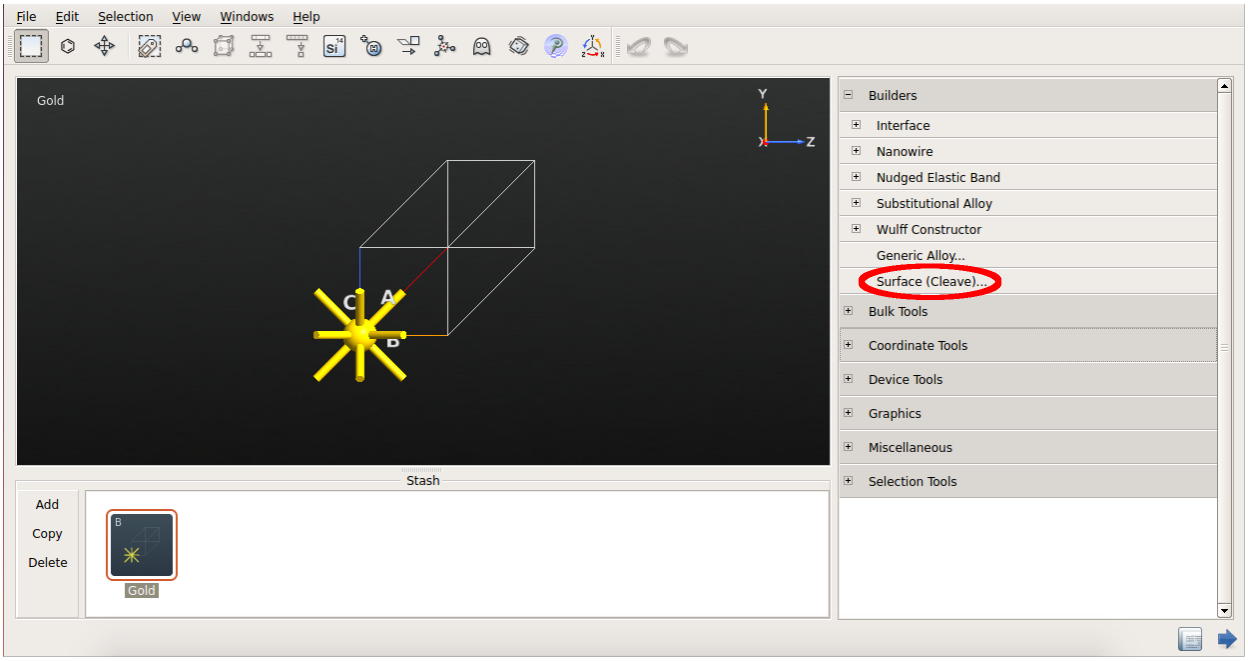


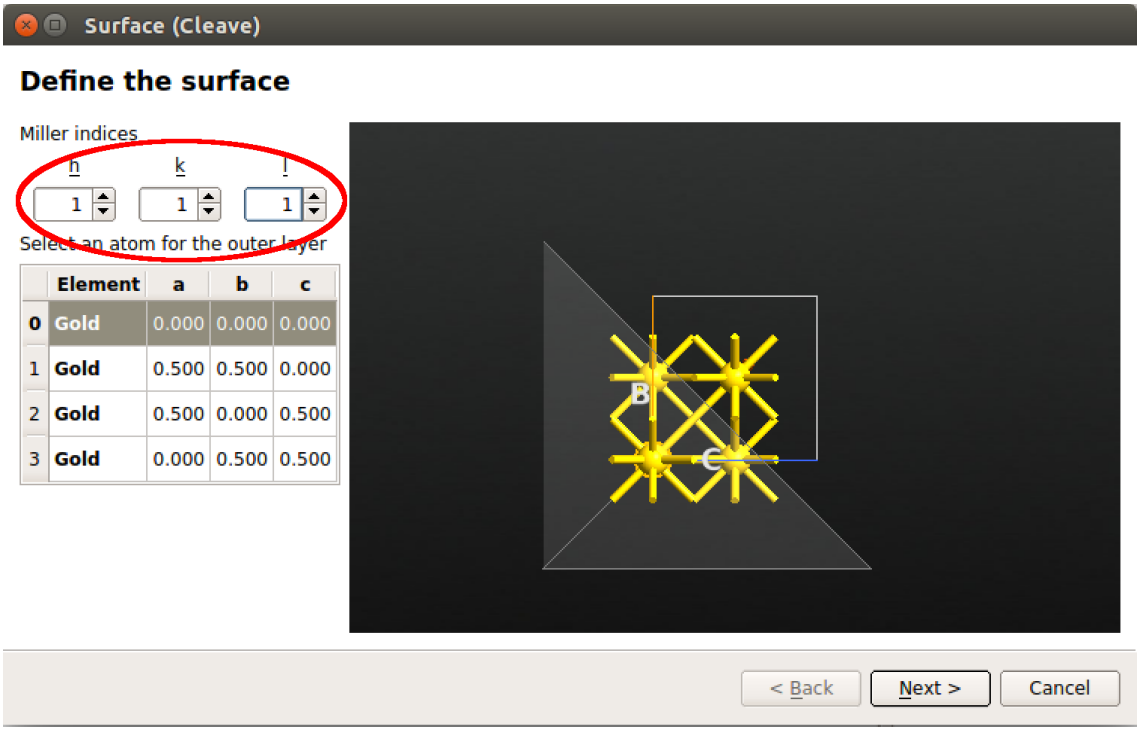
When you are done, close the plugin widget and go back to the Builder.

Au(111) slab

Next step is to cleave the bulk gold along the (111) direction in order to create a slab model of the Au(111) surface.

In the **Builder**, use the *Builders* → *Surface (Cleave)* plugin to cleave the Au crystal using the Miller indices $(h, k, l) = (1, 1, 1)$:



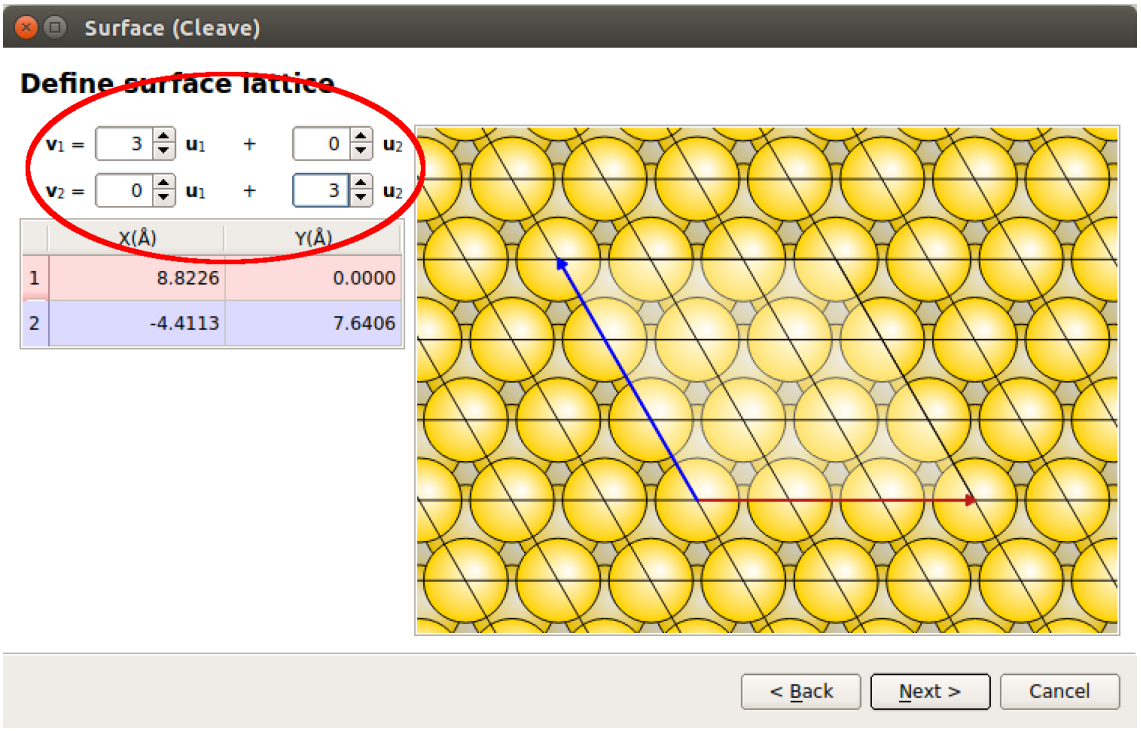


The default supercell lateral size is 1×1. This is sometimes sufficient, but in the present case we aim for a 3×3 slab in

order to minimize in-plane interactions between neighboring Bz molecules.

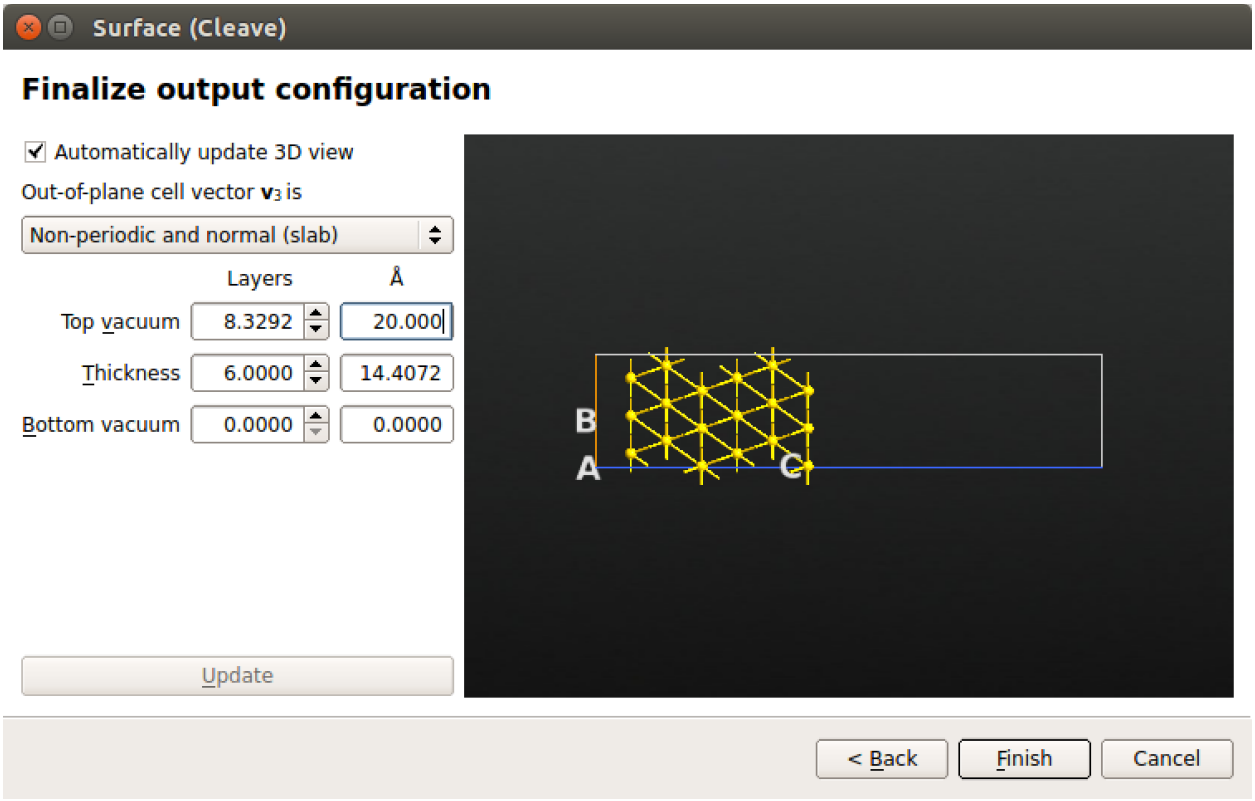
Therefore, increase the lengths of the lattice vectors $\mathbf{v}_1$ and $\mathbf{v}_2$, such that

- $v_1 = 3u_1 + 0u_2$
- $v_2 = 0u_1 + 3u_2$

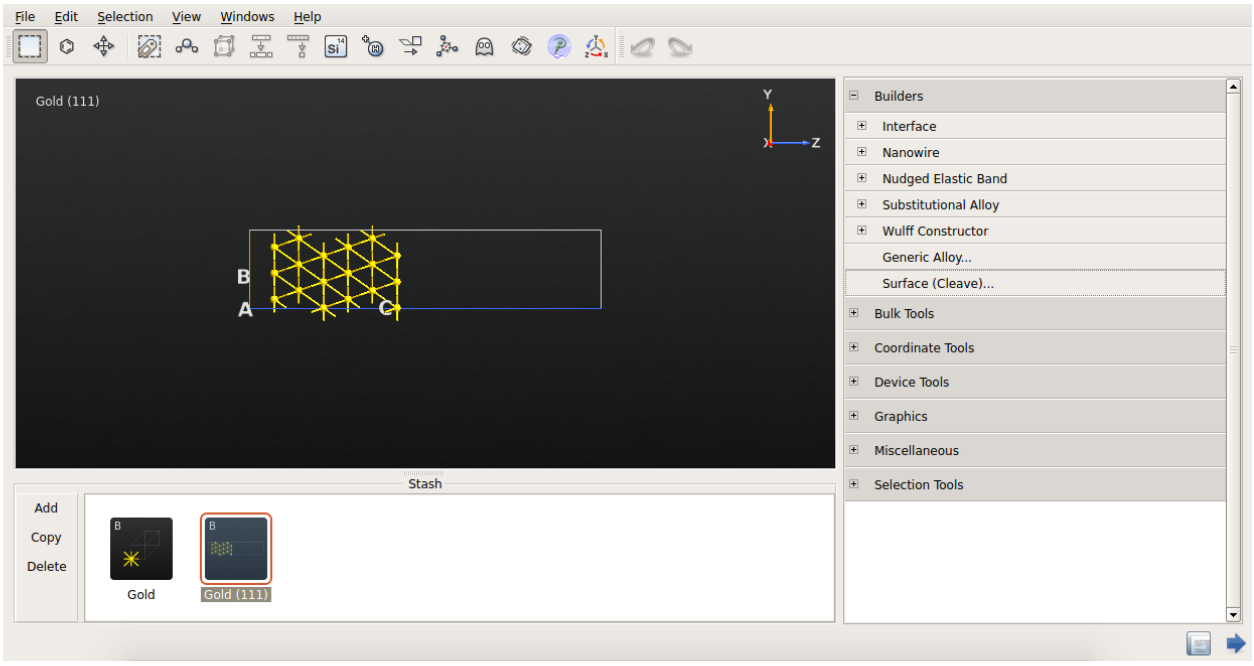


Tip: You can also modify the lattice vectors **interactively** by using the mouse to manually displace the red and blue vectors in the right-hand window showing the in-plane cell.

Finally, use the drop-down menu to select the out-of-plane cell vector $\mathbf{v}_3$ to be **Non-periodic and slab-like** such as to model a surface with vacuum above and below it. Also increase the **Top vacuum** to 20 Å and the slab **Thickness** to 6 layers, as shown in the figure below.



Once you are done, click **Finish** to add the Au(111) slab configuration to the **Stash** and close the plugin widget.

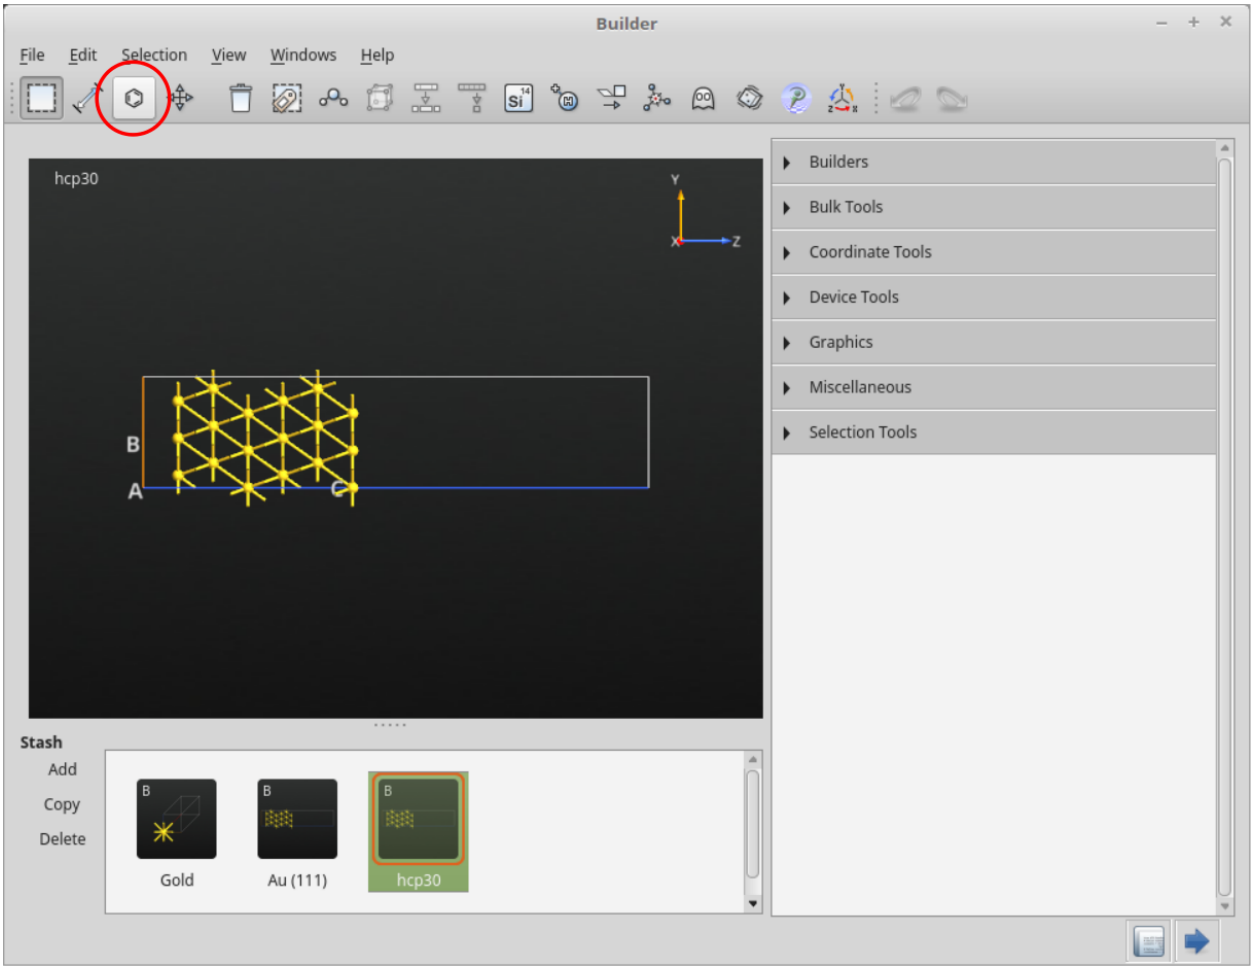


Attaching benzene to Au(111)

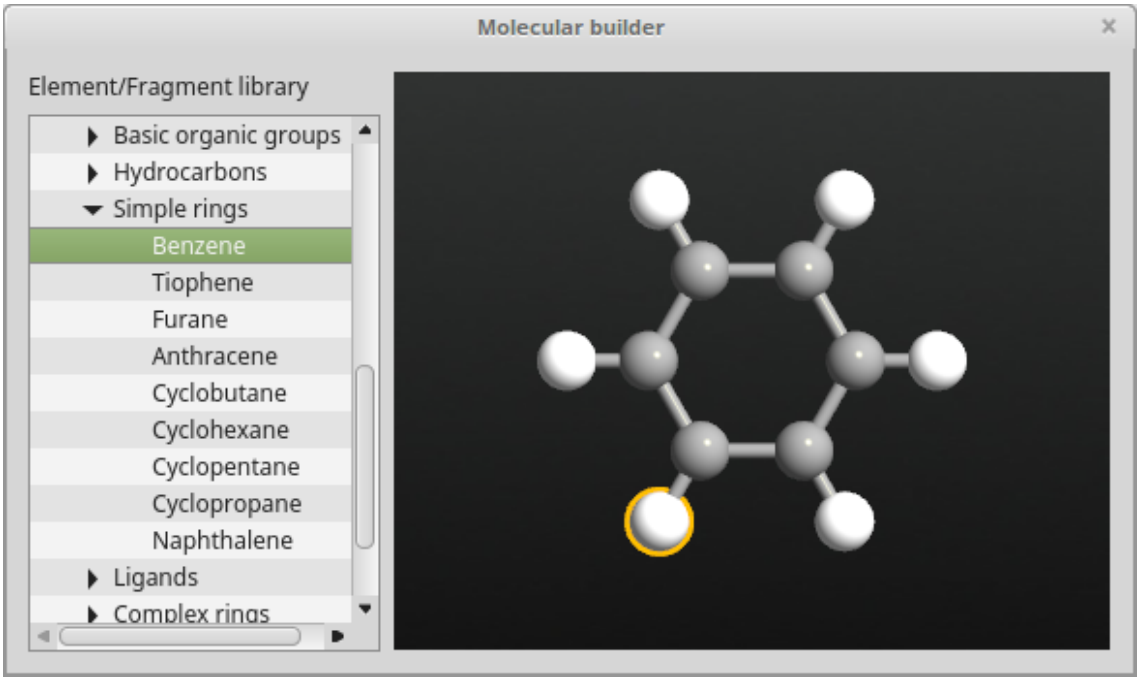
The final step is of course to attach a benzene molecule to the Au(111) slab. We will first aim for the hcp-30° configuration reported in[Page 1287, 1].

Select the *Gold(111)* **Stash** item and rename it to *Au(111)* by using mouse right-click or F2 on the keyboard. Then create a copy of the item, again using mouse right-click. Rename the copy *hcp30*.

In the **Builder**, click the icon to open the **Molecular Builder**.



In the **Molecular Builder**, select *Fragments* → *Simple rings* → *Benzene* from the drop-down menu.

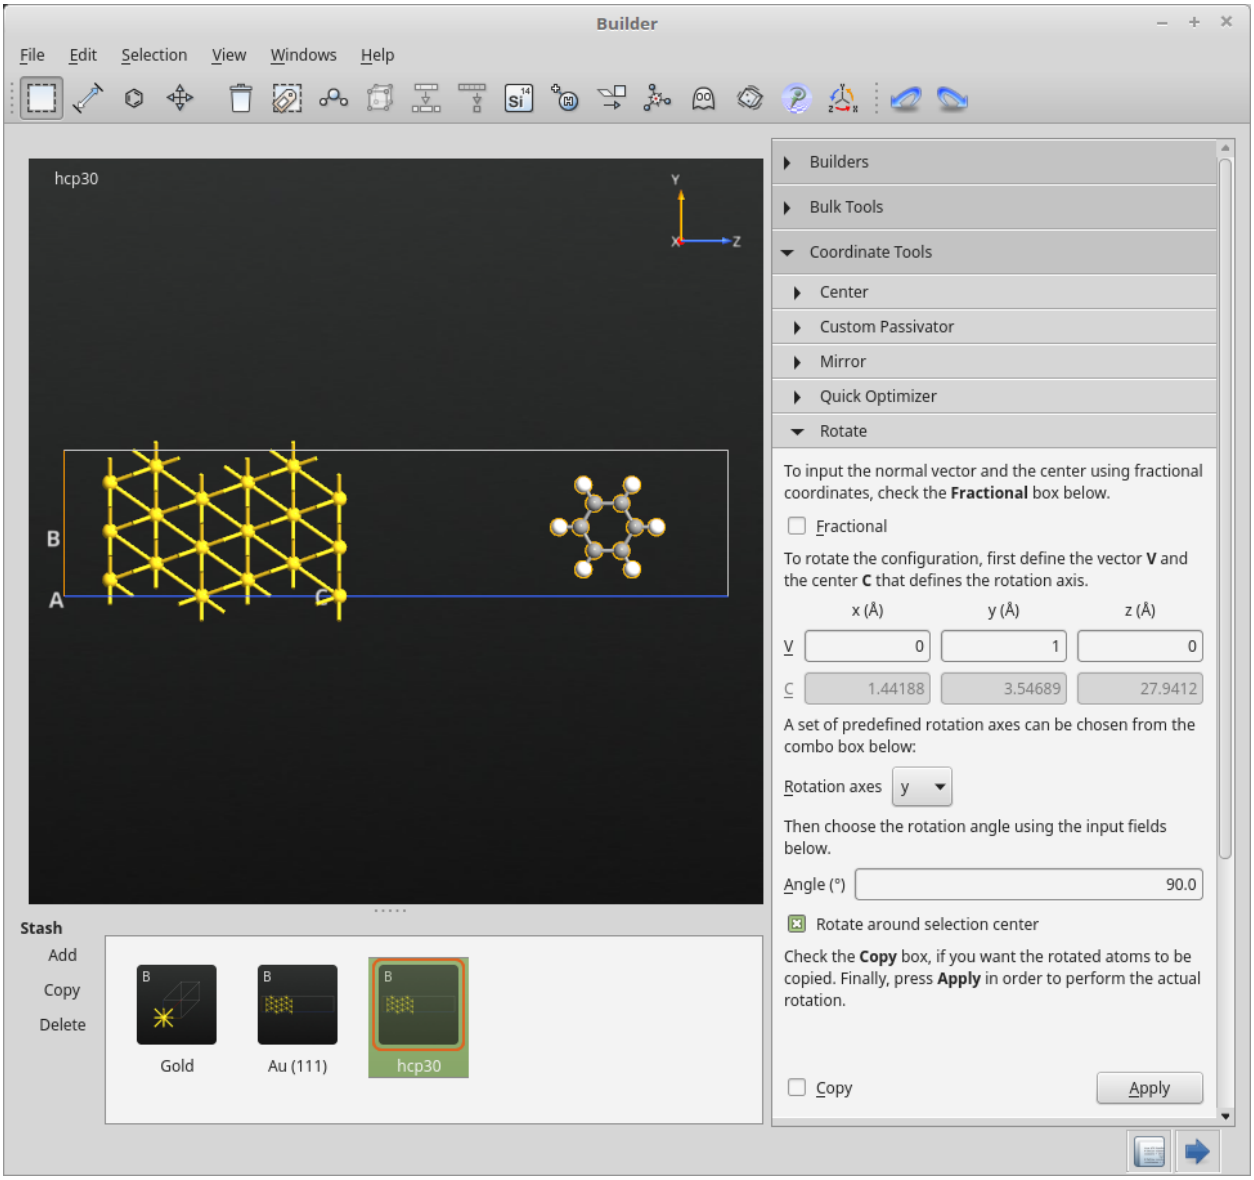


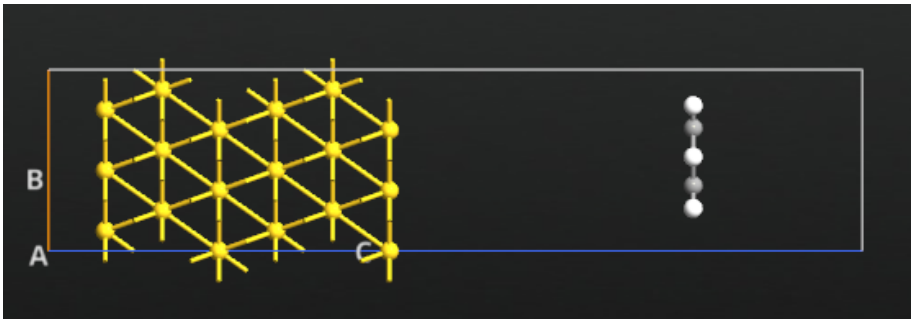
You can now insert the benzene molecule into the Au(111) configuration: Click somewhere in the Au(111) vacuum region to place the molecule there. Then close the Molecular Builder widget.

Warning: Take care to click only once to add the Bz molecule to Au(111). For each click, a new molecule will be added at exactly the same position, so that its atoms will overlap with those of the already existing molecule!

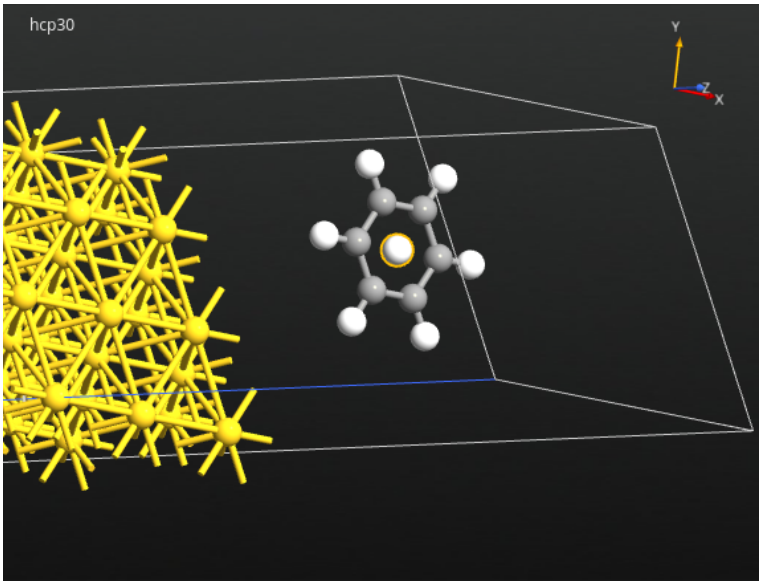
Remember that you can always check for the presence of overlapping atoms by using the *Selection Tools* → *Close Neighbors* plugin and choosing a relatively small threshold (for example, 0.001 Å).

You will then need to rotate the molecule 90°. First select all Bz atoms by using the mouse to draw a rectangle around the molecule. Then open the *Coordinate Tools* → *Rotate* plugin. Set the rotation axis to y and the rotation angle to 90°, and make sure the check-box *Rotate around selection center* is ticked. Click **Apply** to perform the rotation.





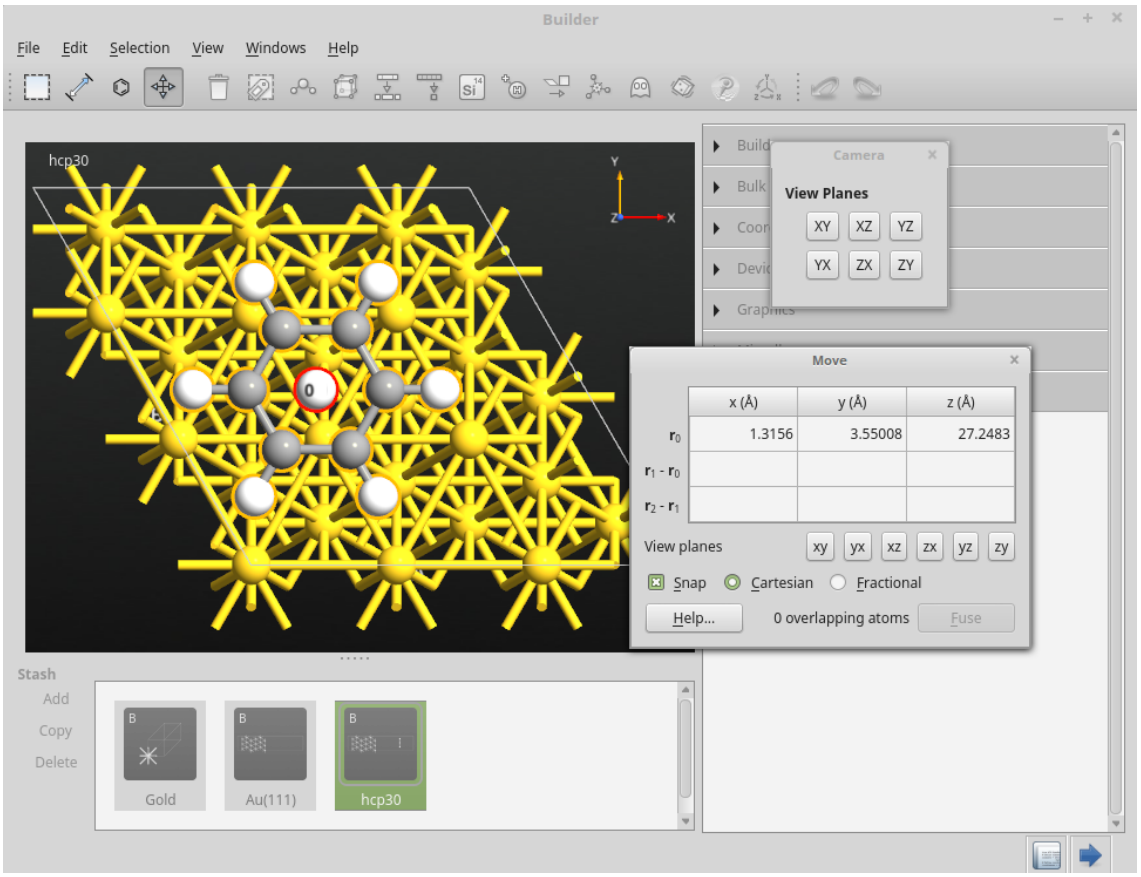
Next step is to move the Bz molecule into position in the hcp-30° adsorption site. First, make sure all Bz atoms are selected. Then click the icon to add a new atom in at the geometrical center of the molecule. You will use this anchor atom to snap the molecule into position above the surface.



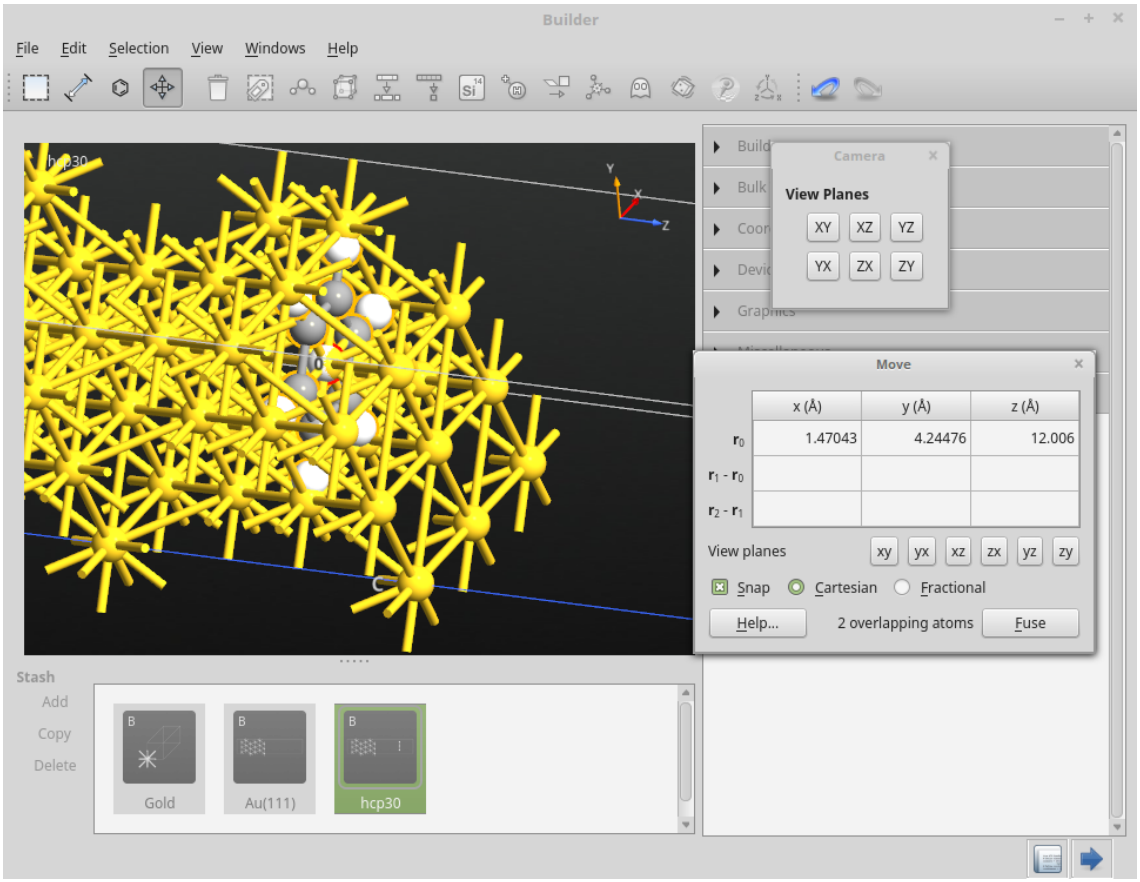
Select again all benzene atoms, including the extra atom, and rotate the view such that you see a top-view of the configuration.

Tip: The **Camera** tool may be useful: Select the **XY** view plane to get a perfect view down along the z-axis.

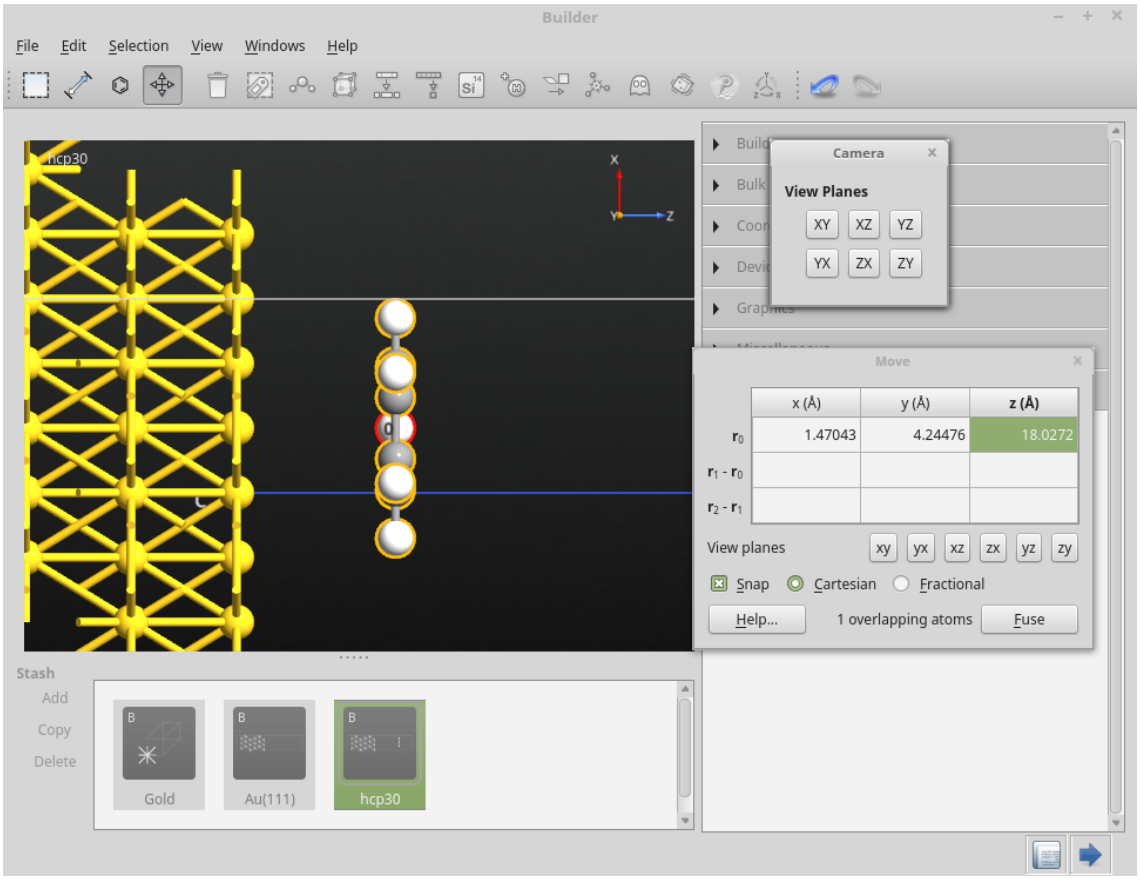
Click the icon to open the **Move** tool, and then click the extra snap-atom in the middle of the molecule to select it as an anchor atom. The selection shade should change color to red.



In the **Move** panel, make sure that the **Snap** option is selected. Use then the mouse to drag the molecule by the anchor atom, and drop it such that the anchor atom snaps onto a gold atom in the second slab layer.

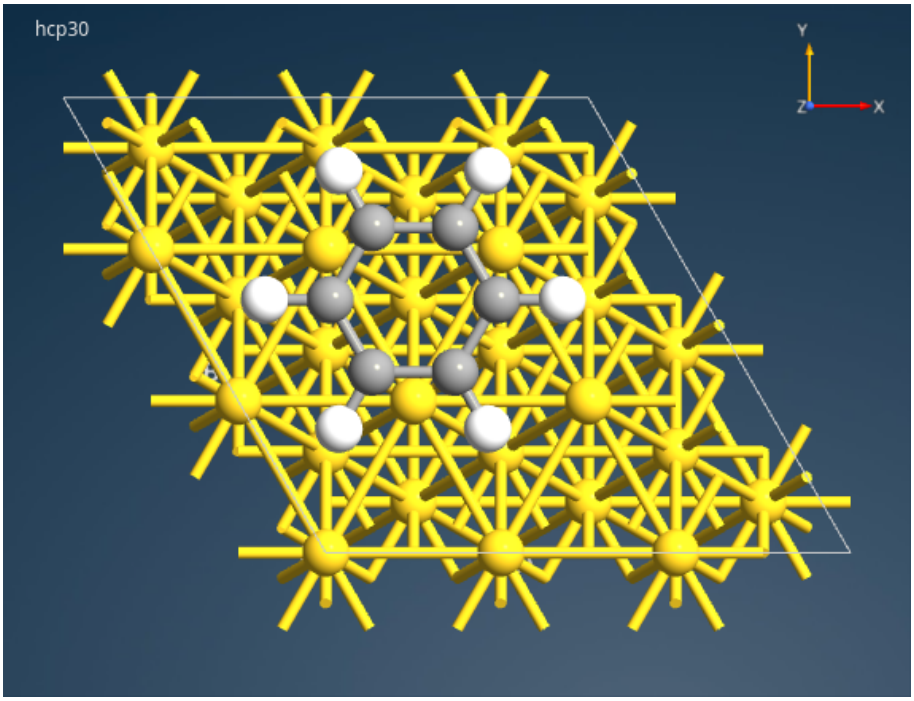


Finally, adjust the molecule–surface distance such that it matches the 3.62 Å reported in[Page 1287, 1]: In the **Move** panel, enter 18.0272 Å for the z-coordinate of the anchor atom position r_0, as shown in the figure below.



Note: In general, to set the desired molecule–surface distance, you of course need to first know the cartesian coordinate Z of the Au topmost layer. This can be done by simply hovering the pointer above one of the atoms of the Au(111) topmost layer.

Finally, remove the anchor atom by selecting it and deleting it. Your *hcp30* configuration should now look like this:



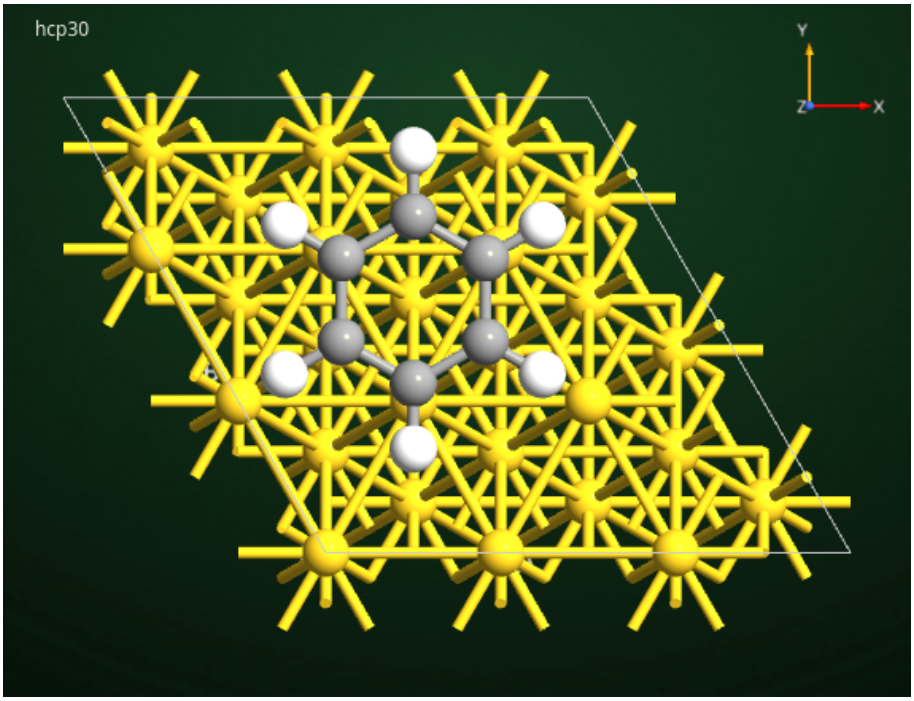
Tip: You may save the configuration as an ATKPython script, or **export** it to a range of popuar file formats.

Creating the hcp-0° configuration

The hcp-0° adsorption configuration is simply related to the hcp-30° one by a 30° rotation of the benzene adsorbate (assuming constant Bz–Au(111) distance).

First, **copy** the *hcp30* Stash item and **rename** the copy to *hcp0*. Then select all benzene atoms in the newly created copy, and open once again the *Coordinate Tools* → *Rotate* plugin.

Apply a rotation of 30° around the z-axis, which is normal to the surface plane. The *hcp0* configuration should now look like this:



References

3.9.2 Building a molecular junction

Note: The work flow described below will walk you through a rather broad overview of the various tools in the Builder. The individual operations are not specific for this surface and this molecule, but can be applied to any other molecule or similar structure. This is the idea of the Builder - by applying a specific sequence of generic operations, you can easily build even highly specialized structures.

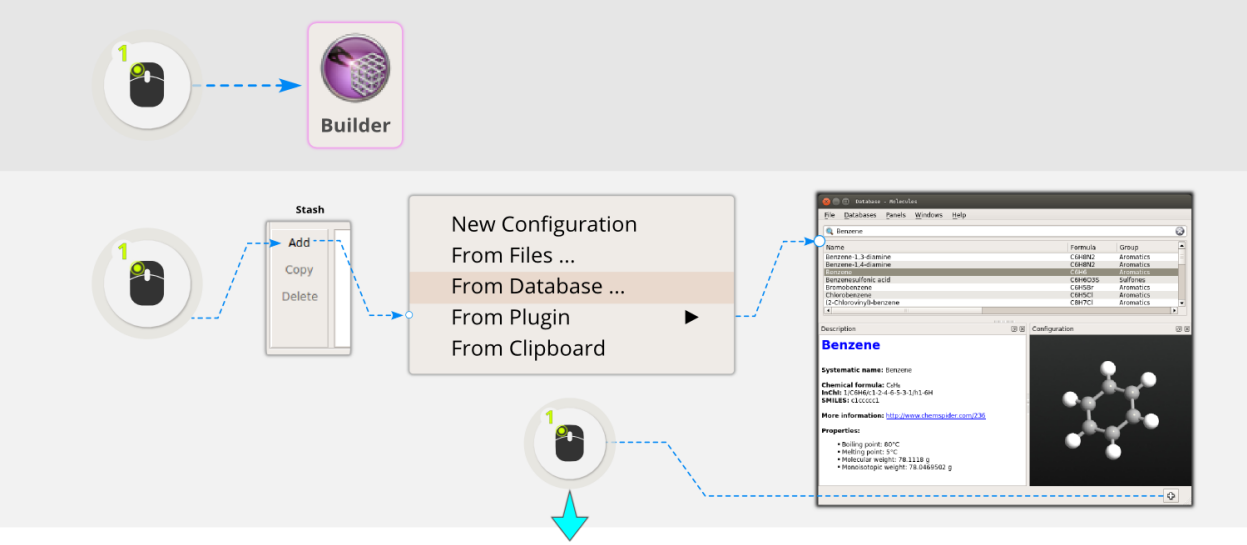
The recipe is quite simple and includes the following simple steps:

Construct the molecule. (Sometimes trivial, if you have it ready in the Database or as an external file; in our case we will modify benzene to make DTB.) Construct the surfaces, by cleaving the bulk crystal and creating a copy, to make two electrodes. Place the molecule on the surface of the left electrode, and connect the right electrode to the molecule. Finalize the device geometry.

The instructions below may appear a bit complicated, since each step contains many operations, but with a bit of training the whole process can be carried out in under 5 minutes. Also remember - if you make a mistake anywhere along the line, use Undo (Ctrl+Z)!

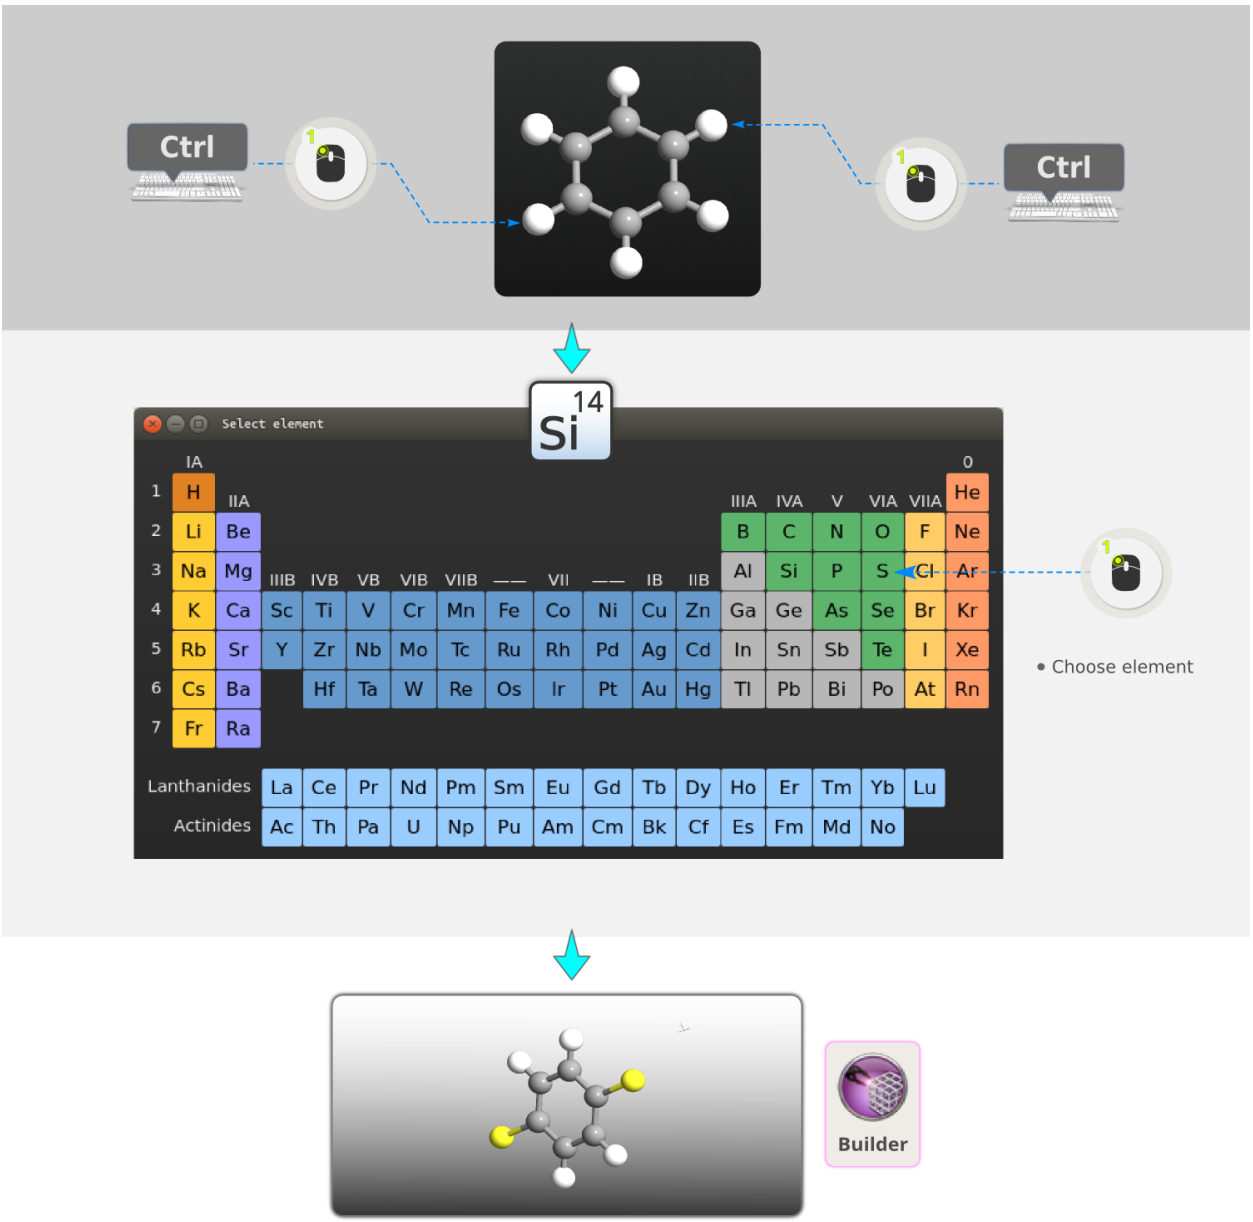
Benzene to DTB: Building the molecule

•**Step 1:** Click *Add* → *Add From Database* and from the menu select *Databases* → *Molecules*. Locate **benzene**, and click the **+** icon in the lower right-hand corner to add the molecule to the stash.



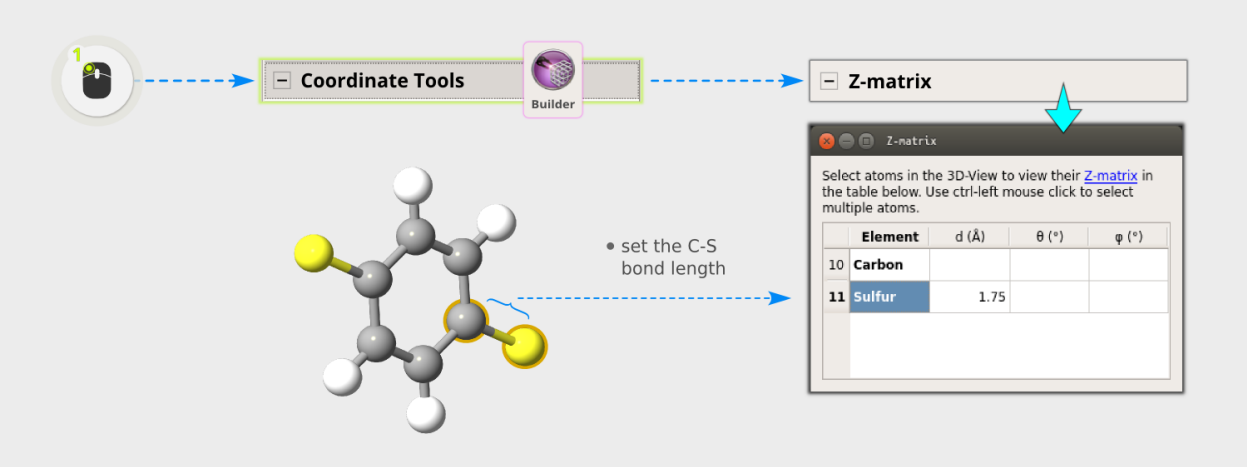
•**Step 2:** To convert the molecule to DTB, select two hydrogen atoms on opposite sides of the molecule by clicking them while holding down Ctrl. Then open the periodic table tool

, and click **Sulfur** (S) element:



•**Step 3:** Deselect all atoms by pressing Esc or clicking the background.

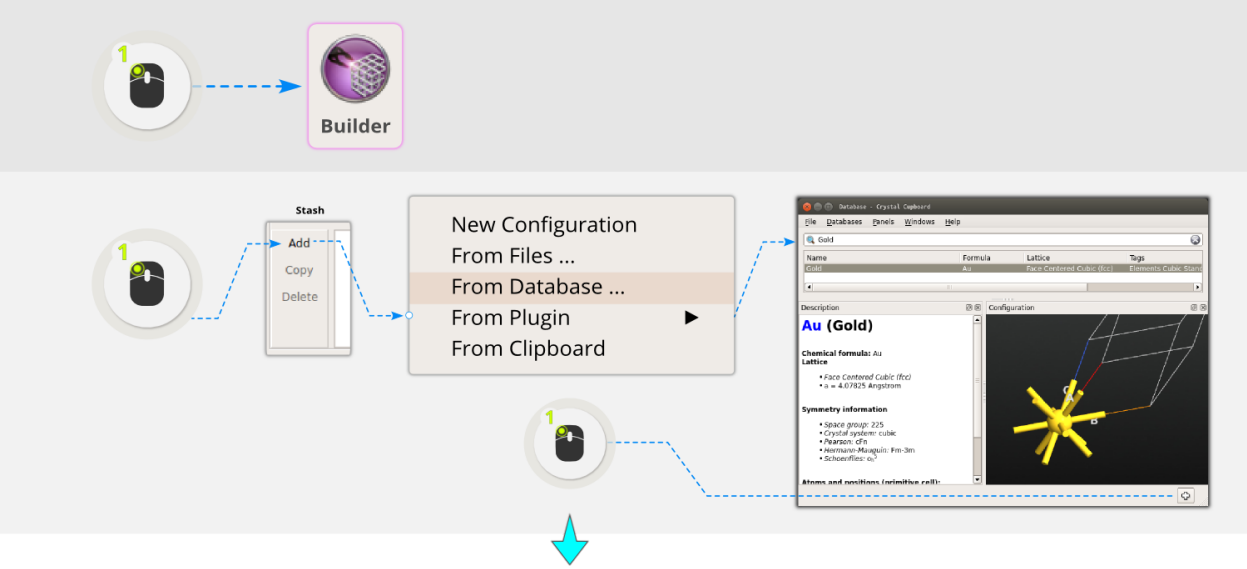
•**Step 4:** The C-S bond lengths need to be adjusted. Select one pair of bonded C-S atoms, taking care to **select the carbon atom first**. So, Open *Coordinate Tools* → *Z-matrix* and set the bond length to 1.75 Å. Note that the second selected atom moves, i.e. the S atom.



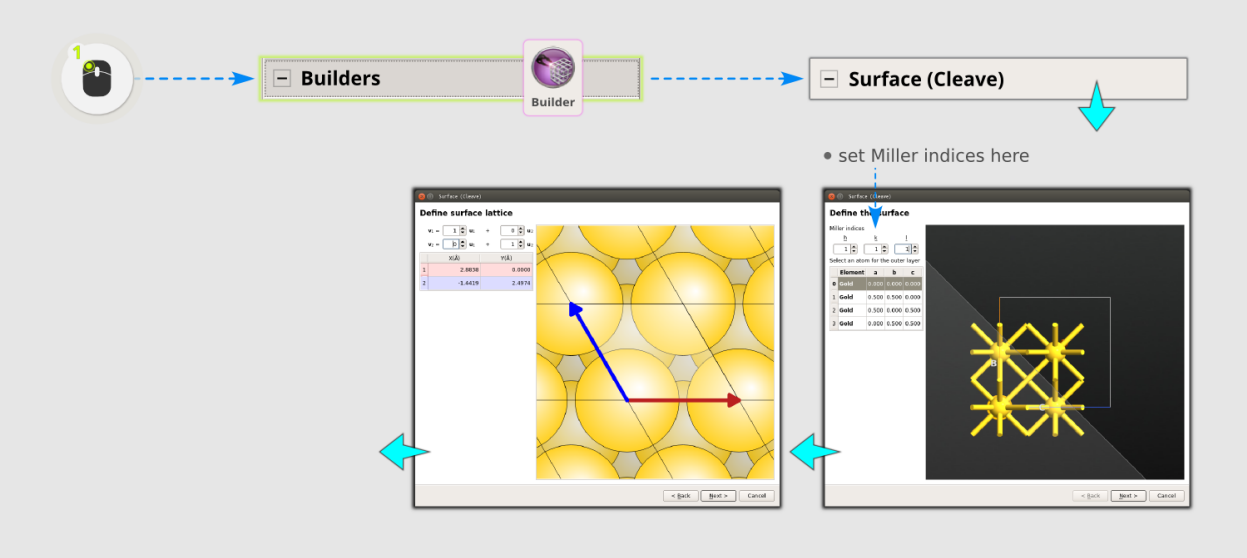
•**Step 5:** Do the same for the other Carbon-Sulfur bond!

Cleaving gold into two surfaces

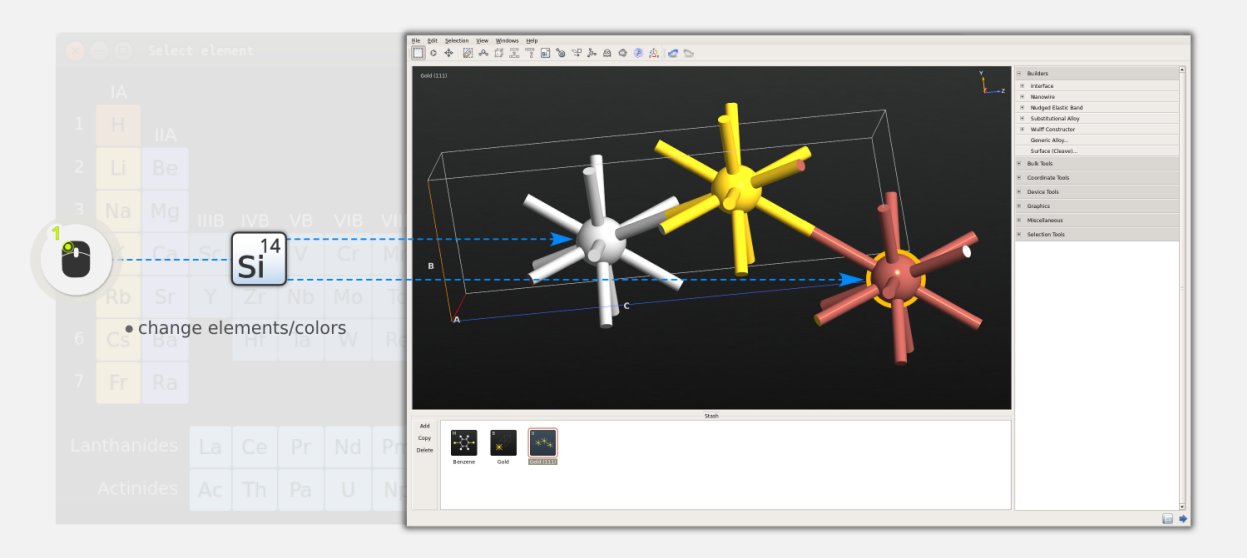
•**Step 6:** Click *Add* → *Add from Database* and this time select *Databases* → *Crystals* from the menu. Locate **Gold** and add it to the stash.



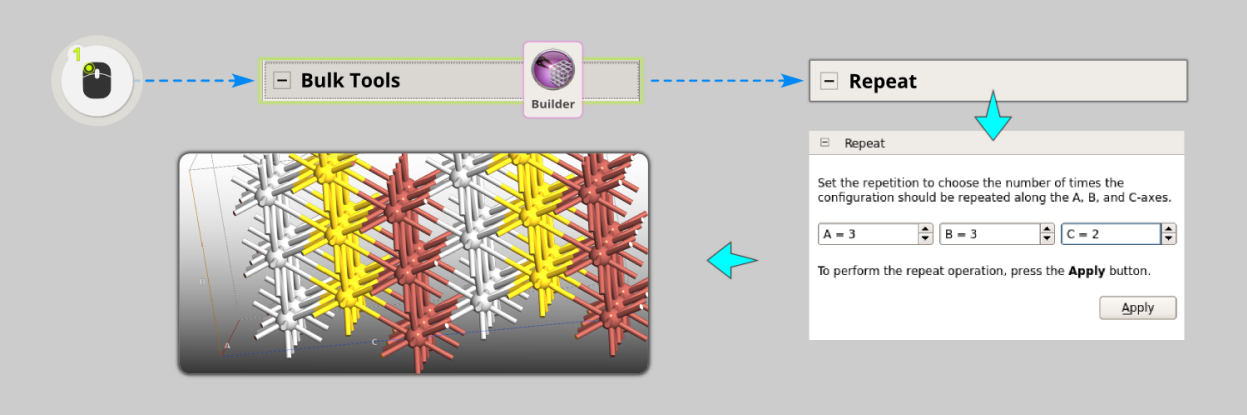
•**Step 7:** To cleave the gold crystal, open *Builders* → *Surface (Cleave)*. Enter Miller indices h=1, k=1, l=1 and click *Next* → *Next* → *Finish*.



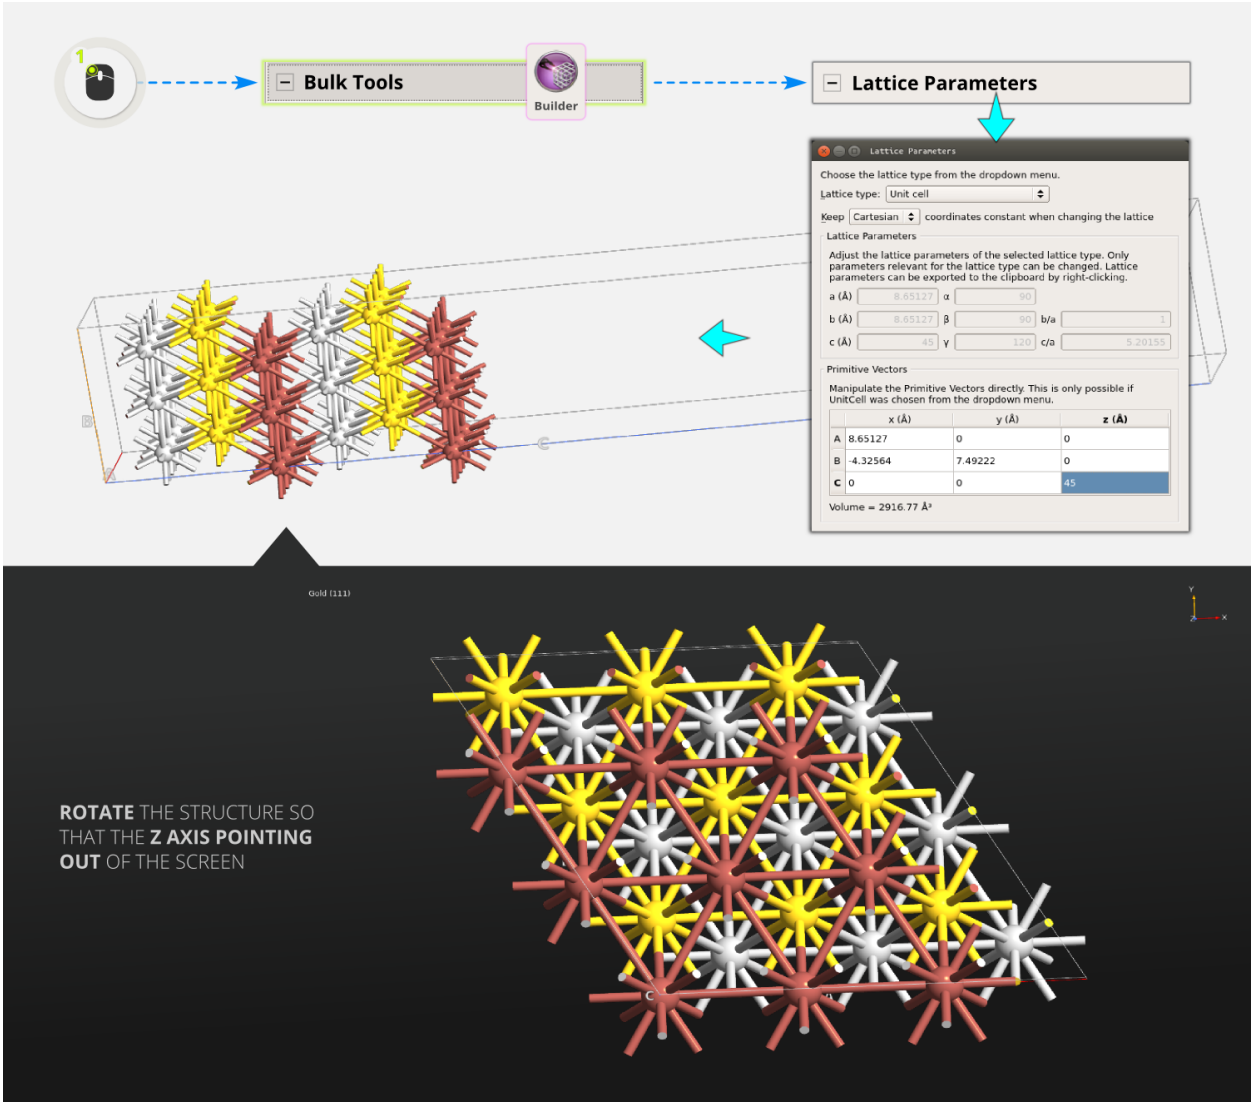
•**Step 8:** To make it easier to visually identify the three layers (ABC) in the fcc stacking sequence, change the gold atom in layer A to Ag and the one in layer C to Tl (these elements are just chosen to give nice colors).



•**Step 9:** To make a large enough surface cell for the molecule, repeat the structure 3x3x2 times using *Bulk Tools* → *Repeat*. The 2x repetition in the C direction is needed so that we later can extract the electrode from the central region.



•**Step 10:** You need to make some room for the molecule on the surface by adding vacuum. Open *Bulk Tools* → *Lattice Parameters* , select to keep Cartesian coordinates, and increase the C vector to 45 Å (still pointing along Z, as is necessary for a device).

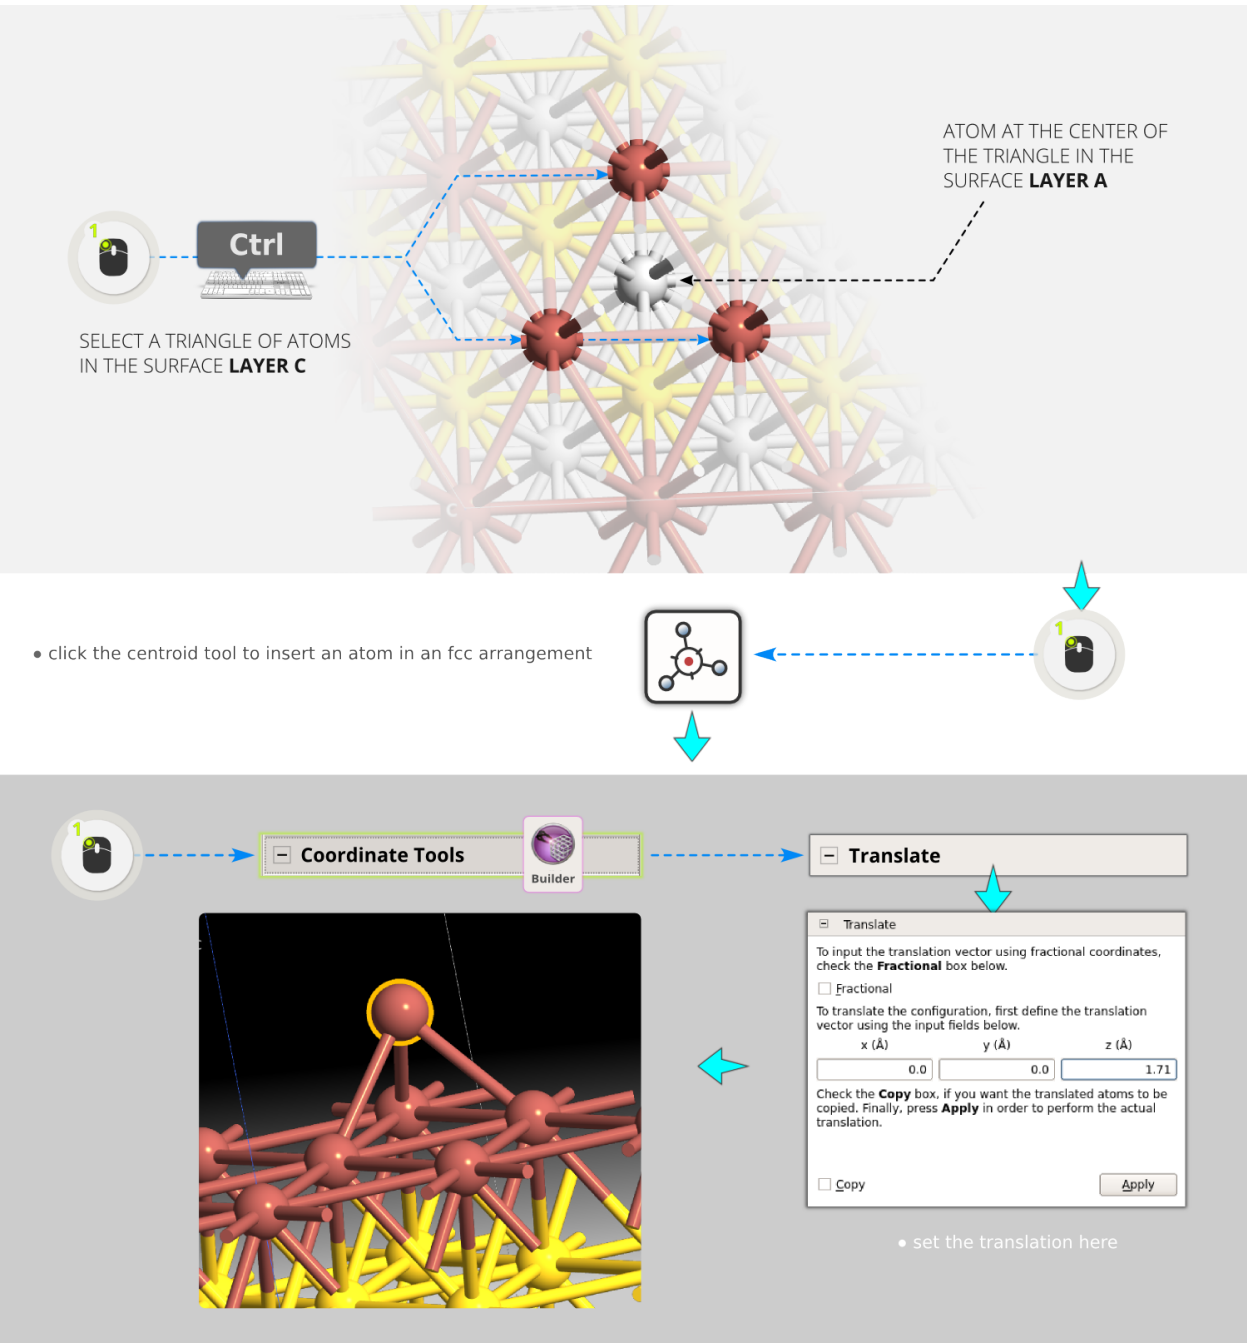


You will now create an alignment point on the surface where we can attach the molecule.

•**Step 11:** Select three atoms in a triangle in the surface layer C (the Tl atoms), such that the center of the triangle is above a silver atom in the A layer. Press the centroid tool to insert another atom in the average position of the three selected atoms. By choosing these particular atoms, the inserted atom sits in an fcc site, which is where we want to attach the molecule.

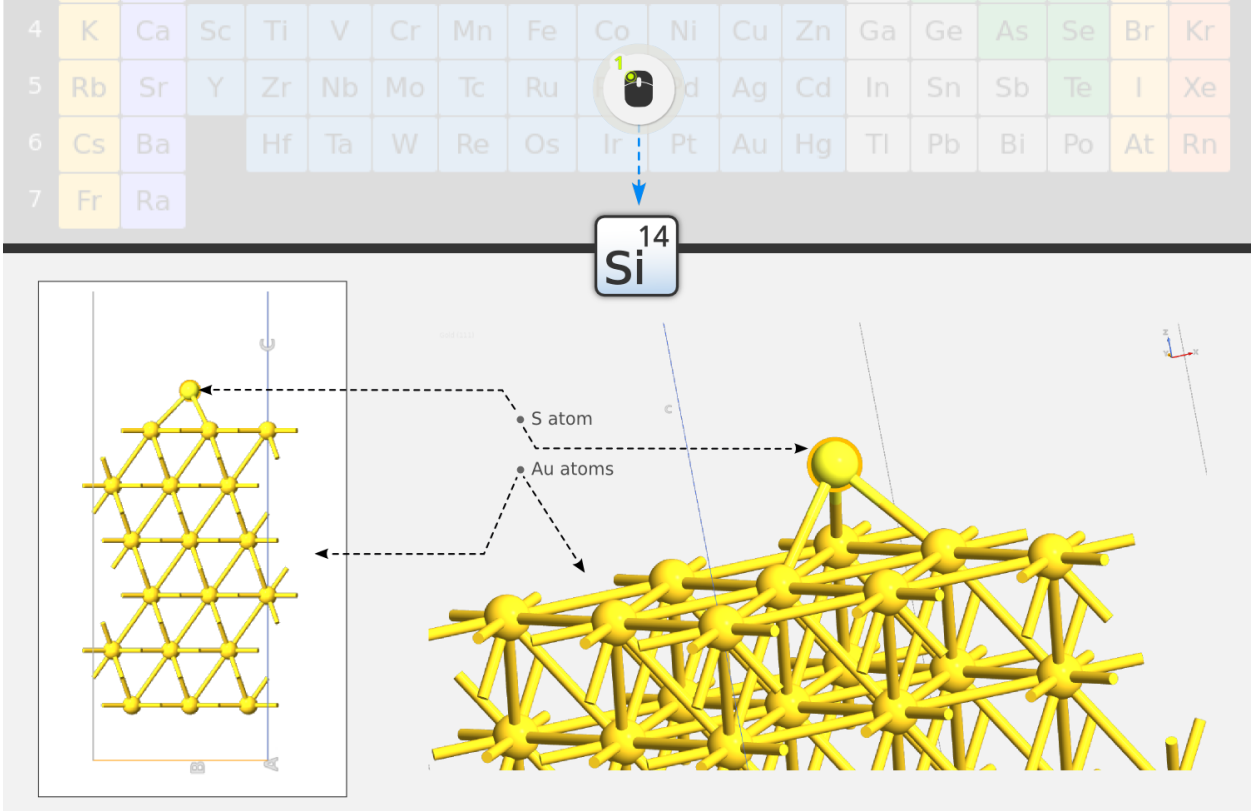
•**Step 12:** Use *Coordinate Tools* → *Translate* to move this atom 1.71 Å in the Z direction. (The value 1.71 Å gives an Au-S distance of 2.39 Å, taken from[1]).

[1] M.ăBrandbyge, J.-L. Mozos, P.ăOrdejon, J.ăTaylor, and K.ăStokbro. Density-functional method for nonequilibrium electron transport. *Phys. Rev. B*, 65:165401, Mar 2002. doi:10.1103/PhysRevB.65.165401.

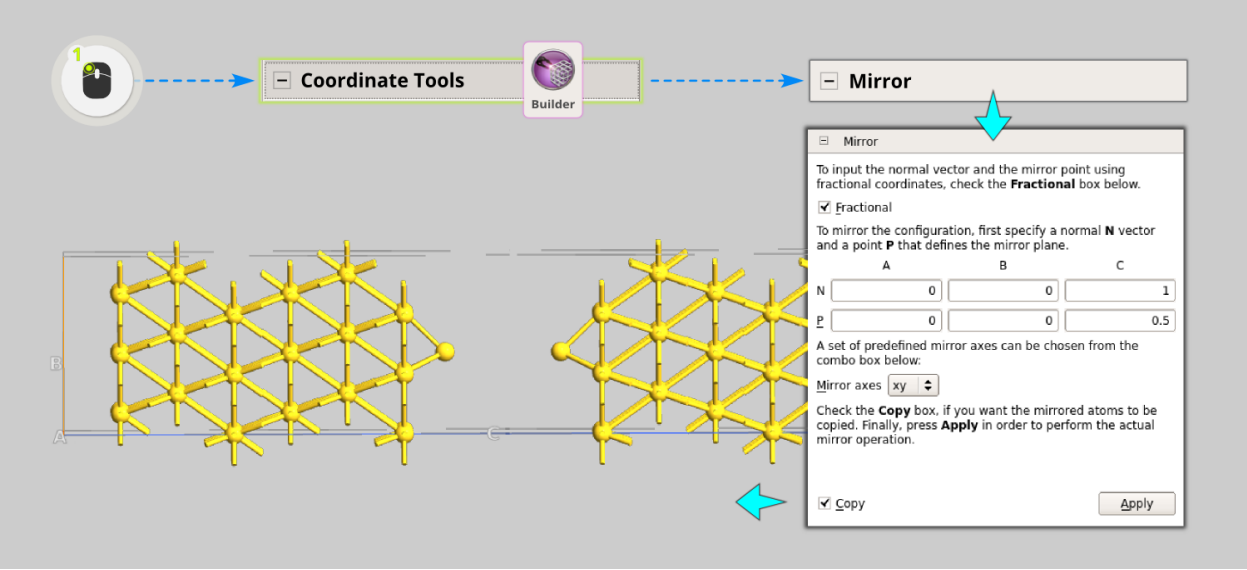


•**Step 13:** Press Ctrl+A to select all atoms, and switch them back to gold.

•**Step 14:** Also, to make it easier to handle the alignment atom later on, convert it to sulfur.



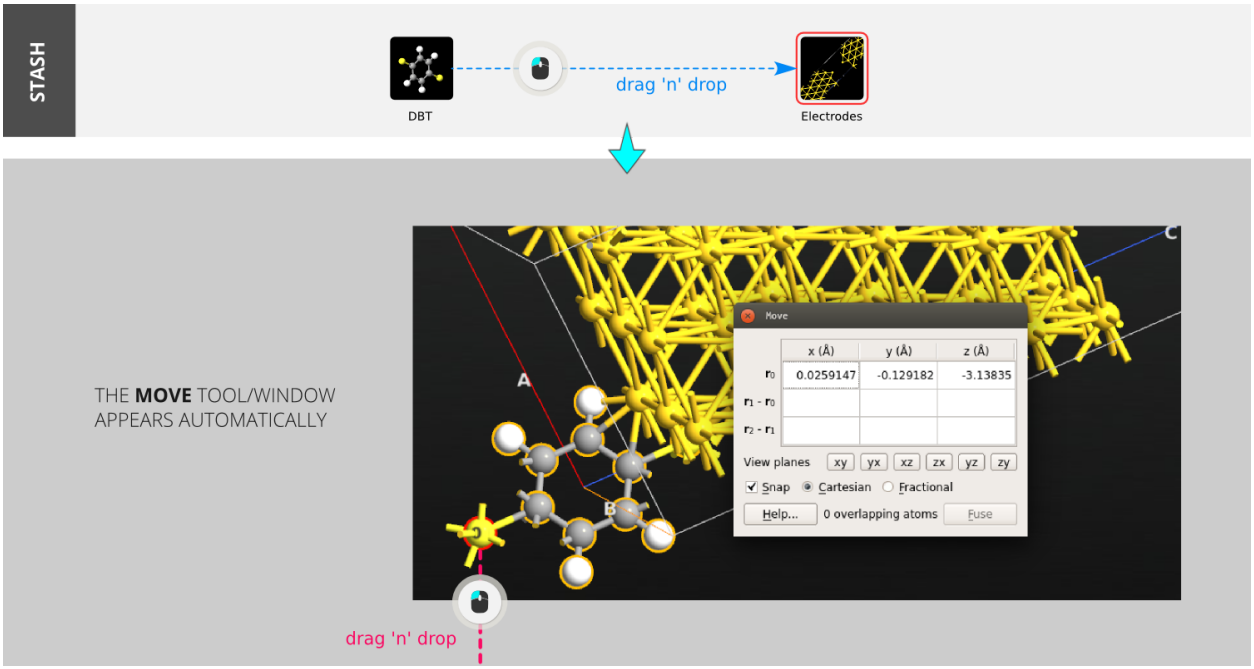
•**Step 15:** So far there is only one gold surface - there should be two. Therefore, press Ctrl+A again and open *Coordinate Tools* → *Mirror* . Select Fractional coordinates and set P=[0,0,0.5]. Tick Copy, then press Apply.



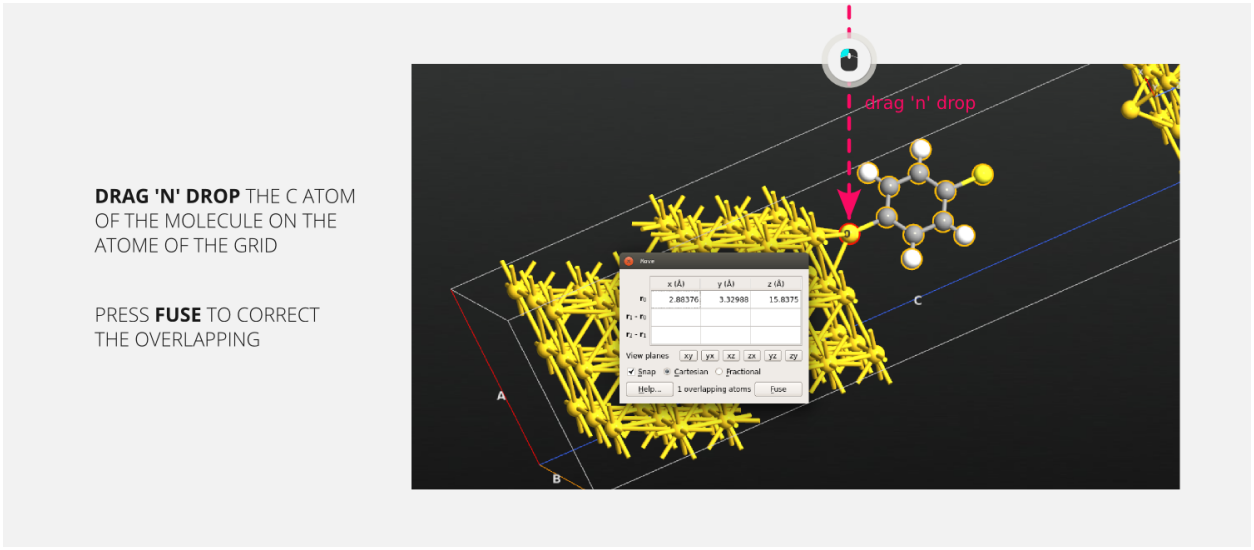
Combining the molecule and the surfaces

•**Step 16:** Add the benzene to the gold structure by dragging it from the stash onto the main window (where the gold surfaces are displayed). When the molecule is added, the Builder automatically activates **Move mode**.

Note: All atoms in the molecule are selected (indicated by the yellow circles around the atoms); in **Move mode**, you cannot change this selection, but you can appoint so-called **anchor atoms** which are used to translate and rotate the selection. **Anchor atoms will be indicated by red circles**.

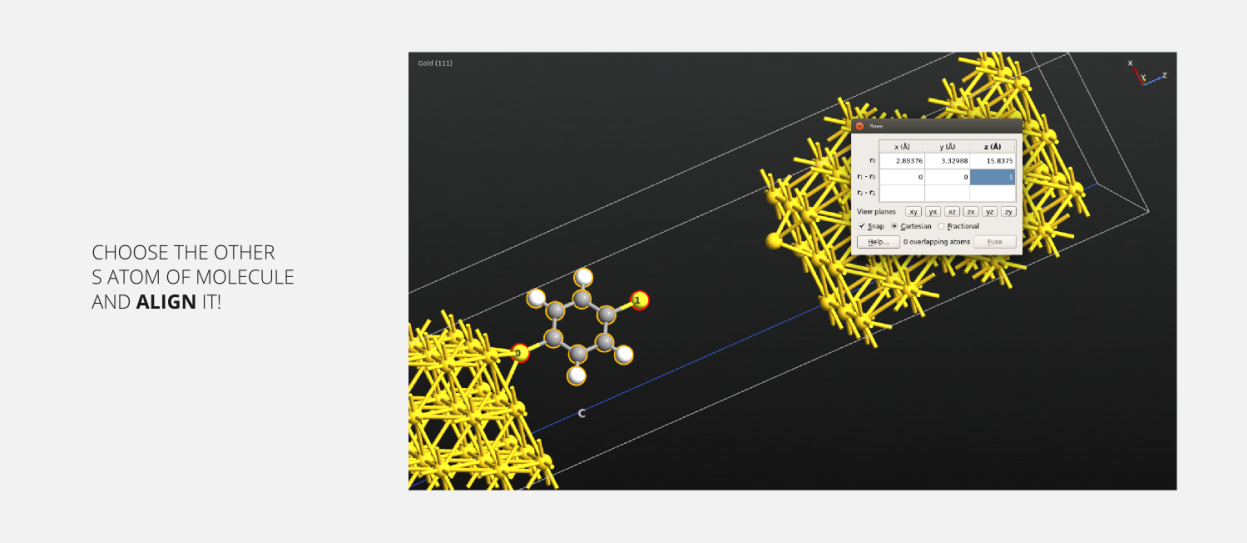


•**Step 17:** Click one of the sulfur atoms - it will become an anchor atom. Then drag it so that it ends up on top of the sulfur alignment atom on the left surface. Since Snap is on, it will latch on to the exact position of the alignment atom, indicated by the selection marker turning blue when the two atoms are on top of each other.



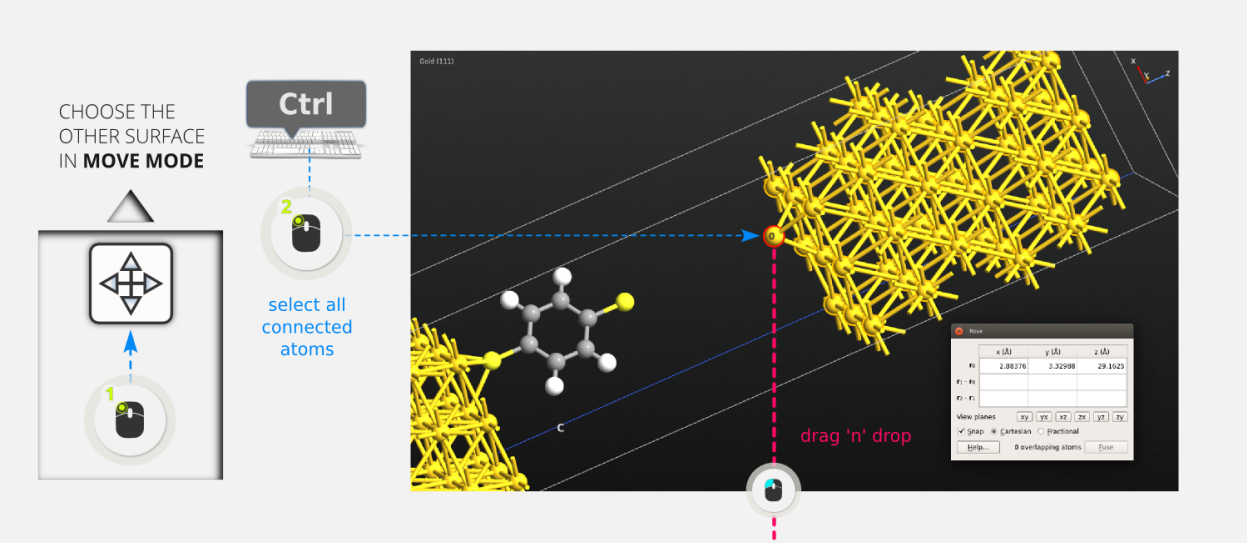
•**Step 18:** Press Fuse - this removes one of the two overlapping sulfur atoms (the one in the surface is removed; atoms in the active selection are always kept when fusing).

•**Step 19:** Now click the other S atom (the first one will remain selected). Then enter [0,0,1] on the **r1-r0** row of the Move tool widget. This aligns the two atoms - and hence the molecule along the Z axis. Close the Move tool widget.



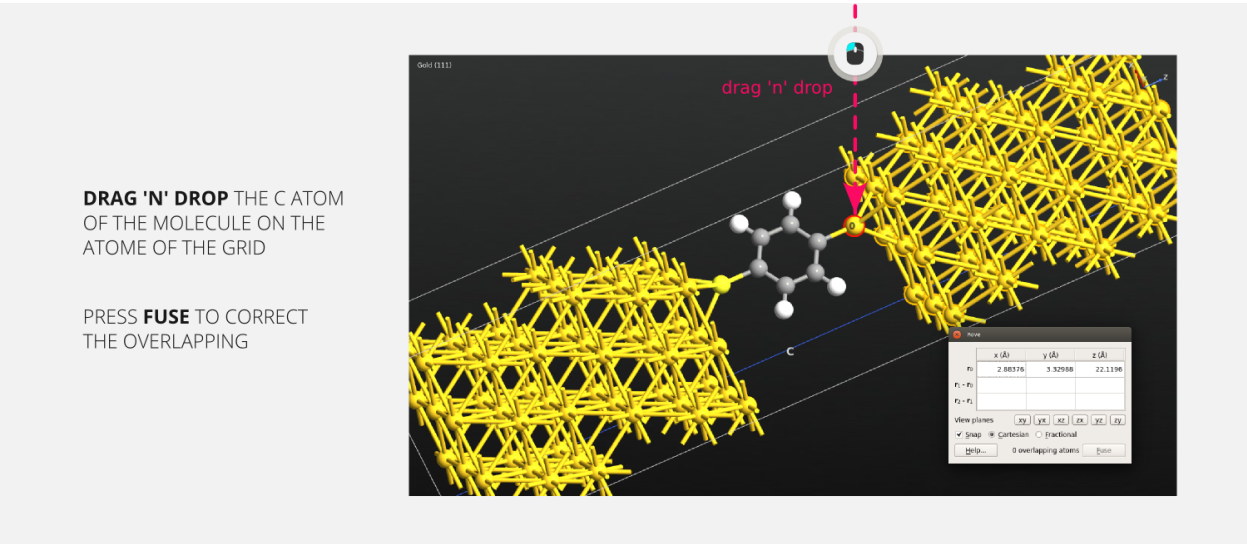
•**Step 20:** Select the second surface by holding down Ctrl while double-clicking one of the atoms in it. This selects all connected atoms.

•**Step 21:** Enter **Move mode** again and click the sulfur alignment atom in the second surface to make it an anchor atom.



•**Step 22:** Drag the right surface so that the anchor/alignment atom ends up on top of the sulfur atom on the free end of the DTB molecule.

•**Step 23:** Press **Fuse** to remove one of the two overlapping sulfur atoms (the one in the molecule, this time). Close the Move tool widget.



You now have a complete central region, and the only thing remaining is to convert it to a device configuration.

Converting the central region to a device configuration

•**Step 24** Open *Devices Tools → Device from Bulk*. The tool automatically figures out the size of the electrodes, since we repeated the gold (111) surface cell 2x in C.

•**Step 25:** This is however a very large central region, which will take a long time to calculate. Therefore, reduce the left and right surfaces to four layers by clicking twice for each surface (left and right). Press OK and you are done!

Note: In order to optimize the geometry of the device you can read the *Advanced device relaxation - manual workflow* tutorial.

3.9.3 Molecular Device

Version: 2016.3

This tutorial focuses on the calculation and analysis of a molecular device. The device consists of a dithiol benzene (DTB) molecule (sometimes also called benzene dithiol, BDT) in contact with two gold (111) surfaces. This is a classic molecular device, sometimes called the fruit fly of molecular electronics, and it has been studied in a large number of publications, see for instance[1][2] and references therein.

Some of the calculations in this tutorial are quite time-consuming; for a quicker introduction to quantum transport studies with **ATK**, see *Transport calculations with QuantumATK*. The example structure you will use is a molecular junction with a benzene ring between two gold electrodes. You can find the instruction of how to build it in Molecular Junction.

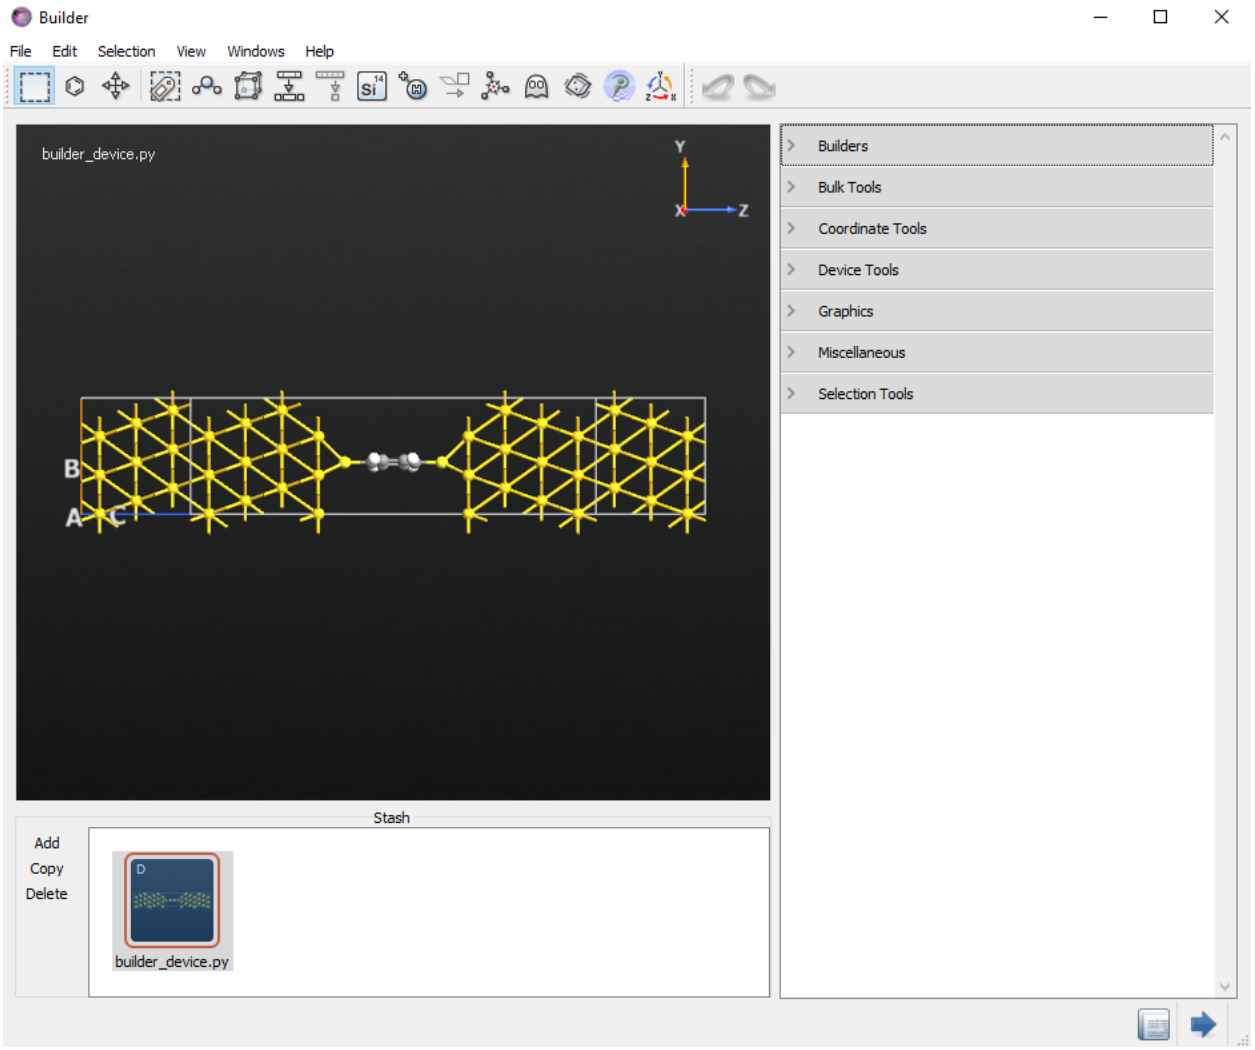
[1] K.ăStokbro, J.ăTaylor, M.ăBrandbyge, J.-L. Mozos, and P.ăOrdejón. Theoretical study of the nonlinear conductance of Di-thiol benzene coupled to Au(111) surfaces via thiol and thiolate bonds. *Computational Materials Science*, 27(1-2):151–160, 2003. doi:10.1016/S0927-0256(02)00439-1.

[2] K.S. Thygesen and K.W. Jacobsen. Molecular transport calculations with Wannier functions. *Chemical Physics*, 319(1-3):111–125, 2005. doi:10.1016/j.chemphys.2005.05.032.

The DFT model in QuantumATK is the underlying calculation engine used in this tutorial. A complete description of all the parameters, and in many cases a longer discussion about their physical relevance, can be found in the ATK reference manual.

Zero-bias calculation

Following the instruction of Molecular Junction, or download the script `builder_device.py`, you will get the following structure.

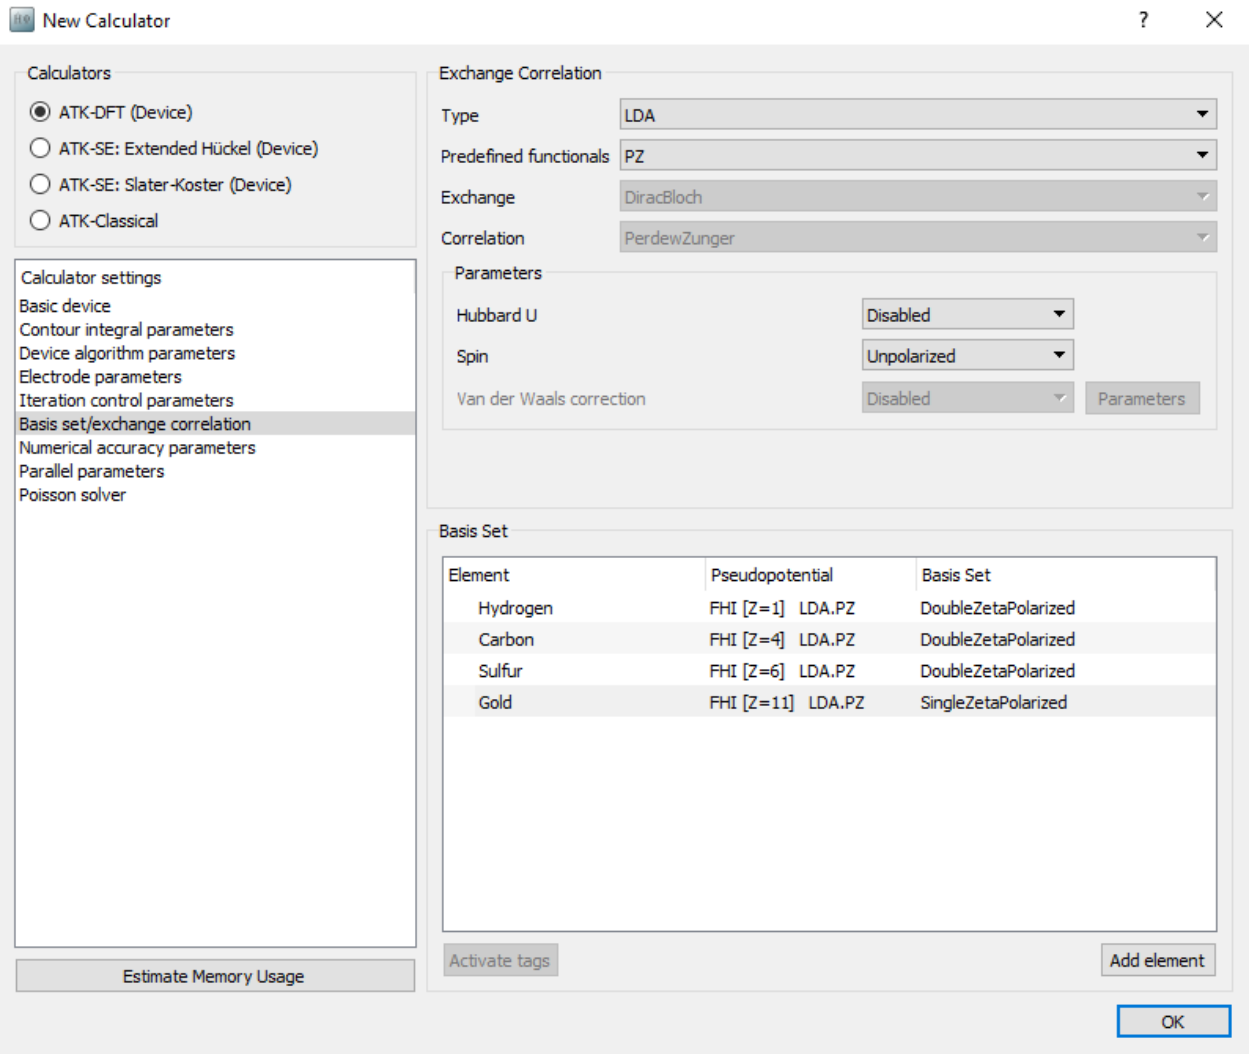


Attention: The geometry was not relaxed. This is not critical for the concepts we will discuss in this tutorial, but it is an important step to consider for any real calculations with **ATK**. To learn how to relax a device geometry, see the *Relaxation of devices using the OptimizeDeviceConfiguration study object*.

Setting up the calculation with the Script Generator

Now send the geometry to the **Script Generator** by pressing the **Send to** button at the lower right-hand corner of the **Builder** and select **Script Generator** from the pop-up menu.

- In the Script Generator, add three blocks:
  - a **New Calculator**
  - an *Analysis* → *DeviceDensityOfStates*
  - an *Analysis* → *TransmissionSpectrum*
- Change the default output filename to `au-dtb-au.hdf5`.
- Open the **New Calculator** block and change the following settings:
  - Set the k-point sampling to 3 x 3 x 50 points.
  - In *Basis set/exchange correlation*, reduce the basis set to *SingleZetaPolarized* for Gold to gain some speed.



- Open the **DeviceDensityOfStates** block by double-clicking it and change the following settings:
  - set the k-point sampling to 3 x 3 points
  - set the energy range to (-3, 3) eV
  - set points from 101 to 401
- Open the **TransmissionSpectrum** block and make the same modifications, i.e.
  - set the k-point sampling to 3 x 3 points.
  - set the energy range to (-3, 3) eV.
  - set points from 101 to 401
- Finally, save the calculation script to the file `au_dtb_au.py` in your working directory for future reference. You can also download the file `au-dtb-au.py` for comparison.

To run the script on your local machine, send it to the **Job Manager** by pressing the **Send to** button at the lower right-hand corner of the **Script Generator** and select **Job Manager** from the pop-up menu. In the **Job Manager**, press **Run Queue** to launch the job. On a modern, single-node computer the script should take around an hour to execute.

Note: The calculation speed can be increased greatly by using a parallel computer. For information about how to run jobs in parallel, see the *Parallelization of QuantumATK calculations*.

Analysis of the zero-bias results

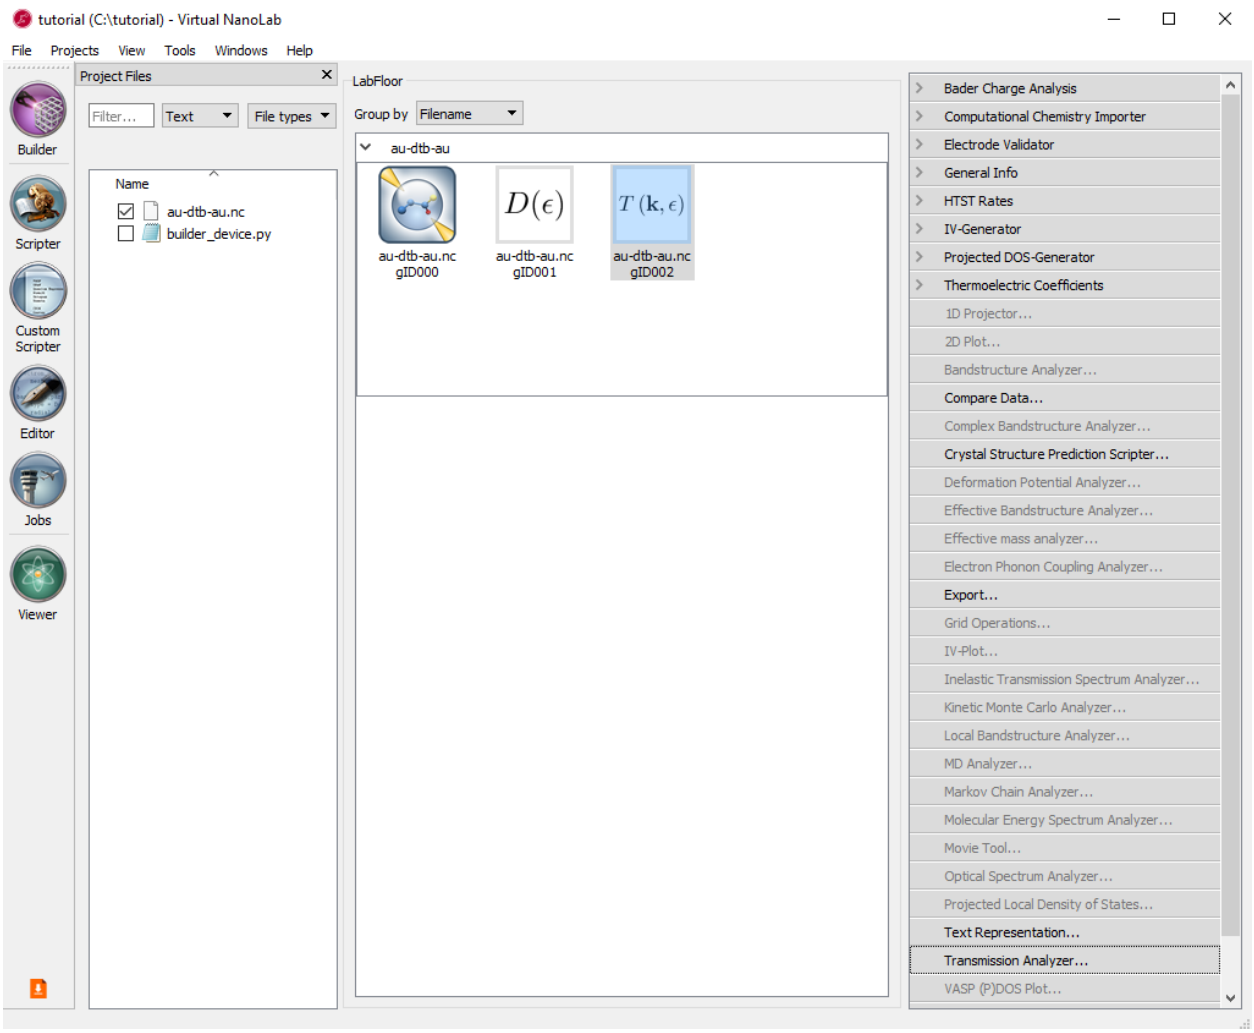
In this chapter you will extract data from the zero-bias calculation. You will do the following analyses:

- Compare the transmission spectrum with the Partial Device Density Of States (PDDOS) of the phenylene ring.
- Calculate the Molecular Projected Self-Consistent Hamiltonian (MPSH), and rationalize the transmission in terms of the MPSH states.
- Calculate the transmission eigenstates.
- Calculate the energy-dependent Local Density of States (LDOS), in order to obtain a spatial view of the energy levels.

The transmission spectrum and density of states

Return to the main **QuantumATK** window. The `au-dtb-au.hdf5` file should now be visible under **Project Files**, and its contents displayed on the **LabFloor**. It contains three objects:

- **DeviceConfiguration** contains the two-probe device configuration and the self-consistent state of the attached calculator.
- $T(\mathbf{k}, \epsilon)$ **TransmissionSpectrum** contains all information about the computed transmission spectrum, including settings and results.
- $D(\epsilon)$ **DeviceDensityOfState** contains all informations about the Density state of the device region.



Select the TransmissionSpectrum object, and click the **Transmission Analyzer** in the right-hand panel bar.

The Transmission Analyzer plugin opens. On the left, named **Spectrum**, is shown the k-point averaged transmission spectrum as function of energy. The average Fermi energy of the two electrodes is set to zero and indicated with a dashed line.

The transmission and energy values in the point marked by the red dot are shown below the plot. You can use the mouse to move the dot along the $T(E)$ curve and read off the values. The *Curves* drop-down menu lets you select the spin components to be plotted. Note that the transmission for spin types X, Y, and Z are only non-zero for calculations with noncollinear spin.

At any particular energy (defined by the red dot), the total transmission is computed as an average over the transmission coefficients in the sampled k-points. The right-hand plot, named **Coefficients**, shows an interpolated contour plot of the transmission coefficients vs. reciprocal vectors k_A and k_B. For example, at the energy, E = -1.4 eV, where you find a spectrum peak at the transmission, the contribution is minimum around the Γ point, as shown in the figure below.

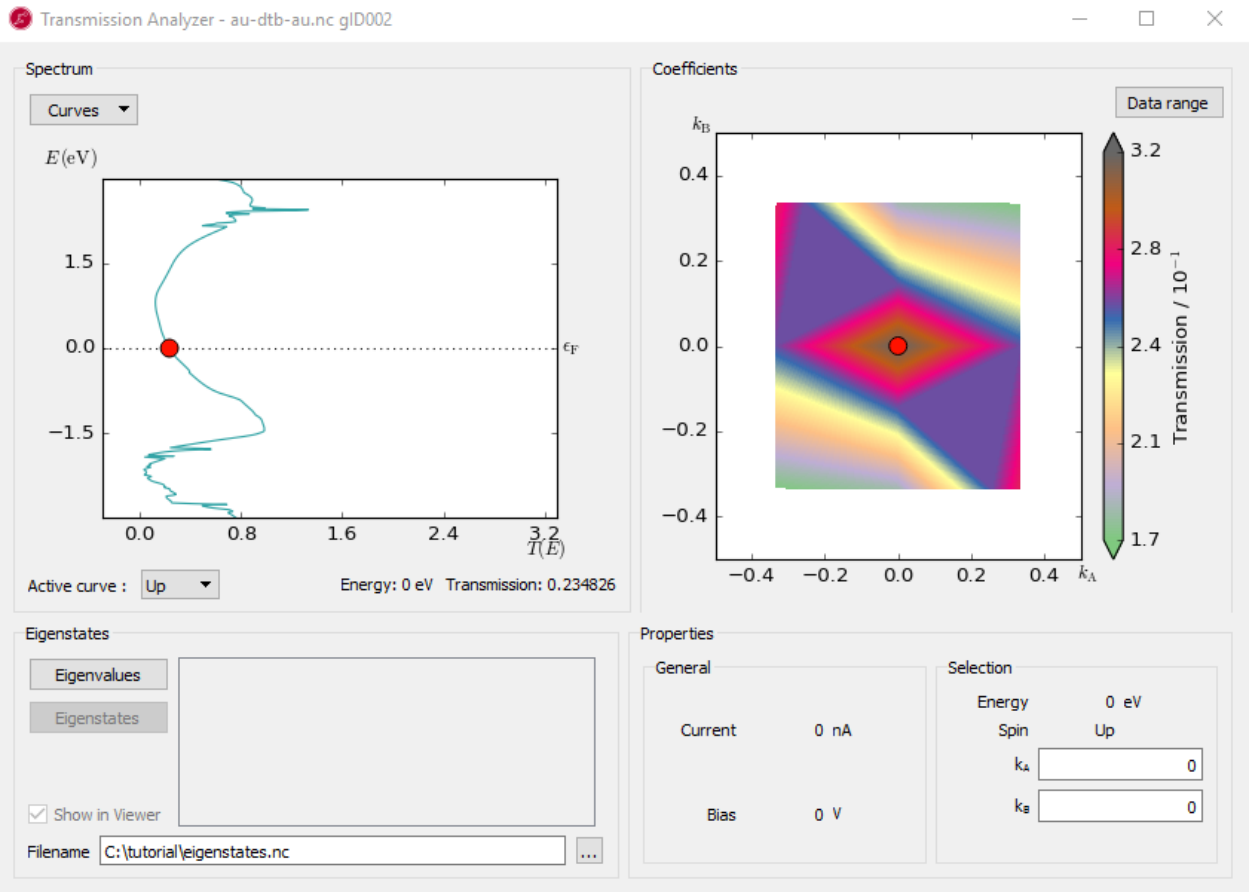


Fig. 3.94: The k-point averaged transmission spectrum as function of energy

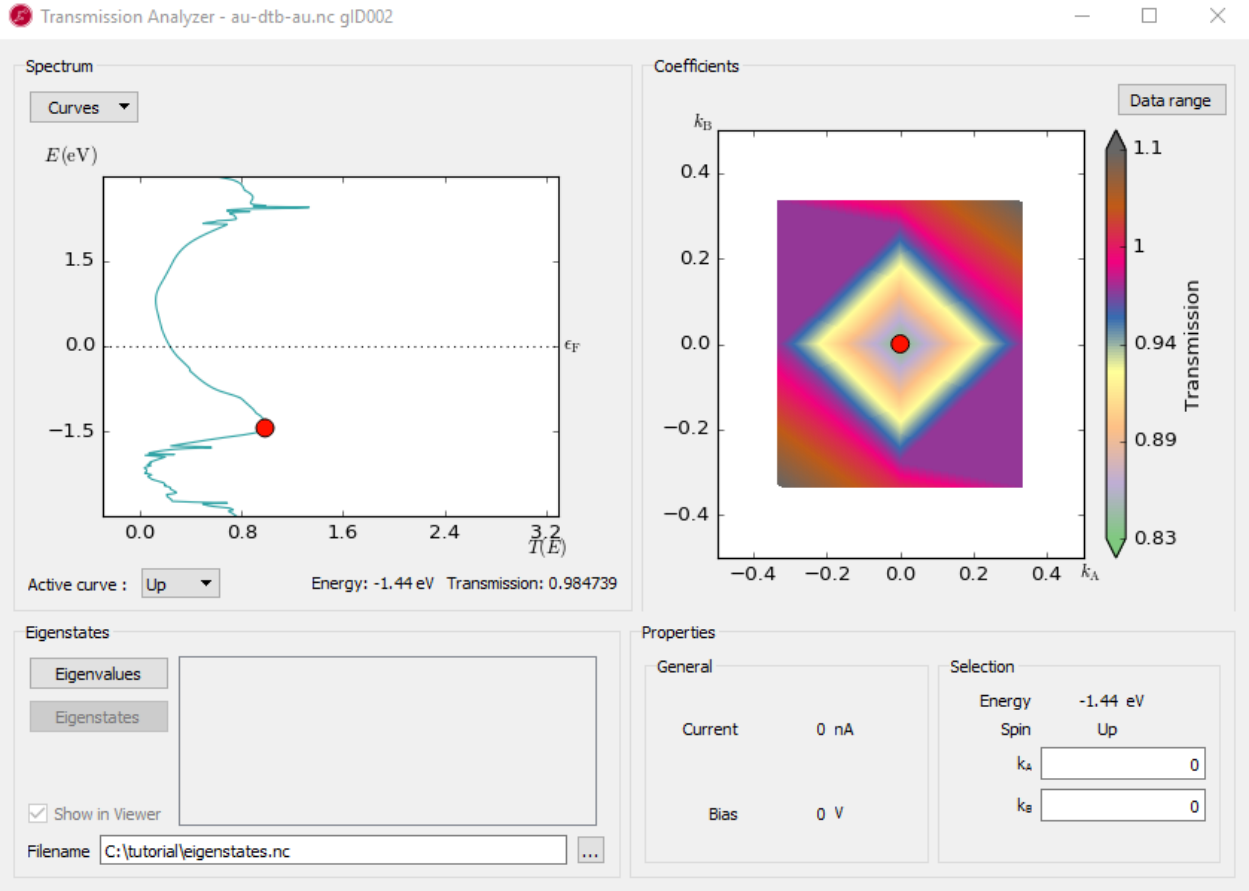
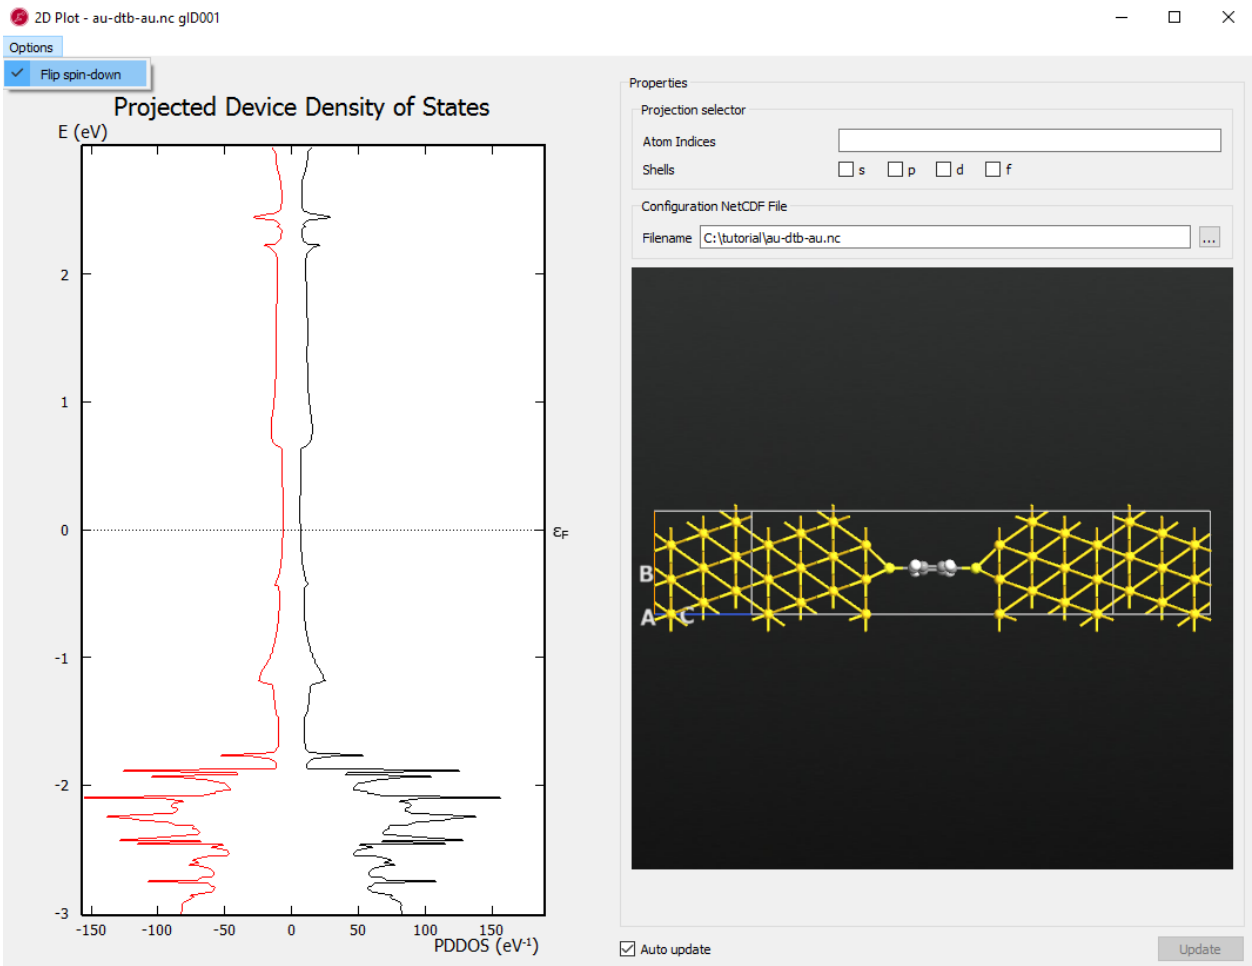
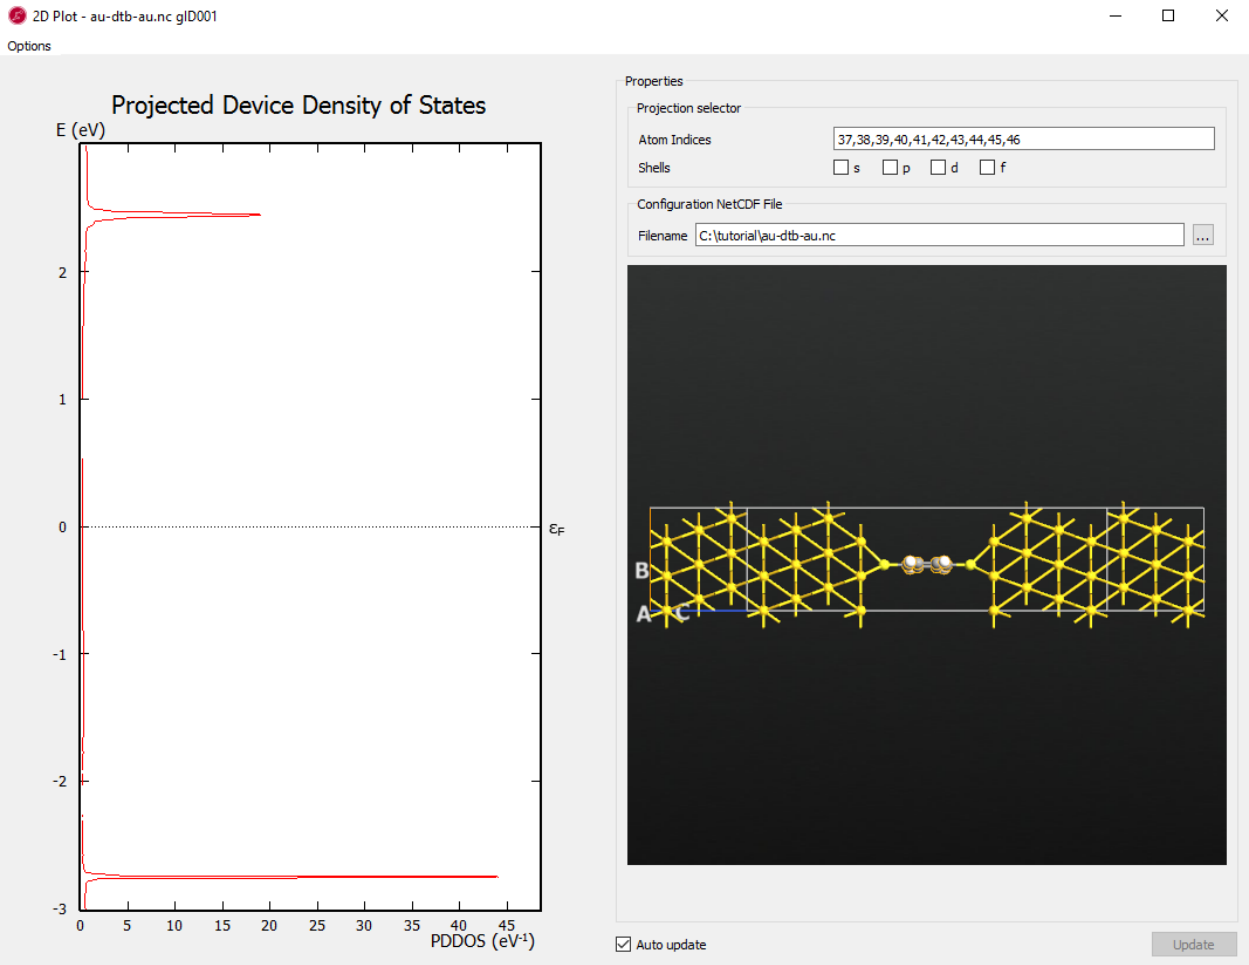


There are three broad peaks, at around -3, -1.4 and 2.5 eV. Also note the narrow peak around 2.4 eV which rises above T(E)=1. In the following you will investigate the origin of these peaks.

Next select the **DeviceDensityOfStates** object $D(\epsilon)$ and click the *Show 2D Plot* button to open the PDDOS analyzer window.To merge both PDDOS lines into one, click the **Options** button on the upper left corner and turning off *flipping*.



Select all carbon and hydrogen atoms by enclosing them with a rectangle using left mouse button (or select the individual atoms with Ctrl left-click).



Tip: Copy the *Atom Indices* here as you will need to input the indices in the next step.

Note: The similarity in the peak structure of the PDDOS and the transmission spectrum indicates a clear correspondence between the energy levels on the phenylene ring and the transmission spectrum.

The Molecular Projected Self-Consistent Hamiltonian (MPSH)

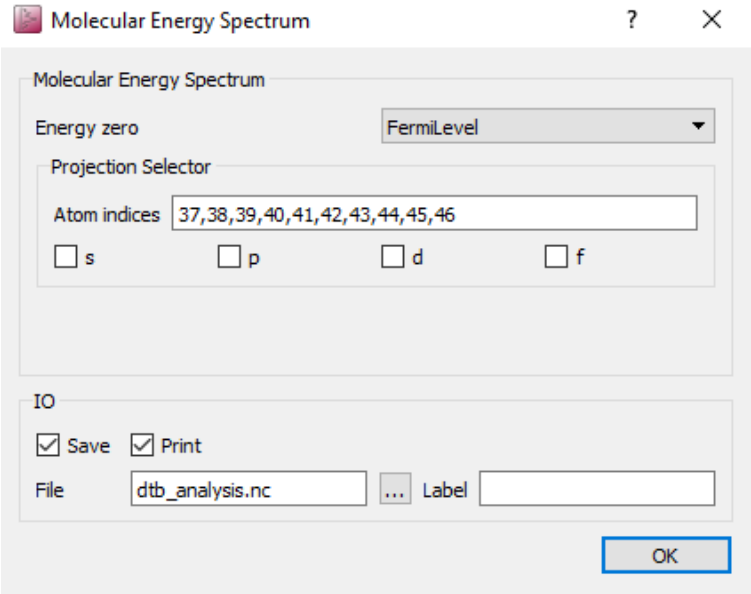
To understand the energy levels of the phenylene ring in the presence of the surrounding electrodes, you will now calculated the MPSH states. The MPSH states are obtained by diagonalizing the molecular part of the full self-consistent Hamiltonian[Page 1313, 1].

Open the **Script Generator** tool and

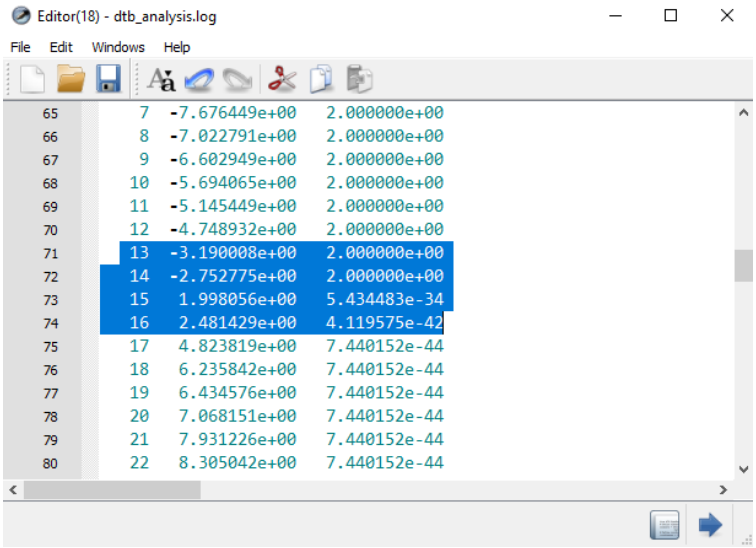
- Double-click **Analysis from File** to add the block .
- Select the file `au-dtb-au.hdf5`, then select *DeviceConfiguration object (gID000)*.
- Add *Analysis* → *MolecularEnergySpectrum*.

•Change the output filename to `dtb_analysis.hdf5`.

•Open the **MolecularEnergySpectrum** block and input the indices of carbon and hydrogen atoms to *Atom indices* (37,38,39,40,41,42,43,44,45,46).



•Send the script to the **Job Manager** and execute it (the execution only takes a few seconds). The MPSH energies are then printed in the log file.



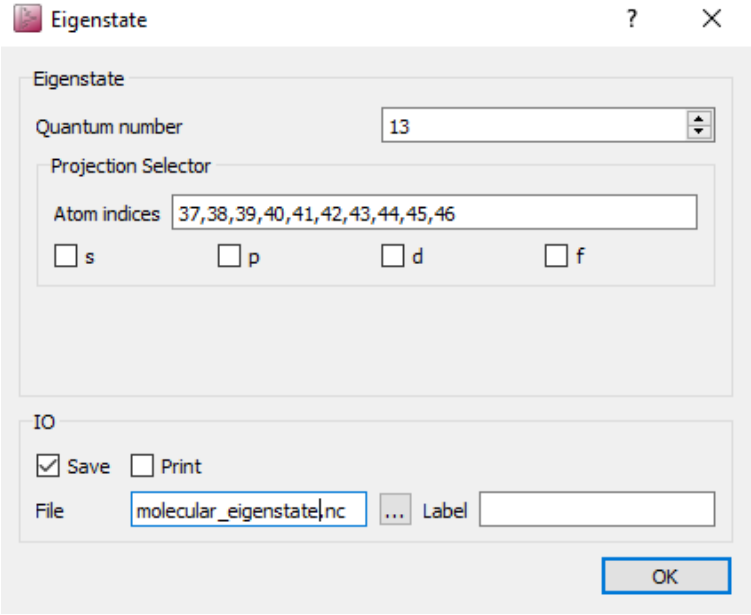
To calculate the eigenstates of the MPSH levels, reopen the last **Script Generator** (it is available from the windows menu at the top of each **QuantumATK** window, if you didnt close it).

•Change the name of the output file to `molecular_eigenstate.hdf5`.

•Add four *Analysis* → *EigenState* blocks.

•Open each EigenState script block and select projection on carbon and hydrogen Set the Quantum number to 13, 14,

15, 16 in each respective block.



•You may delete the **MolecularEnergySpectrum** block , it is no longer needed (select it and press the Delete key).

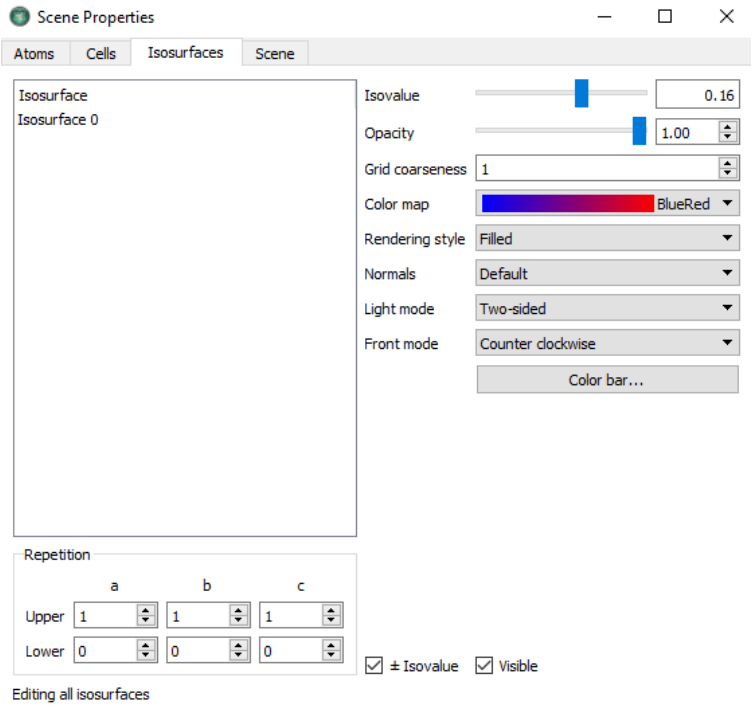
•Send the script to the **Job Manager** and execute the script.

When the calculation is done, the `molecular_eigenstate.hdf5` file should already be ticked under the Project Files, so its objects will appear on the **LabFloor**. Select the first eigenstate object. Click the button *Viewer* in the tool bar on the right-hand side and select *Isosurface*. In the **Viewer**, open the **Properties** menu, select the *Isosurface* tab and do the following settings.

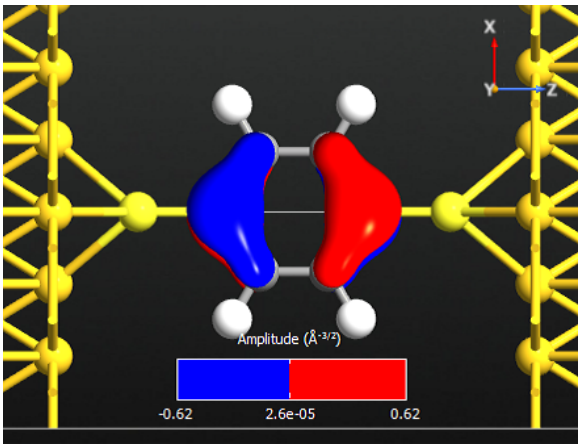
•Set the Isovalue to 0.16.

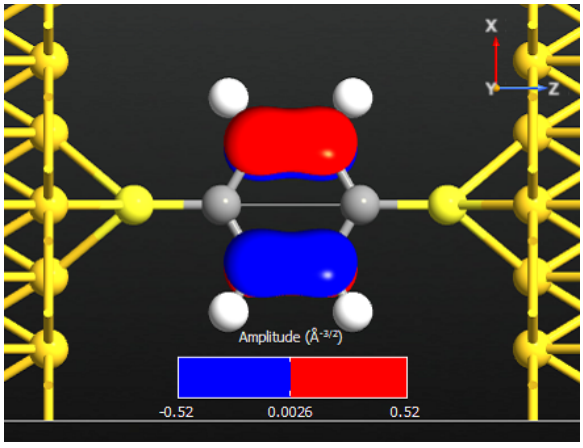
•Set the Color map to BlueRed

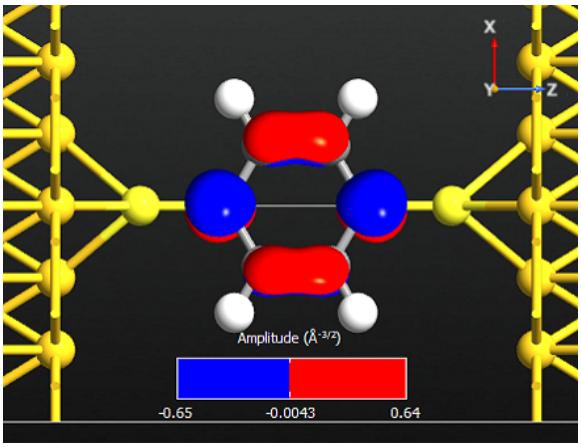
•Tick ± Isovalue

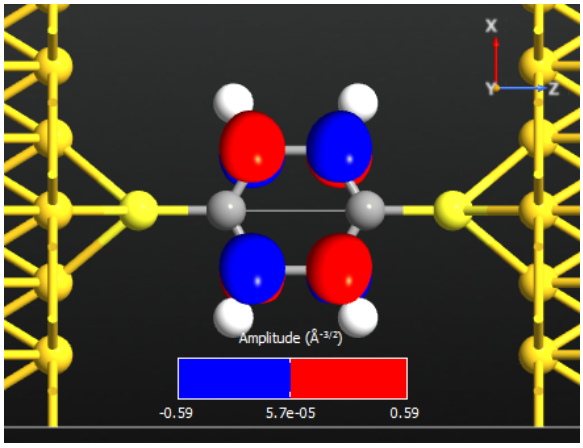


To visualize the eigenstate together with geometry, drag and drop the file `builder_device.py` onto the **Viewer**. Do the same to the other eigenstates and you will get the figures below:





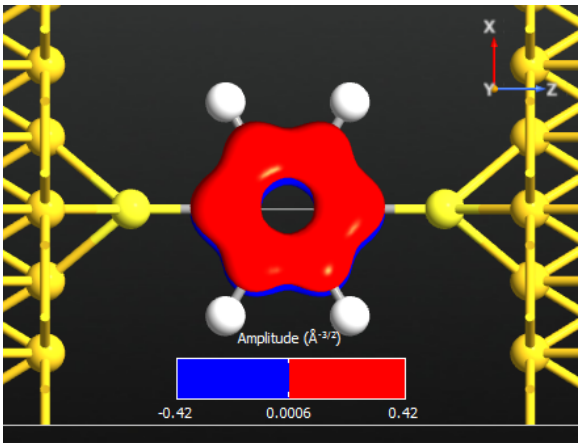


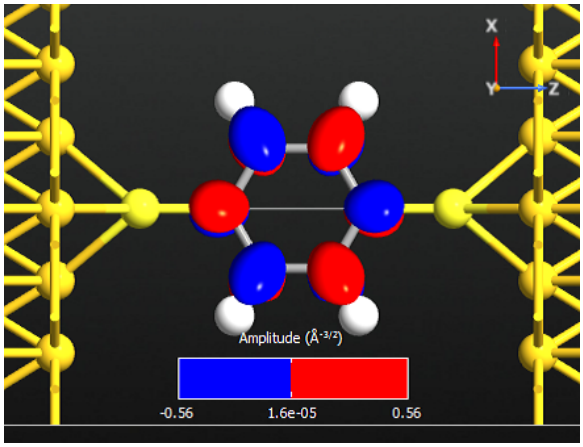


Note that all the states are anti-symmetric in the plane of the benzene ring. This means that they are the π-orbitals of the benzene ring, i.e. they are linear combinations of the p-orbitals on each carbon atom which are perpendicular to the plane of the molecule. There are 6 such p-orbitals which means that there are 6 π-orbitals.

By visually inspecting the symmetry of the different eigenstates the remaining two π-orbitals are identified as state 10 and 18. Use **Editor** to open the previous script, delete two *Eigenstate* blocks and change the *quantum_number* in the remaining two *Eigenstate* blocks to be 10 and 18 respectively. These are visualized below with an iso-value of 0.16.

Note: There are 6 electrons in the π-band, corresponding to that lowest 3 states are occupied. We may therefore denote state 14 the HOMO and state 15 the LUMO.





Transmission eigenvalues and eigenstates

In this chapter you will analyze the transmission eigenstates at the peak positions in the transmission spectrum, i.e. at energies -3, -1.5 and 2.4 eV.

- Re-open the **Script Generator** and delete the **Eigenstate** blocks.
- Instead, add three *Analysis* → *TransmissionEigenvalues* blocks.
- Set the energies to -3, -1.5 and 2.4 eV, into the three **TransmissionEigenvalues** blocks respectively.
- Execute the script using the **Job Manager** and inspect the log file.

```
+------------------------------------------------------------------------+

Eigenvalues (Up):
7.806646e-01
2.244804e-02

Eigenvalues (Up):
7.900386e-01
2.194993e-02

Eigenvalues (Up):
6.175970e-01
1.270894e-02

+------------------------------------------------------------------------+
```

The transmission eigenvalues are obtained by diagonalizing the transmission matrix. The number of eigenvalues indicates the number of individual channels through the molecule, and the eigenvalue shows the strength of each channel. The eigenvalues are the true transmission probabilities, and thus lie in the interval [0,1]. If several channels are available at a particular energy, their sum - and hence the transmission coefficient at this energy - may however be larger than 1.

Most of the eigenvalues are very small and can be neglected. The two largest eigenvalues of each energy are the most important ones.

Note: At the first two energies there is only one dominating eigenstate, while at the last energy there are two dominating eigenvalues. The reason that they do not sum up to the total transmission spectrum T(E) will be discussed in the next section.

The next step is to visualize the transmission eigenstates for the first two peak energies, where there is only one significant eigenvalue.

- Re-open the **Script Generator** and delete the **TransmissionEigenvalues** blocks .
- Add two *Analysis* → *TransmissionEigenstates* blocks.
- Enter the energies -3 and -1.5 into the *Analysis* → *TransmissionEigenstates* blocks . Leave the quantum number at 0, corresponding to the highest eigenvalue.
- Execute the script via the **Job Manager** .

The objects will again be saved in the file `dtb_analysis.hdf5` and can be visualized using the same approach as for the eigenstates. Below are shown isosurfaces of the two transmission eigenstates.

Tip: The transmission eigenstate is a complex wave function. The isosurface shows the absolute value of the wave function while the color of the isosurface indicates the phase. Since the phase is periodic, it is best to use a periodic color map.

The transmission eigenstate at -3.0 eV has a clear resemblance with MPSH state 13, i.e. the HOMO-1 state. The transmission eigenstate at -1.5 eV is also a π-state.

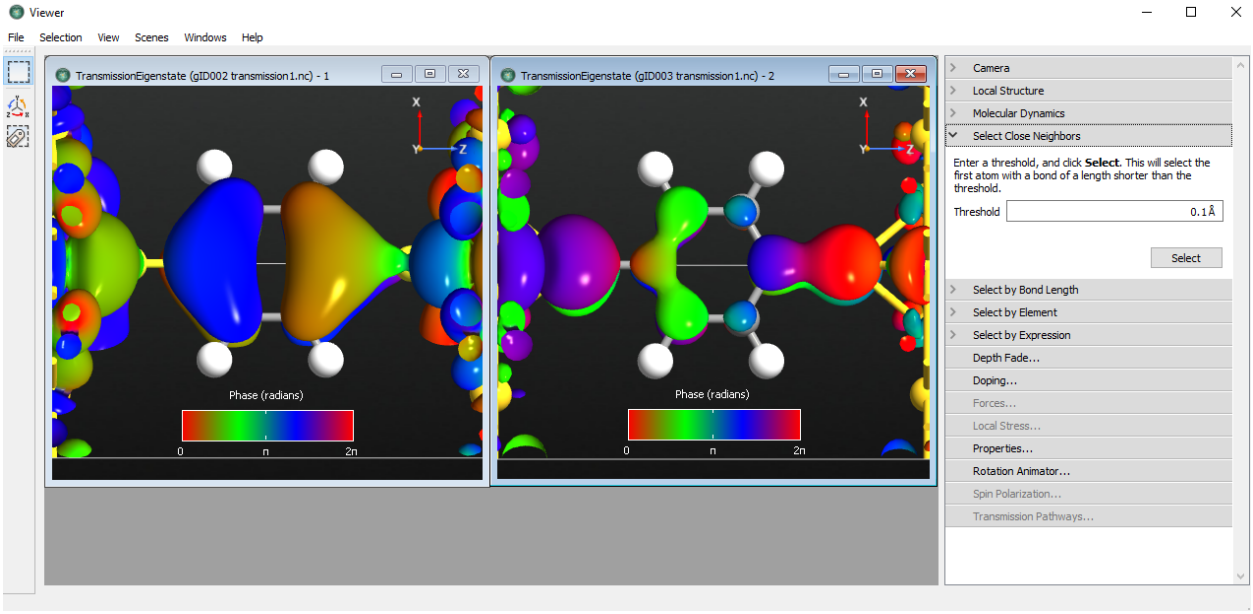


Fig. 3.95: Transmission eigenstates of energy -3 and -1.5 eV

k-dependent transmission and eigenchannels

You will now analyze the transmission at 2.4 eV. Previously, you found that there is an important transmission eigenstate at this energy with transmission probability 0.618 which is different from the value 1.45 obtained from inspecting Fig. 3.94. This is because Fig. 3.94 shows the k-point averaged transmission. You will now calculate the k-dependent transmission coefficients at this energy.

•Re-open the **Script Generator** and delete the **TransmissionEigenstates** blocks.

•Add an *Analysis* → *TransmissionSpectrum* block .

•Open the **TransmissionSpectrum** block and set

–Energy start and end equally to 2.4 eV,

–Number of energy points to 1,

–k-point sampling to 21 x 21 points,

•Execute the script using the **Job Manager** .

When the calculation has finished you can visualize the k-dependent using *Transmission Analyzer*.

The contour plot of the k-dependent transmission above has a pronounced peak at $(k_A, k_B) = (0.0, 0.38)$, with a transmission coefficient of around 1. In the computation of the transmission spectrum earlier, we did not have a dense enough k-point sampling, and hence the transmission was overestimated, i.e. we obtained 1.45 while the 21x21 mesh gives around 1.1.

Attention: This shows the importance of carefully checking the convergence of the results in the k-point sampling of the transmission spectrum. There is no reason to assume that the same number of points used to get a correct

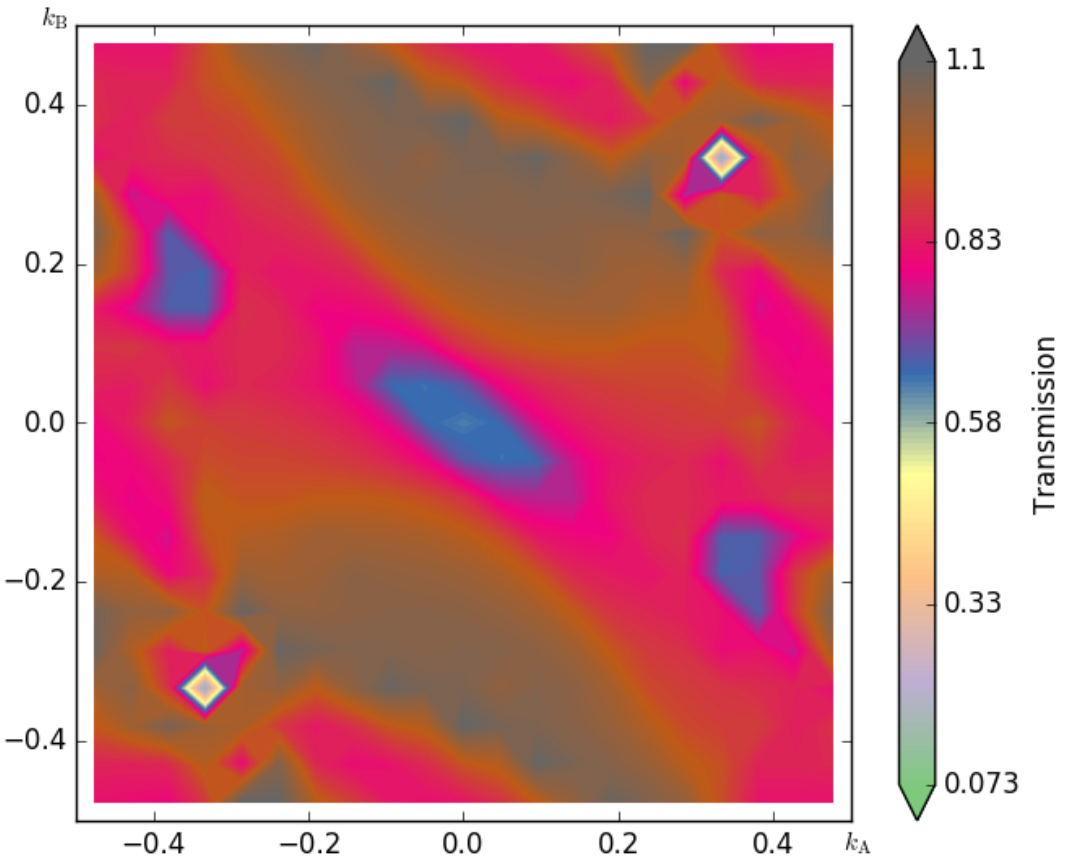

Fig. 3.96: The k-dependence of transmission at energy point 2.4eV

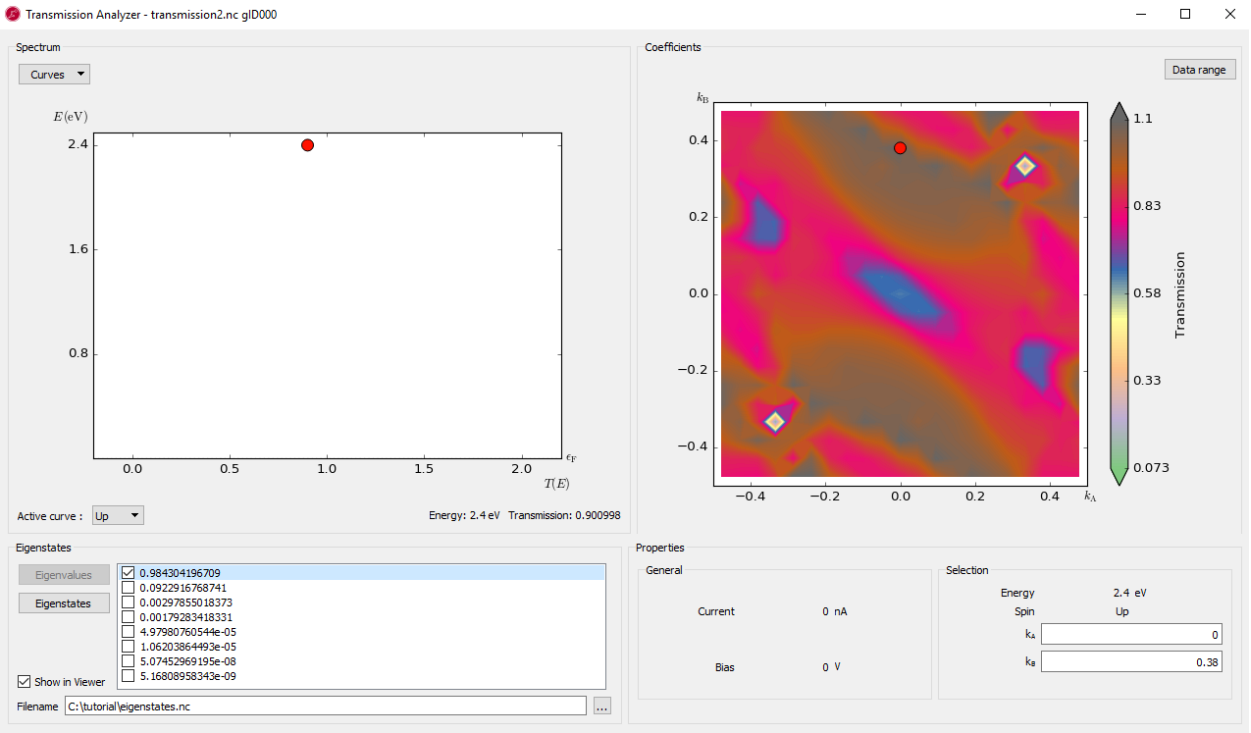
electron density (i.e. the k-points used in the self-consistent calculation) also give an accurate transmission.

You will now calculate the transmission eigenstates at the k-point with the strongest transmission. We can choose either point (0, -0.38) or (0, 0.38), they are equivalent by time-reversal symmetry.

•Click the point (0, -0.38) or (0, 0.38) on the transmission contour plot.

•Click *Eigenvalues* in the **Eigenstates** block on the lower left side. You will get a list of eigenvalues.



•Select the first eigenvalue only, and press the button *Eigenstates*. The first eigenstate will be calculated and the **Viewer** window will pop up with a figure. Tune the isovalue in *Properties* to display the eigenvalue image nicely.

Projected local DOS

In this section you will calculate the local device density of states throughout the device, projected onto the real-space transport direction (the Z-axis).

•Re-open the **Script Generator** and delete the previous analysis blocks.

•Add a *Analysis → ProjectedLocalDensityOfStates* block.

•Open the analysis block and edit it: Increase the energy window to -3 eV to +3 eV, and set the k-point sampling to 3x3.

•Change the output filename to `pldos_0.0V.hdf5` and save the QuantumATK Python script as `pldos_0.0V.py`.

Execute the script – the calculations may take up to an hour to run. The PLDOS item will be added to the QuantumATK LabFloor. Plot the results using the **Projected Local Density of States** plugin in the right-hand plugins menu. Adjust the data range to get a plot like the one shown below.

The PLDOS shows a high density in the metallic gold electrodes (pink regions), while the black color in the middle corresponds to vanishing DOS in the vacuum gap between the electrodes. In the middle, where the molecule is, there

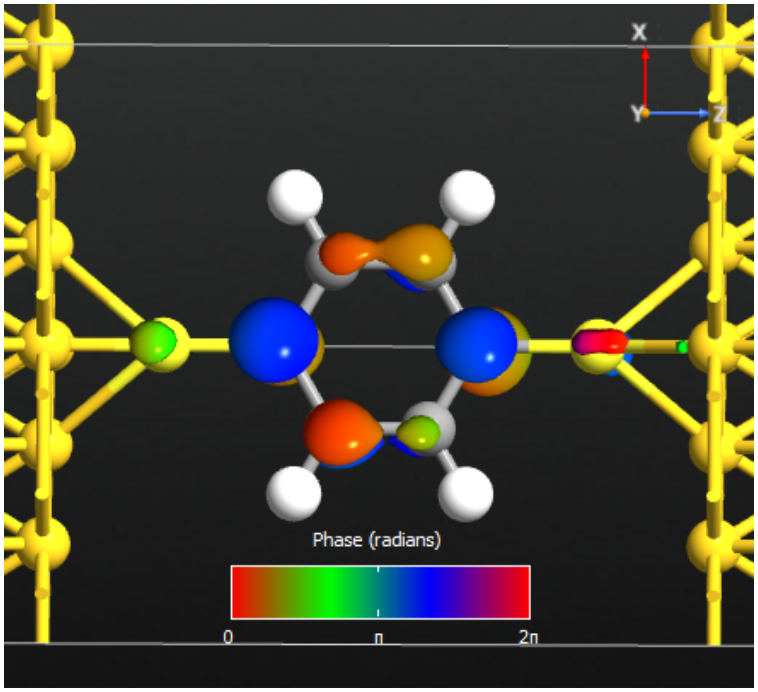


Fig. 3.97: The first eigenstate contributes to the transmission at energy point 2.4 eV.

are three peaks in the local DOS as a function of energy, positioned around -3, -1.4, and +2.5 eV, in agreement with the peaks in the transmission spectrum.

I-V characteristics

In this chapter you will calculate the I-V characteristics of the Au-DTB-Au molecular device, and analyze the device for an applied bias of 1.6 V.

Setting up the calculation

Open a new **Script Generator** window, and do the following:

•Add the Analysis from File block.

•Add the *Analysis* → *IVCurve* block.

•Change the default output filename to `IV-curve.hdf5`.

Edit the Analysis from File block:

•Set *HDF5* file to `au-dtb-au.hdf5`, and use *gID000* to restart from the zero-bias calculation.

Also edit the IVCurve block:

•Set the voltage bias range to end at V_0 = -2V and V_1 = 2 eV.

•Set the number of voltage points to 11.

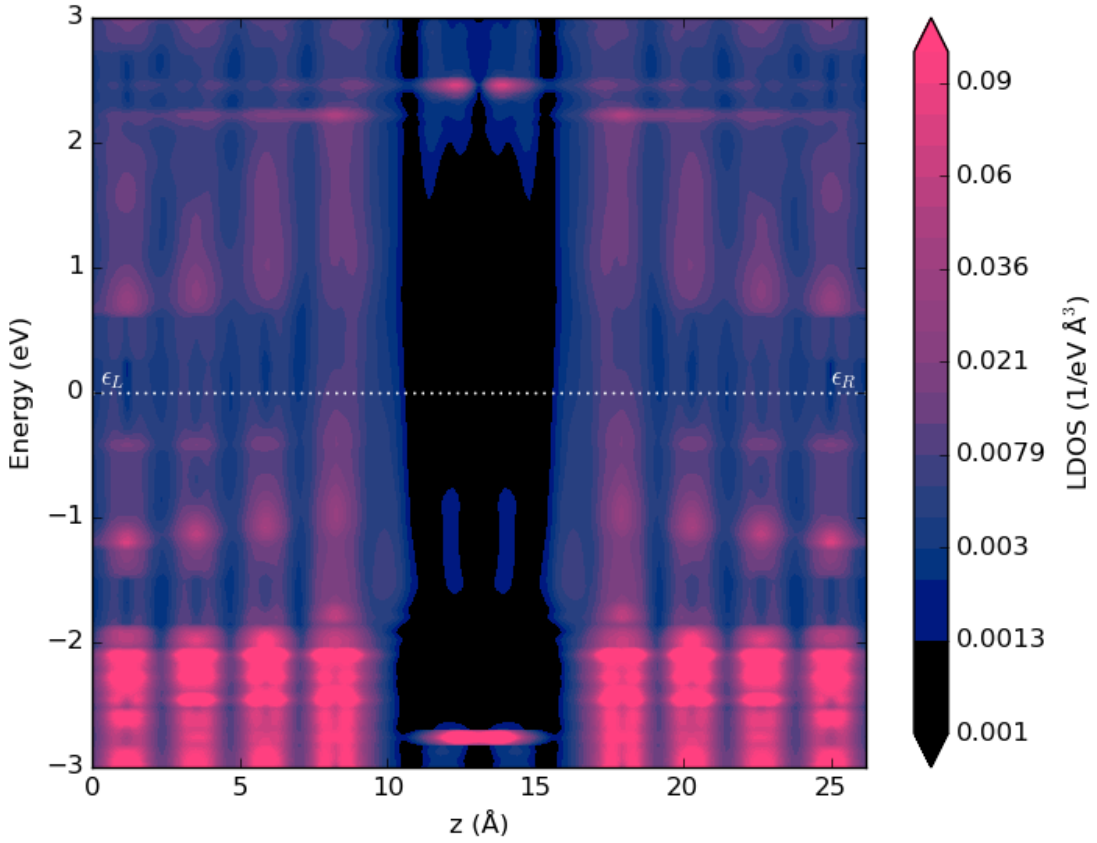

Fig. 3.98: Local device density of states projected onto the device Z-axis.

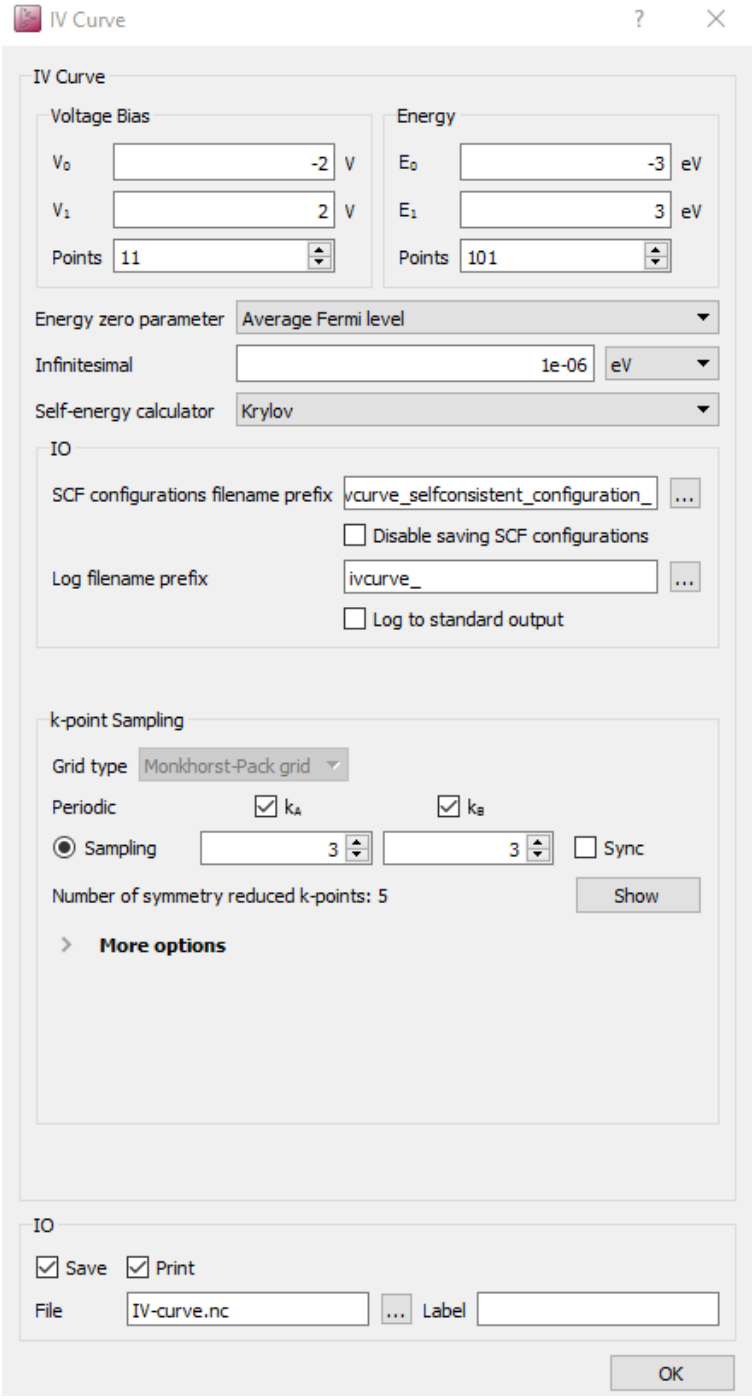
•Set the energy range as (-3,3).

•Use 3x3 transverse k-points.

•Choose the *Krylov* self-energy calculator (for speed).

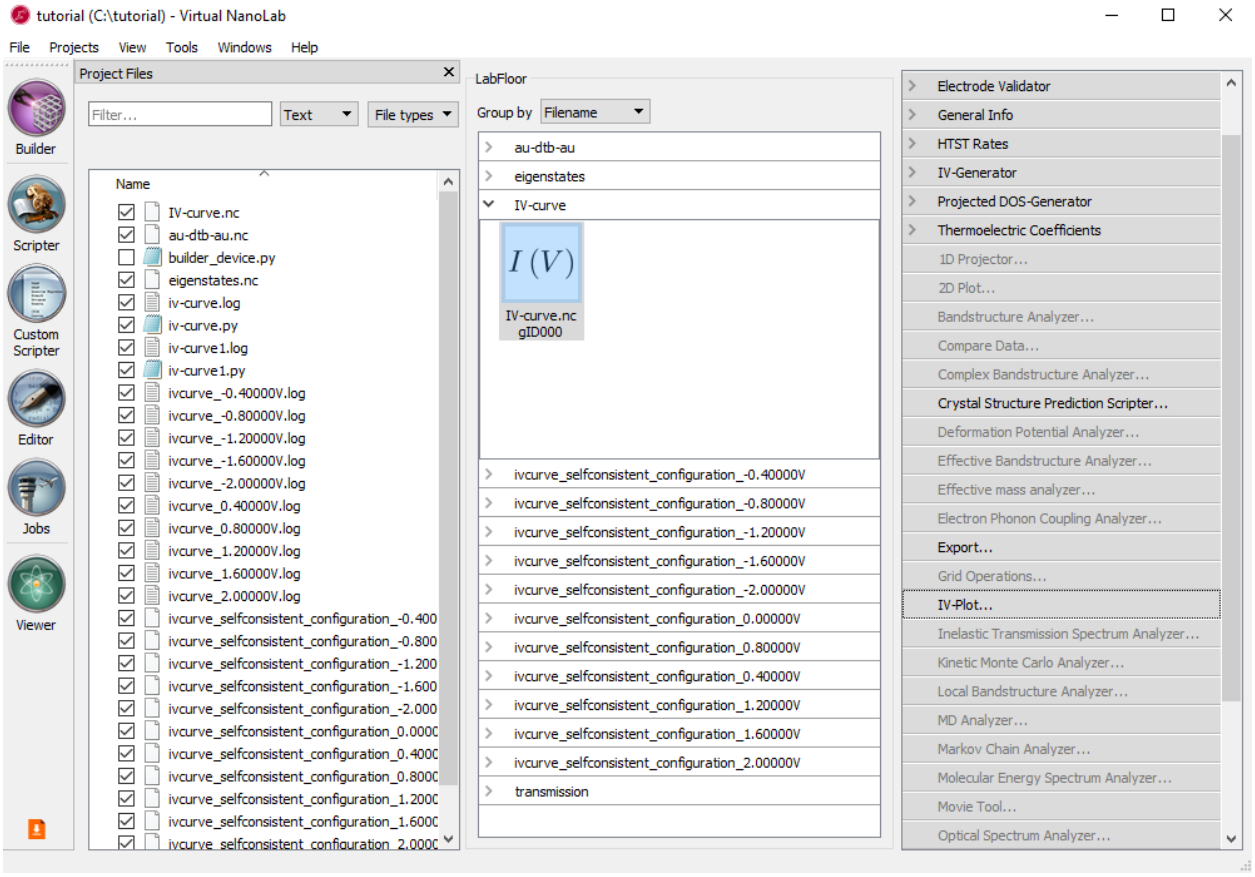


The script is now done. Save it as `iv-curve.py` and execute it using the **Job Manager** or from the command line.

This calculation will take some time, because a self-consistent SCF calculation and a transmission spectrum analysis must be done at each bias point. It takes six hours to finish in a 12-core machine.

IV characteristic analyzation

Once the calculation is done, the file `IV-curve.hdf5` appears in the folder. Eleven new output files are also created, prefixed `ivcurve`; they contain the converged SCF state at each bias point.



Note: The **IVCurve** object contains the calculated I–V curve, including the transmission spectra computed $I(V)$ at each bias voltage.

Select the IV-curve and click the **IV-Plot** analysis tool in the right-hand plugins bar. The I–V curve is plotted in the window that pops up.

Check the box *Additional plots*. Three additional panels appear, plotting the differential conductance (dI/dV), the calculated transmission spectra, and the spectral current.

Attention: Pay special attention to the spectral current: All possible contributions to the total current must be included inside the specified energy window, in order to get accurate $I(V)$ points. If this is not the case, you should consider redoing the analysis using a wider energy window.

Note: The peak in the dI/dV around 1.6 V arises from a resonance in the transmission spectrum entering the bias

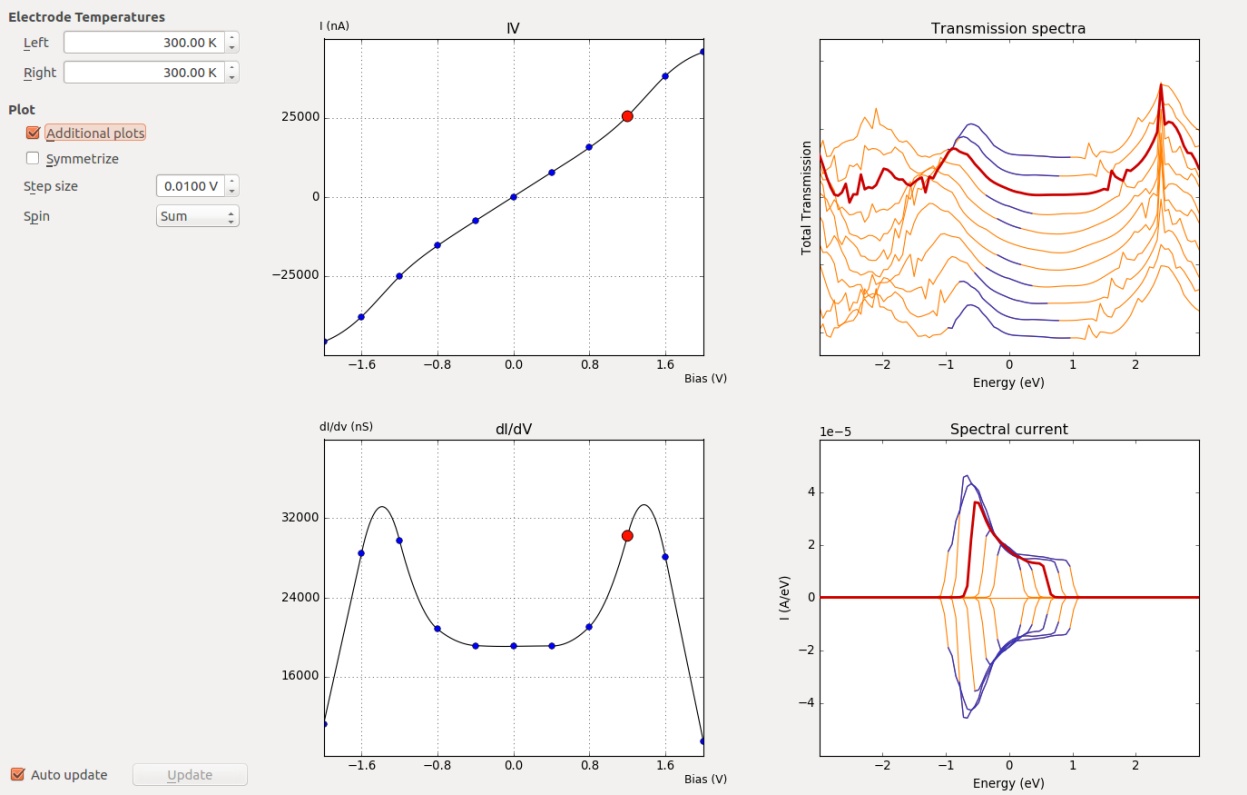


Fig. 3.99: Each transmission spectrum and spectral current correspond to a specific bias voltage point. The energy range corresponding to the bias window is indicated in blue. By moving the mouse cursor to one of the marker points on either the IV or dI/dV plot, the corresponding transmission spectrum and spectral current will be highlighted.

window at this voltage.

PLDOS at 1.6 V bias

To investigate in details the electronic features of the molecular device under bias of 1.6V, you should compute the projected local density of states, just like you did above for zero bias, in section *Projected local DOS*.

•Open a new script by cliking **Script Generator** and add two blocks:

– *Analysis from file*

– *Analysis → ProjectedLocalDensityOfStates*

•Select file `ivcurve_selfconsistent_configuration_1.60000V.hdf5` from the previous calculation after opening the *Analysis from file* block.

•In the PLDOS analysis block, increase the energy window to -3 eV to +3 eV, and set the k-point sampling to 3x3.

•Change the output filename to `pldos_1.6V.hdf5` and save the QuantumATK Python script as `pldos_1.6V.py`.

Run the script and use agin the **Projected Local Density of States** plugin to visualize the results.

Compared with Fig. 3.100, the resonance at -1.5 eV has split into two resonances, at -0.8 and -2 eV, as we saw already in the transmission spectrum above. We also see that the resonance at -0.8 is located towards the right electrode, while the resonance at -2 eV is located towards the left electrode. The splitting arises from the drop in the electrostatic potential through the molecule (due to the applied bias), as will be investigated in the next section.

Calculating the voltage drop

You will now calculate the voltage drop and induced density for an applied bias of 1.6 V. At first, we will calculate the ElectrostaticDifferencePotential and ElectronDifferenceDensity between 1.6 V and 0 V.

•In the **Script Generator** , add three blocks:

–the Analysis from File

–an *Analysis → ElectrostaticDifferencePotential*

–an *Analysis → ElectronDifferenceDensity*

•Open the Analysis from File to load the `ivcurve_selfconsistent_configuration_1.60000V.hdf5`.

•Change the default output filename to `voltage_drop_16V.hdf5`.

•Send it to the **Job Manager** by pressing the **Send to** button.

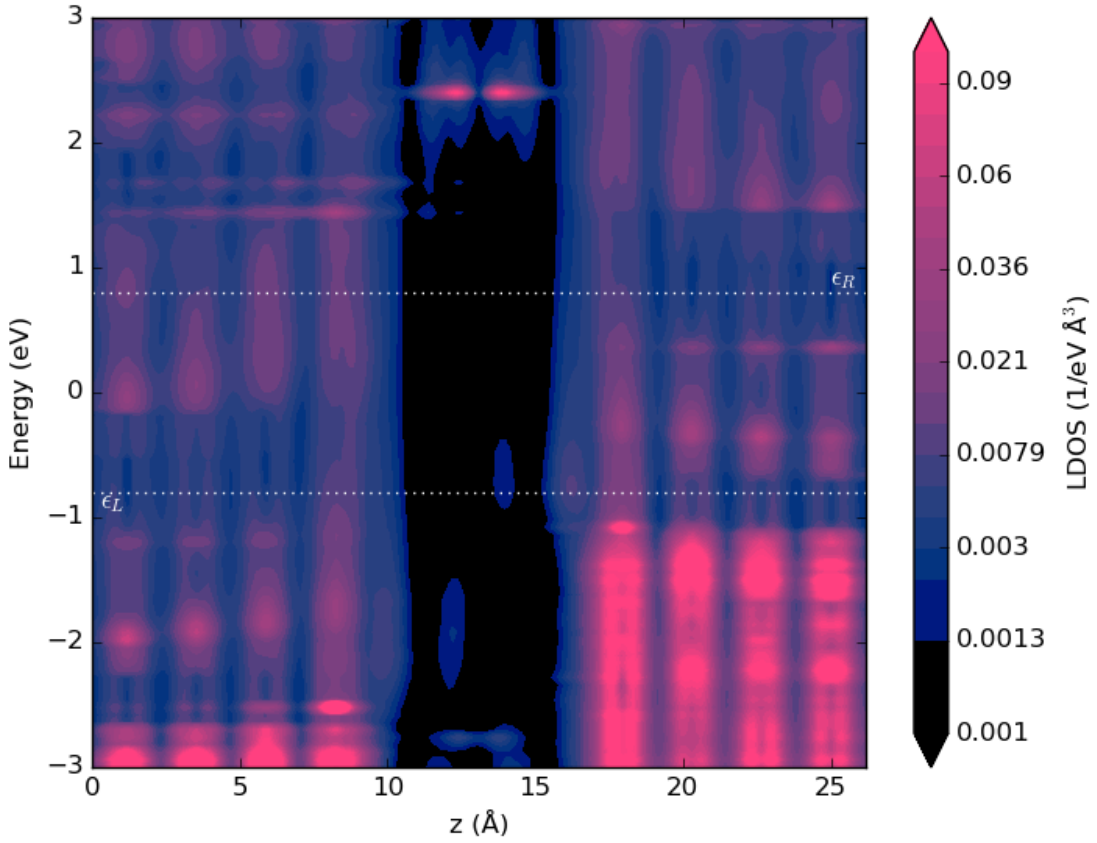

Fig. 3.100: Projected local device DOS at 1.6 V applied bias.

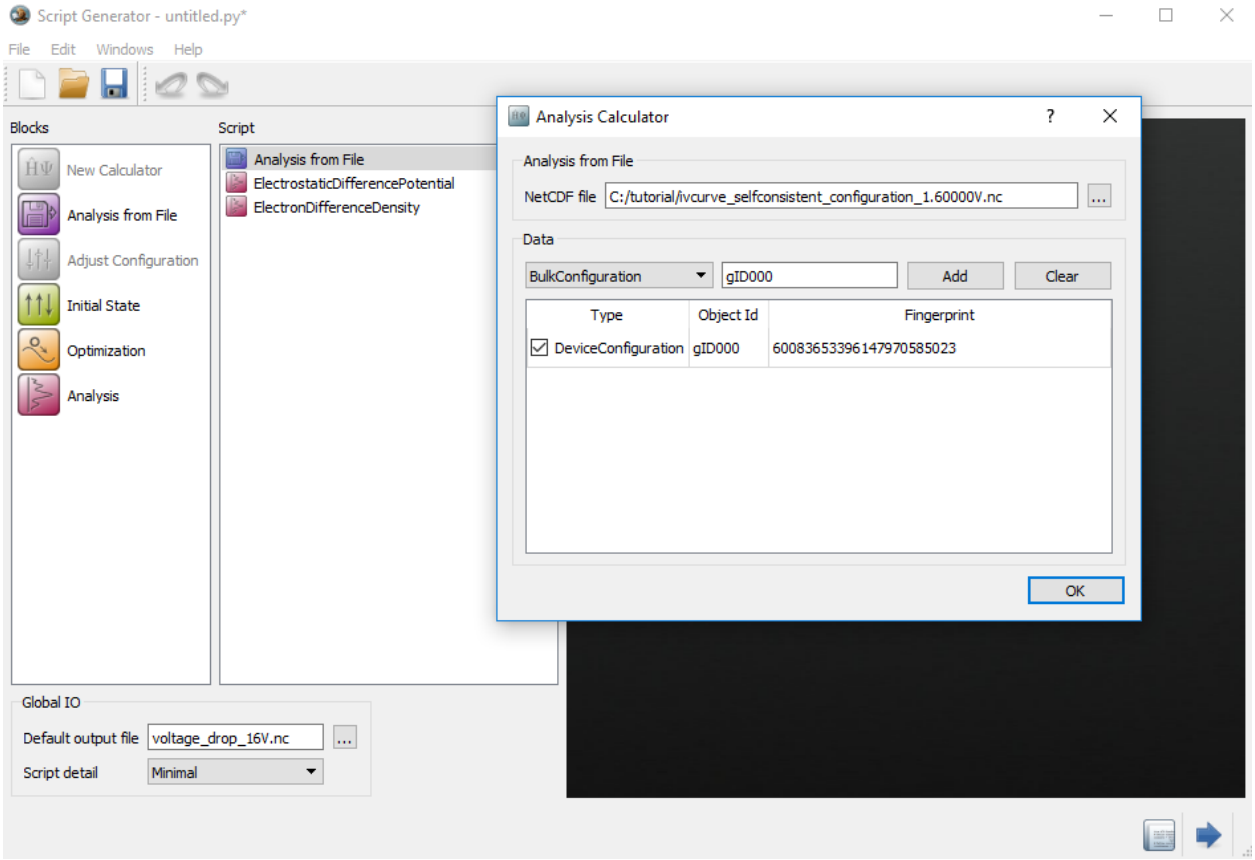
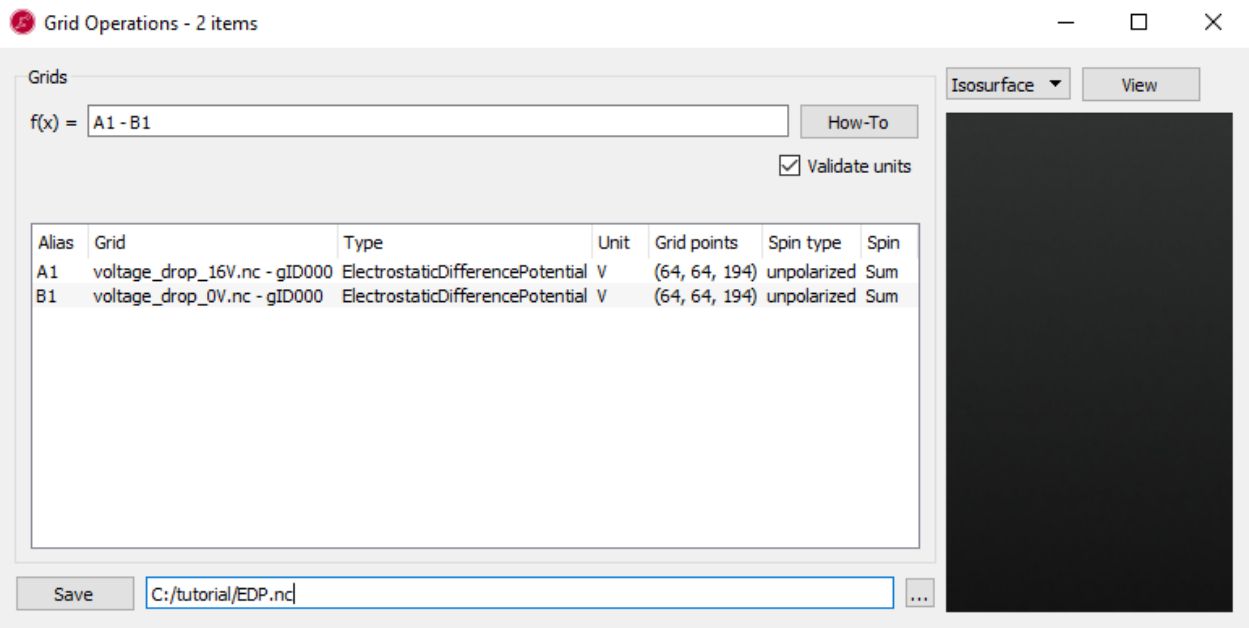


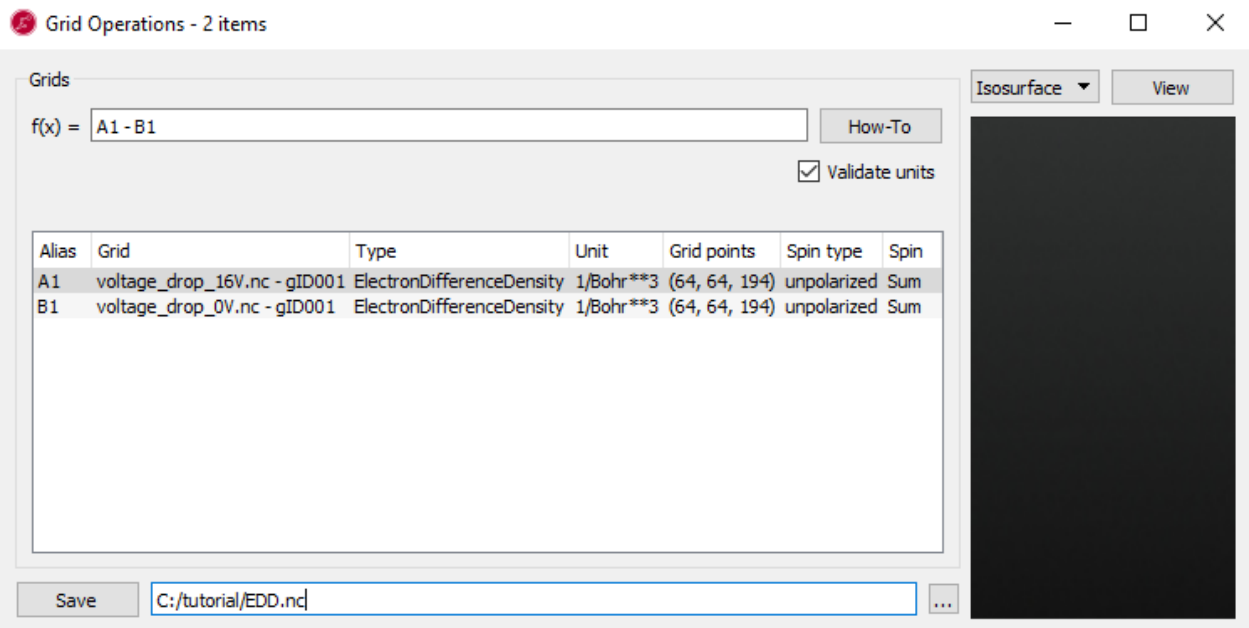
Repeat the above recipe to calculate the ElectrostaticDifferencePotential and ElectronDifferenceDensity at 0 V. Finally, you will have the files `voltage_drop_16V.hdf5` and `voltage_drop_0V.hdf5` under *Project files*.

To calculate the voltage drop using the ElectrostaticDifferencePotential and ElectronDifferenceDensity at 1.6 V and 0 V, we use GridOperations in the right-hand panel bar.

- Select the two objects by holding the `ctrl` key while clicking on each $\delta V_E(\mathbf{r})$ icon in the `voltage_drop_16V` and `voltage_drop_0V` files on the **LabFloor**.
- Open the **GridOperations** widget.
- Make a function such as A1 - B1.
- Save as `EDP.hdf5`.



Repeat the above process for the density to get the voltage-induced density.



You should now have the calculated grids in the files `EDP.hdf5` and `EDD.hdf5`. To visualize the ElectrostaticDifferencePotential and ElectronDifferenceDensity induced by the 1.6 voltage, do the following:

•Select the file `EDP.hdf5` and open the **Viewer** in the panel.

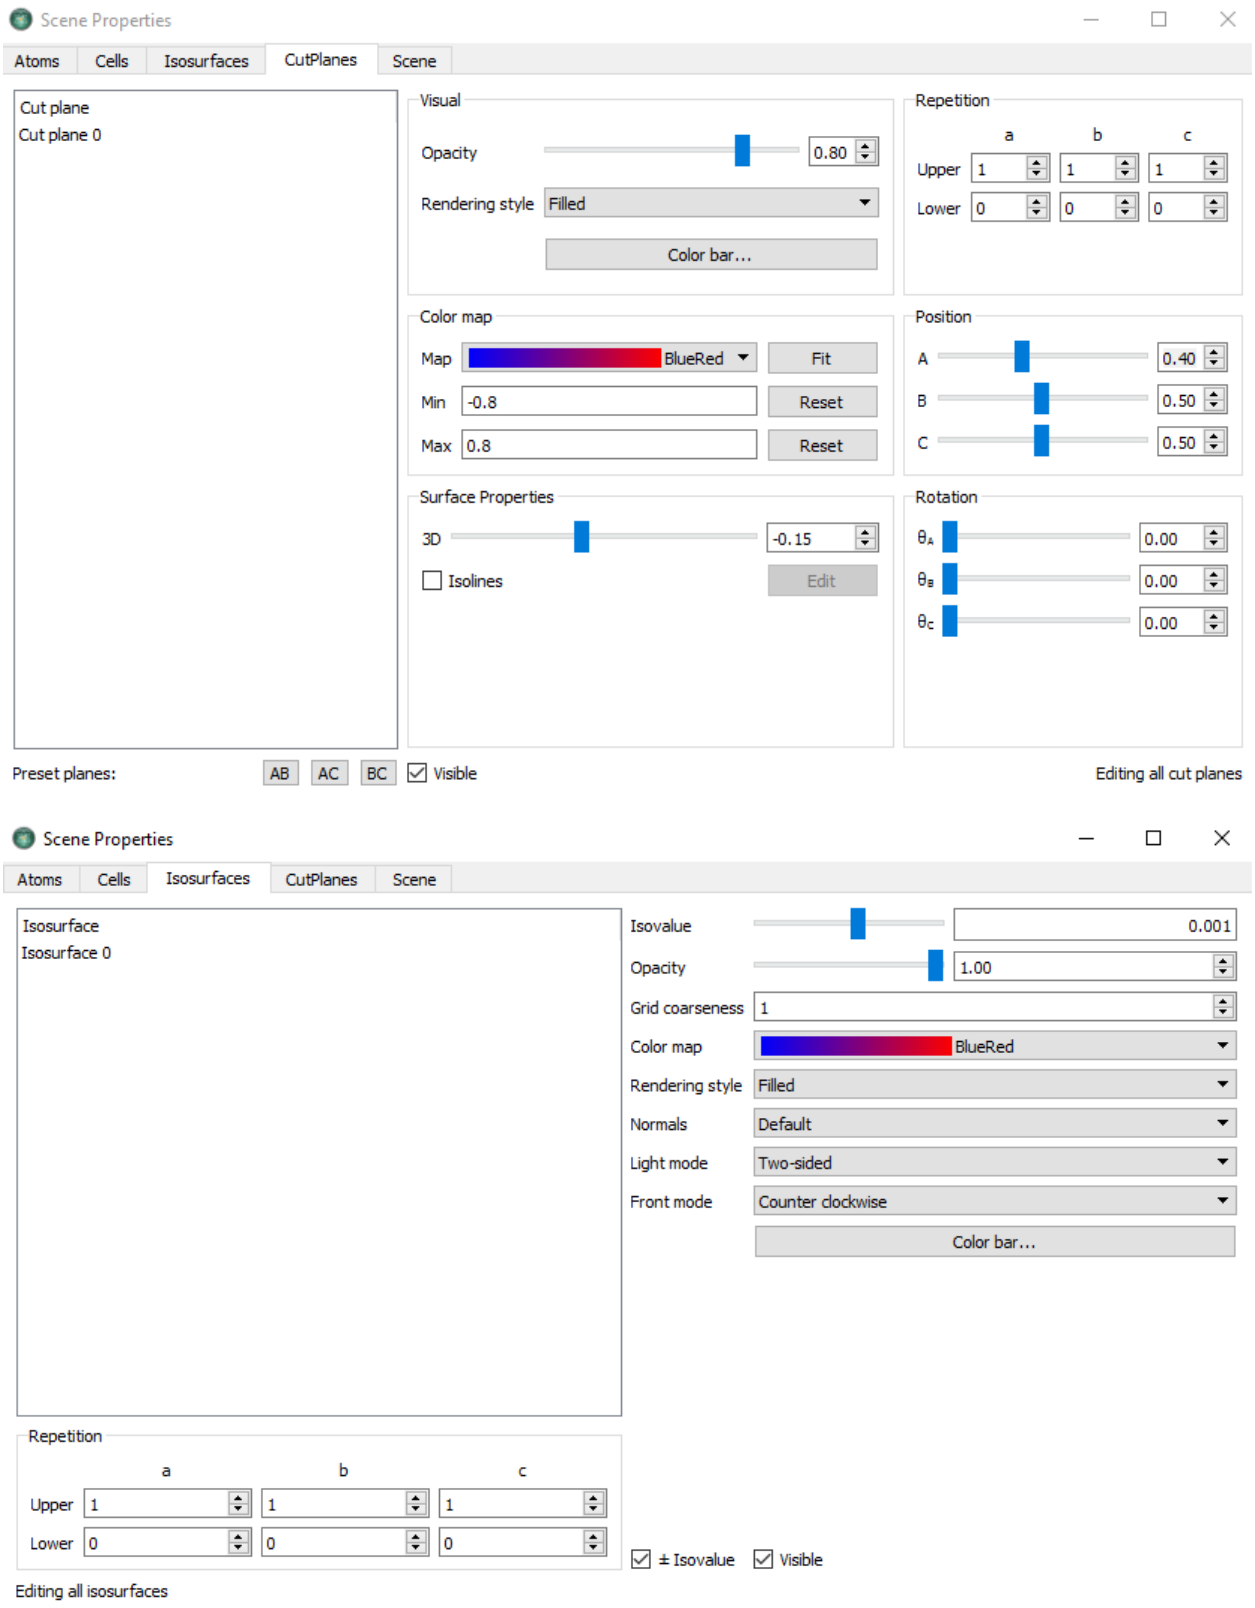
•Change the plot type in the grid visualization selection to the CutPlanes.

•Drag the `builder_device.py` on the window.

•Next, select the file `EDD.hdf5` and drag into the same window.

•Keep the default, Isosurface for the ElectronDifferenceDensity.

You can tune the CutPlanes and Isosurface in the properties. In the case of CutPlanes, you can adjust the 3D and position of the CutPlane.



If you apply the settings shown above, you should now have the following figure:

It is useful to make a 1D plot of the voltage drop. To this end, select the $f(x)$ of the *EDP* in the **LabFloor** and click

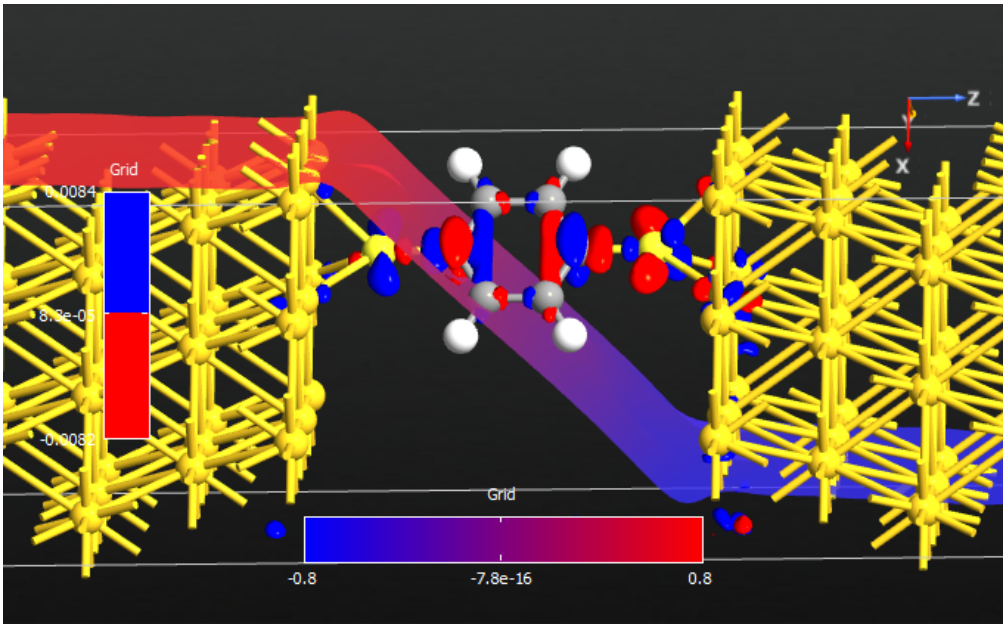


Fig. 3.101: Electrostatic potential drop and electron density difference induced by a bias of 1.6V.

the **1D Projector** in the right hand panel bar. Then change the projection type to *Average* and click *Add line*.

In the case of 1D projection plot, c-axis shows the relative length between 0 and 1 corresponding to the real z distance.

Note: Both Fig. 3.101 and Fig. 3.102 show the total voltage drop of 1.6 V across the device. It is also clear from both figures that most of the voltage drop takes place around the molecule, not in the electrodes. A drop in voltage corresponds to a quantum resistance, and this explains the observed finite-bias splitting of the zero-bias resonance.

3.10.1 Spin Transfer Torque

Version: 2016.3

In this tutorial you will learn about the spin transfer torque (STT) and how to calculate the STT in magnetic tunnel junctions.

We will use a simple model of such a tunnel junction; a magnetic carbon-chain device. The QuantumATK package offers a convenient analysis object for calculating STT linear-response coefficients at zero bias, but you will also calculate the STT using finite-bias calculations and compare results to those obtained using linear response.

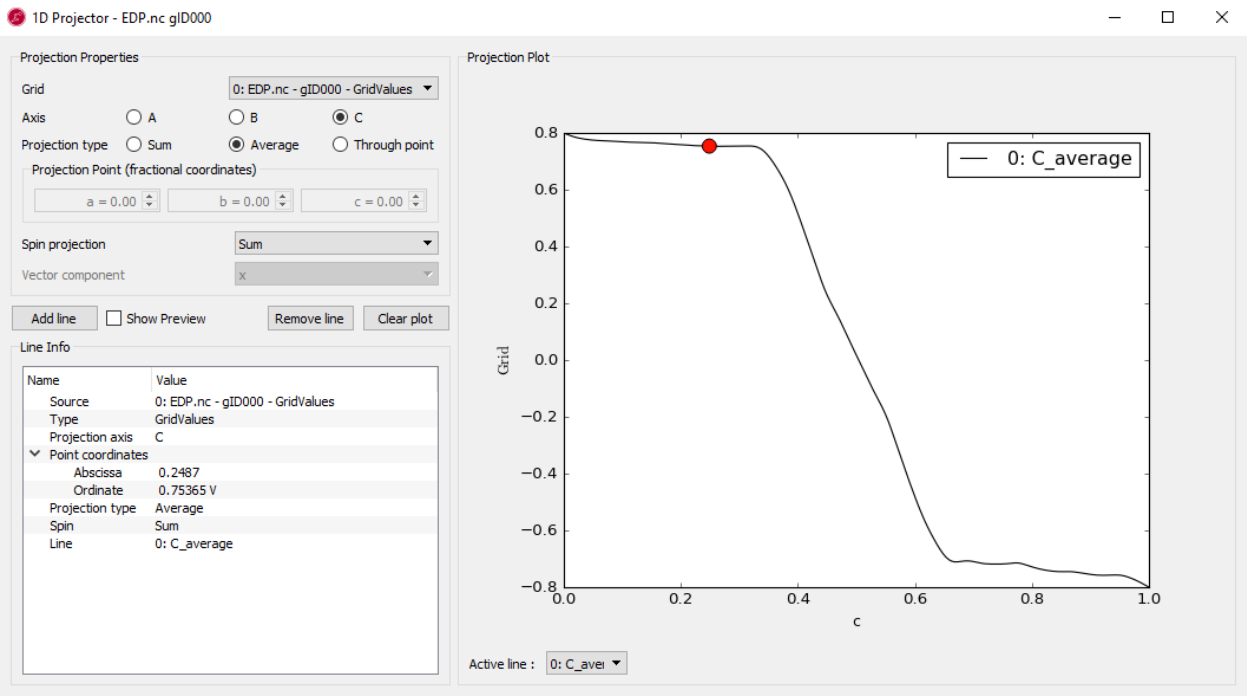

Fig. 3.102: Voltage drop along a line through the molecular axis.

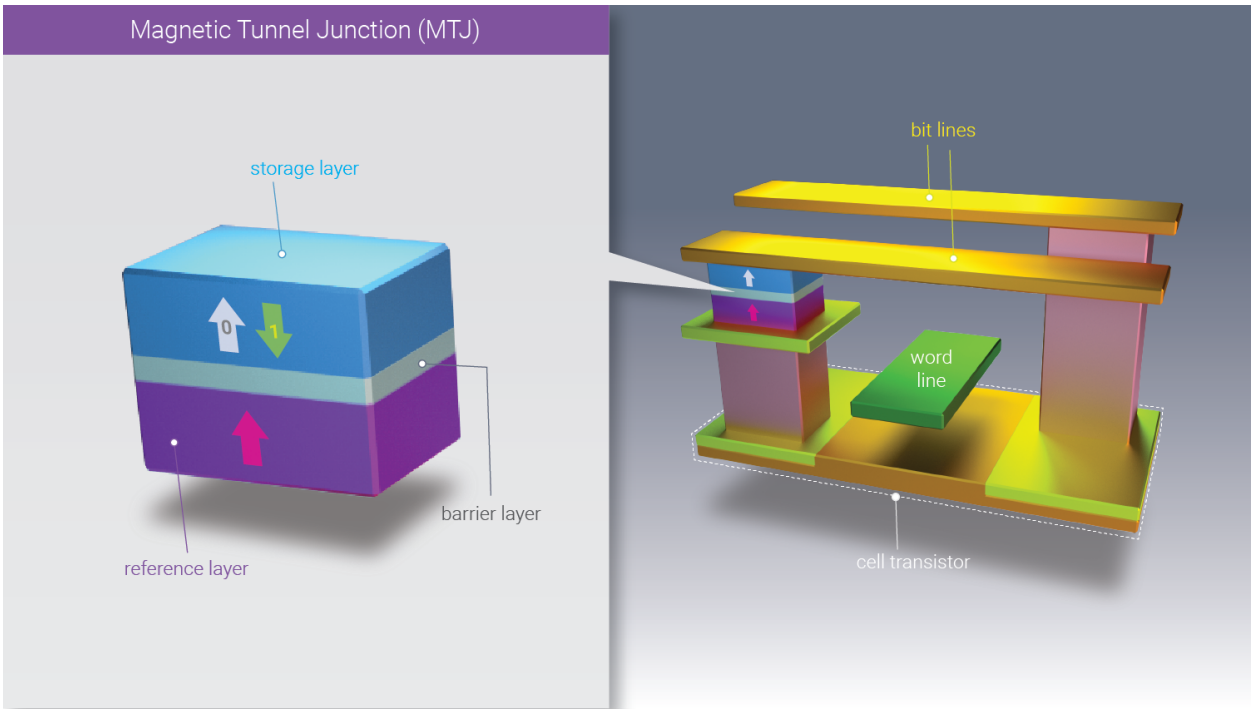
Introduction

Spin transfer torque occurs in situations where a current of spin-polarized carriers from the left part of a device with a particular polarization (given by the unit vector S_1) enters the right part of the device with a different magnetization direction (given by the unit vector S_2). When the electrons incoming from the left side enter the right magnetic part, they will eventually be polarized along S_2, meaning that the right magnetic domain has **exerted a torque** on the electrons in order to rotate their spin angular momentum. However, due to conservation of angular momentum, the electrons exert an **equal but opposite torque** on the right magnetic domain – the spin transfer torque. Note that a noncollinear description of electron spin is needed to study this effect!

Application in Random Access Memory (RAM)

The spin transfer torque can be used to modify the orientation of a magnetic layer in a magnetic tunnel junction (MTJ) by passing a spin-polarized current through it, and can therefore be used to flip the active elements in magnetic random-access memory (MRAM).



Theory

There are two principally different ways to calculate STT from atomic-scale models:

1. The STT can be found from the divergence of the spin current density, $\nabla \cdot I_s$, which in QuantumATK can be directly calculated using Greens function methods.

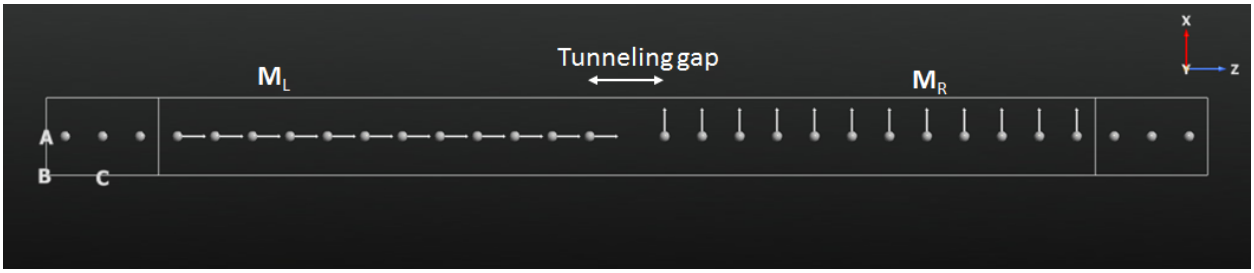
2. Another way to calculate the STT, here denoted $\mathbf{T}$, is from the expression $\mathbf{T} = \mathbf{Tr}(\delta\rho_{\mathrm{neq}}\sigma \times \mathbf{B}_{\mathrm{xc}})$, where $\delta\rho_{\mathrm{neq}}$ is the non-equilibrium contribution to the density matrix, σ is a vector of Pauli matrices, and $\mathbf{B}_{\mathrm{xc}}$ is the exchange-correlation magnetic field.

   Method 2 will be used in this tutorial. We can either calculate $\delta\rho_{\mathrm{neq}}$ from the difference between finite-bias and zero-bias calculations, $\delta\rho_{\mathrm{neq}} = \rho_{\mathrm{neq}} - \rho_{\mathrm{eq}}$, or we can estimate it using linear response theory, $\delta\rho_{\mathrm{neq}} = (G^{\mathrm{r}}\Gamma_{\mathrm{L}}G^{\mathrm{a}})qU$, where $G^{\mathrm{r/a}}$ is the retarded/advanced Greens function, Γ_{L} is the left-electrode coupling operator, U is the bias voltage, and q is the electron charge. The expression for the STT given in method 2 above is then evaluated in real space.

   ATK implements a convenient **analysis object** for calculating the spin transfer torque using method 2 in the linear-response approximation, where the non-equilibrium density response depends linearly on the bias.

Getting Started

You will here consider a device configuration consisting of a carbon chain with a gap in the middle, which the electrons have to tunnel through. The system is highly artificial, but serves as a simple model of a magnetic tunnelling junction.



Note: There is no need for k-point sampling in the A- and B-directions in this 1D device. However, for commonly studied magnetic tunnelling junctions, like Fe|MgO|Fe, a very fine k-point sampling along A and B is often needed.

Collinear Initial State

The 1D carbon-chain device illustrated above is similar to the one used in the tutorial *Introduction to noncollinear spin*, but not identical to it. Download the device configuration as an QuantumATK Python script: `device.py`.

As already mentioned, a noncollinear representation of the electron spin is needed when calculating STT. We will use a collinear, spin-parallel ground state as initial guess for the noncollinear state. First step is therefore a collinear calculation for the 1D device. Send the geometry to the **Script Generator** and set up the ATK-DFT calculation:

- Set the **default output file** to `para.nc`.
- Add a New Calculator block and set the **Spin** to *Polarized*. The **exchange-correlation** functional will automatically switch to *LSDA*. Change the carbon basis set to *SingleZetaPolarized* in order to speed up calculations.
- Add an Initial State block and select **User spin** in order to initialize the calculation with all carbon atoms maximally polarized.

Save the script as `para.py` (it should look roughly like this: `para.py`), and run the calculation using the **Job Manager**.

Noncollinear State: 90ř Spin Rotation

Next step is a noncollinear calculation where the spins on the left side of the tunnelling gap point in a different direction than the spins on the right side of the gap. The basic recipe to do this is fairly simple:

1. The ATK-DFT calculator settings used in the collinear calculation, saved in `para.nc`, are loaded from file and slightly adapted for the noncollinear calculation.
2. The spins in the right-hand part of the device are rotated 90ř around the polar angle θ.
3. The spin-parallel collinear ground state is used as initial state for the noncollinear calculation.

The QuantumATK Python script shown below implements the basic steps given above, but also runs a Mulliken population analysis for visualizing the resulting spin directions throughout the device, and computes the electrostatic difference potential (EDP) and the transmission spectrum.

```
# Read in the collinear calculation
device_configuration = nlread('para.hdf5', DeviceConfiguration)[0]

# Use the special noncollinear mixing scheme
iteration_control_parameters = IterationControlParameters(
    algorithm=PulayMixer(noncollinear_mixing=True),
)

# Get the calculator and modify it for noncollinear LDA
calculator = device_configuration.calculator()
calculator = calculator(
    exchange_correlation=NCLDA.PZ,
    iteration_control_parameters=iteration_control_parameters,
)

# Define the spin rotation in polar coordinates
theta = 90*Degrees
left_spins  = [(i, 1, 0*Degrees, 0*Degrees) for i in range(12)]
right_spins = [(i, 1, theta,     0*Degrees) for i in range(12,24)]
spin_list   = left_spins + right_spins
initial_spin = InitialSpin(scaled_spins=spin_list)

# Setup the initial state as a rotated collinear state
device_configuration.setCalculator(
    calculator,
    initial_spin=initial_spin,
    initial_state=device_configuration,
)

# Calculate and save
device_configuration.update()
nlsave('theta-90.hdf5', device_configuration)

# ------------------------------------------------------------------
# Mulliken Population
# ------------------------------------------------------------------
mulliken_population = MullikenPopulation(device_configuration)
nlsave('theta-90.hdf5', mulliken_population)
nlprint(mulliken_population)

# ------------------------------------------------------------------
# Electrostatic Difference Potential
# ------------------------------------------------------------------
electrostatic_difference_potential = ElectrostaticDifferencePotential(device_
↪configuration)
nlsave('theta-90.hdf5', electrostatic_difference_potential)

# ------------------------------------------------------------------
# Transmission Spectrum
```

(continues on next page)

(continued from previous page)

```
# -----------------------------------------------------------
kpoint_grid = MonkhorstPackGrid(
    force_timereversal=False
)

transmission_spectrum = TransmissionSpectrum(
    configuration=device_configuration,
    energies=numpy.linspace(-2,2,101)*eV,
    kpoints=kpoint_grid,
    energy_zero_parameter=AverageFermiLevel,
    infinitesimal=1e-06*eV,
    self_energy_calculator=RecursionSelfEnergy(),
    )
nlsave('theta-90.hdf5', transmission_spectrum)
```

A special density mixer for noncollinear calculations is employed, and the exchange-correlation is changed to `NCLDA.PZ`. Note how the *InitialSpin* object is used to define the initial spin directions on the calculator.

Save the script as `theta-90.py` and run it using the **Job Manager** – it should not take long to finish.

Visualizations

When the calculation finishes, the file `theta-90.nc` should appear in the QuantumATK Project Files list and the contents of it should be available on the LabFloor:

- DeviceConfiguration

- MullikenPopulation

$\mathrm{Tr}(\boldsymbol{\rho}\mathbf{S})$

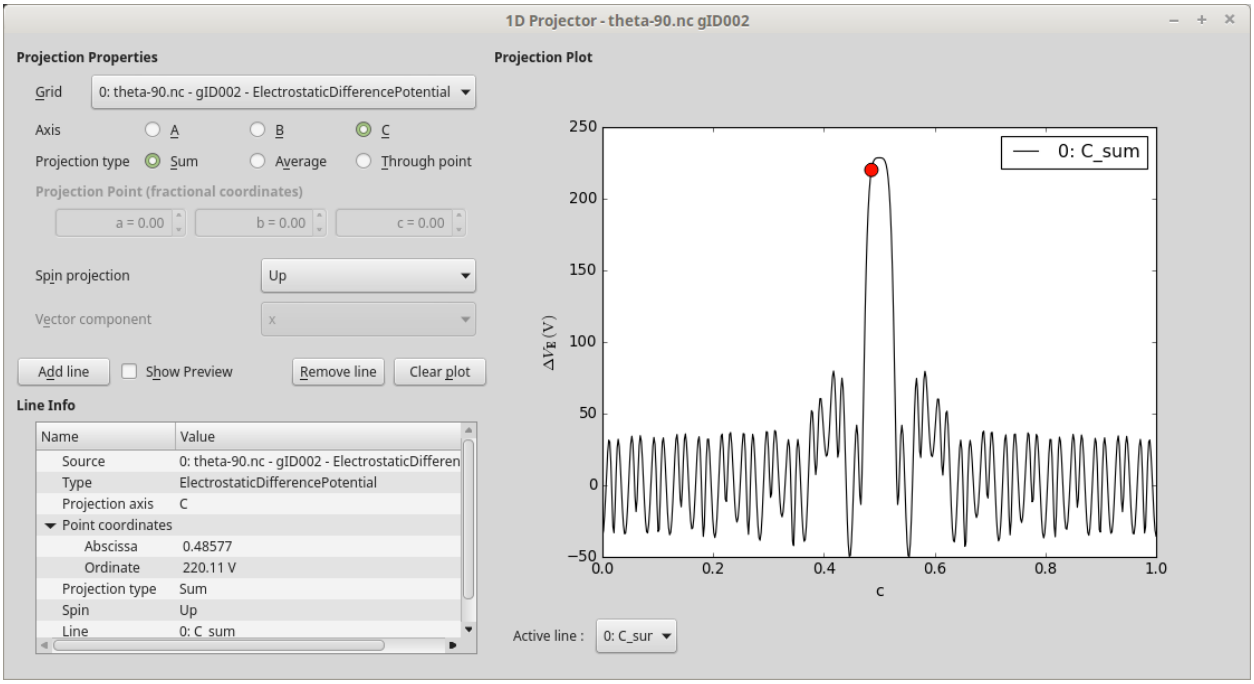
- ElectrostaticDifferencePotential

$\delta V_{\mathbf{E}}(\mathbf{r})$

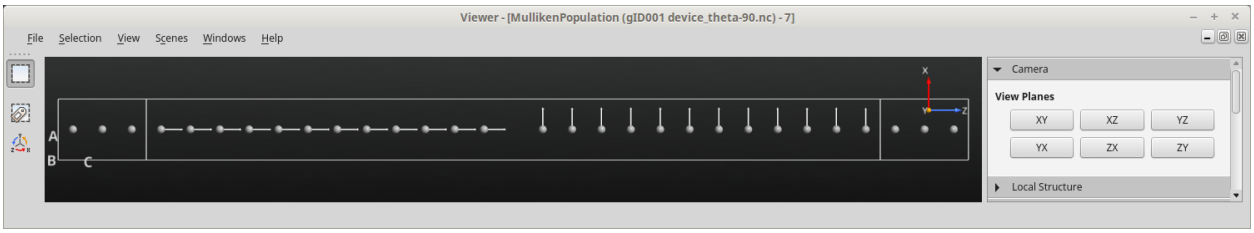
- TransmissionSpectrum

$T\left(\mathbf{k},\epsilon\right)$

First of all, select the **electrostatic difference potential** and plot it using the **1D Projector** in order to check that the NEGF calculation converged to a well-behaved ground state: Project the average EDP onto the C axis, and observe that the ground state electrostatic potential is nicely periodic in both ends of the device toward the electrodes, as it should be, and has the expected non-periodic feature around the gap in the middle of the device.

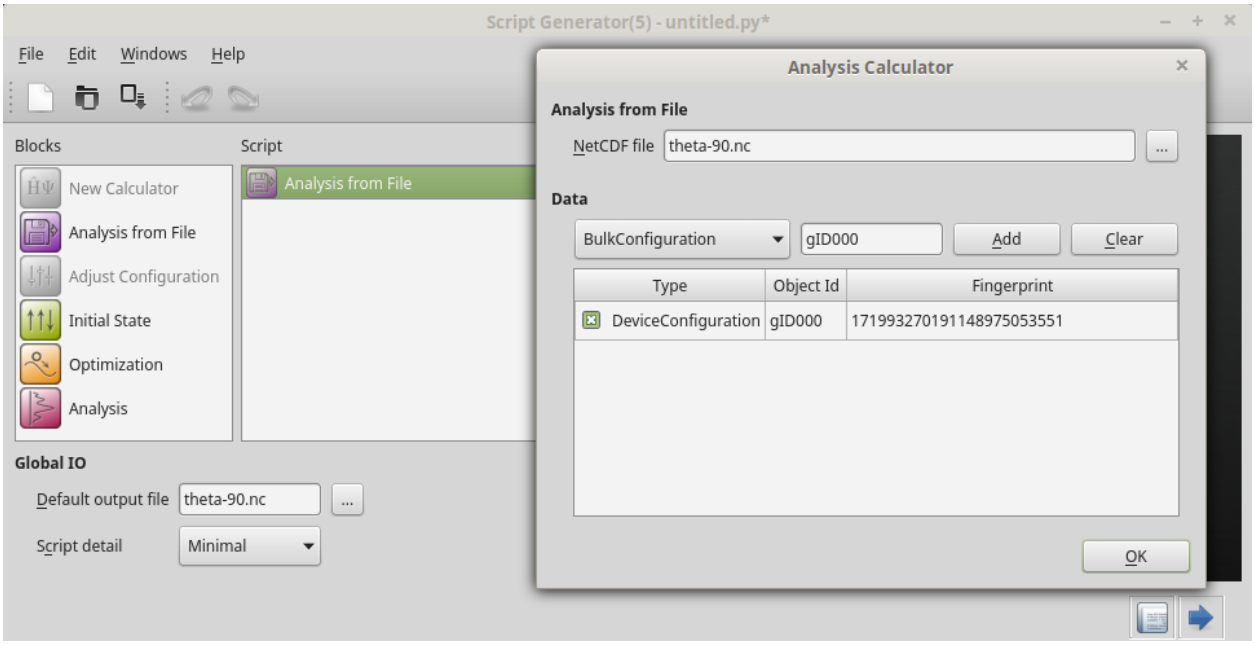


Next, select the **Mulliken population** analysis item and open it in the **Viewer**. Use the *Camera* options (or click) to select the **ZX plane** for a clear view of the spin orientations.



Calculate the STT

You are now ready to use linear response (LR) theory to calculate the spin transfer torque. Open a new **Script Generator** window and add the **Analysis from File** block. Open the block and select the device configuration saved in `theta-90.nc` for post-SCF analysis. Then change the Script Generator default output file to `theta-90.nc` in order to save all calculated quantities in that file.

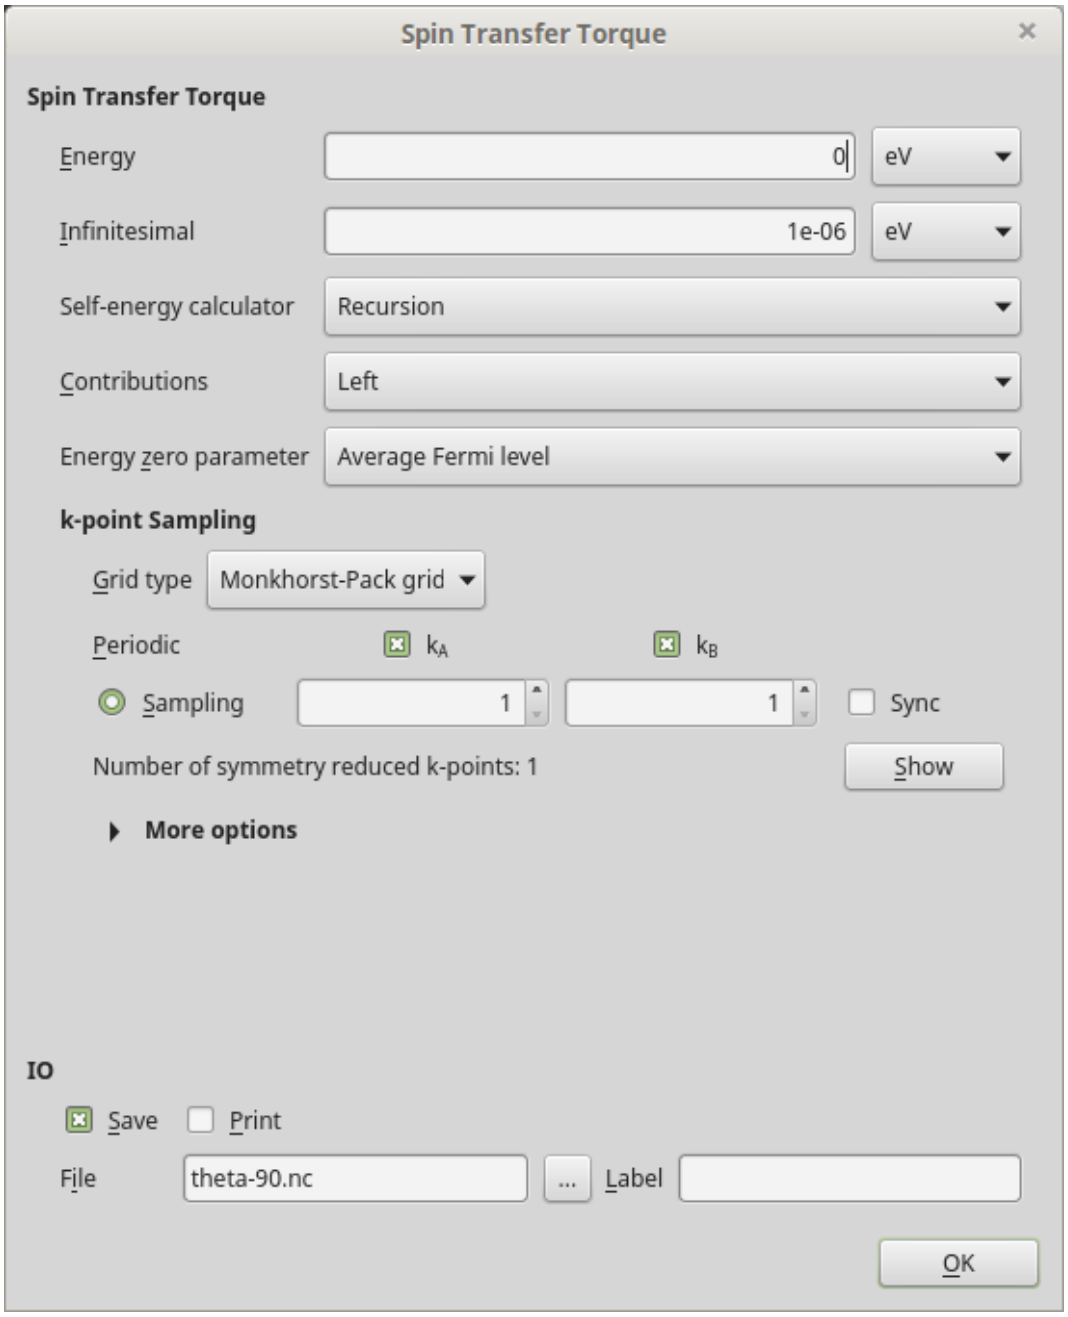


Add also the *Analysis* → *SpinTransferTorque* analysis block, and open it to see the available options. Note in particular 3 important settings:

Energy
The electron energy, with respect to the Fermi level, for which the STT will be calculated.

Contributions
The STT is by default calculated for the left –> right current.

k-points
Fairly dense k-point grids are sometimes needed along periodic directions orthogonal to the transport direction.



Tip: See the QuantumATK Manual entry *SpinTransferTorque* for a full description of all input parameters for the STT calculation and all QuantumATK Python methods available on the object.

Leave all the STT options at defaults and save the script as `stt.py`. The script should look roughly like this: `stt.py`. Run the calculation using the **Job Manager** – it should finish in less than a minute.

The STT analysis object should now have been added to the file `theta-90.nc` and be available on the QuantumATK LabFloor:

- SpinTransferTorque

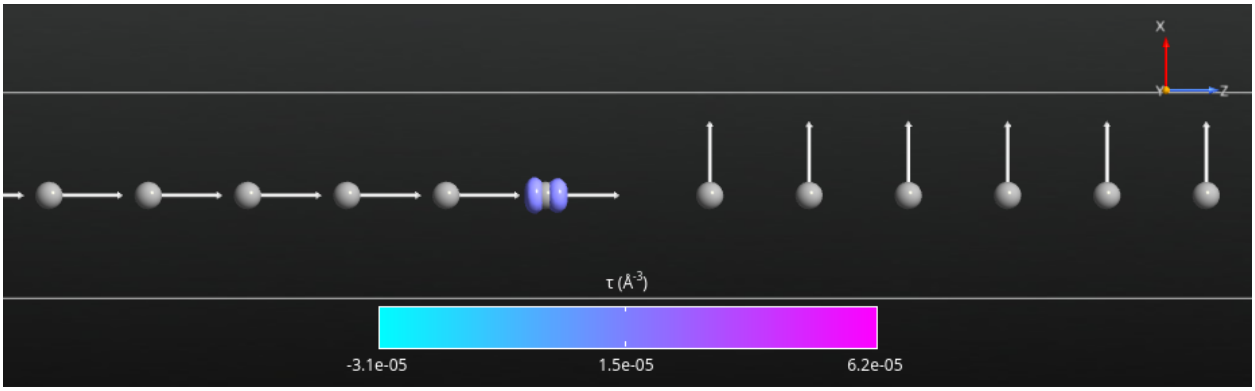
$\tau_i(\mathbf{r})$

Important: The spin transfer torque depends on the bias voltage across the electrodes, and is of course zero at zero bias, since no current flows. The linear-response spin transfer torque (LR-STT) assumes a linear relationship between the STT and the bias voltage V,

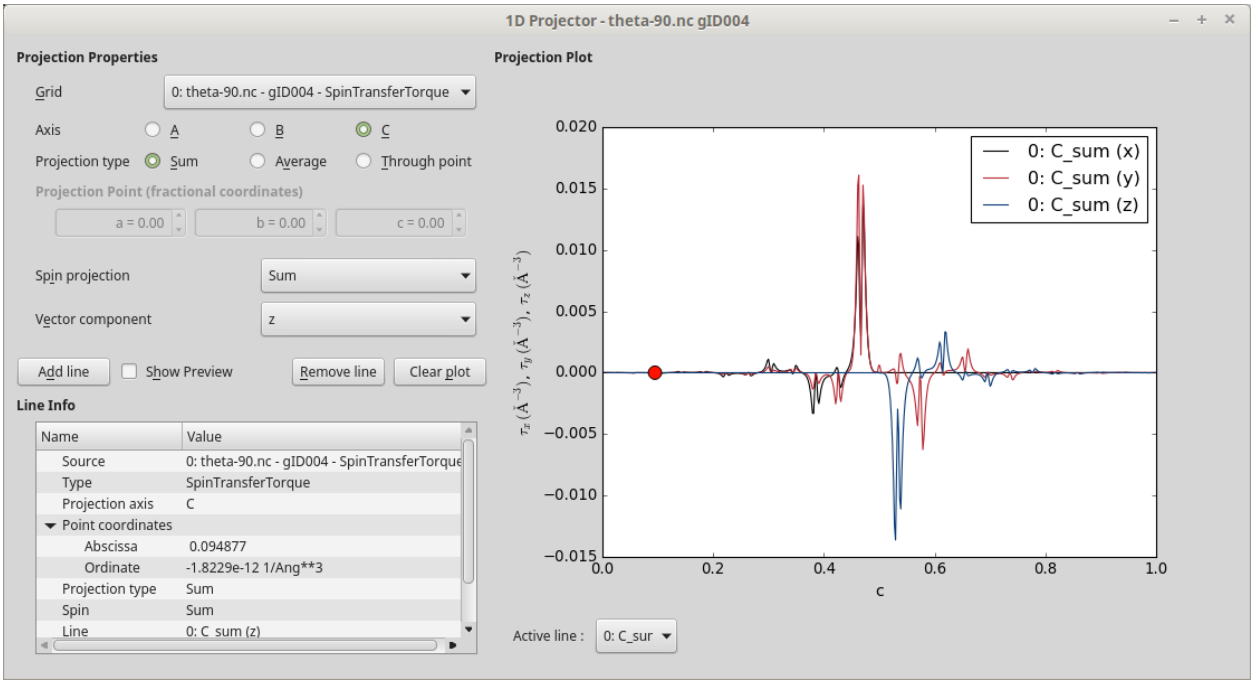
$$\boldsymbol{T}(V) = V\frac{\partial \boldsymbol{T}}{\partial V}\bigg|_{V=0} = V\boldsymbol{\tau}$$

where τ is a **linear-response coefficient**. The QuantumATK SpinTransferTorque analysis object computes the local components of the LR-STT coefficient τ, from which the small-bias STT may be calculated.

Use first the **Viewer** to get a 3D visualization of the values of the LR-STT coefficient for θ=90ř: Open the Mulliken population in the Viewer, and then drag-and-drop the STT item onto the Viewer window. The coefficient τ is represented on a **3D vector grid**, each vector consisting of the local x-, y-, and z-components, so you need to choose which component to visualize. Choose in this case to visualize the y-component as an isosurface:



You can also use the **1D Projector** to visualize the STT components. Select the STT item on the LabFloor, and click the 1D Projector plugin. Plot the x, y, and z vector components in the same plot, projected on the C axis.



It is common to divide the STT into **out-of-plane** and **in-plane** contributions. In the present case, the magnetizations in the left and right electrodes point in the z- and x-directions, respectively, thus defining the in-plane contribution as being in the XZ-plane, while the y-component gives the out-of-plane contribution.

The two figures below show the out-of-plane and in-plane components of the LR-STT coefficient. The spin of the current is oriented along z when entering the right part of the device, and is then turned such as to be aligned along x. The x-component of τ is therefore non-zero only in the left-hand part of the device, while the z-component is non-zero only in the right-hand part. The two components are in this case mirror images of each other.

Tip: Both figures above were generated using the 1D Projector. If you right-click the plot and select **Customize**, a dialog appears where you can customize plot details such as title, legend, colors, etc.

Angle Dependence

Let us next investigate how the LR-STT coefficient depends on the angle θ in the interval 0ř to 180ř. What is needed is a range of range of zero-bias NEGF calculations for different values of θ, each followed by calculation of the SpinTransferTorque analysis object for that particular spin configuration. This is most easily achieved by combining the main parts of the scripts `theta-90.py` and `stt.py` used above:

```
thetas = [0,10,20,30,40,50,60,70,80,100,110,120,130,140,150,160,170,180]

for theta in thetas:
    # Output data file
    filename = 'theta-%i.hdf5' % theta

    # Read in the collinear calculation
    device_configuration = nlread('para.hdf5', DeviceConfiguration)[0]

```

(continues on next page)

(continued from previous page)

```
    # Use the special noncollinear mixing scheme
    iteration_control_parameters = IterationControlParameters(
        algorithm=PulayMixer(noncollinear_mixing=True),
    )

    # Get the calculator and modify it for noncollinear LDA
    calculator = device_configuration.calculator()
    calculator = calculator(
        exchange_correlation=NCLDA.PZ,
        iteration_control_parameters=iteration_control_parameters,
    )

    # Define the spin rotation in polar coordinates
    left_spins  = [(i, 1, 0*Degrees,    0*Degrees) for i in range(12)]
    right_spins = [(i, 1, theta*Degrees, 0*Degrees) for i in range(12,24)]
    spin_list   = left_spins + right_spins
    initial_spin = InitialSpin(scaled_spins=spin_list)

    # Setup the initial state as a rotated collinear state
    device_configuration.setCalculator(
        calculator,
        initial_spin=initial_spin,
        initial_state=device_configuration,
    )

    # Calculate and save

    # ------------------------------------------------------------
    mulliken_population = MullikenPopulation(device_configuration)
    nlsave(filename, mulliken_population)
    nlprint(mulliken_population)

    # ------------------------------------------------------------
    # Transmission Spectrum
    # ------------------------------------------------------------
    kpoint_grid = MonkhorstPackGrid(
        force_timereversal=False
    )

    transmission_spectrum = TransmissionSpectrum(
        configuration=device_configuration,
        energies=numpy.linspace(-2,2,101)*eV,
        kpoints=kpoint_grid,
        energy_zero_parameter=AverageFermiLevel,
        infinitesimal=1e-06*eV,
        self_energy_calculator=RecursionSelfEnergy(),
        )
    nlsave(filename, transmission_spectrum)
```

(continues on next page)

(continued from previous page)

```
    # ------------------------------------------------------------
    # Spin Transfer Torque
    # ------------------------------------------------------------
    kpoint_grid = MonkhorstPackGrid(
        force_timereversal=False,
        )

    spin_transfer_torque = SpinTransferTorque(
        configuration=device_configuration,
        energy=0*eV,
        kpoints=kpoint_grid,
        contributions=Left,
        energy_zero_parameter=AverageFermiLevel,
        infinitesimal=1e-06*eV,
        self_energy_calculator=RecursionSelfEnergy(),
        )
    nlsave(filename, spin_transfer_torque)
```

The Mulliken population and transmission spectrum are not strictly needed, but will prove useful for further analysis later on. Notice that the case θ=90ř is skipped because that calculation was already done above.

Download the script, `angles.py`, and run it using the **Job Manager** – it may take up to 30 minutes to complete.

When the job finishes you have a number of new nc-files on the QuantumATK LabFloor, each for a particular spin angle. You may visualize the Mulliken populations to check for yourself that the spin angle varies correctly.

Use the script `angles_plot.py` to analyze and plot the results. For each angle, it sums the x-, y- and z-components of τ in the right-hand part of the device, and plots them against the angle:

```
# Prepare lists
thetas = [0,10,20,30,40,50,60,70,80,90,100,110,120,130,140,150,160,170,180]
x = []
y = []
z = []

# Read data
for theta in thetas:
    # Data file
    filename = 'theta-%i.hdf5' % theta

    # Read in the STT analysis object
    stt = nlread(filename, SpinTransferTorque)[0]

    # Get the STT 3D vector grid (units Bohr**-3)
    array = stt.toArray()

    # Get the index of middle position along C
    sh = numpy.shape(array)
    k = sh[2]/2

    # Get the volume element of the STT grid.
    dX, dY, dZ = stt.volumeElement()
```

(continues on next page)

(continued from previous page)

```
    volume = numpy.abs(numpy.dot(dX, numpy.cross(dY, dZ)))

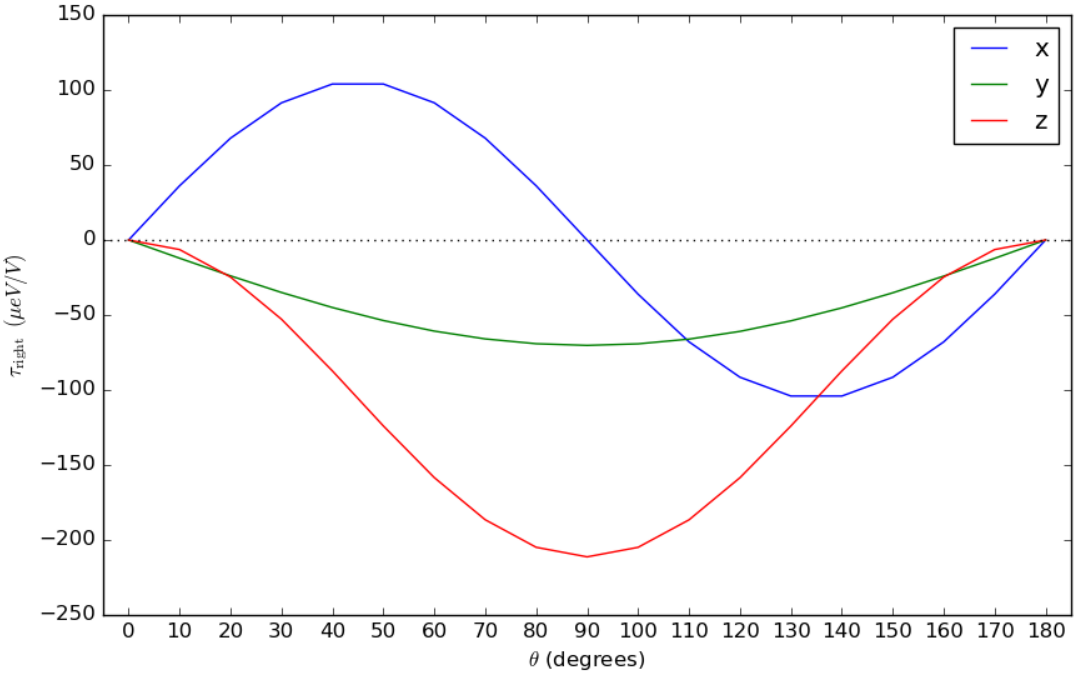
    # Integrate the vector components in the right-hand part of the device
    stt_x = numpy.sum(array[:,:,k:,:,0])*volume*stt.unit()
    stt_y = numpy.sum(array[:,:,k:,:,1])*volume*stt.unit()
    stt_z = numpy.sum(array[:,:,k:,:,2])*volume*stt.unit()

    # append to lists
    x.append(stt_x)
    y.append(stt_y)
    z.append(stt_z)

# Convert lists to arrays
x = numpy.array(x)
y = numpy.array(y)
z = numpy.array(z)

# Save data for future convenience
import pickle
f = open('angles_plot.pckl', 'wb')
pickle.dump((thetas,x,y,z), f)
f.close()

# Plot results
import pylab
pylab.figure(figsize=(10,6))
pylab.plot(thetas, x*1e6, label='x')
pylab.plot(thetas, y*1e6, label='y')
pylab.plot(thetas, z*1e6, label='z')
pylab.axhline(0, color='k', linestyle=':')
pylab.legend()
pylab.xlabel(r'$\theta$ (degrees)')
pylab.ylabel(r'$\tau_\mathrm{right} \, \, \, (\mu eV/V)$')
ax = pylab.gca()
ax.set_xlim((-5,185))
ax.set_xticks(thetas)
pylab.savefig('angles_plot.png')
pylab.show()
```



The in-plane STT may also be compared to an analytic expression from Ref.[1]:

$$\tau_{\parallel}(\theta) = 0.5 \cdot [T_z(180^\circ) - T_z(0^\circ)]\, \mathbf{M}_L \times (\mathbf{M}_R \times \mathbf{M}_L),$$

where $T_z(180^\circ) = h/(4\pi e)[T_\uparrow(180^\circ) - T_\downarrow(180^\circ)]$ is the spin transmission for the anti-parallel configuration, and likewise for $T_z(0^\circ)$. The vector $\mathbf{M}_{L/R}$ is the direction of magnetization in the left/right part of the carbon chain.

Use the script `analytical.py` to do the analysis. It computes the in-plane ($\tau_\parallel = \sqrt{\tau_x^2 + \tau_z^2}$) and out-of-plane ($\tau_\perp = \tau_y$) components in the right-hand part of the device, and also computes $\tau_\parallel$ from the analytical expression using the obtained transmission spectrum at each angle:

```
# Load STT data
import pickle
f = open('angles_plot.pckl', 'rb')
(thetas,x,y,z) = pickle.load(f)
f.close()

# Process STT data
inplane = (x**2 + z**2)**0.5
outplane = y

# Analytical in-plane STT
transmissions = numpy.zeros(2)
for j,theta in enumerate([0,180]):
    # Data file
    filename = 'theta-%i.hdf5' % theta
    # Read the transmission spectrum
    transmission = nlread(filename, TransmissionSpectrum)[0]
```

(continues on next page)

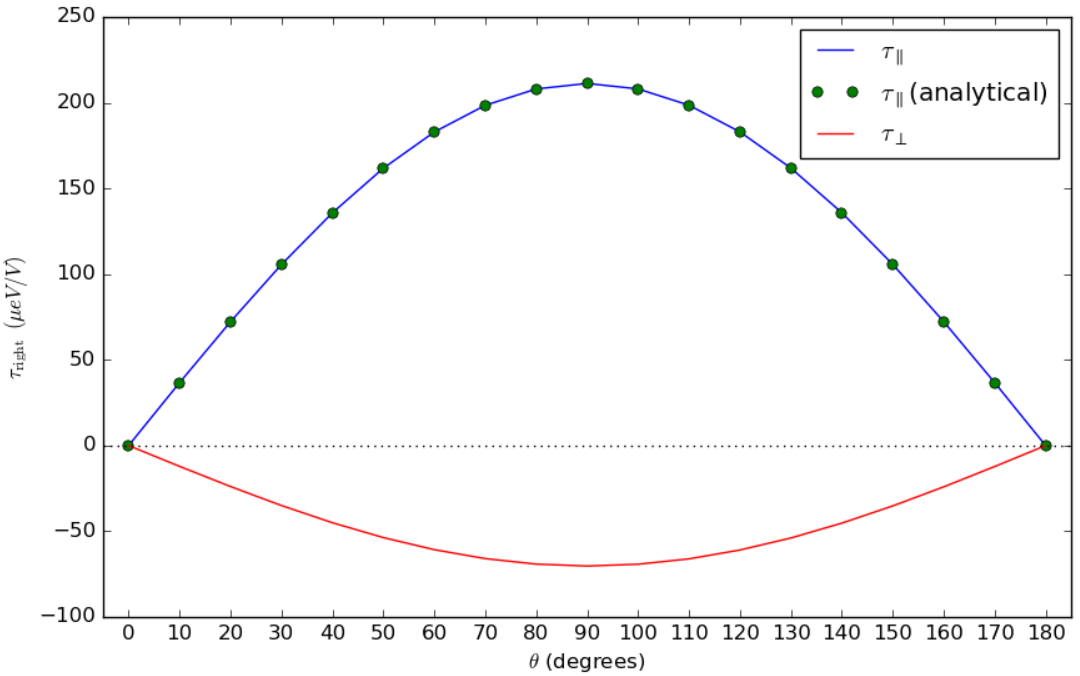
(continued from previous page)

```
    # Get the energies
    energies = transmission.energies().inUnitsOf(eV)
    # Find the index of the Fermi level
    i_Ef = numpy.argmin(abs(energies))
    # Calculate the spin-transmission (Up - Down)
    T = transmission.evaluate(spin=Spin.Up)[i_Ef]-transmission.evaluate(spin=Spin.
↪Down)[i_Ef]
    # Append to list
    transmissions[j] = T
analytical = abs(transmissions[0]-transmissions[1])/2*numpy.sin(numpy.
↪array(thetas)*numpy.pi/180)/(2*numpy.pi)

# Plot results
import pylab
pylab.figure(figsize=(10,6))
pylab.plot(thetas, inplane*1e6,          label=r'$\tau_\parallel$')
pylab.plot(thetas, analytical*1e6, 'o', label=r'$\tau_\parallel$'+'(analytical)')
pylab.plot(thetas, outplane*1e6,         label=r'$\tau_\perp$')
pylab.axhline(0, color='k', linestyle=':')
pylab.legend()
pylab.xlabel(r'$\theta$ (degrees)')
pylab.ylabel(r'$\tau_\mathrm{right} \, \, \, (\mu eV/V)$')
ax = pylab.gca()
ax.set_xlim((-5,185))
ax.set_xticks(thetas)
pylab.savefig('analytical.png')
pylab.show()
```



The agreement between the angle-dependent calculation (blue line) and the analytical results (green dots), obtained

only from the spin transmissions in the parallel and anti-parallel configurations, is excellent.

Transport calculations with QuantumATK `AdaptiveGrid`

`central_region.py` `mgo_para.py` `mgo_relax.py` `tmr.py` `adaptive_grid.py` `zoom.py` `mgo_nonco_dc.py` `mgo_nonco_dc_analysis.py`

Introduction

This tutorial shows you how to simulate and analyze the electronic transport properties of magnetic tunnel junctions (MTJs), commonly studied for spintronic applications. You will consider a Fe|MgO|Fe MTJ, which is a rather complex spin polarized system, initially studied by MacLaren and co-workers[1].

You will use QuantumATK to study the colinear and non-colinear spin-dependent transport properties, including electronic transmission, tunnel magnetoresistance, and spin-transfer torque. You will also become acquainted with the AdaptiveGrid method, which is an adaptive alternative to the conventional Monkhorst–Pack type grid for k-point sampling.

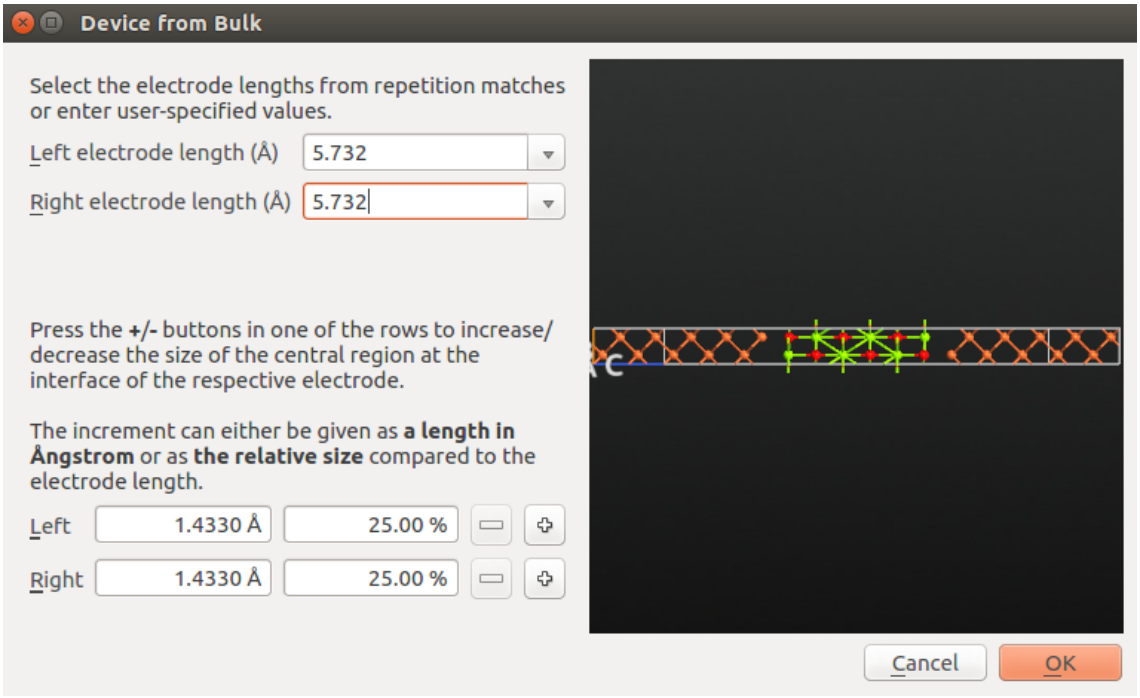
Getting started

It is very easy to create a Fe|MgO|Fe tunnel junction using the *Magnetic Tunnel Junction* Builder plugin. However, the device configuration will then need to be geometry optimized, which is not the main objective of this tutorial. We therefore provide an QuantumATK Python script with the optimized device central region, `central_region.py`, which you should use for building the MTJ device. You can also jump to section *Relaxing the device central region* if you want to learn how the geometry relaxation was done.

For now, just start QuantumATK, create a new project and give it a name, then select it and click *Open*. Download `central_region.py` and save it in the Project Folder. Then drop the script on the QuantumATK **Builder**, and use the **Device from Bulk** plugin to attach electrodes to the central region, and thereby create the Fe|MgO|Fe device.

The default electrode length of 5.732 Å will work fine for the present purposes. This corresponds to two times the iron lattice constant.

[1] W.ăH. Butler, X.-G. Zhang, T.ăC. Schulthess, and J.ăM. MacLaren. Spin-dependent tunneling conductance of Fe/MgO/Fe sandwiches. *Physical Review B*, 63(5):054416, 2001. doi:10.1103/PhysRevB.63.054416.



Note: The Device from Bulk plugin will suggest a few different electrode lengths. These are detected by searching for periodicity in your central region. Always check and carefully choose these important parameters. See the tutorial *Transport calculations with QuantumATK* for more information.

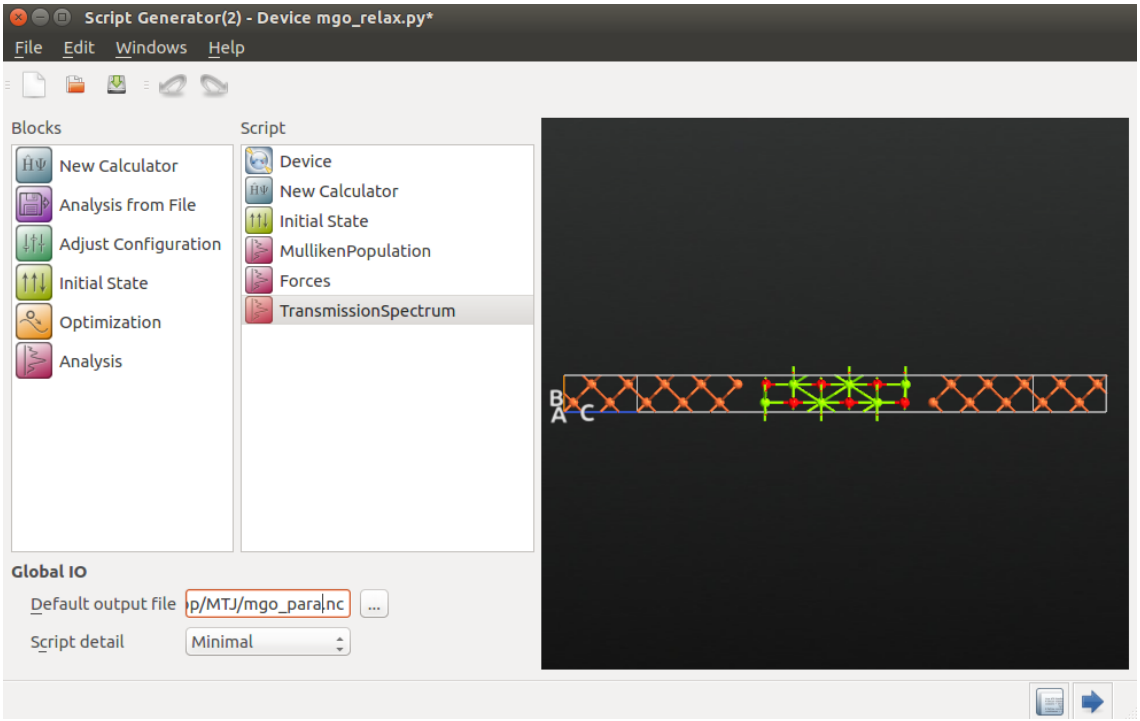
Parallel spin

You will in the following perform a self-consistent NEGF-DFT calculation for the case of parallel spin polarization in the left and right iron parts of the MTJ. You will also compute the transmission spectrum as a function of the k-vector parallel to the transport direction.

Send the device configuration to the **Script Generator** (use the icon for this), and add the following blocks to the script:

- New Calculator
- Initial State
- MullikenPopulation
- Forces
- TransmissionSpectrum

Then change the default output file name to `mgo_para.nc`.



Next, adjust the settings in a some of the script blocks:

•**Calculator**:

–Select the SGGA exchange-correlation method, to perform a spin polarized GGA calculation using the PBE functional.

–Increase the electron temperature to 1200 Kelvin, to ease the self-consistent convergence.

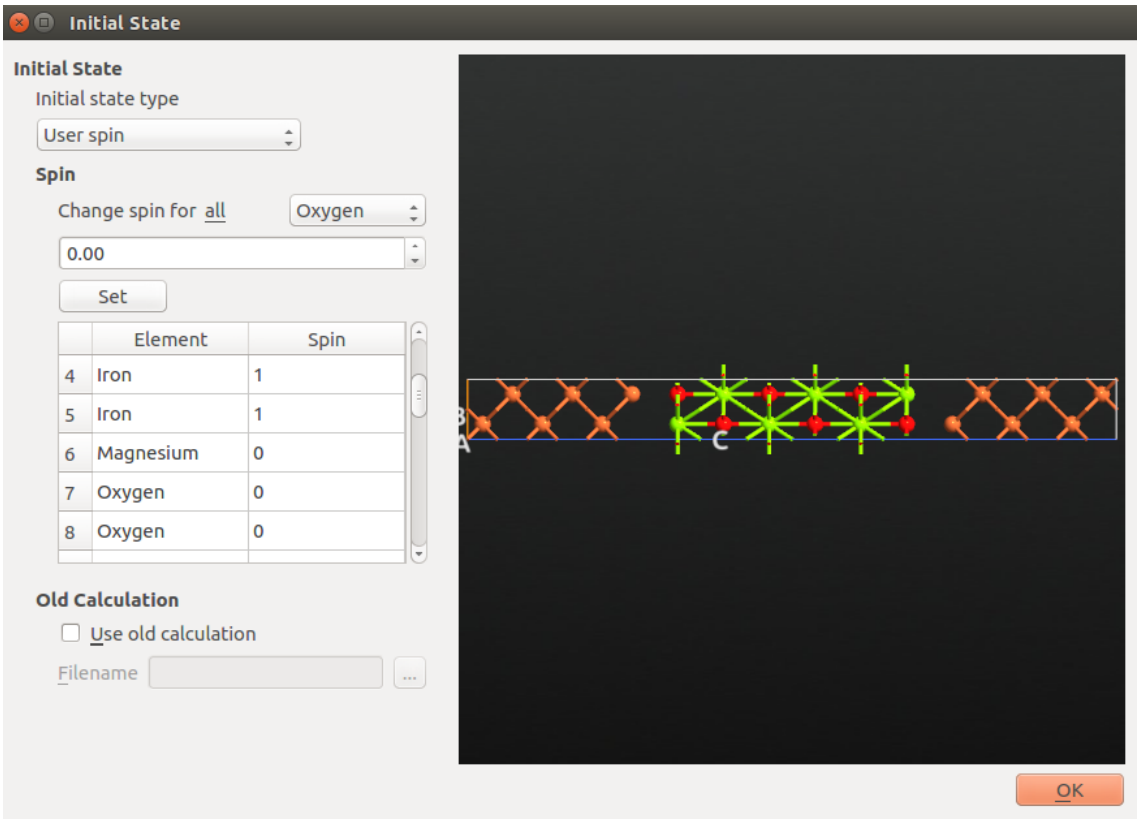
–Use a 7x7x100 k-point grid.

–Select the SingleZetaPolarized basis set for iron.

•**Initial State**:

–Choose *User spin* for as the type of initial state.

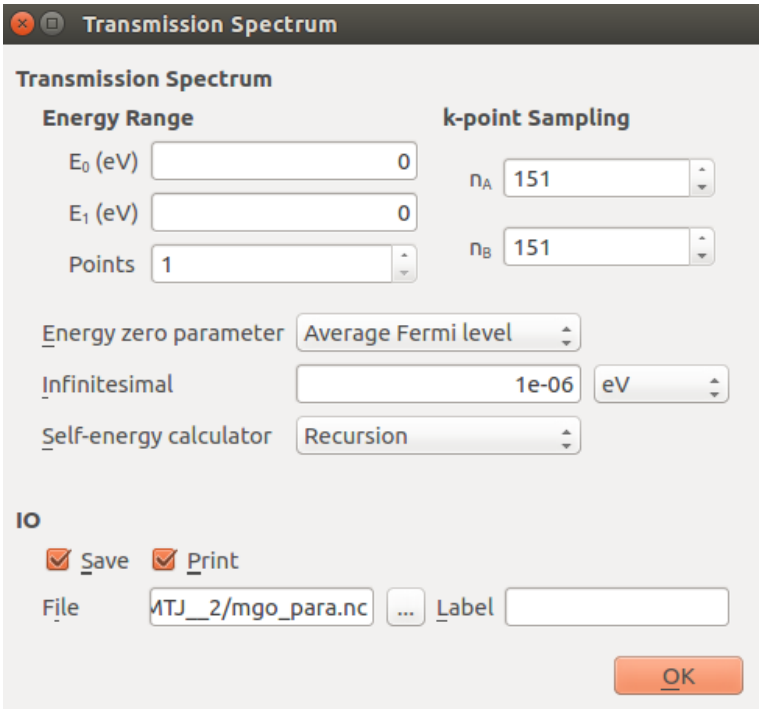
–Set the relative spins on O and Mg atoms to 0.



•**TransmissionSpectrum**:

–You will in this example compute the transmission only at the Fermi level, to save time. Use the settings $E_0 = E_1 = 0.0$ eV and just a single energy point to achieve this.

–151x151 grid for k-point sampling.

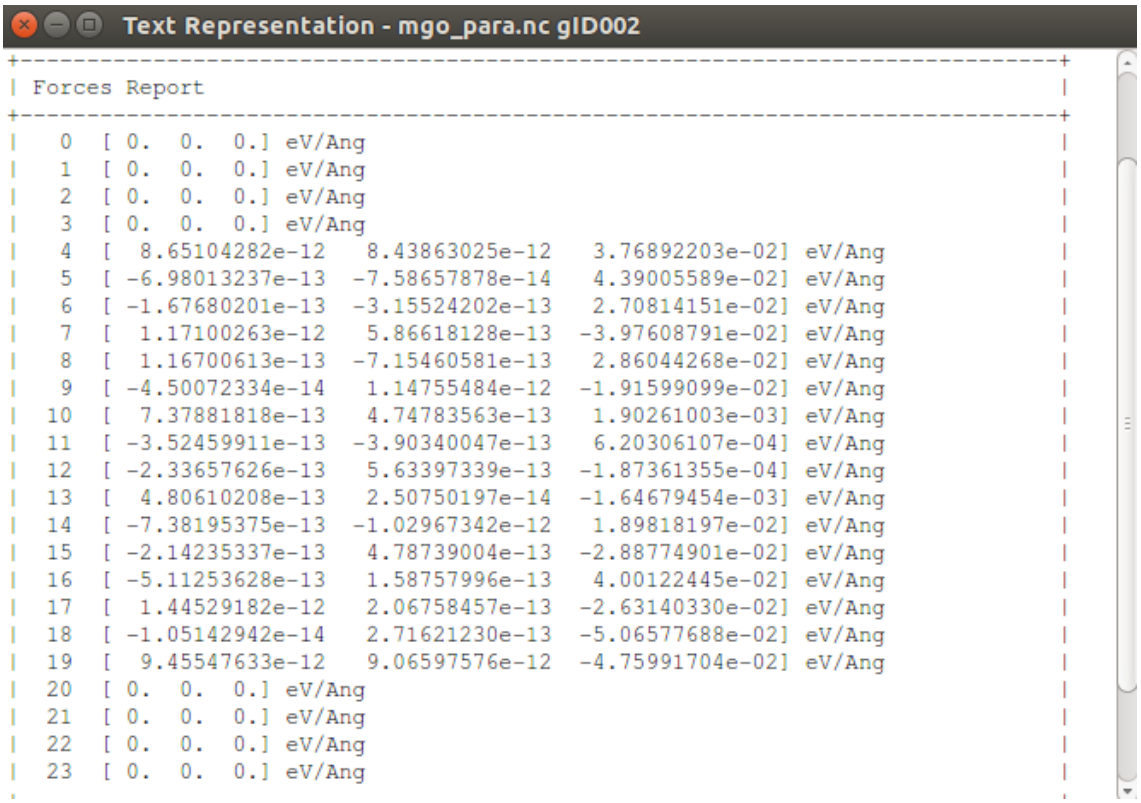


Save the script as `mgo_para.py` and run the calculation, e.g. using the **Job Manager**. The calculations may take an hour on a single core, but it is possible to obtain a very good speedup by executing in parallel, reducing the computational time down to roughly 20 minutes with 4 MPI processes. If needed you can also download the script: `mgo_para.py`.

Important: Do not close the Script Generator window. You will need it again later on for setting up calculations for the anti-parallel spin configuration.

Inspecting the forces

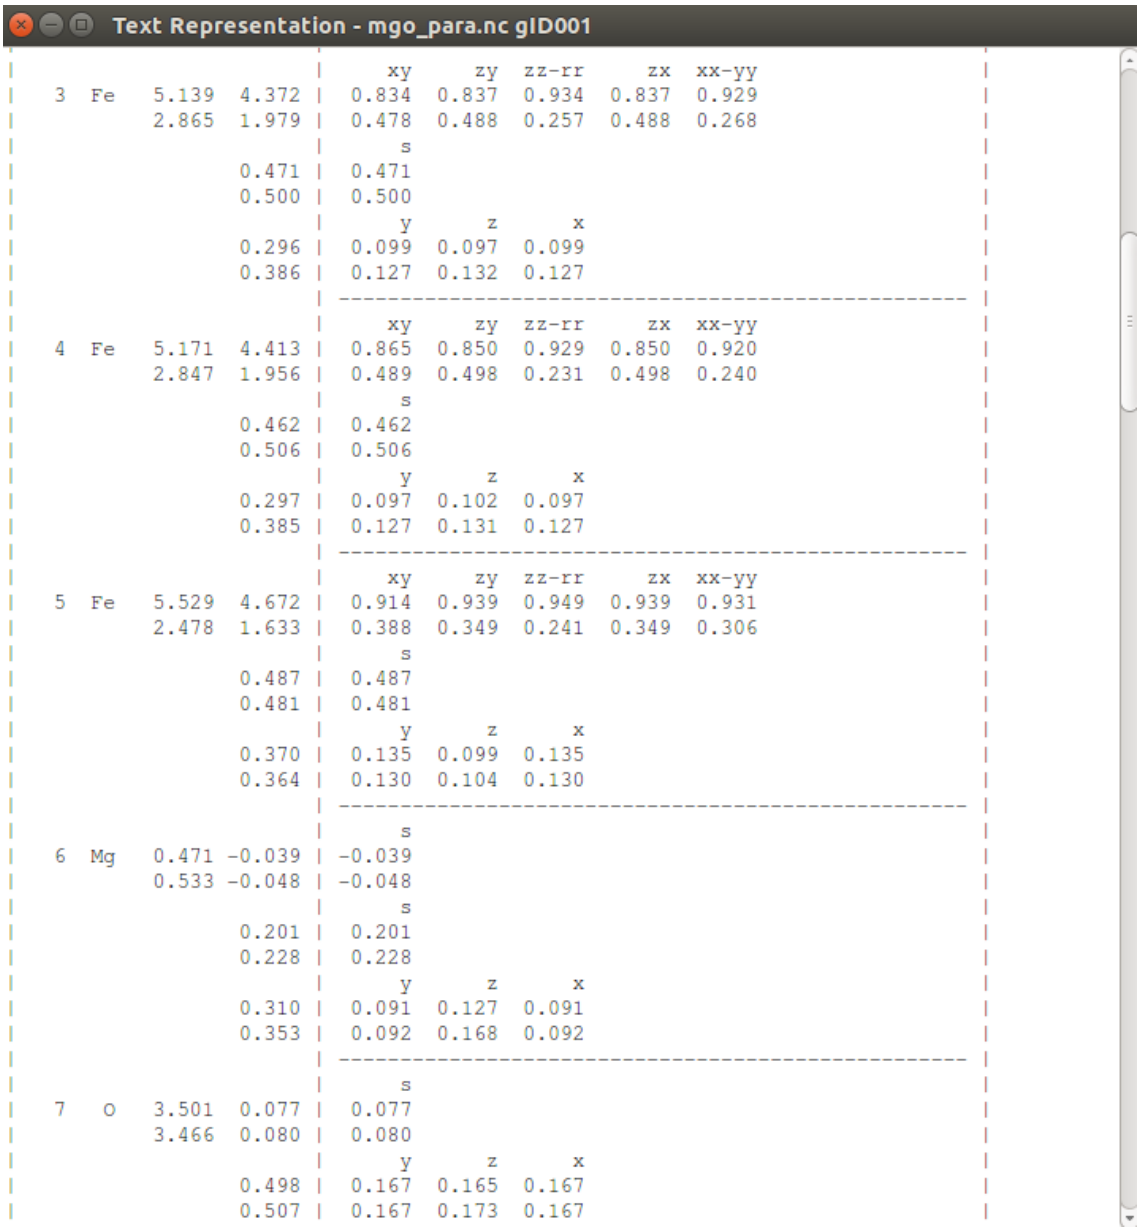
The output data file `mgo_para.nc` should now have appeared in the Project Files list. Make sure it is selected, such that the data items are visible on the LabFloor. Then select the **Forces** item and use the **Text Representation** tool in the right-hand Panel Bar to see a report of the forces:



The forces on the atoms belonging to the electrode extension regions are not calculated, and these are therefore set to zero. For the other atoms, the forces are small.

Mulliken population

You can also use the Text Representation tool to inspect the calculated **Mulliken populations**:



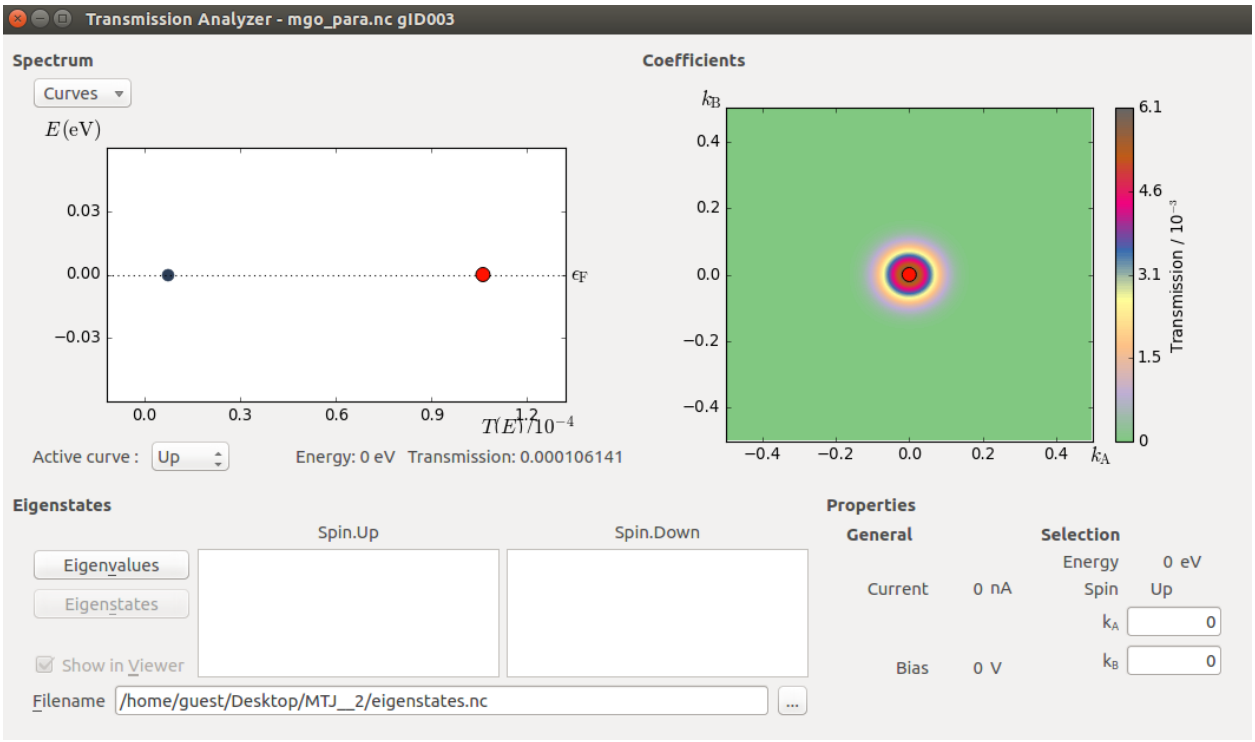
The leftmost column lists the total Mulliken population per spin channel for each atom. It is important to inspect this result in order to check that each atom is correctly spin polarized. Note that all Fe atoms are polarized with their majority spin pointing up, while the O atoms are essentially unpolarized. The Mg atoms next to the interfaces (on both sides) couple anti-parallel with the Fe atoms, while the Mg atoms further away from the interfaces are unpolarized.

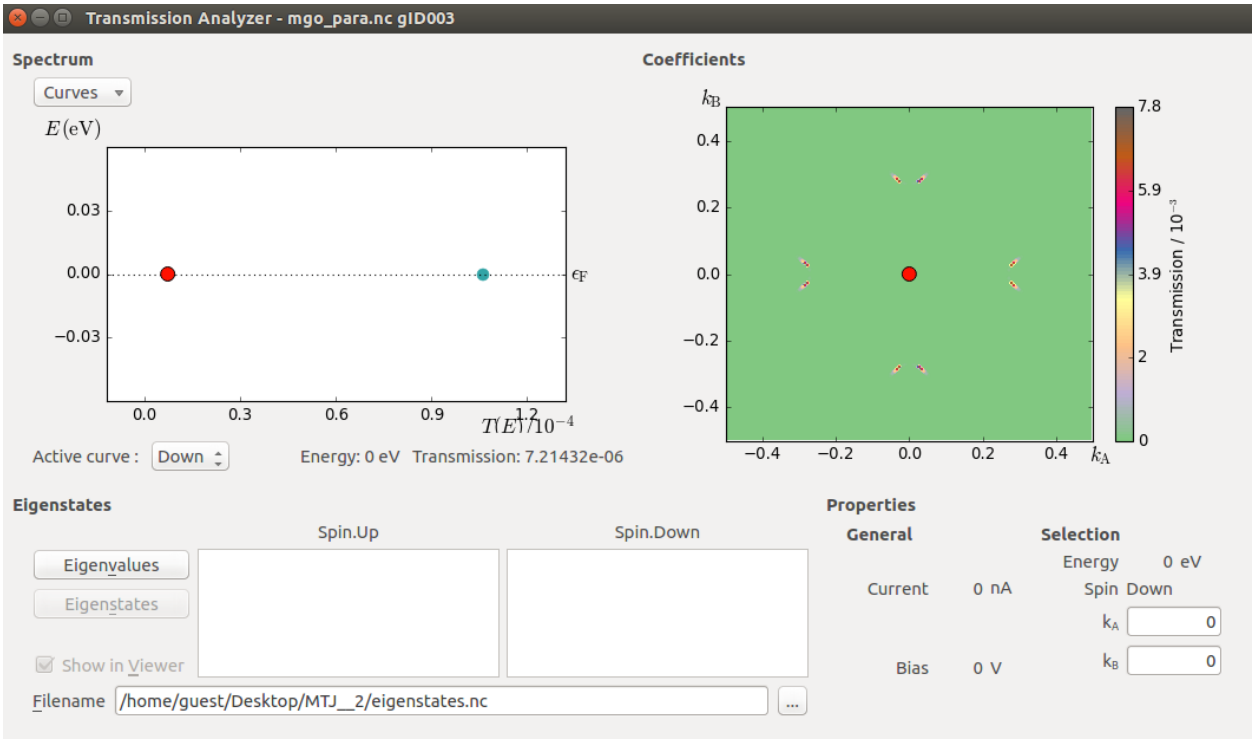
The report also shows the population for each shell and resolves it on individual orbitals.

Electron transmission

Use the **Transmission Analyzer** plugin to analyze the calculated transmission spectrum. A few modifications of the plotting options make this spectrum easier to analyze:

- Right-click the right-hand plot of the k-dependent transmission coefficients, and select the color map named *Spectral*.
- In the **Curves** menu, tick off Up and Down.
- Using the **Active Spin** menu, you can now choose between the k-dependent transmission for spin-up and spin-down electrons:



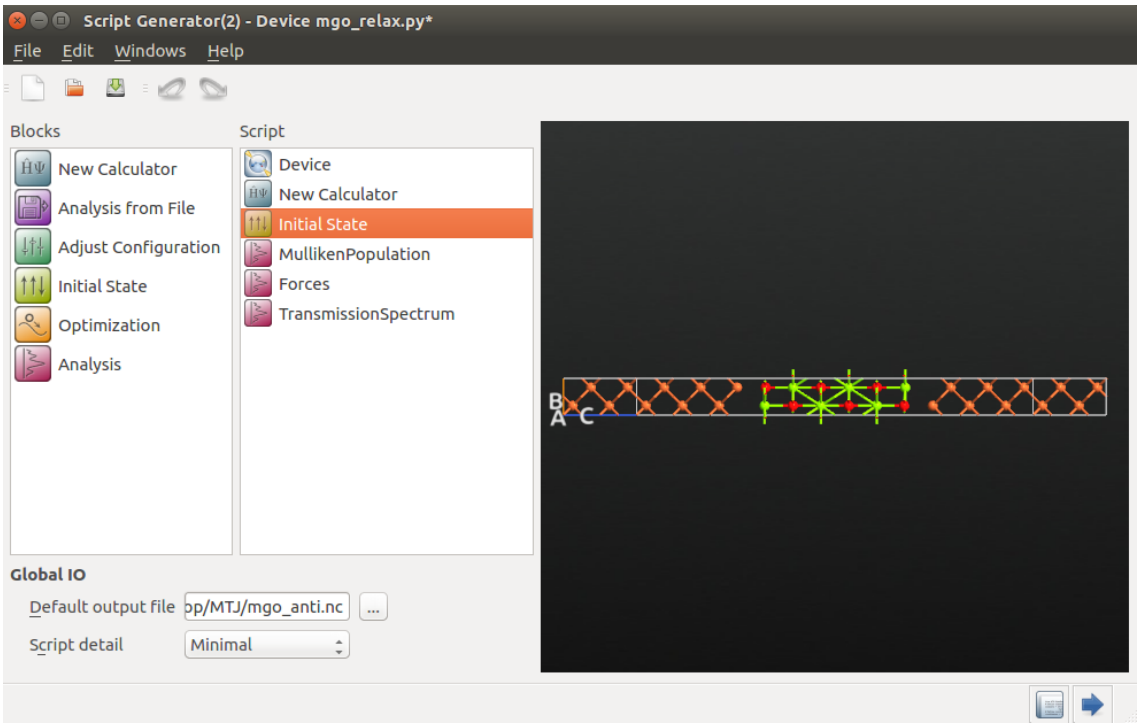


As for the results of the calculation, it is clear from the plots above that the spin-down (minority) transmission is strongly suppressed in magnitude, and exhibits spikes at certain points in the Brillouin zone, corresponding to resonant tunneling, whereas the spin-up (majority) transmission indicates regular barrier tunneling. This is all in agreement with the accepted picture of the tunneling mechanism in the Fe|MgO|Fe tunneling junction (compare to Figures 6 and 10 in[Page 1358, 1]).

Anti-parallel spin

We now turn to the case of anti-parallel alignment of the spins in the left and right iron parts of the Fe|MgO|Fe junction. The self-consistent state of the parallel configuration computed above will be used as an initial guess for the anti-parallel state. This speeds up SCF convergence as compared to starting the anti-parallel calculation completely from scratch.

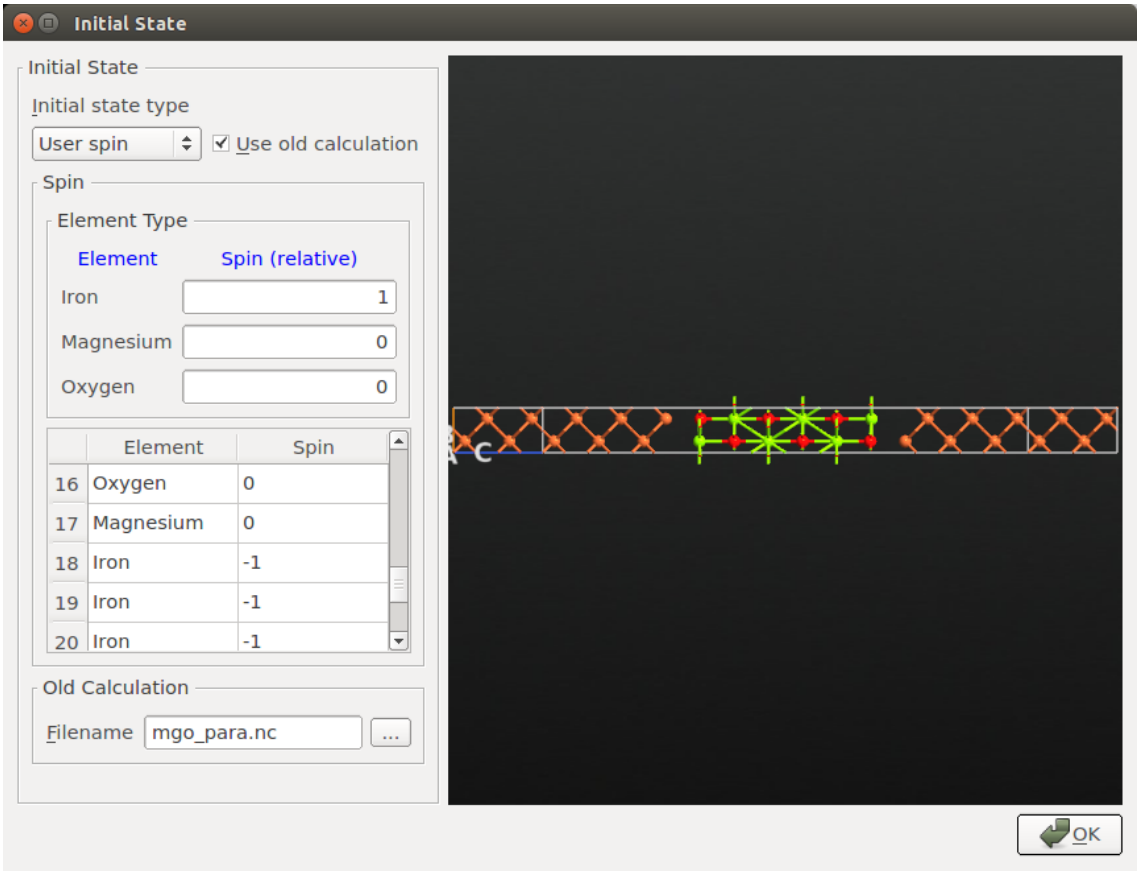
Return to the **Script Generator**. If you did not close it after setting up the parallel calculation, only a few modifications are needed. Otherwise, drop the script `mgo_para.py` on the Scripter and start by setting up the script identically to what you did above for the parallel calculations.



Setting the initial state

Open the **Initial State** block, and do the following to set up the anti-parallel spin configuration and use the parallel calculation as an initial guess for the device density matrix:

- Set again the relative spin for all iron atoms to 1 and set it to 0 for magnesium and oxygen atoms.
- Change the initial spin to -1 for all iron atoms on the right-hand side of the junction.
- Check the *Use old calculation* tick box and enter `mgo_para.nc` as the filename from which the old calculation should be loaded from.



Note: The method ouitlined above works like this: The converged density matrix from the parallel-spin calculation is used as initial state. However, the spin densities for atoms in the right-hand side of the device are flipped, resulting in an anti-parallel initial density matrix for the full device.

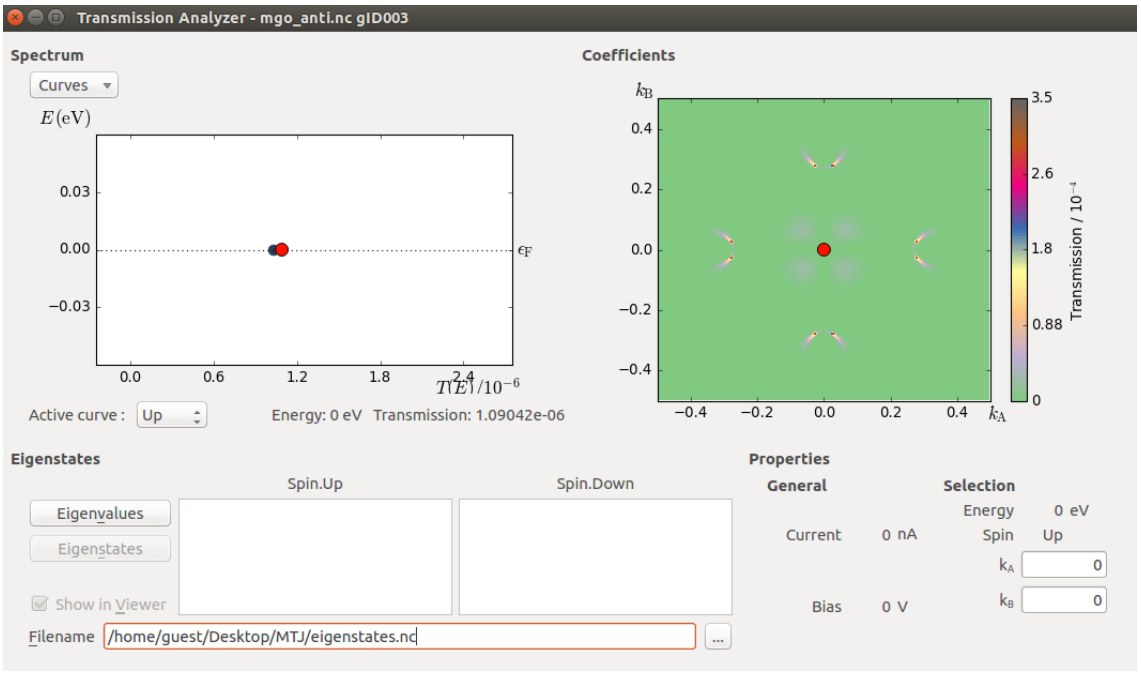
Finally, change the default output file name to `mgo_anti.nc` and make sure the **TransmissionSpectrum** analysis block is identical to the one used for the spin-parallel case.

Save the QuantumATK Python script as `mgo_anti.py` and run it.

Analyzing the results

Check that the forces on each atom are still negligible. Also check the Mulliken populations to ensure that each atom has the expected spin polarization.

Use again the **Transmission Analyzer** to analyze the electronic transmission. In this case, the transmission for up and down (majority and minority) spins are identical because of the mirror symmetry of the system. We find again that the k-dpendent transmission coefficients exhibit highly localized peaks surrounded by regions of zero transmission.



To understand why the transmission is identical for spin-up and -down, first note that due to time inversion symmetry, propagation from left to right is always identical to propagation from right to left. The up component of the transmission spectrum corresponds to up electrons from the left electrode propagation into the right electrode. The down component of the transmission spectrum corresponds to down electrons in the right electrode propagating into the left electrode.

Due to the anti-symmetric spin, the up electrons in the left electrode and the down electrons in the right electrode are both majority channels. Because of the mirror symmetry of the device, the propagation of the left majority channels into the right minority channels (the first transmission coefficient spin component) and the propagation of the right majority channels into the left minority channels (the second transmission coefficient spin component) are the same.

Thus, for symmetric devices, the equivalence of the two spin channels is an important check for anti-symmetric calculations at zero bias.

Tunneling magnetoresistance

The tunneling magnetoresistance (TMR) is defined as

$$\mathrm{TMR} = \frac{G_P - G_{AP}}{G_{AP}},$$

where G_P is the conductance through the junction with parallel spin alignment and G_{AP} the conductance for anti-parallel spin alignment.

The conductances can be calculated from their respective transmission spectra. The script below performs this calculation. You can download it here: `tmr.py`.

```
# Calculate conductance for parallel spin
transmission_para = nlread('mgo_para.hdf5', TransmissionSpectrum)[0]
conductance_para_uu = transmission_para.conductance(spin=Spin.Up)
conductance_para_dd = transmission_para.conductance(spin=Spin.Down)
conductance_para = conductance_para_uu + conductance_para_dd

# Calculate conductance for anti-parallel spin
```

(continues on next page)

(continued from previous page)

```
transmission_anti = nlread('mgo_anti.hdf5', TransmissionSpectrum)[0]
conductance_anti_uu = transmission_anti.conductance(spin=Spin.Up)
conductance_anti_dd = transmission_anti.conductance(spin=Spin.Down)
conductance_anti = conductance_anti_uu + conductance_anti_dd

print('Conductance Parallel Spin (Siemens)')
print('Up=%8.2e, Down=%8.2e' % (conductance_para_uu.inUnitsOf(Siemens),
                                conductance_para_dd.inUnitsOf(Siemens)))
print('Total = %8.2e' % (conductance_para.inUnitsOf(Siemens)))
print()

print('Conductance Anti-Parallel Spin (Siemens)')
print('Up=%8.2e, Down=%8.2e' % (conductance_anti_uu.inUnitsOf(Siemens),
                                conductance_anti_dd.inUnitsOf(Siemens)))
print('Total = %8.2e' % (conductance_anti.inUnitsOf(Siemens)))
print()

print('TMR (optimistic)  = %8.2f percent' % \
      (100.*(conductance_para-conductance_anti)/conductance_anti))
print('TMR (pessimistic) = %8.2f percent' % \
      (100.*(conductance_para-conductance_anti)/(conductance_para+conductance_anti)))
```

Execute the script, and find the TMR:

```
Conductance Parallel Spin (Siemens)
Up=4.11e-09, Down=2.79e-10
Total = 4.39e-09

Conductance Anti-Parallel Spin (Siemens)
Up=4.22e-11, Down=4.00e-11
Total = 8.22e-11

TMR (optimistic)  =  5240.12 percent
TMR (pessimistic) =    96.32 percent
```

Adaptive k-point grid

The **AdaptiveGrid** class implements an alternative to the traditional Monkhorst–Pack (MP) grid for k-point sampling. As described in great detail in the QuantumATK Reference Manual entry for *AdaptiveGrid*, an adaptive k-point grid can be used to automatically zoom in on the significant features of the electron transmission spectrum. This is particularly useful when the k-dependent transmission is dominated by localized peaks, like for the Fe|MgO|Fe MTJ, where the total computed transmission may depend critically on resolving those peaks.

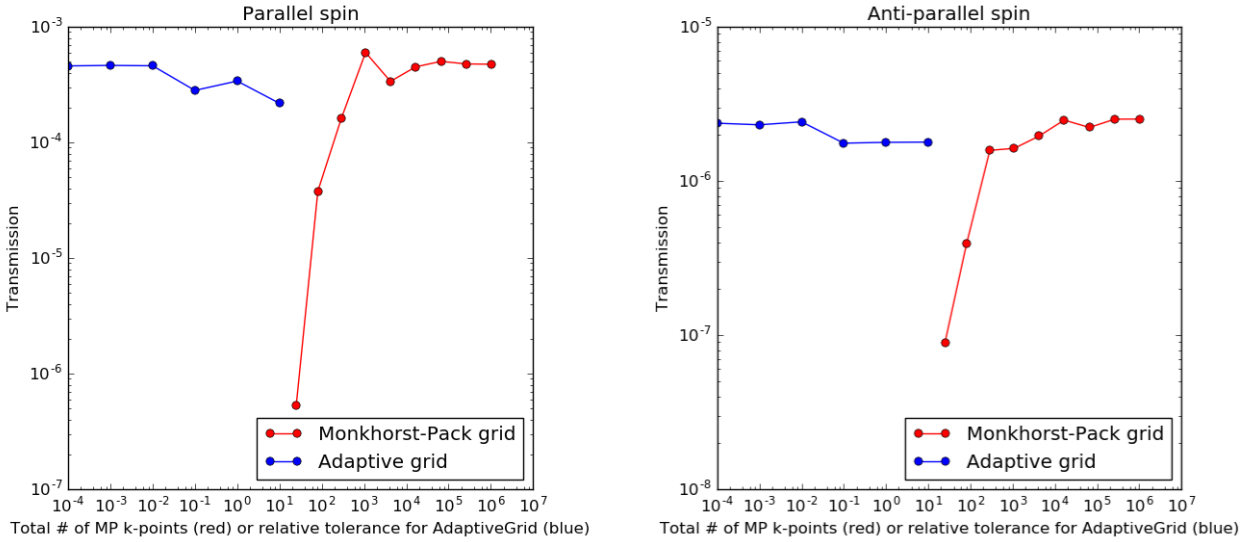
The adaptive algorithm essentially divides the Brillouin zone (BZ) into triangles and integrates over each triangle. Each triangle becomes increasingly small in an iterative manner until convergence is reached, but stops if the number of refinement levels reach the `maximum_number_of_levels`, which is 20 by default. Two types of error measures are available:

Absolute
Converged when the *absolute* value of the BZ integral in all triangles is lower than the chosen **tolerance**.

Relative
Converged when the *relative* value of the BZ integral in all triangles is lower than the chosen **tolerance**.

Note: The AdaptiveGrid functionality is available from QuantumATK 2016 an onwards.

The figures below show how the total transmission through the Fe|MgO|Fe MTJ depends on the k-point resolution used for sampling the k-dependent transmission function for the parallel and anti-parallel cases. Results using the MP k-point grid are compared to those from using the adaptive k-point grid.



Well converged calculations of the total transmission through the MTJ considered here are obtained with no less than 10^3 Monkhorst–Pack k-points, roughly corresponding to a 31x31 grid. With the adaptive k-point grid, a **relative tolerance** of 10^{-2} seems to be quite sufficient.

Note: The computational load for producing the data shown in the figures above increase from right to left with AdaptiveGrid (blue curves), and from left to right with MonkhorstPack (red curves).

Parallel transmission

The script `adaptive_grid.py` calculates the transmission for the Fe|MgO|Fe device with parallel spin orientation using both a dense MP grid and the AdaptiveGrid method:

```
# ------------------------------------------------------------
# Load device configuration
# ------------------------------------------------------------
device_configuration = nlread('mgo_para.nc', DeviceConfiguration)[0]

# ------------------------------------------------------------
# Transmission Spectrum using a dense Monkhorst-Pack grid.
# ------------------------------------------------------------
transmission_spectrum = TransmissionSpectrum(
    configuration=device_configuration,
    energies=numpy.linspace(0,0,1)*eV,
    kpoints=MonkhorstPackGrid(500,500),
    )
```

(continues on next page)

(continued from previous page)

```
nlsave('adaptive_grid.nc', transmission_spectrum)

# ------------------------------------------------------------
# AdaptiveGrid.
# ------------------------------------------------------------
adaptive_grid = AdaptiveGrid(
    tolerance=0.01,
    error_measure=Relative)

# ------------------------------------------------------------
# Transmission Spectrum using the AdaptiveGrid.
# ------------------------------------------------------------
transmission_spectrum = TransmissionSpectrum(
    configuration=device_configuration,
    energies=numpy.linspace(0,0,1)*eV,
    kpoints=adaptive_grid,
    )
nlsave('adaptive_grid.nc', transmission_spectrum)
```

The Monkhorst–Pack grid has 500x500 k-points, while the adaptive grid is set up with a relative tolerance of 10^{-2}. Download and run the script. It should finish in roughly 25 minutes if executed in parallel with 4 MPI processes on a modern laptop.

Spin-up transmission

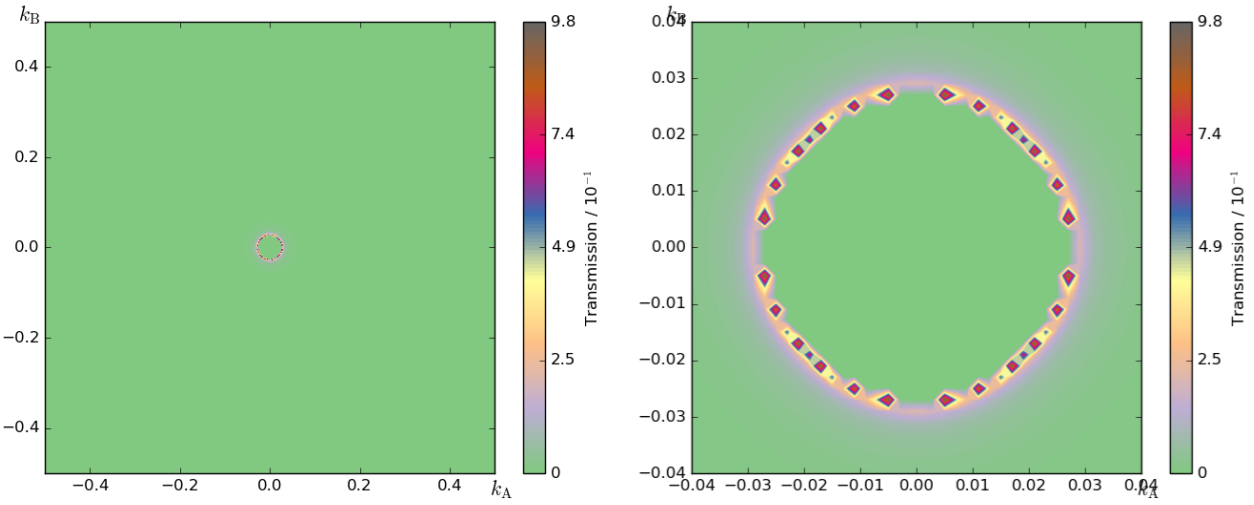


Fig. 3.103: Spin-up transmission spectrum evaluated using a 500x500 Monkhorst–Pack grid. The total k-point averaged spin-up transmission is 4.6 $\cdot 10^{-4}$. Left: Full BZ view. Right: Zoom-in around the point.

The spin-up spectrum obtained with the dense Monkhorst–Pack grid is different from the one obtained in section *Electron transmission* using a less dense grid: We now see that the feature in the middle of the spectrum is actually circular, with zero transmission immediately around the point. Clearly, a very dense grid is needed to resolve this fact. Note, however, that the improved k-point sampling has only increased the total k-point averaged spin-up transmission by a factor of 4.

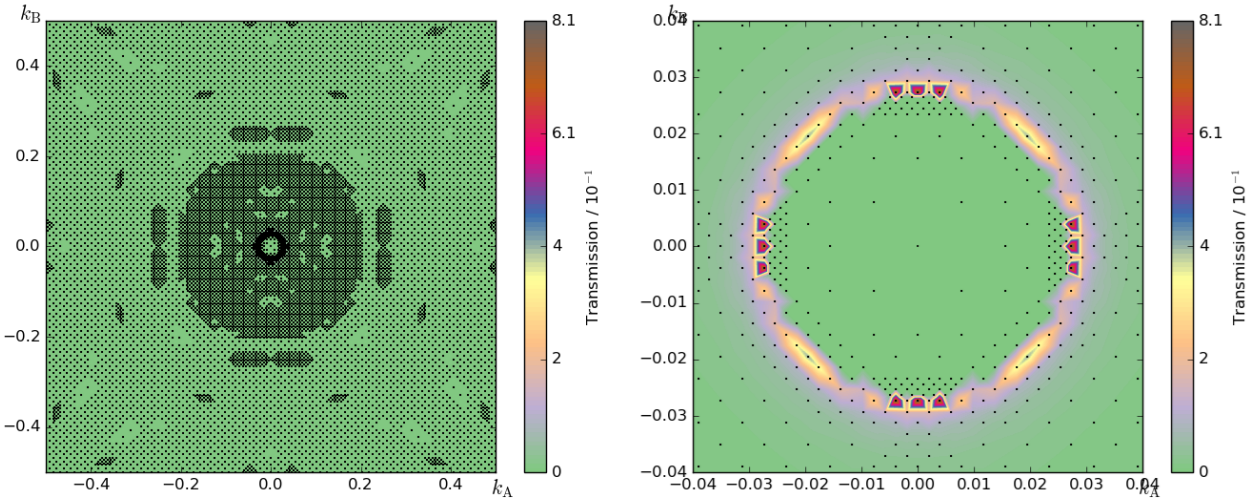

Fig. 3.104: Spin-up transmission spectrum evaluated using an adaptive grid using a relative tolerance of 10^{-2}. The black dots indicate the sampled k-points. The total k-point averaged spin-up transmission is $4.2 \cdot 10^{-4}$. Left: Full BZ view. Right: Zoom-in around the point.

The spin-up transmission spectrum evaluated using an adaptive grid is shown in the figure above, where the black dots indicate the sampled k-points. The adaptive algorithm has clearly zoomed in on the circular feature of the k-dependent transmission, causing the k-point density to be largest around the circular transmission feature.

Spin-down transmission

The 4 peaks in the densely sampled spin-down transmission are hardly visible before zooming in on one of them. Comparing the transmission obtained using the MP grid (above) to that obtained using the adaptive grid (below), it is again clear that the adaptive algorithm has zoomed in on the transmission peaks. However, the total k-point averaged spin-down transmission has changed only 5%.

Restricting the grid range

The AdaptiveGrid class can also be used to resolve only a specific part of the k-dependent transmission. The script shown below (`zoom.py`) gives an example of this, where the adaptive grid is restricted to specific k_A, k_B ranges, and thereby zooms in on specific features of the spin-up and spin-down k-dependent transmissions, respectively. A relative tolerance of 10^{-3} is used to fully resolve the transmission features.

The resulting spin-up and spin-down transmissions are illustrated below. Note the different scales on the figure axes.

```
# ------------------------------------------------------------
# Load device configuration
# ------------------------------------------------------------
device_configuration = nlread('mgo_para.nc', DeviceConfiguration)[0]

# ------------------------------------------------------------
# Transmission Spectrum zoom #1.
# ------------------------------------------------------------
adaptive_grid = AdaptiveGrid(
```

(continues on next page)

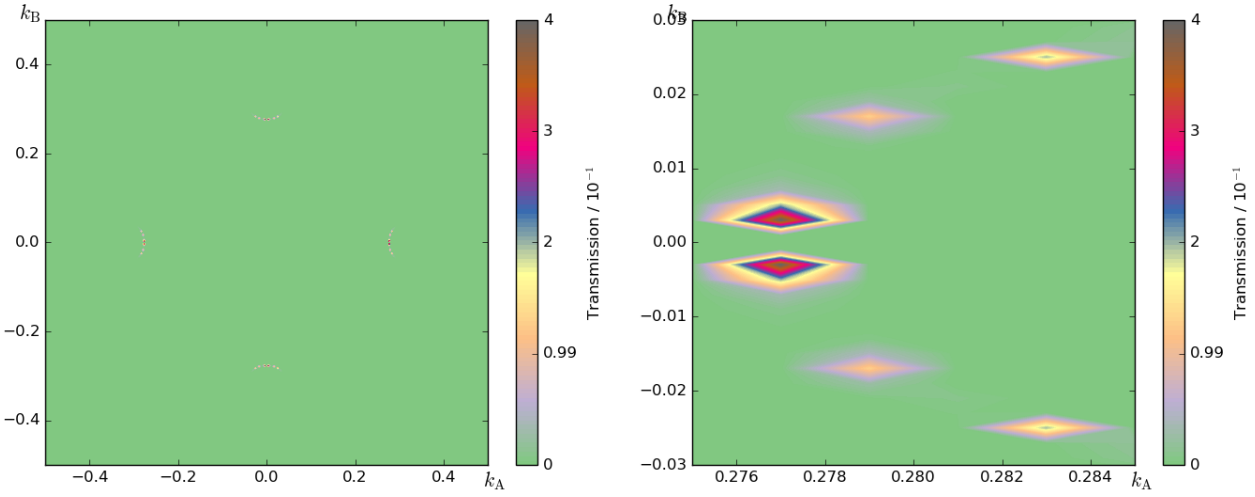

Fig. 3.105: Spin-down transmission spectrum evaluated using a 500x500 Monkhorst–Pack grid. The total k-point averaged spin-down transmission is 3.7 $\cdot 10^{-5}$. Left: Full BZ view. Right: Zoom-in around the right-hand transmission peak.

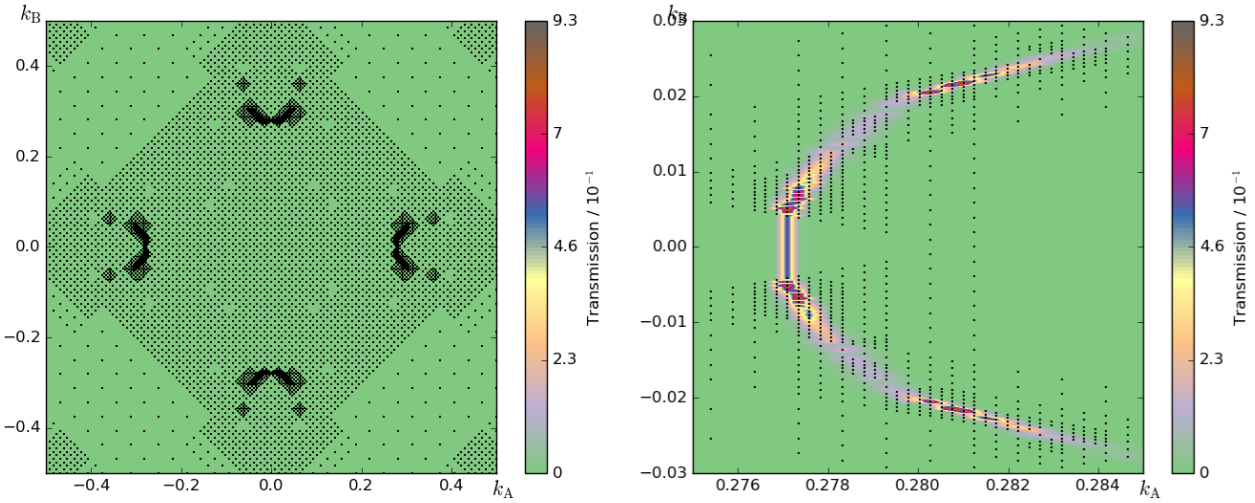

Fig. 3.106: Spin-down transmission spectrum evaluated using an adaptive grid using a relative tolerance of 10^{-2}. The black dots indicate the sampled k-points. The total k-point averaged spin-down transmission is 3.5 $\cdot 10^{-5}$. Left: Full BZ view. Right: Zoom-in around the right-hand transmission peak.

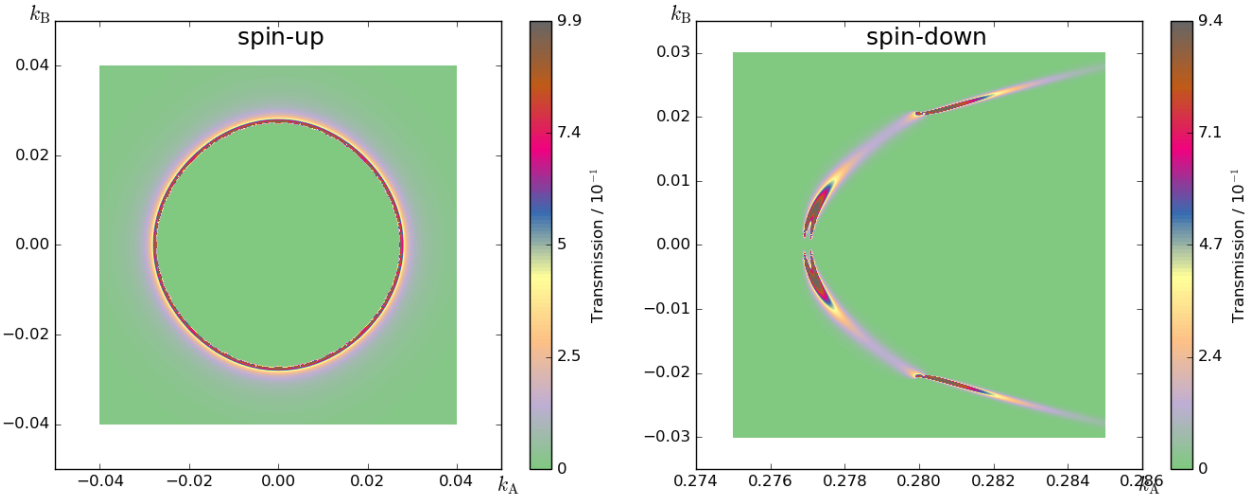
(continued from previous page)

```
    kA_range=[-0.04, 0.04],
    kB_range=[-0.04, 0.04],
    tolerance=0.001,
    error_measure=Relative)

transmission_spectrum = TransmissionSpectrum(
    configuration=device_configuration,
    energies=numpy.linspace(0,0,1)*eV,
    kpoints=adaptive_grid,
    )
nlsave('zoom.nc', transmission_spectrum)

# ------------------------------------------------------------
# Transmission Spectrum zoom #2.
# ------------------------------------------------------------
adaptive_grid = AdaptiveGrid(
    kA_range=[0.275, 0.285],
    kB_range=[-0.03, 0.03],
    tolerance=0.001,
    error_measure=Relative)

transmission_spectrum = TransmissionSpectrum(
    configuration=device_configuration,
    energies=numpy.linspace(0,0,1)*eV,
    kpoints=adaptive_grid,
    )
nlsave('zoom.nc', transmission_spectrum)
```



Warning: The total (k-point averaged) transmission is most likely not correct if you choose to sample only a specific part of the Brillouin zone. Use full-zone sampling to compute the total transmission through the device, which is also the default setting.

Spin-transfer torque

You will in this section compute the spin transfer torque (STT), which requires non-colinear spin. The tutorial *Introduction to noncollinear spin* gives for more information on how to perform STT calculations and non-colinear spin.

In the following, you will:

1. calculate the non-colinear device configuration;
2. calculate the Mulliken population and spin transfer torque.

Computing the non-colinear device configuration

The script `mgo_nonco_dc.py` calculates the non-colinear ground state of the device configuration by using the colinear ferromagnetic calculation as starting point and a density mixing scheme which diagonalizes the density matrix before mixing it. Please, note that this script replaces the spin polarized exchage-correlation (SGGA.PBE) by the non-colinear one (NCGGA.PBE).

```
# Read in the collinear calculation
device_configuration = nlread('mgo_para.nc', DeviceConfiguration)[0]

# Use the special noncollinear mixing scheme
iteration_control_parameters = IterationControlParameters(
    algorithm=PulayMixer(noncollinear_mixing=True)
    )
# Get the calculator
calculator = device_configuration.calculator()
new_calculator = calculator(
       exchange_correlation=NCGGA.PBE,
       iteration_control_parameters = iteration_control_parameters
       )
# Define the spin rotation
theta = 120*Degrees
left_spins = [(i, 1, 0*Degrees, 0*Degrees) for i in range(3)]
center_spins = [(i+3, 1, theta*i/5, 0*Degrees) for i in range(6)]
right_spins = [(i+9, 1, theta, 0*Degrees) for i in range(3)]
spin_list = left_spins+center_spins+right_spins
initial_spin = InitialSpin(scaled_spins=spin_list)

# Setup the initial state
device_configuration.setCalculator(
    calculator=new_calculator,
    initial_spin=initial_spin,
    initial_state=device_configuration)

# Calculate and save
device_configuration.update()
nlsave("mgo_nonco_dc.nc", device_configuration)
```

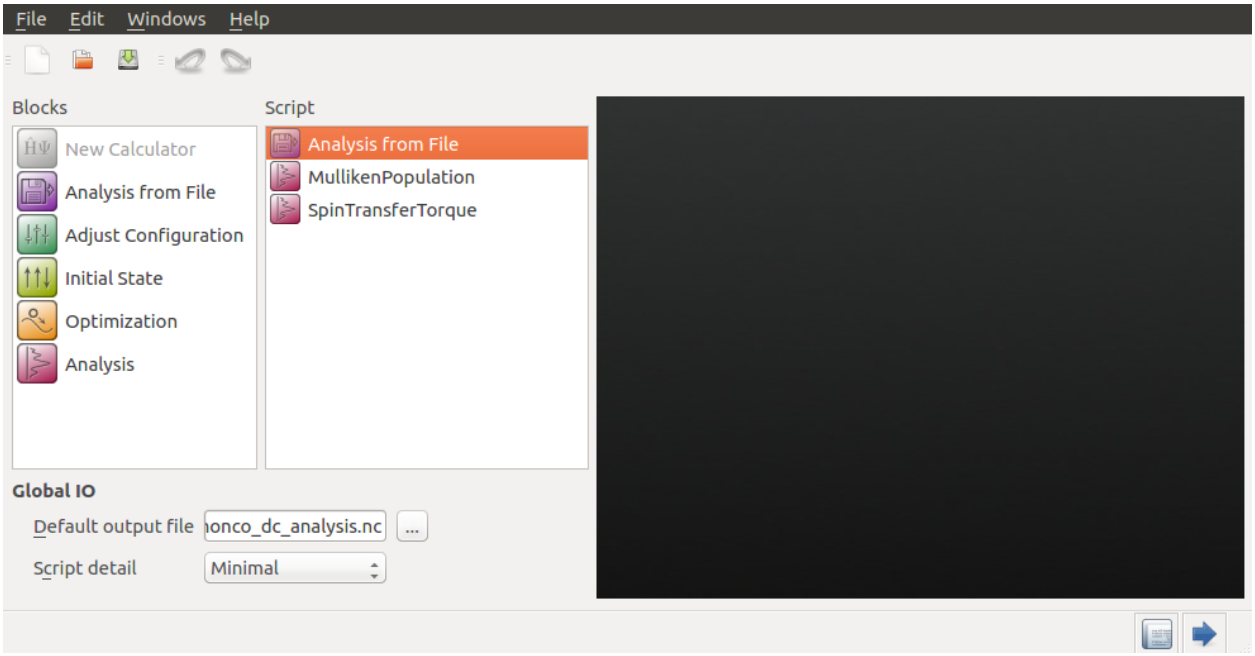
The spin setup corresponds to the spin polarization of the atoms in the left electrode pointing along the transport axis Z, while in the right electrode the polarization is rotated 120 degrees. In the central region, the angle is interpolated between these two values. Note that this is just the initial spin configuration – the actual spin polarization vectors will be computed selfconsistently and may therefore change (you can see the results in the next section).

Calculate the Mulliken population and spin transfer torque

Once the calculation is finished you can find the non-colinear device configuration in the LabFloor. In order to calculate the Mulliken population and spin transfer torque, go to the **Script Generator** and add the following blocks to the script:

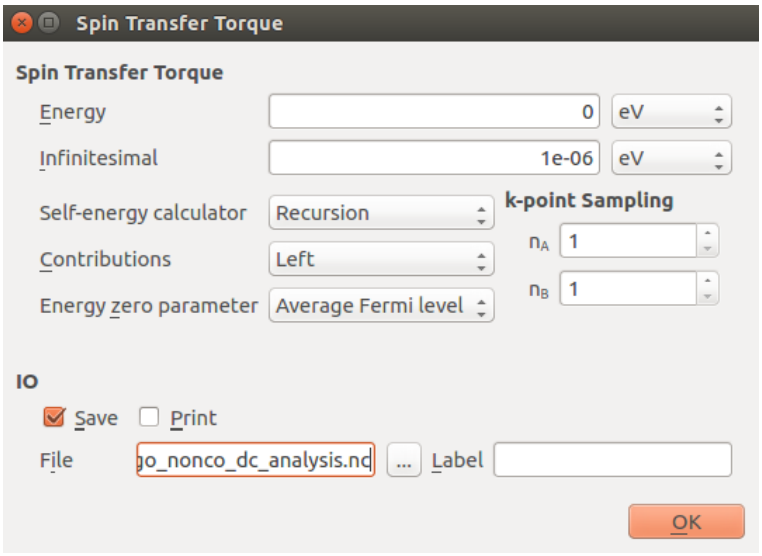
- Analysis from File
- MullikenPopulation
- SpinTransferTorque

Then, change the default output file name to `mgo_nonco_dc_analysis.nc`.



Adjust the settings in some of the blocks:

- **Analysis From File**:
  - select the `mgo_nonco_dc.nc` file.
- **SpinTransferTorque**:
  - Select **Left** for the contributions. This way, you will calculate the **left –> right** linear response current.

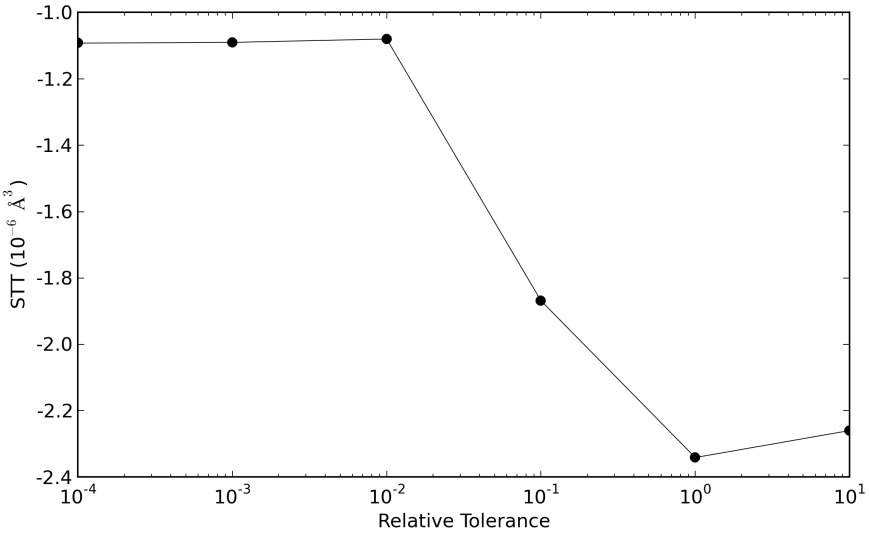


Send the script to the editor using the send to button (the icon) and replace the Monkhorst-Pack grid with the Adaptive grid as shown below.

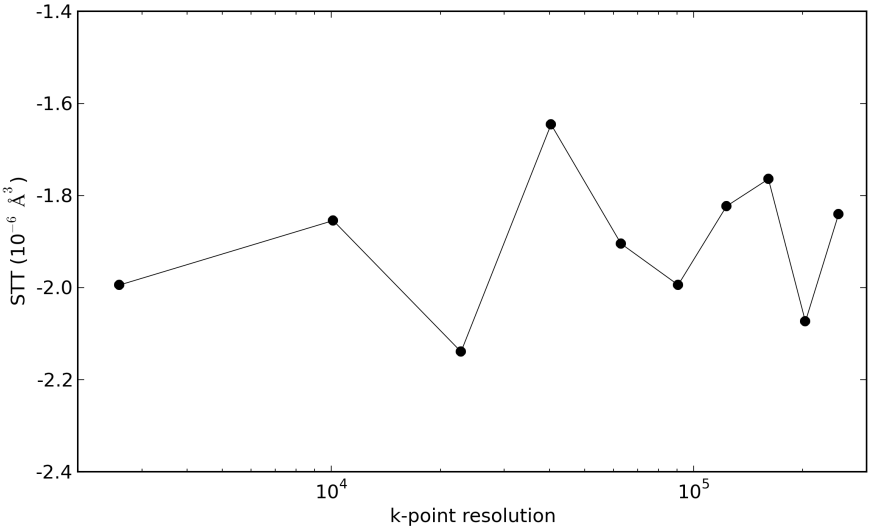
```
# Setup adaptive grid object.
adaptive_grid = AdaptiveGrid(
        kA_range=[-0.5, 0.5],
        kB_range=[-0.5, 0.5],
        tolerance=1e-2,
        error_measure=Relative,
        )
# ------------------------------------------------------------
# Spin Transfer Torque
# ------------------------------------------------------------
spin_transfer_torque = SpinTransferTorque(
    configuration=device_configuration,
    energy=0*eV,
    kpoints=adaptive_grid,
    contributions=Left,
    energy_zero_parameter=AverageFermiLevel,
    infinitesimal=1e-06*eV,
    self_energy_calculator=RecursionSelfEnergy(),
    )
nlsave('mgo_nonco_dc_analysis.nc', spin_transfer_torque)
```

If you wish, you can download the script here (`mgo_nonco_dc_analysis.py`).

The STT should be computed using a k-point sampling that is dense enough to get a well-converged value for the total torque on the right-hand side of the device. In this script we are using the adaptive grid with a relative tolerance of 10^{-2}. The below figure shows the total spin transfer torque transfered at the right side through Fe|MgO|Fe MTJ for different relative tolerances.



This plot shows that the use of a relative tolerance of 10^{-2} seems to be sufficient to obtain converged calculations of the MTJ considered in this tutorial. We have also computed the total spintransfertorque at the right side using a increasingly denser Monkhorst-Pack grid.



It can be seen that using a Monkhorst-Pack grid the total STT does not reach full convergece.

Analysis of the results

Once the calculation is finished, you will get the **MullikenPopulation** and **SpinTransferTorque** objects in the LabFloor. You can inspect the Mulliken charge and the component of the spin polarization vector using the text representation.

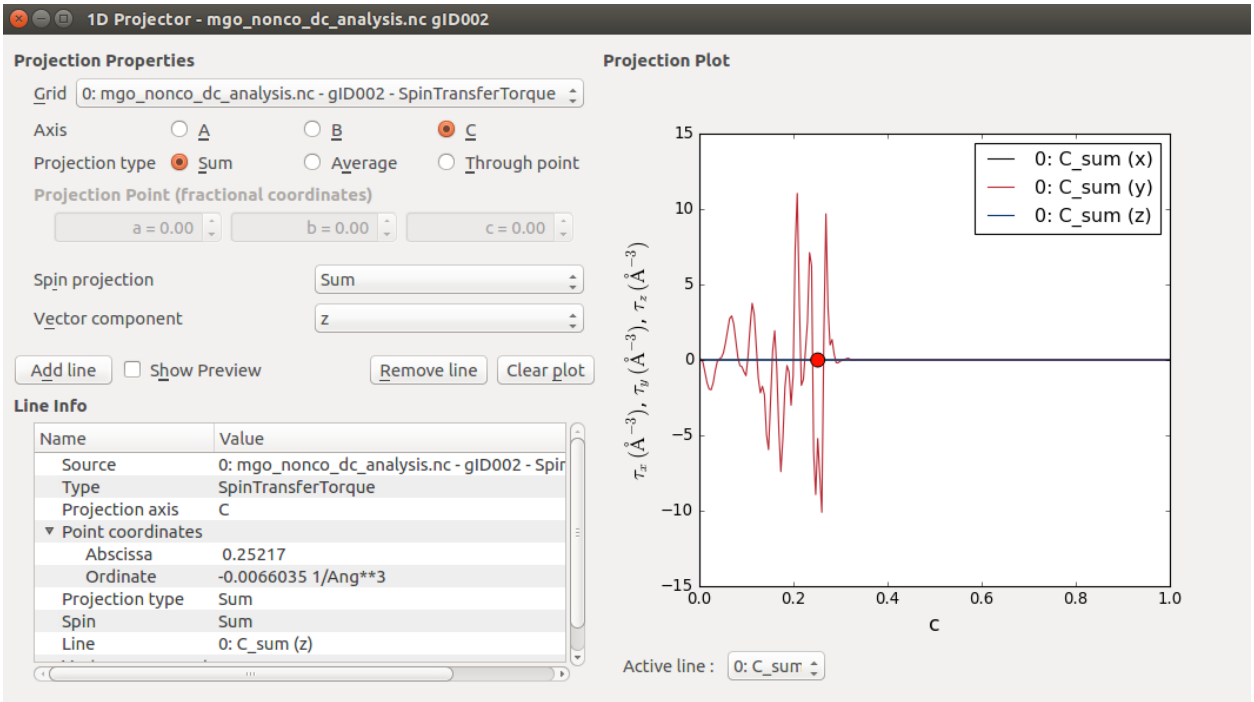
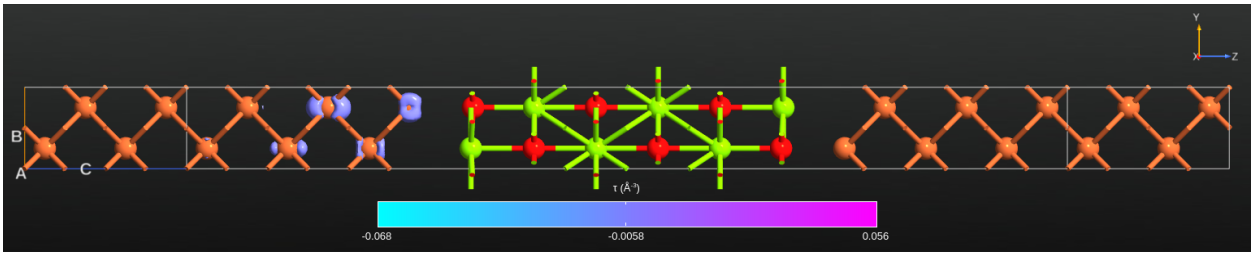
In the noncolinear calculations, the sum of the up and down populations corresponds to the usual Mulliken charge (the number of electrons), and their difference – combined with the two angles – forms the spin polarization vector. This vector can be visualized using the **Viewer**:

You can also plot the spatial components of the STT using the **1D Projector**:



The figure below shows the MTJ configuration and the y component of the STT.



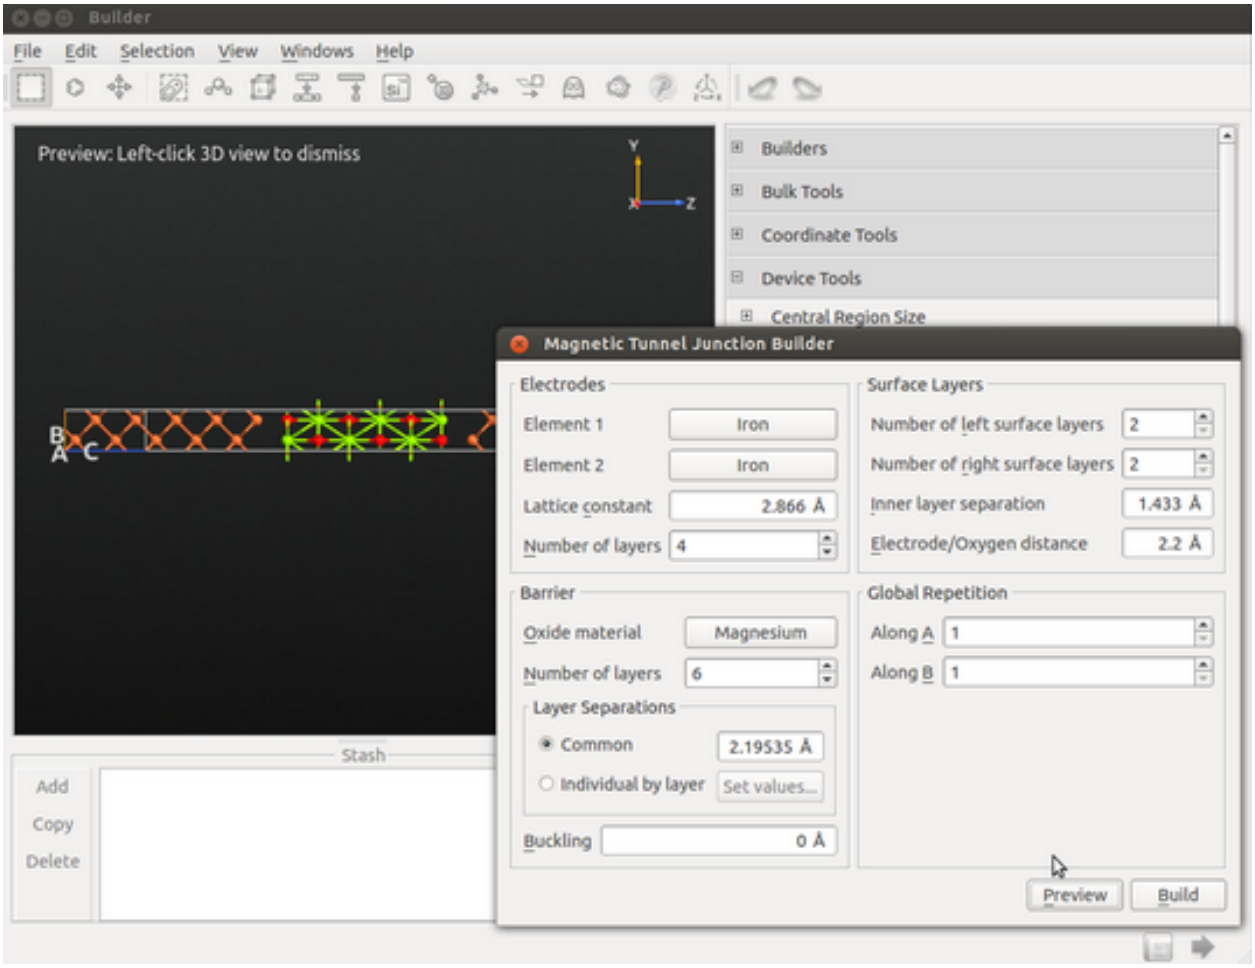
Relaxing the device central region

This section shows you how to create and geometry optimize the central region in the Fe|MgO|Fe junction. The tutorial *Advanced device relaxation - manual workflow* gives more detailed instructions for full device optimizations, including relaxed electrodes and optimum central region length. For the sake of simplicitly, we here perform force minimization for the device central region only.

Initial configuration

First, open the Builder. To set up the initial geometry of the Fe|MgO|Fe device you will use the **MTJ Builder** plugin, which is designed specifically for constructing this type of geometry. Locate it like this: *Add → From Plugin → Magnetic Tunnel Junction (FeMgO-style)*.

The MTJ builder can build a range of different magnetic tunnel junction geometries. For the present purpose, change the number of barrier layers to 6, and the number of surface layers to 2 on both the left and right side, but leave the other parameters as they are by default. Click the **Preview** button to see the geometry, then click **Build** to add it to the Stash.



Tip: Hover the mouse over each input field to get a description of the input parameters.

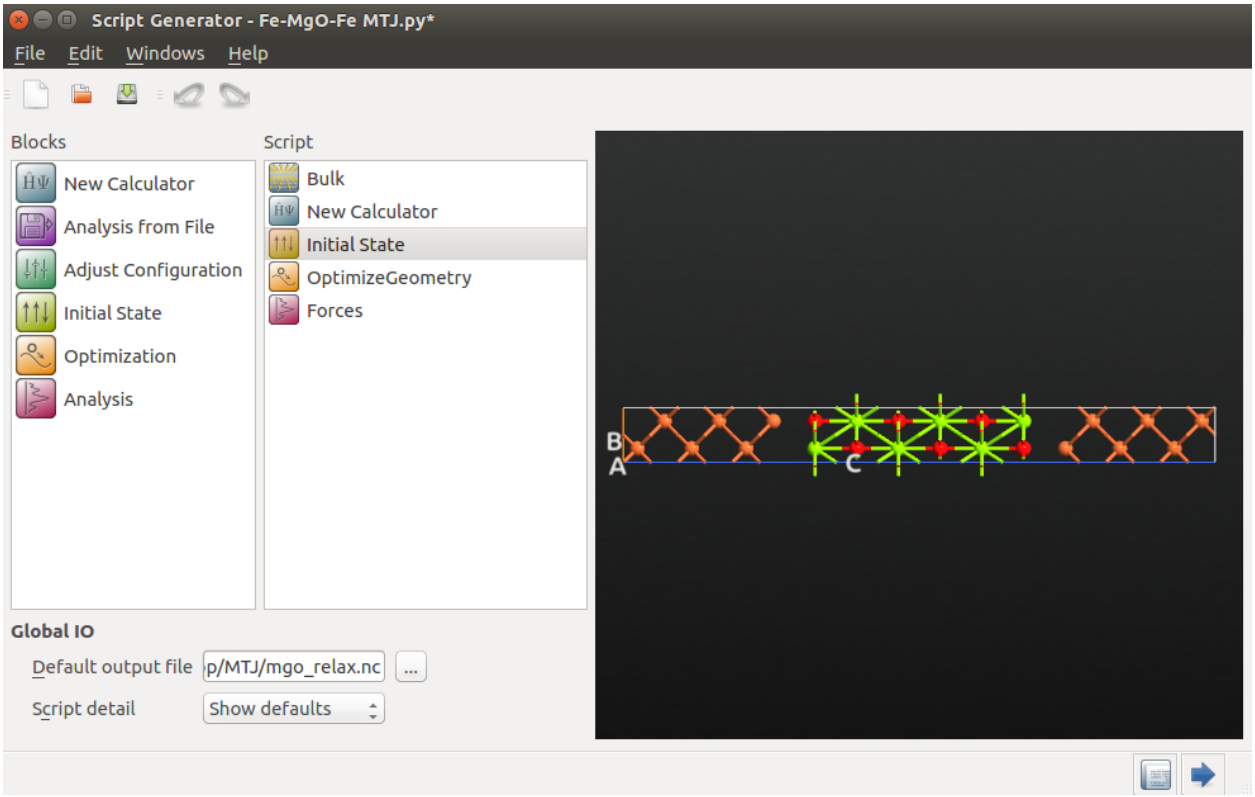
Convert the device geometry to a bulk configuration by clicking the **Bulk** tool on the plugins toolbar. This simply removes the electrodes and leaves you with the bulk central region.

Geometry optimization

Send the device central region to the **Script Generator** and add the following blocks to the script:

- New Calculator
- Initial State
- OptimizeGeometry
- Forces

Also, change the default output filename to `mgo_relax.nc`



The Calculator and InitialState settings should be very similar to those used in section *Parallel spin*:

•**Calculator**:

–Select the SGGA exchange-correlation method.

–Increase the electron temperature to 1200 Kelvin.

–Set the k-point grid to 7x7x2. This choice gives a reasonable k-point sampling in the x and y directions. In the z direction, you would like to model a device configuration, so the iron atoms at the edges must be bulk-like. Selecting 2 k-points in the z-direction improves the bulk like description of the Fe edge atoms.

–Select the SingleZetaPolarized basis set for iron.

•**Initial State**:

–Choose *User spin* for as the type of initial state.

–Set the relative spins on O and Mg atoms to 0.

Next, open the **Optimization** block to specify that the first and last four atoms in the central region (the atoms in the electrode extensions) should be kept fixed during the relaxation. This is very important – if any of these atoms move you no longer have a periodic structure at the edges of the central cell, which is required for generating and attaching device electrodes later on.

Click *Add Constraints* to open the **Constraints Editor**. Then do the following:

•Select the atoms indicated in the image below by holding down the Ctrl key and drawing a rectangle around them. Then click *Add tag from Selection* to assign the tag Selection 0 to those atoms. Change the constraint type to Rigid for this tag group.

•Do the same for the right-hand electrode extension atoms, but leave the constraint type as Fixed.

Save the script as `mgo_relax.py` and run it using the Job Manager or from the command line:

```
atkpython mgo_relax.py > mgo_relax.log
```

If needed, you can also download the script here: `mgo_relax.py`. This calculation will take a 1-2 hours on a standard PC, but may finish in 20 minutes if distributed over 4 parallel MPI processes.

Inspecting the results

Locate the calculation data items on the **LabFloor**. Select the **Forces** item (*gID002*), and click the **Text Representation** plugin. You will now see a report of the final forces on all atoms.

|  23  [ -7.04845969e-14  -2.85051189e-13   9.13089459e-02] eV/Ang               |
+-------------------------------------------------------------------------------+
```

Note that all forces in the x-y direction are for all practical purposes zero. For the atoms which have been relaxed, the forces are less than the optimization criterion of 0.05 eV/Ang. For the electrode extension atoms, the forces are slightly larger. Moreover, the force vectors point out of the cell, indicating that the cell is under compressive strain. Adding more surface layers to increase the cell length in the z-direction would lower the strain, but would have very little effect on results in the present case.

You can now use the optimized device central region for calculations of transport properties of the device, c.f. section *Getting started*.

References

3.10.3 Relativistic effects in bulk gold

Gold is one of the more heavy transition metals, and the electronic structure of bulk gold is therefore significantly affected by relativistic effects, including spin-orbit coupling (SOC (spin-orbit coupling)).

Relativistic *ab initio* band structure calculations for gold were first reported in the early 1970s, see e.g. Refs.[1],[2], and[3]. Those studies, and later ones, found that relativistic effects cause a significant reorganization of the electronic energy bands in gold. In particular, inclusion of relativistic effects removes a large part of the band crossings in the deeper valence bands found in standard calculations. In this tutorial, you will demonstrate this using ATK-DFT for standard scalar-relativistic (GGA) and relativistic (SOGGA) calculations of the gold band structure.

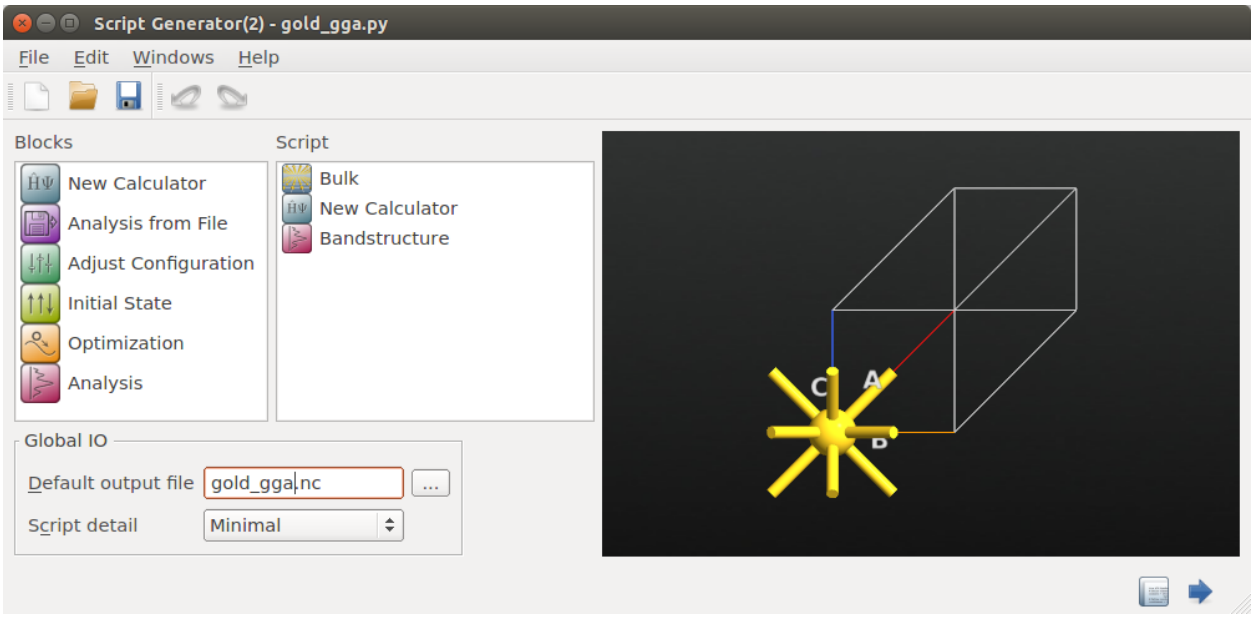
[3] N.ăEgede Christensen. High-energy band structure of gold. *Phys. Rev. B*, 13(6):2698–2701, 1976. doi:10.1103/PhysRevB.13.2698.

GGA band structure

Use the QuantumATK Builder to create the gold bulk configuration. This is most easily done using the *Add* → *From Database* tool. Keep the gold lattice constant at the experimental value (4.078 Å).

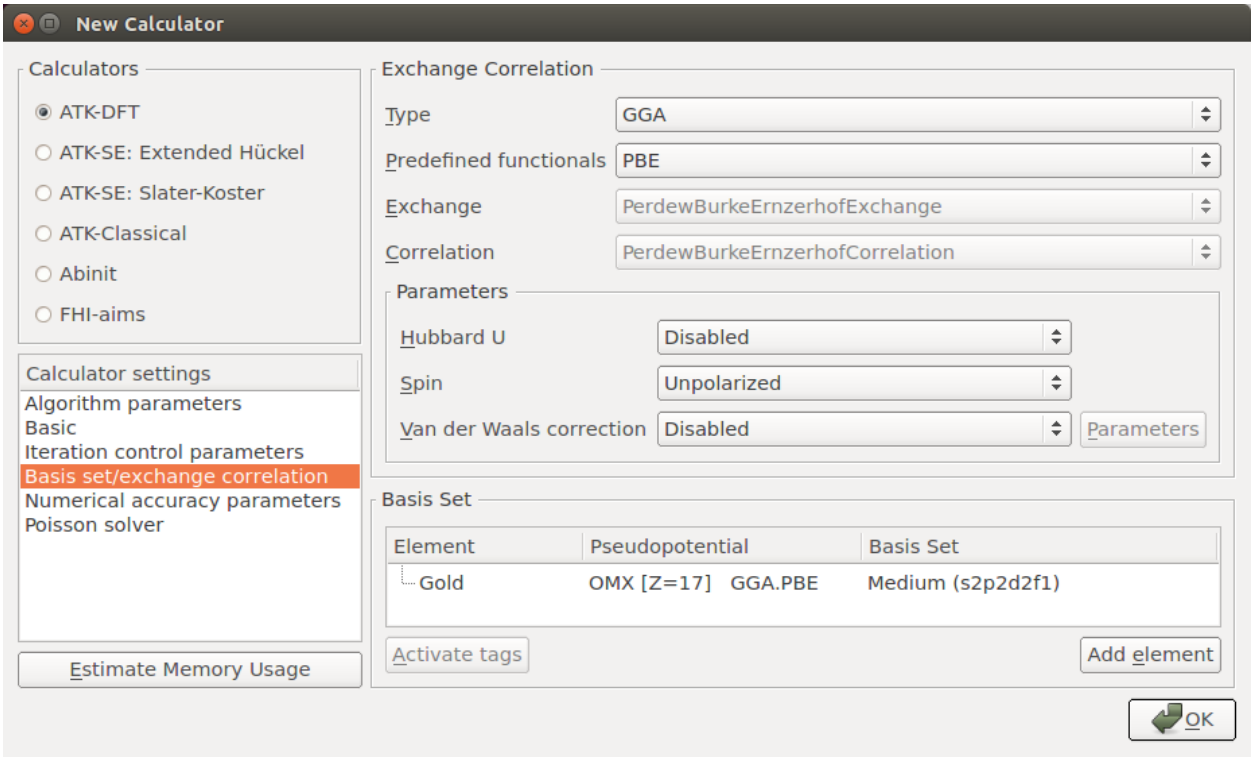
Then transfer the configuration to the Script Generator and set up a standard GGA-PBE band structure calculation using an OMX pseudopotential.

First, add a New Calculator block and a Bandstructure analysis block, and set `gold_gga.nc` as the output file.

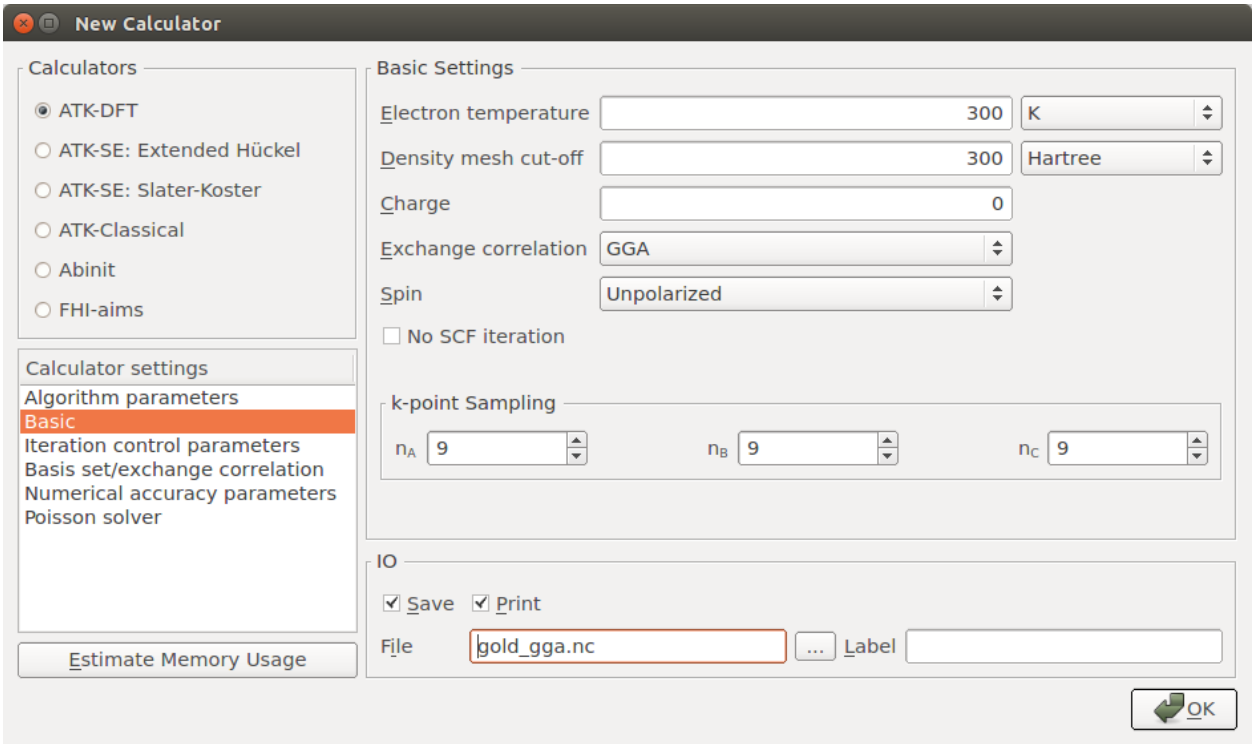


Edit the New Calculator settings:

- In the **Basis set/exchange correlation** panel, choose the GGA-PBE exchange-correlation functional and the OMX pseudopotential with a *Medium* accuracy basis set.

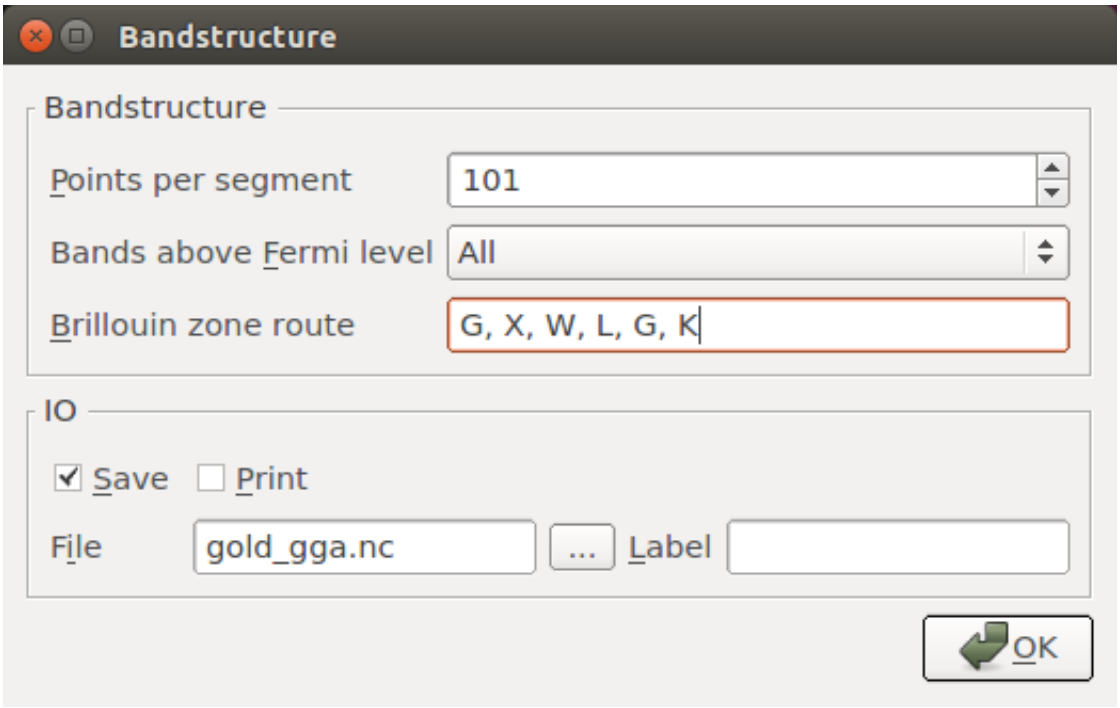


•In the **Basic** panel, set the *Density mesh-cutoff* to 300 Hartree and increase the *k-point Sampling* to 9x9x9.



Open the Bandstructure block and edit it:

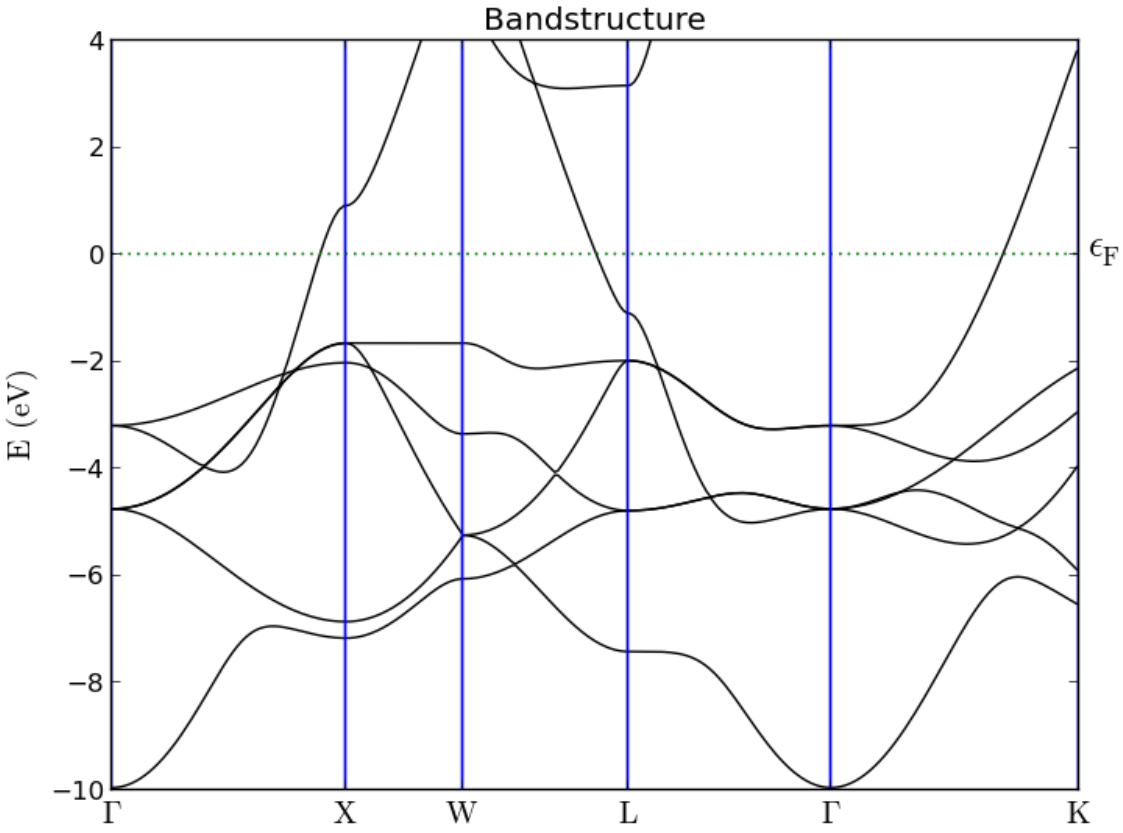
•Increase *Points per segment* to 101 in order to finely sample the band structure between each high-symmetry point, and trim the default *Brillouin zone route* such that it reads G, X, W, L, G, K.



Save the script as `gold_gga.py` and run it. You can use the Job Manager for this. It should take around a minute if executed on a single processor.

Results

Find the Bandstructure object in the output file on the QuantumATK LabFloor and use the **Bandstructure Analyzer** to plot it. The results are shown below and are very similar to those reported in Refs.[Page 1385, 2] and[Page 1385, 3]. Gold is clearly not an insulator, since there are plenty of bands crossing the Fermi level. Also note the frequent band crossing in the deeper valence bands, from ca. -2 to -5 eV below the Fermi energy. As we shall see, most of these crossings disappear in a relativistic calculation including SO interactions.



Spin-orbit GGA band structure

You will here set up and execute a GGA calculation that includes the SOC. This must be done in a noncollinear representation of electron spin, which is computationally more expensive than the GGA calculation and can exhibit poor SCF convergence. You should therefore apply two tricks: a) start the noncollinear calculation from a converged spin-polarized state (SGGA), and b) use a special electron density mixing scheme.

Note: We know that gold is not magnetic, so it may seem a bit silly to do a spin-polarized calculation for gold. After all, the results should not differ from those found in the collinear spin-compensated calculation done in the previous section.

Indeed, they do not, but the converged spin-polarized state offers a much better initial guess for the self-consistent noncollinear+SO state than the spin-compensated state does: Fewer noncollinear SCF steps are required if starting from the spin-polarized state, and computational time is therefore saved.

SGGA initial state

You have two options for setting up a script for the SGGA calculation:

a. Use the **Scripter**: Set up the script exactly like in the previous section, but choose Polarized for the *Spin* parameter, remove the Bandstructure analysis object, set the output file to `gold_sgga.nc`, and save the new script as `gold_sgga.py`.

b. Use the **Editor**: Copy `gold_gga.py` to `gold_sgga.py` and open the new script in the Editor and edit it a bit. Set the exchange-correlation to `SGGA.PBE`, remove the bottom lines that execute the bandstructure calculation, and rename the output file to `gold_sgga.nc`.

In any case, the script should look like this:

```
# ------------------------------------------------------------
# Bulk Configuration
# ------------------------------------------------------------

# Set up lattice
lattice = FaceCenteredCubic(4.07825*Angstrom)

# Define elements
elements = [Gold]

# Define coordinates
fractional_coordinates = [[ 0.,  0.,  0.]]

# Set up configuration
bulk_configuration = BulkConfiguration(
    bravais_lattice=lattice,
    elements=elements,
    fractional_coordinates=fractional_coordinates
    )

# ------------------------------------------------------------
# Calculator
# ------------------------------------------------------------
#----------------------------------------
# Basis Set
#----------------------------------------

GoldBasis = OpenMXBasisSet(
    element=PeriodicTable.Gold,
    filename="openmx/pao/Au7.0.pao.zip",
    atomic_species="s2p2d2f1",
    pseudopotential=NormConservingPseudoPotential("normconserving/upf2/Au_PBE13.upf.zip
↪"),
    )

basis_set = [
    GoldBasis,
    ]

#----------------------------------------
```

(continues on next page)

(continued from previous page)

```
# Exchange-Correlation
#-------------------------------------
exchange_correlation = SGGA.PBE

numerical_accuracy_parameters = NumericalAccuracyParameters(
    k_point_sampling=(9, 9, 9),
    density_mesh_cutoff=300.0*Hartree,
    )

calculator = LCAOCalculator(
    basis_set=basis_set,
    exchange_correlation=exchange_correlation,
    numerical_accuracy_parameters=numerical_accuracy_parameters,
    )

bulk_configuration.setCalculator(calculator)
nlprint(bulk_configuration)
bulk_configuration.update()
nlsave('gold_sgga.nc', bulk_configuration)
```

Run the script, it should be very fast. Note that the output file `gold_sgga.nc` is generated and that it contains only a single object; the gold bulk configuration including the self-consistent SGGA electronic state, which will be used in the next step.

SOGGA band structure

Use the script below to perform the following work-flow:

1. Read the `bulk_configuration` from the file `gold_sgga.nc`.
2. Get the `calculator` used in the SGGA calculation and modify it slightly; use the SOGGA exchange-correlation and a special mixing scheme for noncollinear calculations.
3. Use the converged SGGA state as initial guess for the SOGGA electron density.
4. Do the SOGGA ground state calculation followed by band structure analysis.

```
# ------------------------------------------------------------
# Bulk Configuration
# ------------------------------------------------------------
bulk_configuration = nlread('gold_sgga.nc', BulkConfiguration)[0]

# ------------------------------------------------------------
# Calculator
# ------------------------------------------------------------

# Use the special noncollinear mixing scheme
iteration_control_parameters = IterationControlParameters(
    algorithm=PulayMixer(noncollinear_mixing=True)
    )
```

(continues on next page)

(continued from previous page)

```
# Get the calculator and modify it for spin-orbit GGA
calculator = bulk_configuration.calculator()
calculator = calculator(
    exchange_correlation = SOGGA.PBE,
    iteration_control_parameters = iteration_control_parameters
    )

# Setup the initial state from the GGA calculation
bulk_configuration.setCalculator(
    calculator,
    initial_state = bulk_configuration
    )
nlprint(bulk_configuration)
bulk_configuration.update()
nlsave('gold_sogga.nc', bulk_configuration)

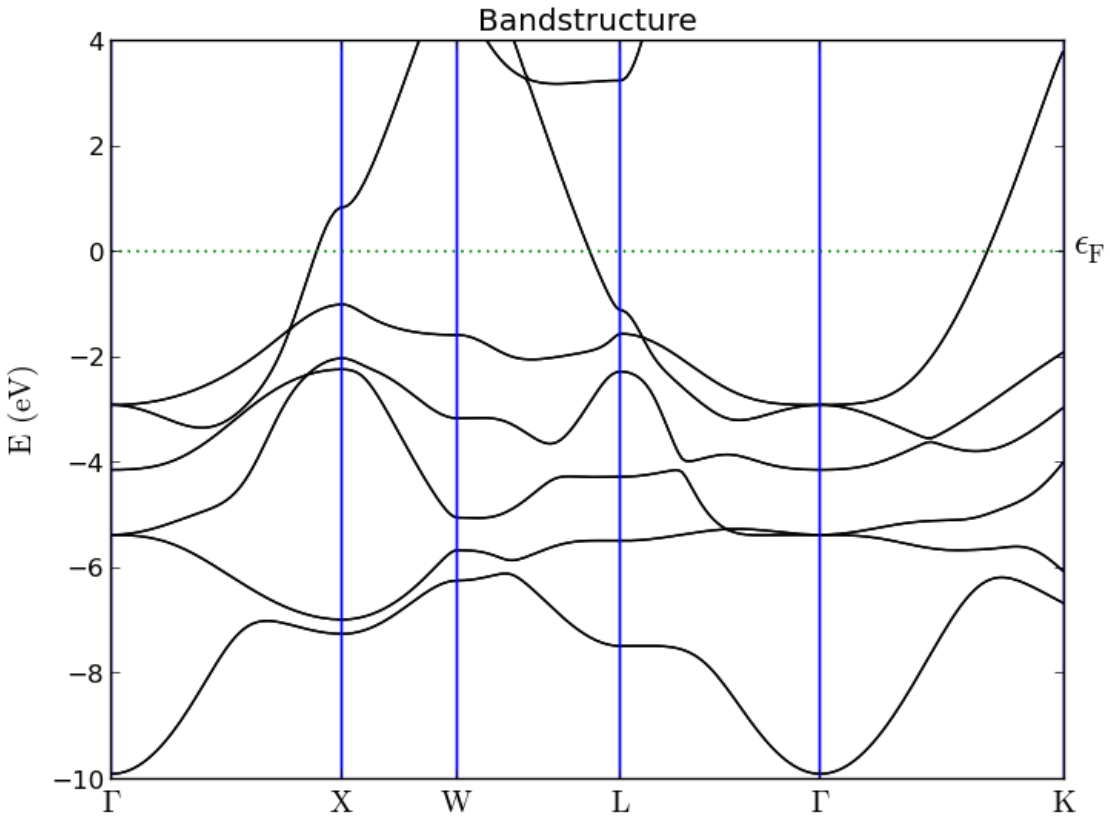
# ------------------------------------------------------------
# Bandstructure
# ------------------------------------------------------------
bandstructure = Bandstructure(
    configuration=bulk_configuration,
    route=['G', 'X', 'W', 'L', 'G', 'K'],
    points_per_segment=101,
    bands_above_fermi_level=All
    )
nlsave('gold_sogga.nc', bandstructure)
```

Save the script as `gold_sogga.py` and run the calculation. It should take roughly 6 minutes to finish if executed in parallel on 4 CPUs.

Results

The plot below shows the band structure obtained from the SOGGA calculation. It follows very closely the literature results in Refs.[Page 1385, 2] and[Page 1385, 3] and is virtually identical to the SOGGA band structure of gold recently published in Ref.[4]. Note how most of the valence band crossings found in the standard GGA calculation have now been lifted.

[4] T.ăRangel, D.ăKecik, P.ăE. Trevisanutto, G.-M. Rignanese, H.ăVanăSwygenhoven, and V.ăOlevano. Band structure of gold from many-body perturbation theory. *Phys. Rev. B*, 86:125125, Sep 2012. doi:10.1103/PhysRevB.86.125125.



You can also use the **Compare Data** plugin for a more direct comparison of the two band structures, as illustrated below. Simply highlight both the GGA and the SOGGA bandstructure objects, and click the plugin. It is quite clear that relativistic effects have a significant impact on the gold valence bands. The data illustrated below is essentially identical to that in Figure 6 of Ref.[4].

3.10.4 Noncollinear calculations for metallic nanowires

Version: 2016.3

In the tutorial *Introduction to noncollinear spin* you learned how to perform a simple noncollinear calculation. In this tutorial you will apply the same procedure to more advanced systems. In a first example, you will consider a metal nanowire connecting two electrodes of the same material. In the second example, you will consider an infinite wire and study the effect of spin-orbit coupling and spin-orientation on the electronic structure. The calculations will be very similar to the two works published by Czerner et al.:[1][2].

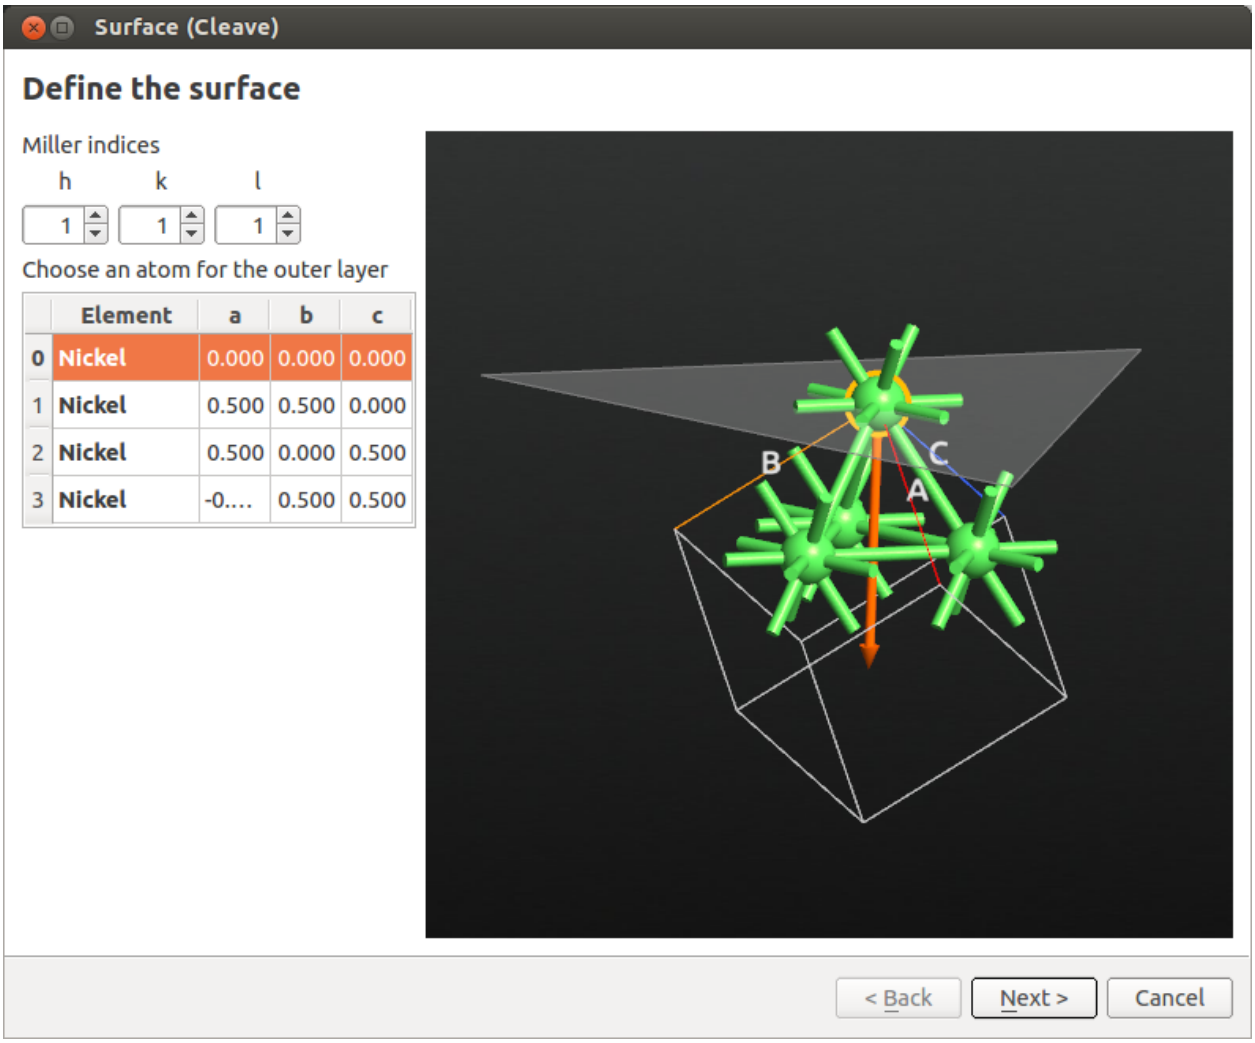
Building the device

Set up the Ni(111) surface

Open the **Builder**, click on *Add* → *From Database*, search for the Nickel *fcc* bulk structure and add it to the Stash. Open *Builders* → *Surface (Cleave)*, enter Miller indices (111) as shown in the figure below, and click Next.



In the next window, define a 2×2 surface supercell as shown below, then click Next.

Set the out-of-plane direction to *Periodic and normal (electrode)*, set the thickness to 6 layers (see image below) and click Finish.

Finally, add some vacuum above the (111) surface. Go to *Bulk Tools* → *Lattice Parameters* and set the C vector length to 40 Å. Be careful to select to *Keep Cartesian coordinates constant when changing the lattice*.

Note: In principle, you can also create the surface by adding the vacuum in the **Surface (Cleave)** tool by choosing a slab configuration. The procedure followed here will make the visualization of the next steps easier.

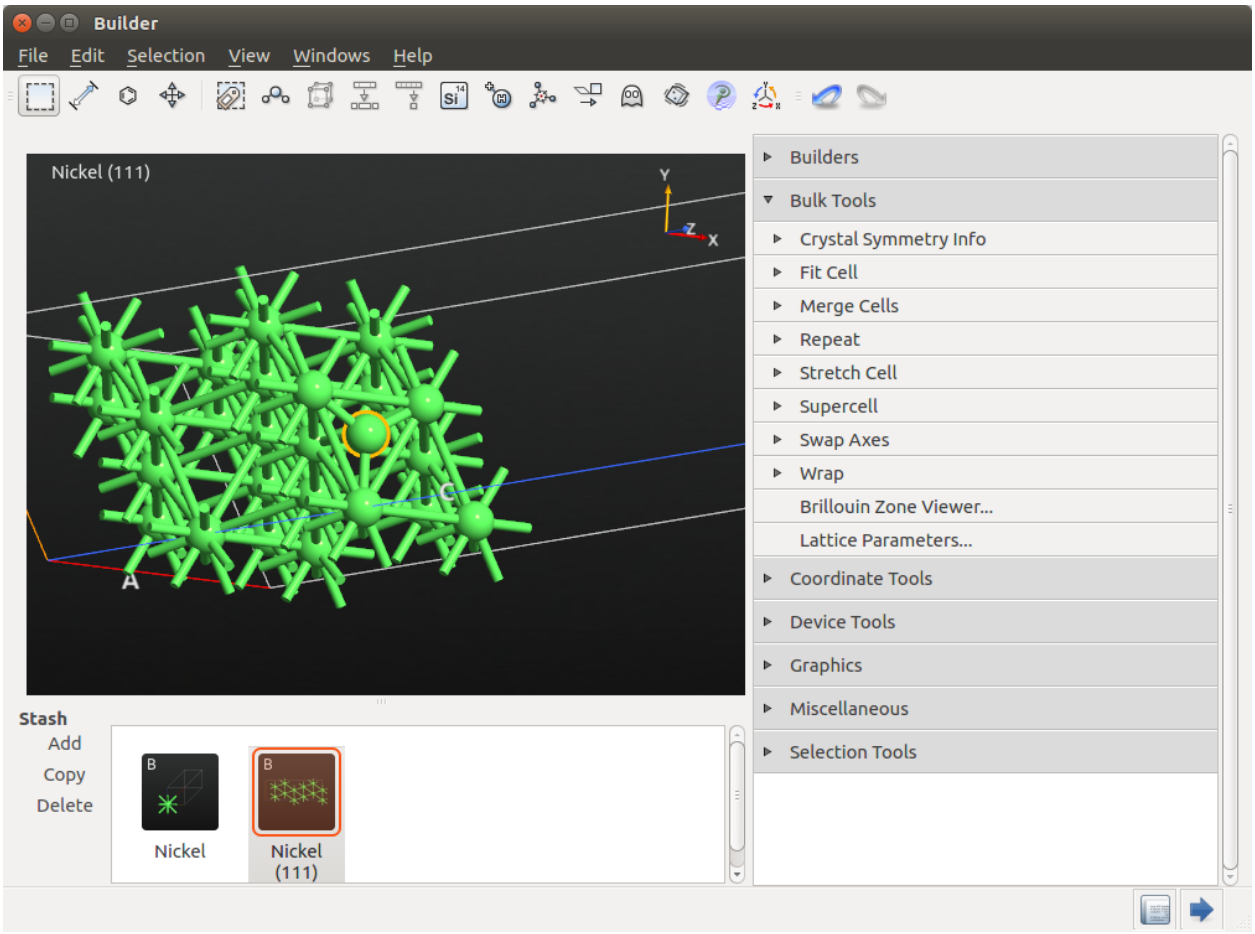
Set up the Ni wire between two Ni(111) surfaces

Select three Ni atoms at the surface and click the centroid plugin on the toolbar at the top of the **Builder** to add a Ni atom in the geometric center of the selected atoms.



Then, go to *Coordinate Tools* → *Translate tool* to move this atom by 2.035 Å above the surface. This distance corresponds approximately to the Ni(111) interlayer distance.

To create the wire, use again *Coordinate Tools* → *Translate* but this time select the *Copy* option and translate by 2.49248 Å, which corresponds to the Ni-Ni distance. Do it twice and you are halfway to creating a 5-atom wire embedded between two Ni electrodes.

Take note of the Z coordinate of the last Ni atom added to the chain (19.2306 Å) and select all the Ni atoms in your system except this last Ni atom. Then, go to *Coordinate Tools* → *Mirror*, select the predefined xy mirror axes and enter 19.2306 Å as the Z coordinate of the mirror point P. Remember to check the Copy box to make a copy of the mirrored object, and press Apply and you will obtain the structure shown below.

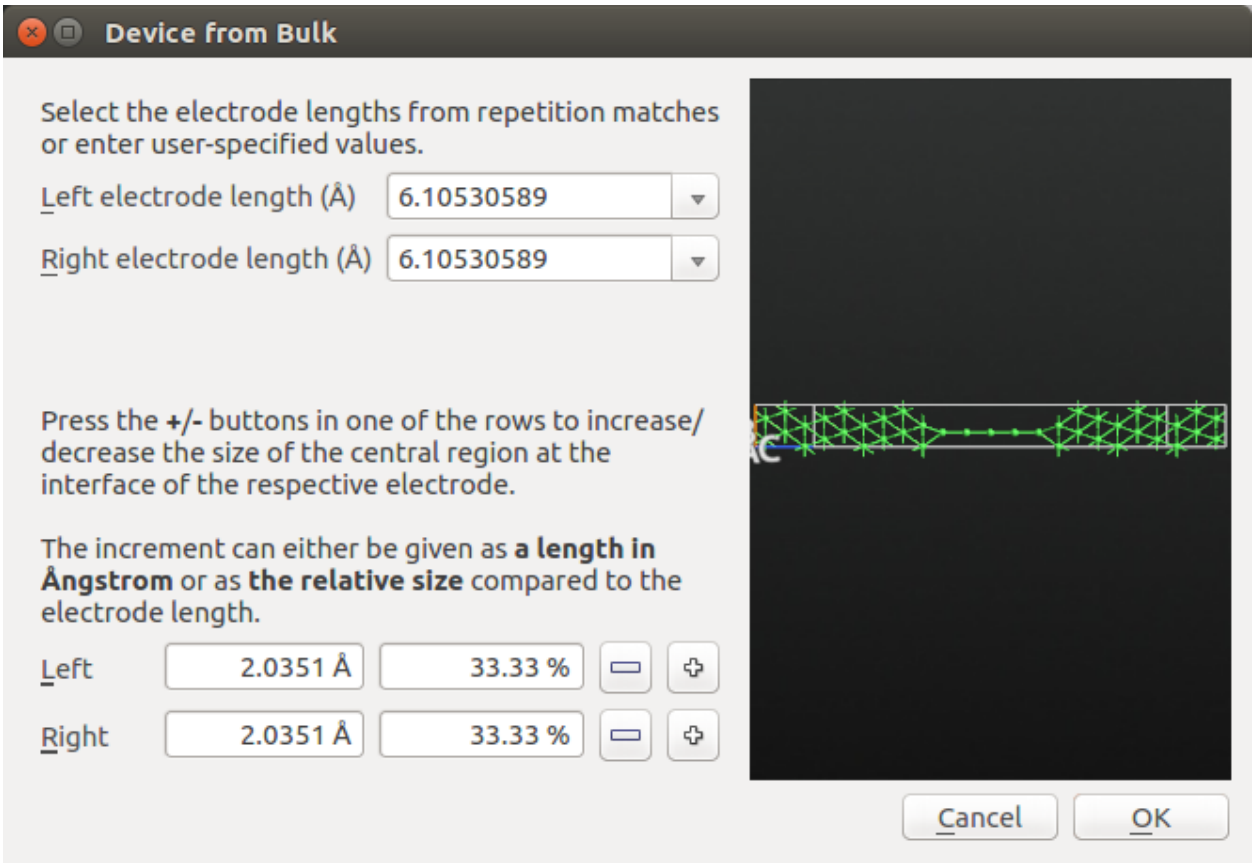
Create the device

Click on *Device Tools* → *Device From Bulk* and keep the predefined electrode lengths corresponding to three Ni layers.



Setting up the collinear calculation and analyzing the results

In this step you will run a collinear calculation and save the corresponding state in a HDF5 file. In the next step, you will run a noncollinear calculation by using the collinear state as an initial guess. In this way, you will save a lot of computational time, since the convergence of a noncollinear calculation can be hard to achieve otherwise.

Send the device structure you have previously created to the **Script Generator** and add the following blocks:

- Add a New Calculator with the following parameters:
  - *LDA* exchange-correlation functional
  - Spin-polarized calculation
  - $4 \times 4 \times 100$ grid for k-points sampling
  - *SingleZetaPolarized* basis set
  - Electron temperature set to *2400 K*
- Add an Initial State with the following options:

–Select *User spin* and check that *Spin* for Nickel is set to 1.

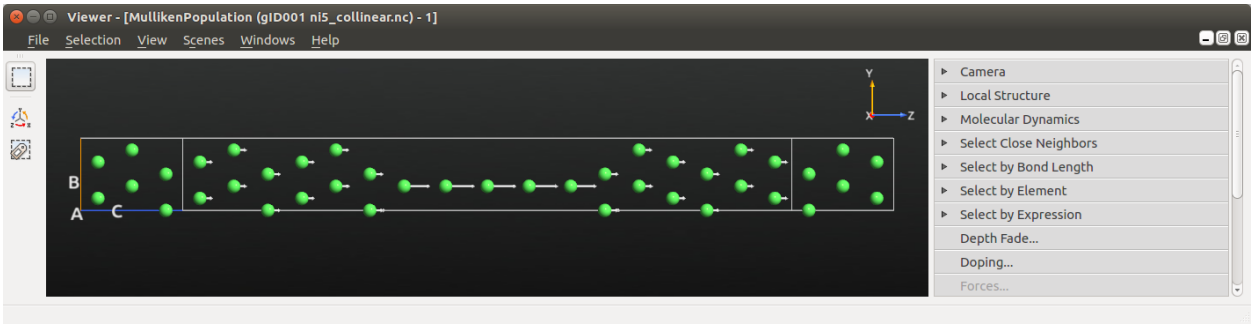
•Add an Analysis > MullikenPopulation

•Change the output file name to *Ni5_collinear.hdf5*.

Note: The high electron temperature considerably improves convergence.

Send the script to the **Job Manager** and run the calculation. Once the job is done (in serial it can take up to three hours), the LabFloor will be populated by the DeviceConfiguration and MullikenPopulation objects.

Select the MullikenPopulation and drag and drop it on the **Viewer** to visualize the converged collinear spin state.



The directions of the arrows is not so interesting or surprising - this is a collinear calculation with the electrodes polarized parallel to each other. We do however see a strong net spin polarization in the atomic wire compared to the surface layers.

Setting up the noncollinear calculation

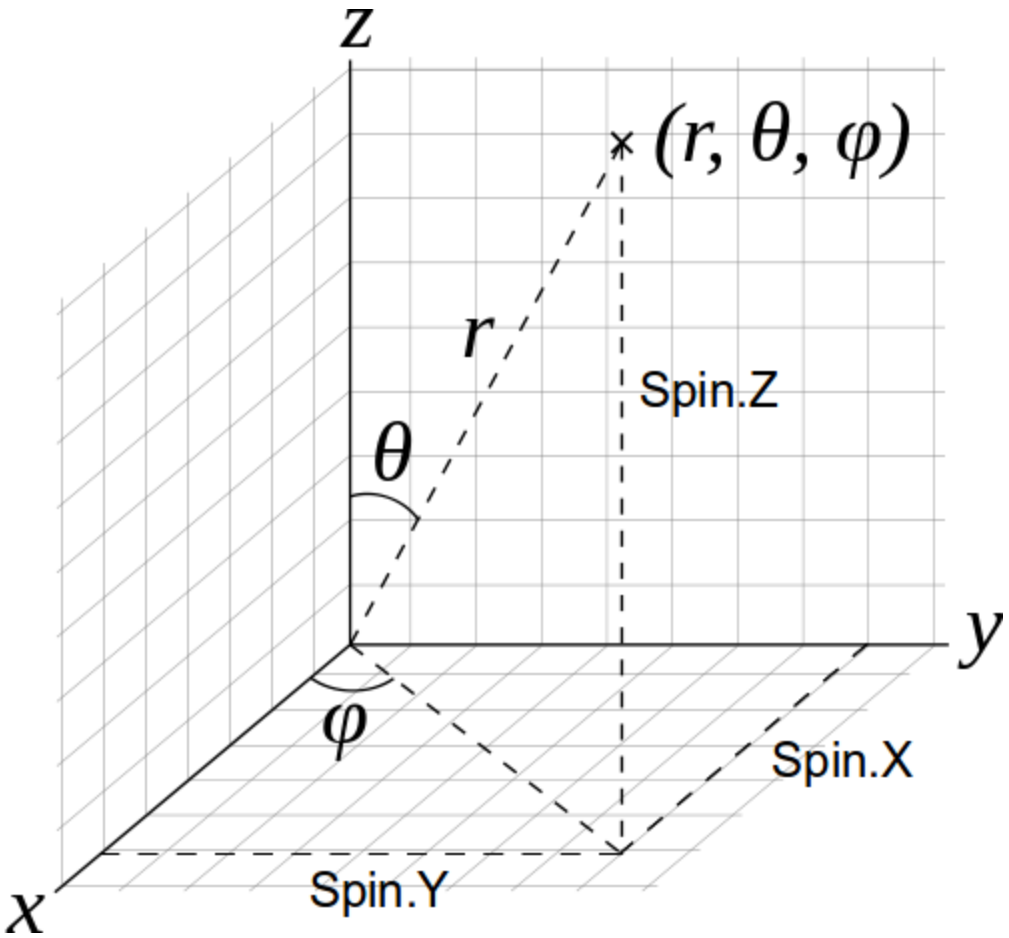
In the tutorial *Introduction to noncollinear spin* you have learned how to set up a noncollinear calculation. Here you will learn how to set up the initial spins of a noncollinear calculation based on the collinear converged result.

In order to set the initial spin state you need to specify the spin direction in physical spherical coordinates (r, ,), with the following important definitions (see also the figure below):

• is the angle with the z axis

• the polar angle in the xy plane relative to the x-axis

Warning: If you start your job by reading a previously converged spin state, as described below in this tutorial, the reference axis (Z in the picture above) for each spin of each atom is the axis of the corresponding converged spin state.



z
(r, θ, φ)
r
Spin.Z
θ
y
φ
Spin.X
Spin.Y
x

Drag and drop the DeviceConfiguration from the LabFloor to the **Script Generator** and modify the following parameters:

- In the existing New Calculator, set the spin option to *Noncollinear*
- Add an Initial State with the following options:
  - Select *User spin* and check that *Spin* for Nickel is set to 1
  - Check the option *Use old calculation* and use as filename *ni5_collinear.hdf5*
- Add Analysis > MullikenPopulation

Send the script to the **Editor** and modify the Initial State block as follows:

```
# ------------------------------------------------------------
# Initial State
# ------------------------------------------------------------

# Define the spin rotation
theta = 180*Degrees
left_spins = [(i, 1, 90*Degrees, 0*Degrees) for i in range(24)]
center_spins = [(i+24, 1, 90*Degrees-theta*(i+1)/6, 0*Degrees) for i in range(5)]
right_spins = [(i+29, 1, 90*Degrees-theta, 0*Degrees) for i in range(24)]
spin_list = left_spins+center_spins+right_spins
initial_spin = InitialSpin(scaled_spins=spin_list)

old_calculation = nlread('ni5_collinear.hdf5', DeviceConfiguration)[0]

device_configuration.setCalculator(
    calculator,
    initial_spin=initial_spin,
    initial_state=old_calculation,
)
device_configuration.update()
nlsave('ni5_noncollinear_out-plane.hdf5', device_configuration)
nlprint(device_configuration)
```

The setup above corresponds to an out-of-plane spin rotation between two anti-ferromagnetic electrodes, as reported in Refs.[Page 1394, 1] and[Page 1394, 2] (cf. Figure 1 in Ref.[Page 1394, 1]). In a later section you will also consider an in-plane rotation.

Note: The scaled_spin argument follows the format (atom index, initial scaled spin, ,) as documented in the *InitialSpin* entry in the Reference Manual.

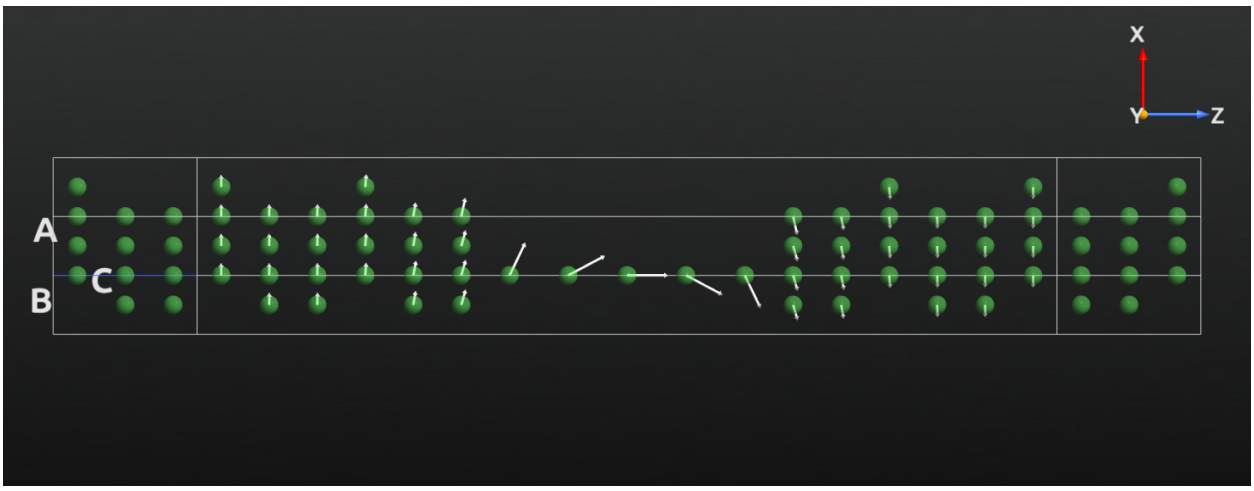
Remember that the spin orientation you enter here is relative to the collinear spin state read before. In this case, the collinear state is ferromagnetic, which corresponds to =0 and =0.

Save the script in your project directory, check that the *ni5_collinear.hdf5* file is present in the same directory and run the script.

Analyzing the results

Antiparallel configuration, out-of-plane rotation

From the LabFloor drag and drop the $\mathrm{Tr}(\rho\mathbf{S})$ MullikenPopulation object contained in *Ni5_non-collinear_out-plane.hdf5* file into the **Viewer** to visualize the converged noncollinear spin state.



For a more detailed analysis, open the text representation of $\mathrm{Tr}(\rho\mathbf{S})$ MullikenPopulation. Here you can read the spin-up, spin-down, and components for each atom.

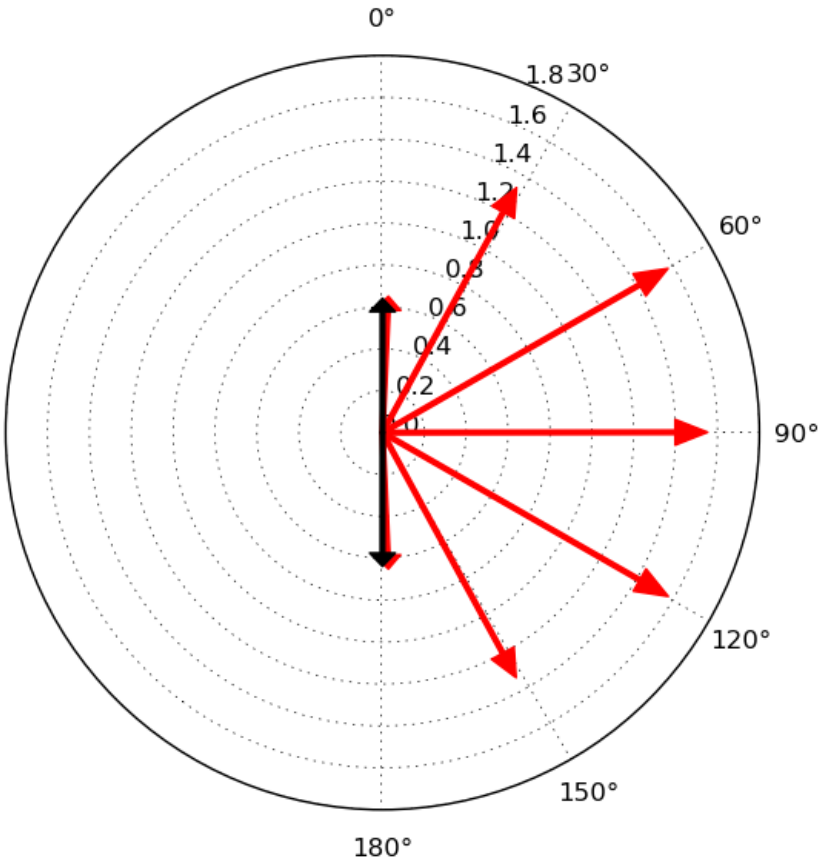
The figure below shows the direction and size of the spin state of the atoms in the wire (red arrows) and also of two atoms in the electrode extension regions (black arrows) for comparison. You can compare this plot to the results reported in Refs.[Page 1394, 1] and[Page 1394, 2].

Antiparallel configuration, in-plane rotation

Another possibility is to rotate the spins in th xy plane by changing the angle. To achieve this, modify the script above as indicated below:

```
# Define the spin rotation
phi = 180*Degrees
left_spins = [(i, 1, 90*Degrees, 0*Degrees) for i in range(24)]
center_spins = [(i+24, 1, 90*Degrees, 0*Degrees+phi*(i+1)/6) for i in range(5)]
right_spins = [(i+29, 1, 90*Degrees, 0*Degrees-phi) for i in range(24)]
spin_list = left_spins+center_spins+right_spins
initial_spin = InitialSpin(scaled_spins=spin_list)
```

Run the calculation for this initial spin configuration and display the corresponding $\mathrm{Tr}(\rho\mathbf{S})$ MullikenPopulation in



0°

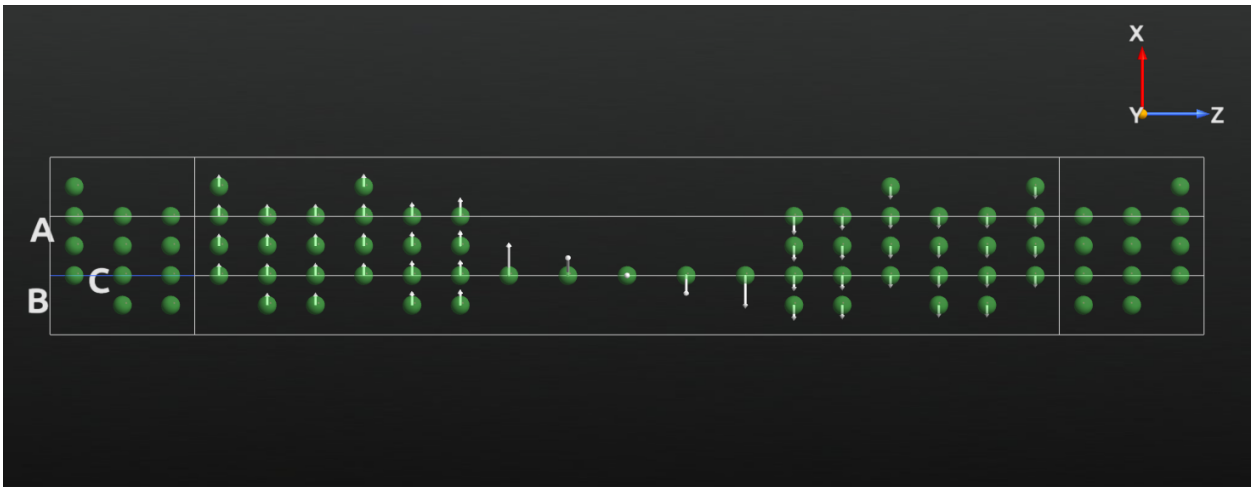
the **Viewer**:



Including spin-orbit coupling in noncollinear calculations

ATK also allows you to perform noncollinear calculations including spin-orbit coupling (SOC). In this example, you will investigate the effects of noncollinear spin and spin-orbit coupling to the simple case of an infinite Ni chain[Page 1394, 2]. In order to improve the convergence of the calculation, you will first set up a spin polarized calculation and only afterwards perform a noncollinear and finally a calculation with SOC, starting from the previously converged state.

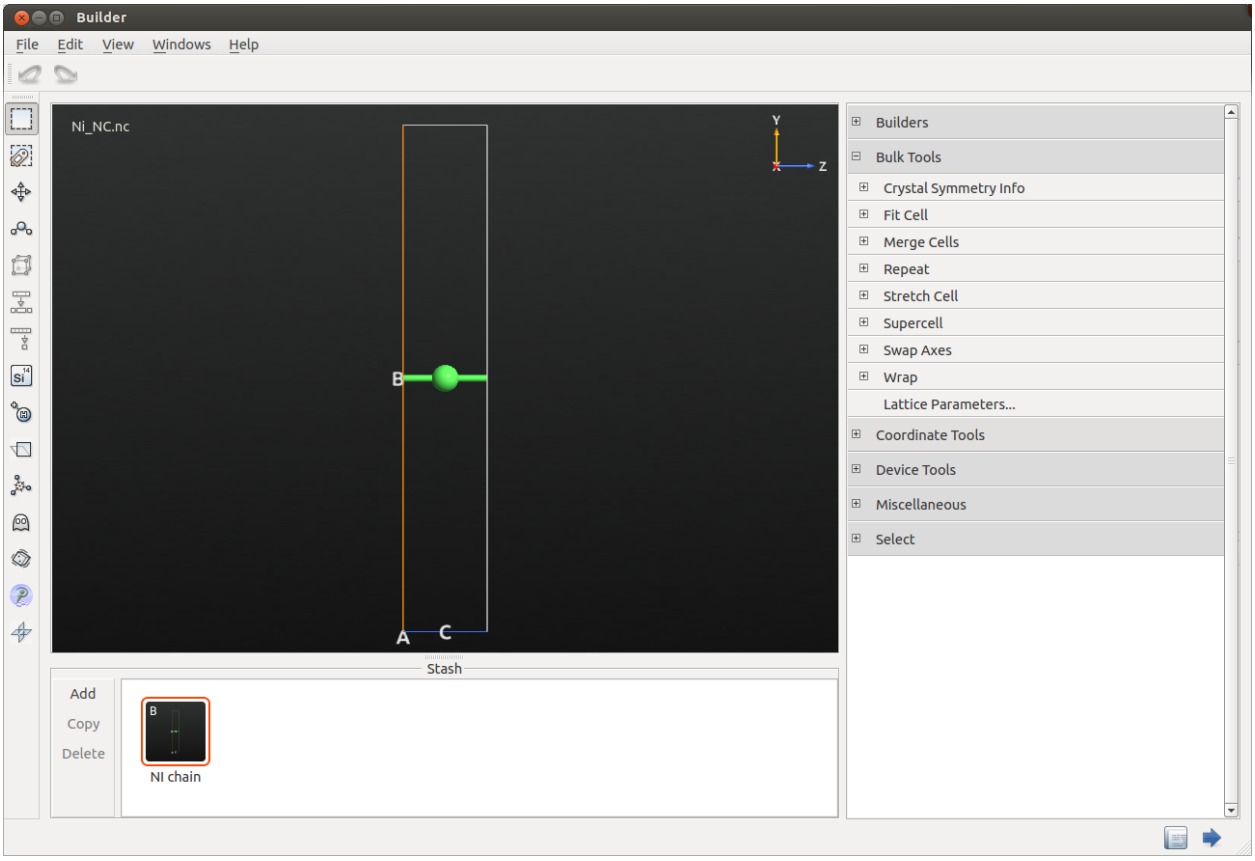
Building the Ni wire

Open the **Builder** and create a bulk configuration corresponding to an infinite chain of Ni atoms with an interatomic distance of 2.49248 Å (Ni-Ni distance).

Collinear calculation

Send the structure to the **Script Generator**, and setup the calculation as follows:

- Add a New Calculator with the following parameters
  - *PBE* exchange-correlation functional
  - Spin-polarized calculation
  - $1 \times 1 \times 13$ k-points sampling
  - *SG15-Medium* basis set
- Initial State
  - Select *User spin* and check that *Spin* for Nickel is set to 1.
- Change the output file name to *ni_collinear.hdf5*.



Note: In order to run a calculation including spin-orbit later on you need fully relativistic pseudopotentials. In this case you will use the *SG15 Pseudopotentials and basis sets* .

Once you are ready, run the calculation.

Noncollinear calculation with spin-orbit coupling

Drag and drop the DeviceConfiguration contained in the *ni_collinear.hdf5* file from the LabFloor to the **Script Generator** and modify the following parameters:

- In the existing New Calculator, set the spin option to *Noncollinear Spin-Orbit*
- Add an Initial State
  - Select *User spin* and check that *Spin* for Nickel is set to 1.
  - Check the option *Use old calculation* and use as filename *ni_collinear.hdf5*
- Add Analysis > BandStructure
  - 200 points
  - *G,Z* path

Send the script to the **Editor** and modify the Initial State block as follows:

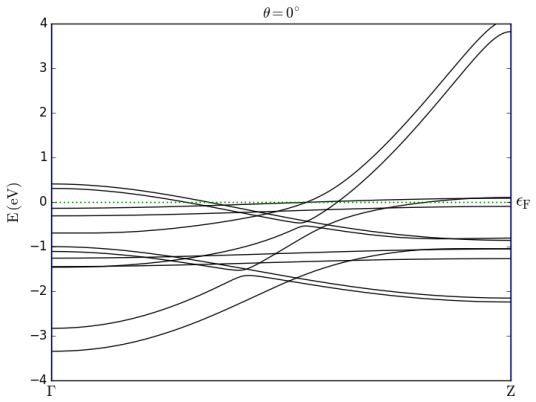
```
# ------------------------------------------------------------
# Initial State
# ------------------------------------------------------------

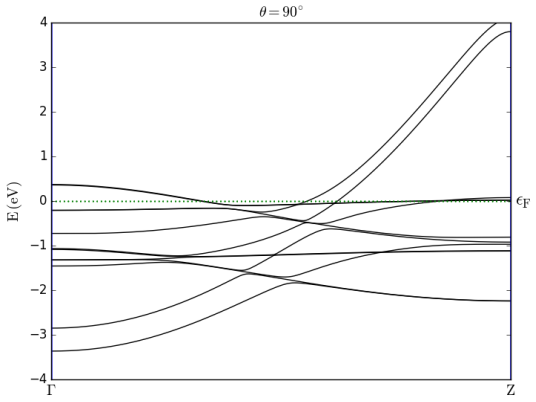
# Define the spin rotation
theta = 0*Degrees
left_spins = [(0, 1, theta, 0*Degrees) ]
initial_spin = InitialSpin(scaled_spins=left_spins)

old_calculation = nlread('Ni_collinear.hdf5', BulkConfiguration)[0]

bulk_configuration.setCalculator(
    calculator,
    initial_spin=initial_spin,
    initial_state=old_calculation,
)
bulk_configuration.update()
nlsave('Ni_noncollinear_phi0.hdf5', bulk_configuration)
nlprint(bulk_configuration)
```

Then run the calculation. You can notice that in the calculation the direction of the spin is parallel to the C axis (`theta=0*Degrees`). Once the calculation is done, repeat the calculation by setting the spin direction perpendicular to C (`theta=90*Degrees`), and compare the two resulting band structures (see figure below).





The results are in good agreement with the observations reported in[Page 1394, 2]. In particular, the effect of the SOC is clearly visible from the band splitting when the spin is oriented parallel to the wire axis. For both spin orientations you can also observe anticrossing of bands.

3.10.5 Electronic structure of NiO with DFT+U

Version: 2017

By tuning the empirical Hubbard parameter U, one can sometimes obtain the correct band gap for semiconductors even with LDA or GGA. This tutorial shows how to approach this type of calculations by taking NiO as an example, and at the same time it also introduces the density of states (DOS) functionality in QuantumATK.

Introduction

The self-interaction error is probably the most serious drawback of the LDA and GGA approximations to the exchange-correlation energy. This self-interaction can be described as the spurious interaction of an electron with itself. It has two main consequences:

- Electrons are over-delocalized;
- Band gaps in semiconductors and insulators are predicted to be much lower than their real counterpart.

The mean-field Hubbard correction, popularly called DFT+U, is a semi-empirical correction which tries to improve on these deficiencies.

In the DFT+U an additional energy term,

$$E_U = \frac{1}{2} \sum_{\mu} U_{\mu} \left(n_{\mu} - n_{\mu}^2 \right),$$

is added to the *Exchange-correlation energy*[1]. In this equation, n_{μ} is the projection onto an atomic shell and U_{μ} is the value of the *Hubbard U* for that shell. The E_U energy term is zero for a fully occupied or unoccupied shell, while positive for a fractionally occupied shell.

The energy is thereby lowered if states become fully occupied. This may happen if the energy levels move away from the Fermi Level, i.e. increasing the band gap, or if the broadening of the states is decreased, i.e. the electrons are localized. In this way, the Hubbard U improves on the deficiencies of LDA and GGA.

[1] M.ăCococcioni and S.ădeăGironcoli. Linear response approach to the calculation of the effective interaction parameters in the LDA+U method. *Phys. Rev. B*, 71:035105, Jan 2005. doi:10.1103/PhysRevB.71.035105.

The NiO crystal has a too low band gap in LDA and GGA and is one of the standard examples of how the DFT+U approximation can be used to improve the description of the electronic structure of solids[2]. In this tutorial you will compare the DFT and DFT+U models for this system using the GGA.

Further details of the Hubbard U implementation in QuantumATK can be found in the ATK Reference Manual, particularly the section *XC+U mean-field Hubbard term*.

The electronic structure of NiO calculated with DFT

NiO has a fcc crystal structure with two atoms in the unit cell. The Ni atoms have a net magnetic moment and form an anti-ferromagnetic arrangement in the (111) direction of the fcc cell. The structure can be described by a rhombohedral unit cell with 4 atoms in the basis[1]. The structure is given below in the QuantumATK *ATK-Python* format:

```
# Set up lattice
lattice = Rhombohedral(5.138*Angstrom, 33.5573*Degrees)

# Define elements
elements = [Nickel, Oxygen, Nickel, Oxygen]

# Define coordinates
fractional_coordinates = [[ 0.  ,  0.  ,  0.  ],
                          [ 0.25,  0.25,  0.25],
                          [ 0.5 ,  0.5 ,  0.5 ],
                          [ 0.75,  0.75,  0.75]]

# Set up configuration
bulk_configuration = BulkConfiguration(
    bravais_lattice=lattice,
    elements=elements,
    fractional_coordinates=fractional_coordinates
    )
```

Copy the script and save it as `NiO.py`, or download it directly: `NiO.py`.

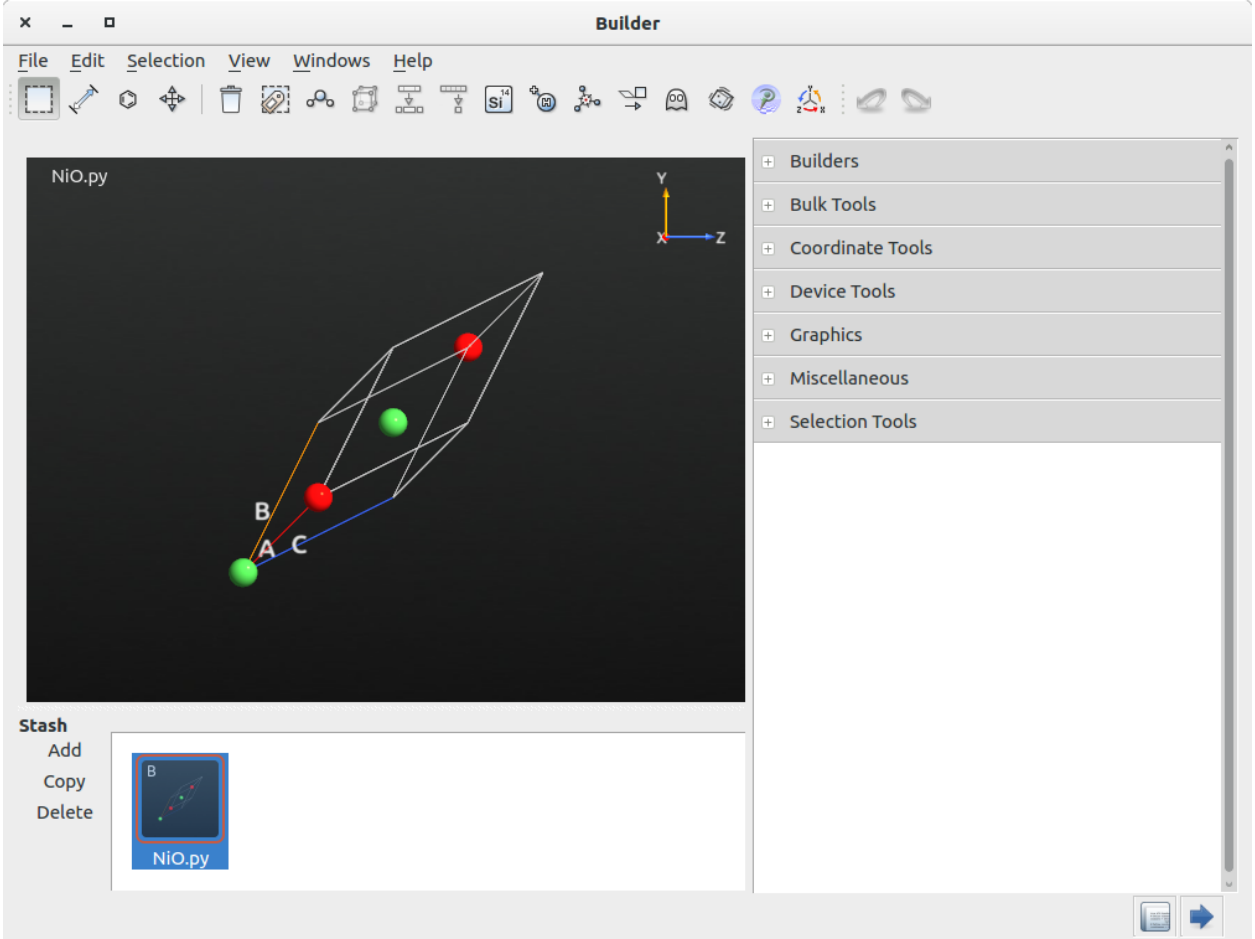
Note: The rhombohedral unit cell vectors are given as $(1, \frac{1}{2}, \frac{1}{2})a$, where a is the fcc lattice constant. The length of the rhombohedral unit cell vectors are therefore given by $\sqrt{\frac{3}{2}}a$, and are in accordance with the experimental fcc lattice constant of 4.19 Å.

Setting up the calculation

You will in this section set up a spin-polarized DFT calculation using the spin-polarized version of the generalized gradient approximation (SGGA) for the NiO electronic structure and calculate the Mulliken population and density of states. If you are not familiar with the workflow of QuantumATK you are recommended to first go through the Basic QuantumATK Tutorial.

Start up QuantumATK and drag the script `NiO.py` onto the **Builder**. The NiO crystal will be added to the Stash.

[2] A.ăB. Shick, A.ăI. Liechtenstein, and W.ăE. Pickett. Implementation of the LDA+U method using the full-potential linearized augmented plane-wave basis. *Phys. Rev. B*, 60:10763–10769, Oct 1999. doi:10.1103/PhysRevB.60.10763.

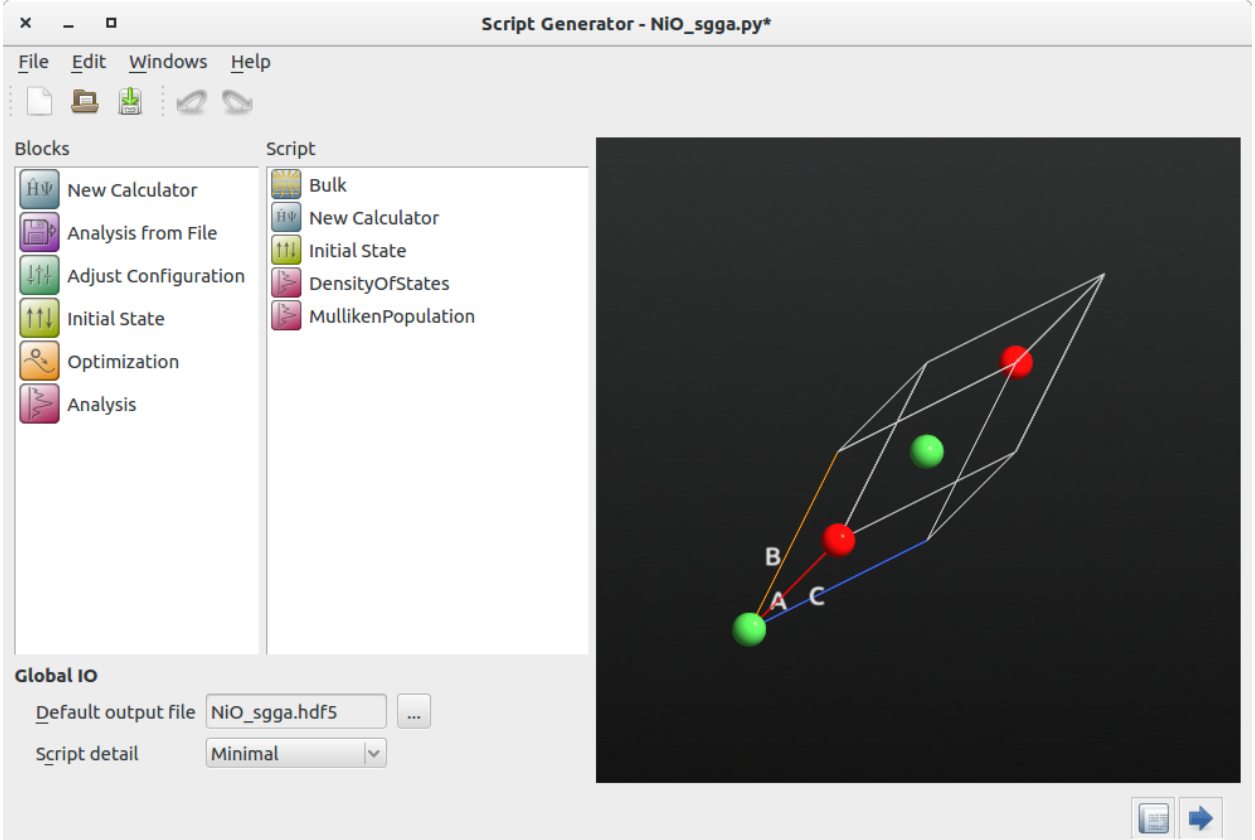


Next, click the the button and select the **Script Generator**.

Tip: Alternatively you can drag the script `NiO.py` directly onto the **Scripter** from the QuantumATK Project Files list.

Change the default output file name to `NiO_sgga.hdf5` and add the following blocks to the script:

- *New Calculator*
- *Initial State*
- *Analysis → DensityOfStates*
- *Analysis → MullikenPopulation*



Now double-click the **New Calculator** to open the calculator widget, and set the k-points sampling to 6x6x6.

Note: When an even sampling grid is used, the grid is automatically shifted to make sure that the Γ-point is included. The automatic shift can be avoided by unticking the option *Shift to* Γ.

The next step is to set up the anti-ferromagnetic NiO spin arrangement. For this purpose, open the **Initial State** block.

Select *User spin* – this will allow you to individually set the spin on each atom. Set opposite spins on the two nickel atoms and no spin on the oxygen atoms as illustrated below.

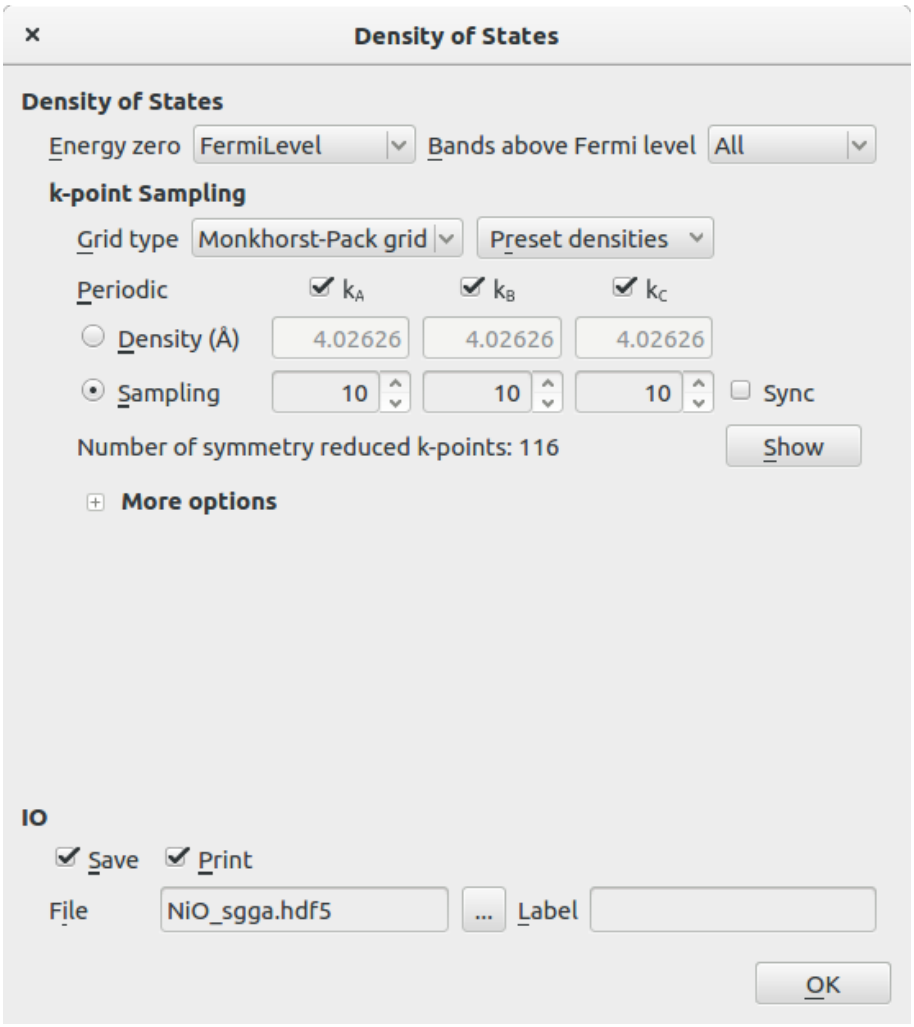
Important: The initial spin on each atom is given relative to the atomic spin of the element as obtained by Hunds rule. For nickel the electronic configuration of the atom is $[Ar]3d^8 4s^2$ (see periodic table in the ATK Reference Manual.). The 3d shell is fractionally occupied, and only this shell will contribute to the spin of the atom. According to Hunds rule the 3d shell has 5 electrons in the up direction and 3 electrons in the down direction, giving a total atomic spin of $2\mu_B$ for nickel.

Finally, open the **DensityOfStates** block and set the k-points sampling to 10x10x10. In general, one should choose a quite dense k-points grid for DOS analyses, in order to capture possible sharp features in the density of states.



Save the script as `NiO_sgga.py`, but do not close the Scripter window – you will need it again later.

Performing the calculation

To start the calculations, send the script to the **Job Manager** by using the button.

Choose a *Local* machine for executing the job and click start. The job will finish after 1-2 minutes and you can inspect the results.

Analysing the results

Mulliken Population

To inspect the Mulliken population reported in the calculation log file, scroll down to the end of the log file and you will find a report as shown below.

```

|                          |      y      z      x                               |
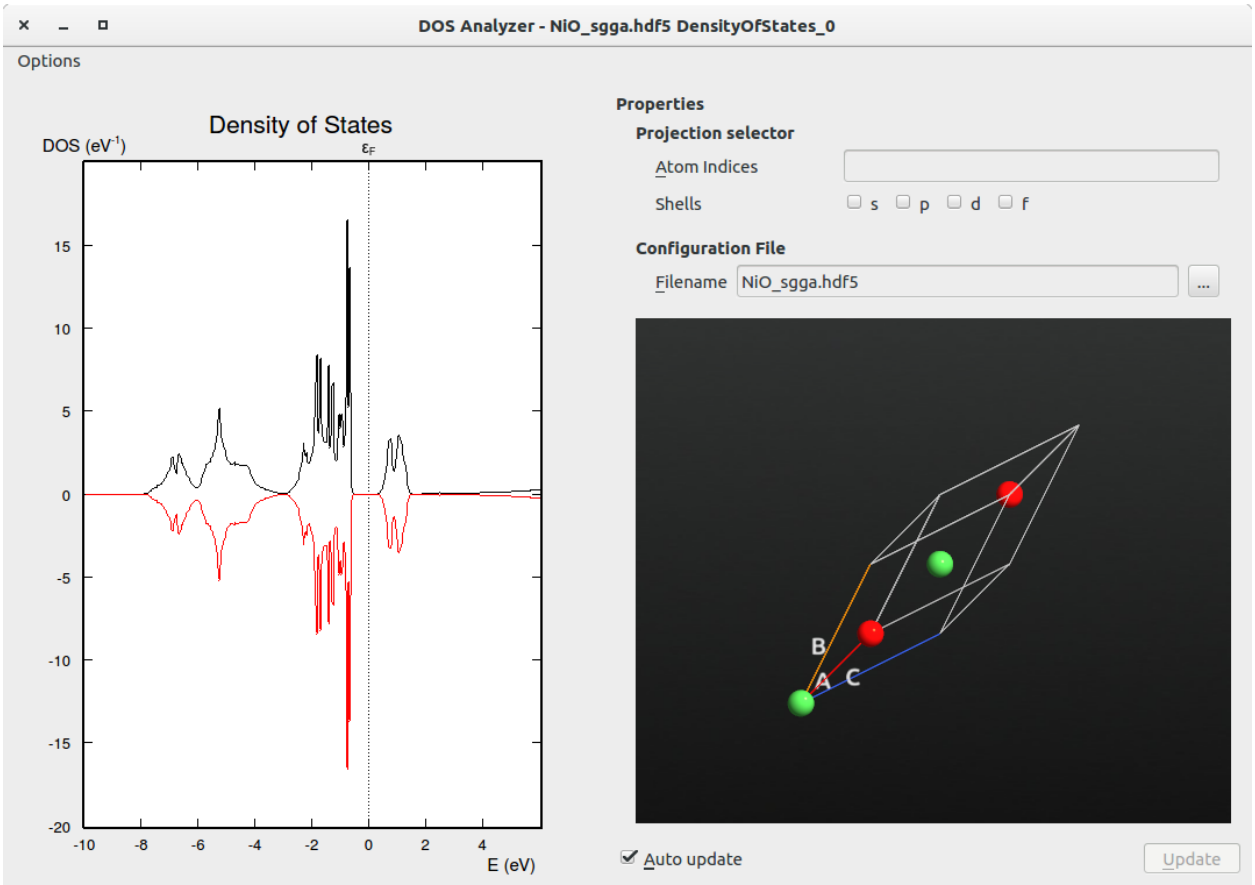
|                  0.140   |  0.047  0.047  0.047                               |
|                  0.145   |  0.048  0.048  0.048                               |
|                          | ------------------------------------------------- |
```

Tip: The Mulliken population can also be inspected by selecting the $\mathrm{Tr}(\boldsymbol{\rho}\mathbf{S})$ Mulliken Population item on the QuantumATK LabFloor. Use the **Text Representation** tool in the right-hand panel to see the results.

The Mulliken population reports the numbers of electrons per spin and orbital, as well as the orbital sum for each atom. Note that oxygen atoms are not polarized while the two nickel atoms are polarized in opposite directions, thus forming an anti-ferromagnetic arrangement. The polarization can be calculated from the difference between the number of electrons in the spin-up channel (9.244) and that in the spin-down channel (7.892). The resulting value of $1.35\mu_B$ is in good agreement with other DFT calculations[Page 1412, 1].

Projected density of states

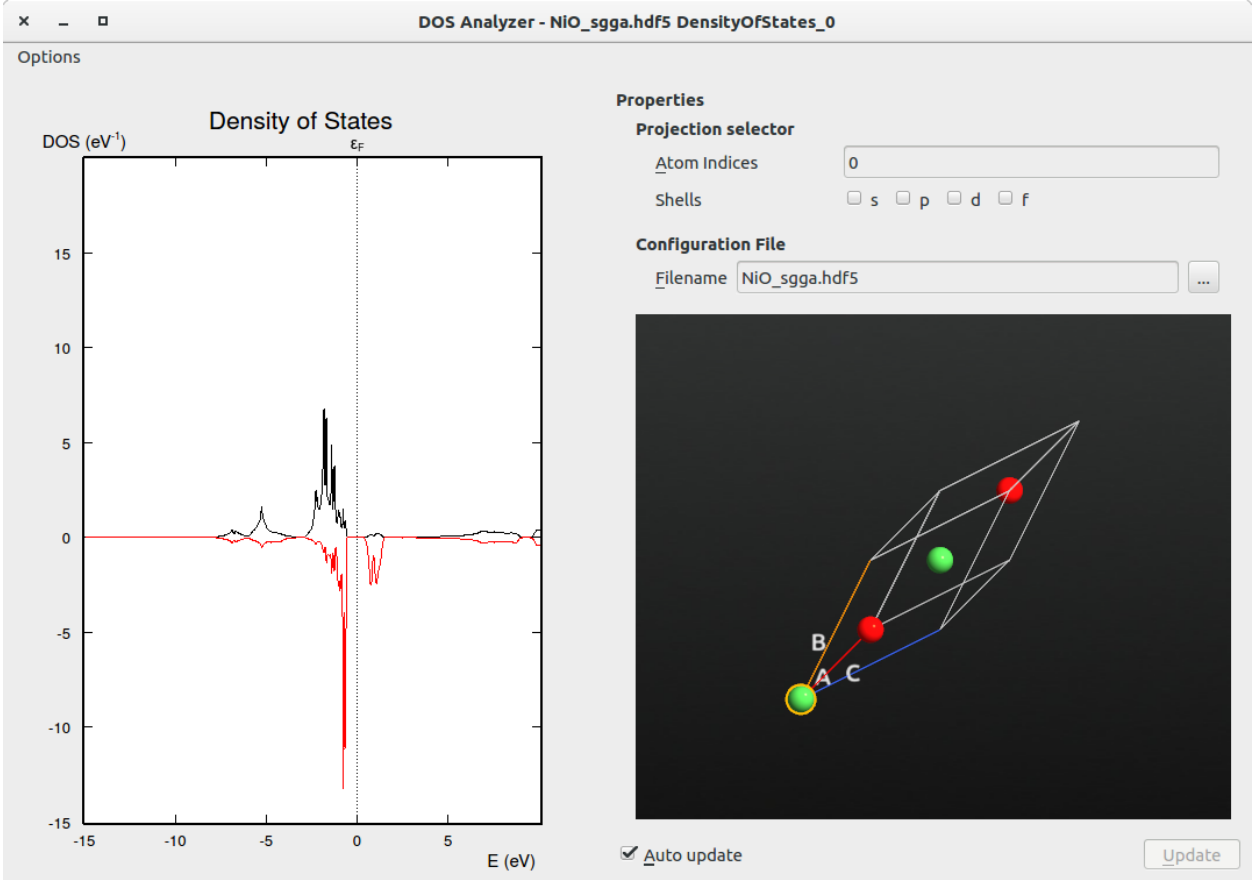
To investigate the NiO density of states (PDOS), select the **DensityOfStates** item on the LabFloor, click the $D(\epsilon)$ **2D Plot** tool in the right-hand panel. You may need to zoom in a little on the plot; use the left mouse button for this.



Tip: The plot shows the total density of states of the spin-up channel with a black line and minus the result for the spin-down channel with a red line. If you de-select Flip spin-down in the Options menu, the density of states of the spin-down channel will also be plotted on the positive axis.

The total DOS shows no difference between the two spin channels. However, you saw from the Mulliken population that the nickel atoms are spin polarized!

To inspect the projected DOS corresponding to just one nickel atom, select a nickel atom with the left-hand button of the mouse, as illustrated below.



The PDOS is simply the total DOS projected onto the selected nickel atom. The expected difference between the spin-up and spin-down DOS channels is now apparent.

Tip: You can also create combined projections by selecting multiple atoms (use the left-hand button of the mouse while holding `Ctrl`) and more than one shell.

The calculation predicts a band gap of ~0.8 eV, which is much smaller than the experimental value of 4.0 eV[3]. In the next chapter you will see how the description of the band gap is improved with the DFT+U approximation.

[3] VladimirăI Anisimov, FăAryasetiawan, and AăI Lichtenstein. First-principles calculations of the electronic structure and spectra of strongly correlated systems: the LDA+U method. *Journal of Physics: Condensed Matter*, 9(4):767, 1997. doi:10.1088/0953-8984/9/4/002.

DFT+U calculation for the NiO crystal

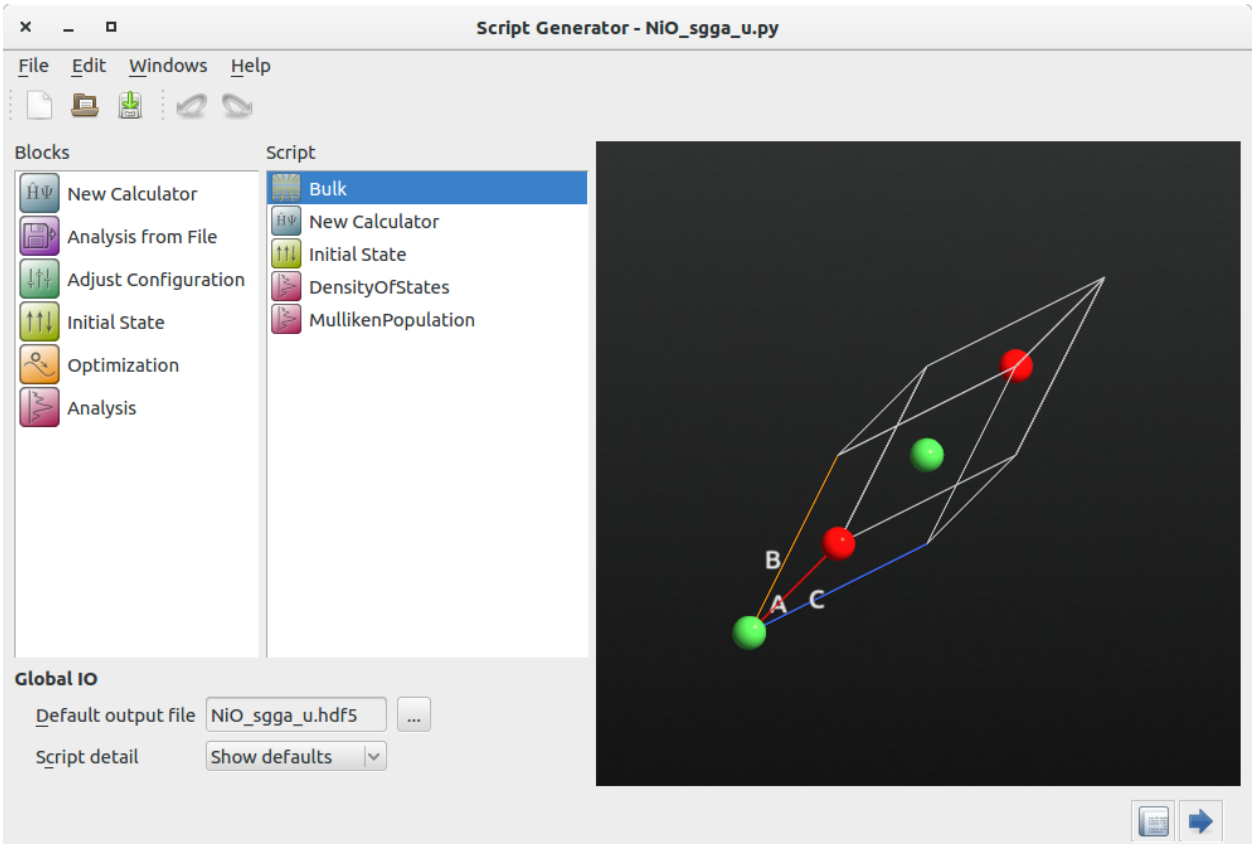
You will now perform a DFT+U calculation of the NiO crystal, using U = 4.6 eV for the nickel *d*-states, as proposed in[Page 1412, 1].

Calculations

You will need to modify the script generated above for the SGGA calculation. Open the **Scripter** used in the previous chapter and make the following modifications:

•Change the default output file name to `NiO_sgga_u.nc`.

•Change the **Script detail** to *Show defaults*.

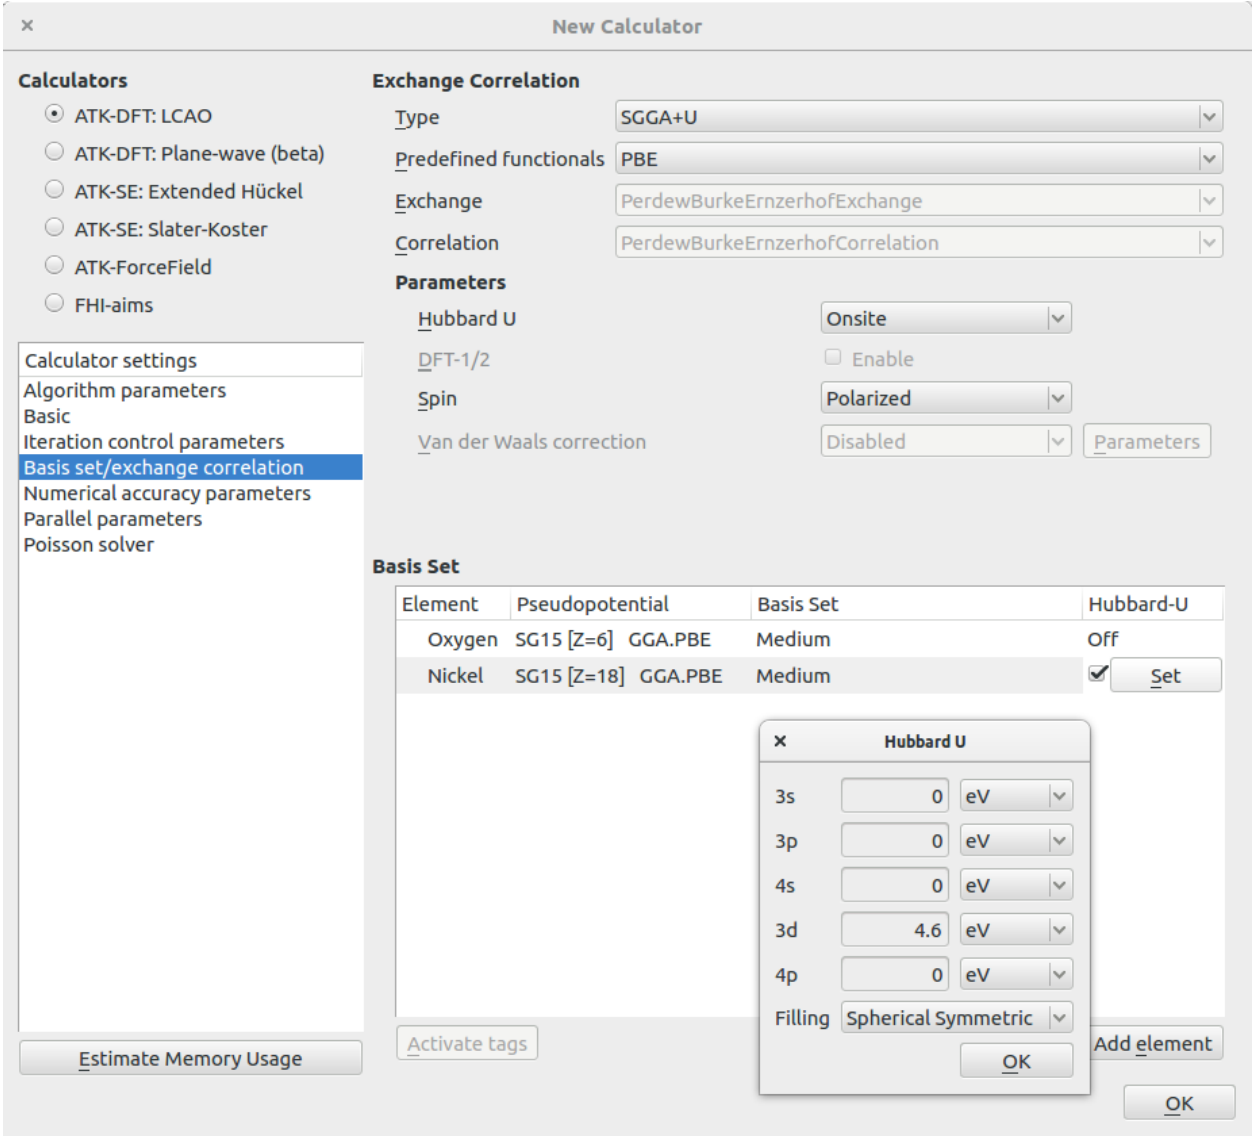


Open the **New Calculator**:

•Switch to the **Basis set/exchange correlation** tab.

•Change the option **Hubbard U** from *Disabled* to *Onsite*.

•In the **Basis set** section, click **Set** in the column on the right-hand side on the row corresponding to nickel, and set the Hubbard U parameter for the 3d orbital to 4.6 eV.



Next transfer the script to the **Editor** using the send to button, in order to check that all the parameters are properly set.

In the editor locate the line where the nickel basis is defined and check that the hubbard U parameter is set to 4.6 eV for the `nickel_3d` and `nickel_3d_0` orbitals.

```
NickelBasis = BasisSet(
    element=PeriodicTable.Nickel,
    orbitals=[nickel_3s, nickel_3p, nickel_4s, nickel_3d, nickel_3p_0, nickel_3d_0,␣
↪nickel_4p],
    occupations=[2.0, 6.0, 0.0, 8.0, 1.0, 1.0, 0.0],
    hubbard_u=[0.0, 0.0, 0.0, 4.6, 0.0, 4.6, 0.0]*eV,
    dft_half_parameters=Automatic,
    filling_method=SphericalSymmetric,
    onsite_spin_orbit_split=[0.0, 0.0, 0.0, 0.0, 0.0, 0.0, 0.0]*eV,
    pseudopotential=NormConservingPseudoPotential("normconserving/sg15/gga/28_Ni.upf"),
    )
```

Now save the script as `NiO_sgga_u.py` and execute the job using the **Job Manager**.

Analyzing the results

First inspect the Mulliken population in the log file. You should find a magnetic moment of $1.80\mu_B$ on a nickel atom, which is in good agreement with the experimental result of $1.64 - 1.9\mu_B$[Page 1421, 3].

To determine the band gap, inspect the printed density of states in the log file. You should find that the DOS is zero in the range -1.69 to 1.69 eV, corresponding to a band gap of 3.38 eV. This is much higher than the SGGA value of 0.8 eV, and in better agreement with the experimental value of 4.0 eV[Page 1421, 3].

Comparing the DFT and DFT+U projected DOS

The final step is to compare the nickel PDOS obtained with DFT and DFT+U. You will here use Python scripting to perform the analysis.

The script `dos-comparision.py` performs the analysis. It is shown below:

```
#read in the dos object
dos = nlread('NiO_sgga.hdf5',DensityOfStates)[0]
#generate some energies
energies = numpy.linspace(-5,5,400)*eV
#calculate the spectrum
n0_up = dos.tetrahedronSpectrum(energies=energies,
                                spin=Spin.Up,
                                projection_list = ProjectionList([0]))

n0_down = dos.tetrahedronSpectrum(energies=energies,
                                  spin=Spin.Down,
                                  projection_list = ProjectionList([0]))
e = dos.energies()

#do the same for GGA+U
dos_u = nlread('NiO_sgga_u.hdf5',DensityOfStates)[0]
n0_up_u = dos_u.tetrahedronSpectrum(energies=energies,
                                    spin=Spin.Up,
                                    projection_list = ProjectionList([0]))

n0_down_u = dos_u.tetrahedronSpectrum(energies=energies,
                                      spin=Spin.Down,
                                    projection_list = ProjectionList([0]))

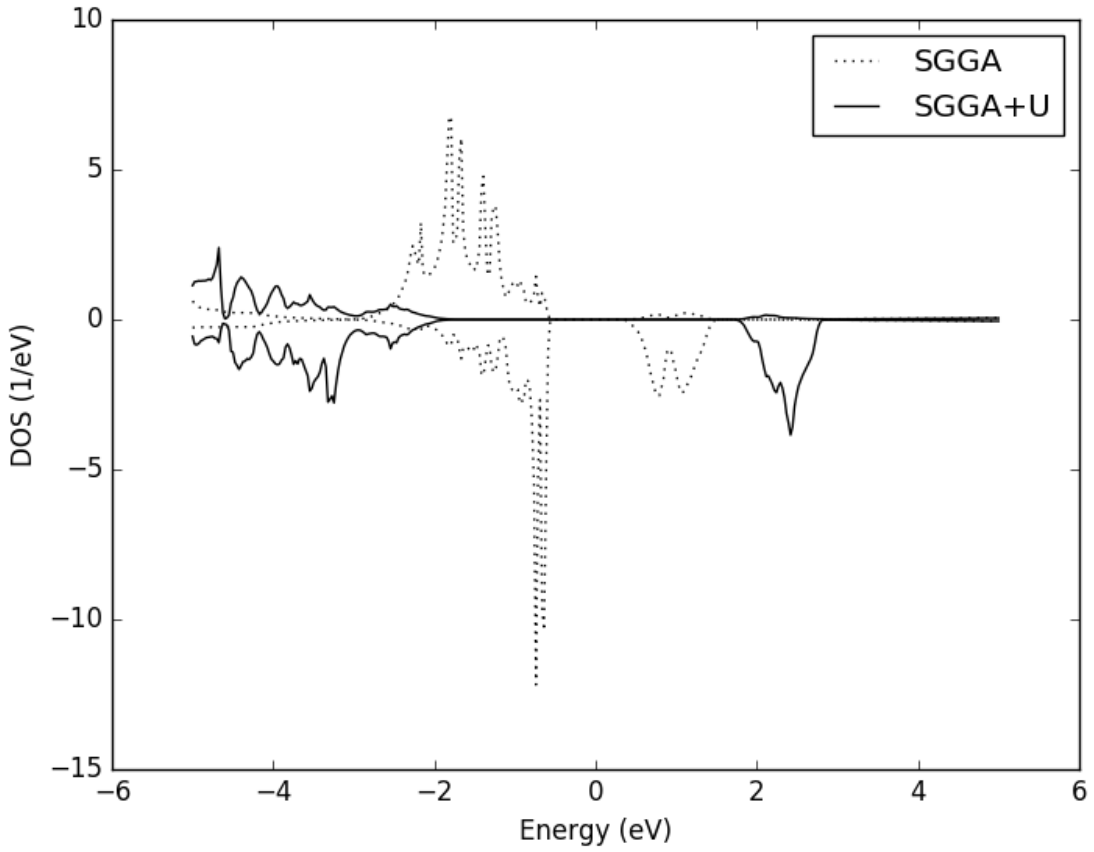
#plot the spectrum using pylab
import pylab
#first plot the up component with dots
pylab.plot(e.inUnitsOf(eV), n0_up.inUnitsOf(eV**-1), 'k:',label = 'SGGA')
#now plot the down component with negative values and dots
pylab.plot(e.inUnitsOf(eV), -1.*n0_down.inUnitsOf(eV**-1), 'k:')
#now plot the GGA+U up  components with solid
pylab.plot(e.inUnitsOf(eV), n0_up_u.inUnitsOf(eV**-1),'k',label = 'SGGA+U')
#now plot the  GGA+U down component with negative values and solid
```

(continues on next page)

(continued from previous page)

```
pylab.plot(e.inUnitsOf(eV), -1.*n0_down_u.inUnitsOf(eV**-1),'k')
#show legends
pylab.legend()
pylab.xlabel("Energy (eV)")
pylab.ylabel("DOS (1/eV)")
pylab.show()
```

Download the script and execute it using the **Job Manager**. The following plot is produced, illustrating the projected DOS for the nickel atom obtained using SGGA and SGGA+U. Notice the large difference in band gap between the two calculations (region of zero DOS around the Fermi level, at 0 eV energy).



Note: The plotting is based on the matplotlib package which is part of QuantumATK, see *Plotting using pylab* for more information.

`sio2_nanoparticle.hdf5` `sio2_surface.hdf5` *`ForceCappedEquilibration`* *`PolymerSequence`* *`OPLSPotentialBuilder`* *`DreidingPotentialBuilder`* More About Polymer Simulations

In this tutorial you will learn how to use the **Polymer Builder** to build polymers such as homopolymers and polymer blends, and how to include embedding of molecules, nanoparticles, or a surface, all using the Nanolab GUI. The Polymer Builder is introduced with the Q-2019.12 version of QuantumATK. After building the inital polymer model, you can proceed to perform realistic atomistic simulations for studies of the polymer properties such as polymer melting, glass transition temperature, mechanical properties, miscibilty, and so on.

This tutuorial guides how to build an initial polymer using the **PolymerBuilder** script block located in the **Script Generator**.

Contents

•*Polymer Builder*

–*Procedure of the Polymer Builder*

∗*Homopolymer*

∗*Polymer blend*

∗*Polymer with embedded molecules*

∗*Nanoparticles in a melted polymer*

∗*Polymers around a surface*

∗*Customized monomers*

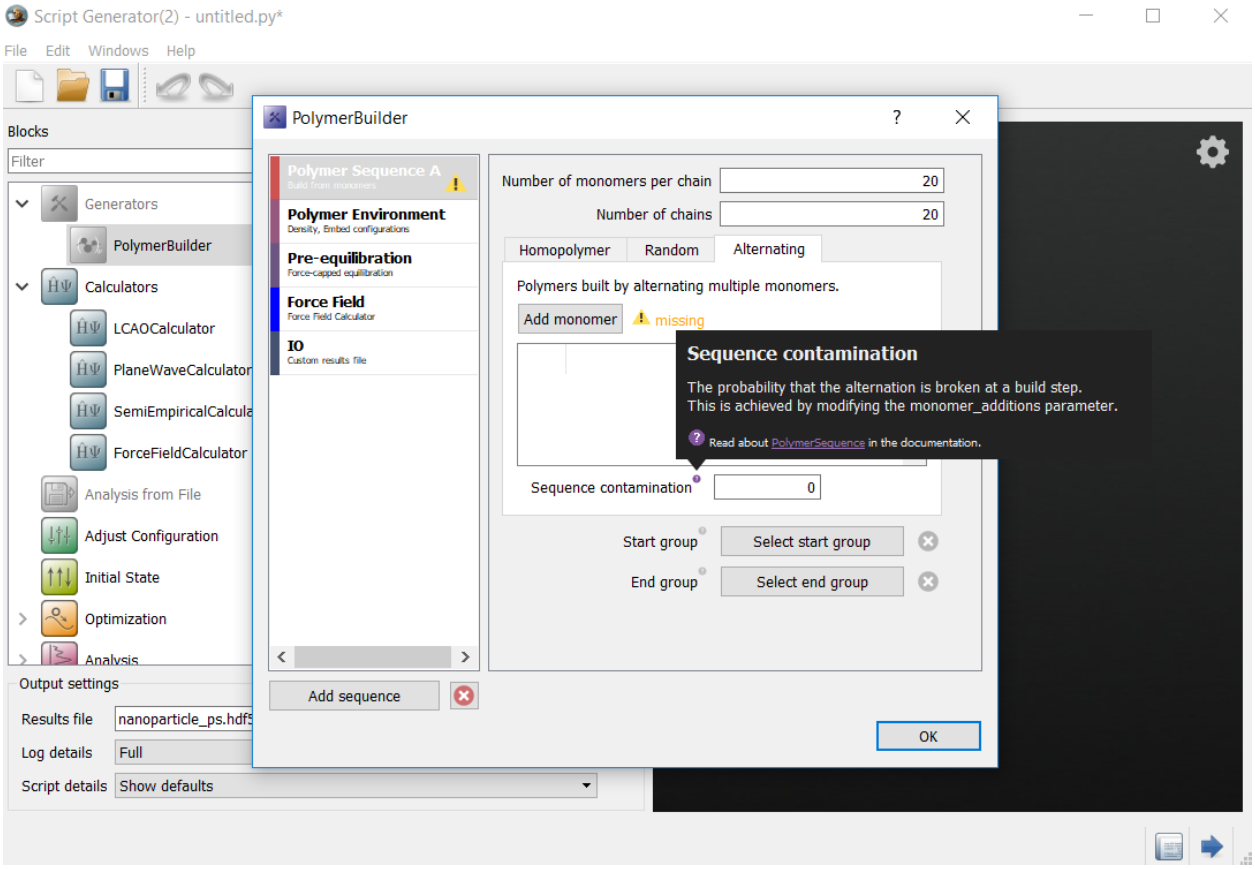
Procedure of the Polymer Builder

1. Open the **Script Generator**.
2. Add the **PolymerBuilder** block under the **Generator** into the the templates.

Note: The **PolymerBuilder** object is located in **Script Generator** not in **Builder**. Monomers of polymer sequences are stored in the **Monomer Database** which is newly implemented in Q-2019.12. You can also create and

add customized monomers into the **Monomer Database**. You will learn it in the *Customized monomer* section of tutorial.

3. Decide the polymer sequences. In the **Polymer Sequence A**, you see `Homopolymer`, `Random`, `Alternating`. The `Homopolymer` builds one main monomer chain, while `Random` and `Alternating` can build the polymer chains consisting more than two monomers randomly or alternatively. When you click the small question sign, you get a short description such as the below figure.



Tacticity or Sequence contamination is in a range of 0 and 1. And the number of monomer per chain and the number of chains are each 20 as a default. You can also add the different polymer sequence clicking the button of `Add Sequence`. When you select the `monomer`, `start group`, or `end group`, **Monomer Database** will be pop-up automatically.

4. In the **Polymer Enviroment**, you can set up the polymer density and embeded host configuration and molecules. PolymerBuilder builds melted polymer with a defined density controlling a periodic box size. But in the embedded case with a host configuraiton, polymers are packed in the periodic box of host configuration. And many applications include not only polymer, but also nanoparticles, surfaces or molecules. You can setup to build polymer with embedded other material types.

5. **Polymer Monte Carlo** *`PolymerMonteCarloBuilder`* runs with above defined conditions.

6. **Pre-equilibration** is performed after Polymer Monte Carlo. It is using the **Force-Capped Molecular Dyanmics** `ForceCappedMolecularDynamics`. Initial configuration by Polymer Monte Carlo includes overlapped atoms or artifically closed atoms. Optimization and Force-capped molecular dynamics run to make a reasonable configuration.

7. PolymerBuilder runs by `Dreiding` or `OPLS` force field. The desired polymer system should be parameterized in `Dreiding DreidingPotentialBuilder` or `OPLS`*`OPLSPotentialBuilder`* force field types.

8. Run it using the **Job manager**. Polymer is usually much larger than molecular/bulk system. Due to the number of

atoms and scale of size, it takes a bit longer time, especially for the pre-equilibrium step.

Homopolymer

You will build *polyvinylidene fluoride (PVDF)* polymer as an example.

•Open the **PolymerBuilder**.

•In the **Polymer Sequance A**, see `Homopolymer`. You can create a polymer model from a single monomer in this section.

•Click the `Select monomer` to load the monomer. It is pop-up the **Monomer Database** which includes common monomers.

•Select `tetrafluroethylene` to build the *polyvinylidene fluoride (PVDF)*. There is an option to define the tactic ratio. `Isotactic` is `0` and `Syndiotactic` is `1`. Default is `Atatic` with `0.5` ratio of isotactic and syndiotactic. You can also customize the atatic ratio in the `Custom`.

•Move to the **Polymer Environment**. You can set the desired density with a unit of g/cm ^{3}. Change the density into `1.78` g/cm ^{3} in experiment for *PVDF*.

You can also see the **Pre-equilibration** section. After generating an initial polymer model by Polymer Monte Carlo, PolymerBuilder follows the pre-equilibration using the Force-capped equilibration method. It is for preventing the overlapping or artifically closed atoms. Detailed information is documented in the manual page, *ForceCappedEquilibration*. You will keep the default condition for others.

•Change the output file as `pvdf.hdf5` and open the **Editor** to confirm the settings as an input script.

You can see the following information in the input python file.

The first part of script shows the definition of monomer configuration as *MoleculeConfiguration* with information of tags and bonds using the `Dreiding` or `OPLS` force field. QuantumATK PolymerBuilder includes the `Dreiding` or `OPLS` force field. The `Dreiding` force field is much simpler than `OPLS` force field. PolymerBuilder can automatically indicate the types of `Dreiding` force field. Therefore, when you use `Dreiding` force field, you dont need to add the tags manually. But it is too simple not to describe the tacticity or partial charge. On the other hand, the `OPLS` force field is able to consider the tacticity and partial charge of atomic types. It is more complex but more accuracy. You can use it adding tags connected to the `OPLS` parameters for monomer configuration.

PolymerBuilder uses the `Dreiding` and `OPLS` force field parameters to build a polymer model using the Polymer Monte Carlo and Force capped equilibration.

In the following section as shown in the below script, polymer Monte Carlo builder is defined. After building an initial polymer, pre-equilibration will be performed using the force capped equilibarion method. Force capped equilibration will run 4 cycles. Each simulation runs 40,000 times with 0.5 fs timestep as a default. The `OPLS` potential is used in Force capped equilibration.

```
# ------------------------------------------------------------
# Polymer Monte Carlo Builder
# ------------------------------------------------------------
polymer_builder = PolymerMonteCarloBuilder(
    polymer_sequence=polymer_sequences,
    density=1.7800*gram/cm**3,
    monte_carlo_temperature=300.0*Kelvin,
    angle_sampling_points=20,
    repack_molecules=False,
    )
```

(continues on next page)

(continued from previous page)

```
bulk_configuration = polymer_builder.buildPolymerConfiguration()

# ----------------------------------------------------------------
# Calculator for Force Capped Equilibration
# ----------------------------------------------------------------
potential_builder = DreidingPotentialBuilder(
    include_electrostatic=False,
    )
calculator = potential_builder.createCalculator(bulk_configuration)
bulk_configuration.setCalculator(calculator)

# ----------------------------------------------------------------
# Force Capped Equilibration
# ----------------------------------------------------------------
equilibration_method = ForceCappedEquilibration(
    temperature=300.00*Kelvin,
    md_steps_per_force_capped_simulation=40000,
    md_time_step=0.50*fs,
    force_capped_simulations=4,
    starting_factor=1.040,
    ending_factor=0.800,
    fixed_indices=None,
    )
bulk_configuration = equilibration_method.runEquilibration(bulk_configuration)
nlsave('pvdf.hdf5', bulk_configuration)

# ----------------------------------------------------------------
# Calculator
# ----------------------------------------------------------------
potential_builder = OPLSPotentialBuilder(
    lennard_jones_cutoff=10.0*Angstrom,
    electrostatic_accuracy=0.0001,
    )
calculator = potential_builder.createCalculator(bulk_configuration)
bulk_configuration.setCalculator(calculator)
nlsave('pvdf.hdf5', bulk_configuration)
```

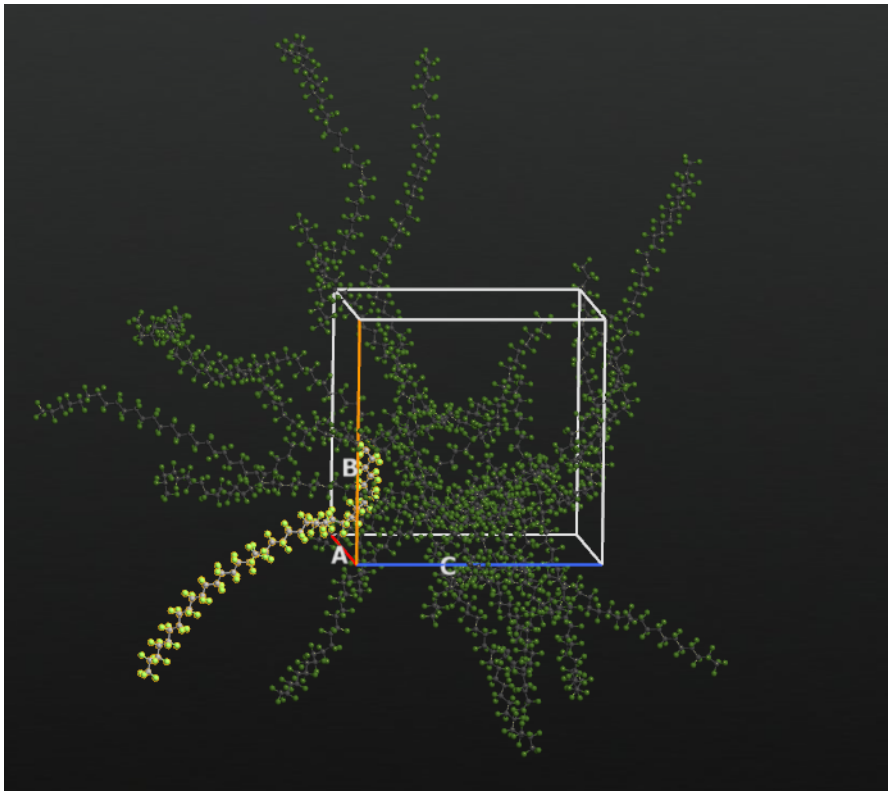
Now you are ready to run the script. Go to the **Job manager** after saving the script as `pvdf.py`. It takes around 15 minutes on your laptop.

After the job finishes, you can visualize the results using the **Viewer**. .. , when you select the `pvdf.hdf5`, .. you can see 2 objects of `BulkConfiguration_0` and `BulkConfiguration_1` .. on the **labfloor**. .. `BulkConfiguration_0` is the configuration after polymer Monte Carlo .. and `BulkConfiguration_1` is the configuration after pre-equilibration process. .. You can compare them in the **Compare Configurations** plug-in. .. You can also visualize it using the **Viewer**.

As shown in the below figure, you can see the 20 chains with 20 monomers per each chain of *PVDF* with `1.78` g/cm ^{3} density. The periodic box is automatically controlled to fit the requested density.

You may need to increase the *Fuzz factor* (ex. `1.15`) in the **Graphics Properties** of **Viewer** to see reasonable polymer chains. And the default configuration shows unwrapped configuration. When you check the *wrap atom*, you can see

the wrapped configuration in a periodic box.



Polymer blend

Pactically, polymer blend is important to mix different polymers. You can easily build the polymer blend using the **PolymerBuilder**. We will blend *Poly Methyl Methacrylate (PMMA)* and *Poly Vinyl Chloride (PVC)* in a periodic box as an example.

•Open the **PolymerBuilder**.

•Click `Add sequence` in the botton side of **PolymerBuilder** widget.

Now you can make two different polymer sequences. If you need more different polymer sequence, you can add it more from here.

•In the **Polymer Sequance A**, select the `Methyl Methacrylate` in the Monomer Database.

•In the **Polymer Sequance B**, select the `Vinyl Chloride` in the Monomer Database.

To demonstrate it in a short time, you will blend simply two different polymers of 5 chains possessing 20 monomers per chain.

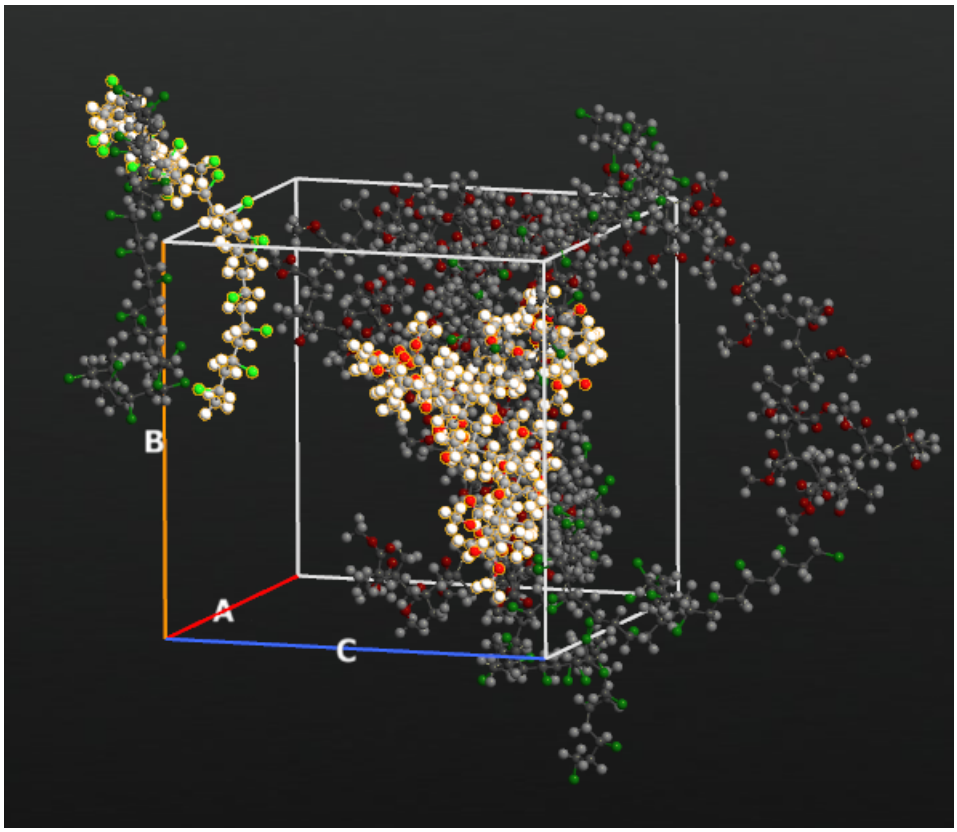
•Change the number of chains into 5 in the Polymer Sequance A and B.

•Change the output file name as `pmma-pvc.hdf5`. Other options are default.

•Open the **Editor**. You can see molecular configuration and parameters of 2 monomers from polymer sequence a and b in the script.

•Save the script as `pmma-pvc.py` and run it in the **Job Manager**.

It takes around 20 minutes in your laptop. As shown in the following figure, you get the polymer blend system including 5 *PMMA* and 5 *PVC* chains.



Polymer with embedded molecules

In many cases, polymer is melted in liquid. The tutorial guides how to embed molecules into the polymer, as building the *PMMA* polymers with methane molecules as a simple example.

It starts with one monomer and one molecule.

•In the **Polymer Sequance A**, select the `Methyl Methacrylate` in the Monomer Database. And change the number of chain as `5`.

•Open the **Builder** and import `Methane` **From Database** of Molecules.

•In the **Polymer Environment**, click `Add molecule from file` button.

You see saved configurations in your project and also see *MoleculeConfiguration Methane* in the `Builder_Stash.hdf5`.

•Select *MoleculeConfiguration Methane* and modify `Count` as `10`.

•In the **Force Field**, change `OPLS` into `Dreiding` force field. Because the new embedded methane will run using the Dreiding force field without assigning the OPLS tag for methane manually.

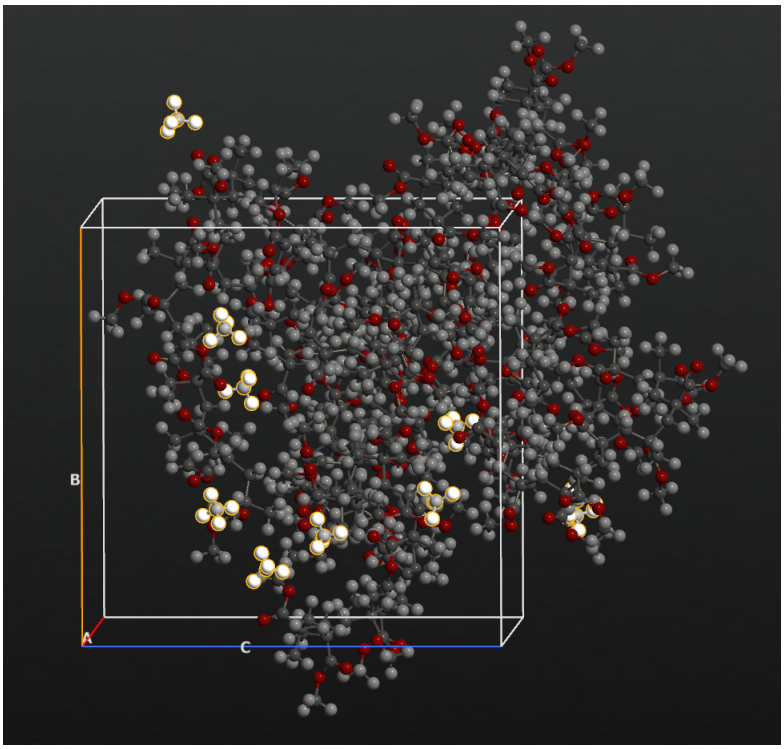
•Save the output file as `pmma_methane.hdf5`.

•Open the **Editor** and confirm the script.

Embedded molecules are defined as called *Included Molecule 1* with configuration and bonds information in the polymer Monte Carlo builder. In this condition, 5 *PMMA* chains will be generated by embedded 10 *Methane* molecules.

•Run the job in the **Job Manager**.

It takes around 15 minutes on the laptop. You can see 5 chains of *PMMA* and 10 methanes in a periodic box as shown in the below figure.



Nanoparticles in a melted polymer

There are two ways to embed nanoparticles in a melted polymer system.

1. Embed nanoparticles as a host configuration. The host configuration will be fixed during the polymer Monte Carlo and force capped molecular dynamics. Therefore polymer will be positioned in space defined by the host configuration.
2. Embed nanoparticles as molecules. Smaller sized nanoparticle can be assumed as molecules. You can load a nanoparticle from `Add molecule from file`. Such as embedded molecules *Polymer with embedded molecules*, you can also add how many particles will be embedded. In this case, embedded nanoparticle configuration should be a type of `MoleculeConfiguration`. And it is randomly positioned with polymers by Polymer Monte Carlo.

In this tutorial, you will embed about `15` Å sized *Silica* nanoparticle with *poly-stylene* polymer.

You will firstly embed a nanoparticle using the host configuration.

Note: The host configuration is fixed, while polymers are generated into the host configuration by polymer Monte Carlo builder. You can import and embed any kinds of host configuration with polymers.

Polymer Monte Carlo is parameterized by `Dreiding` or `OPLS` force fields. Considering atomic types should be able to use in `Dreiding` or `OPLS` force field parameter.

•Open the **PolymerBuilder**.

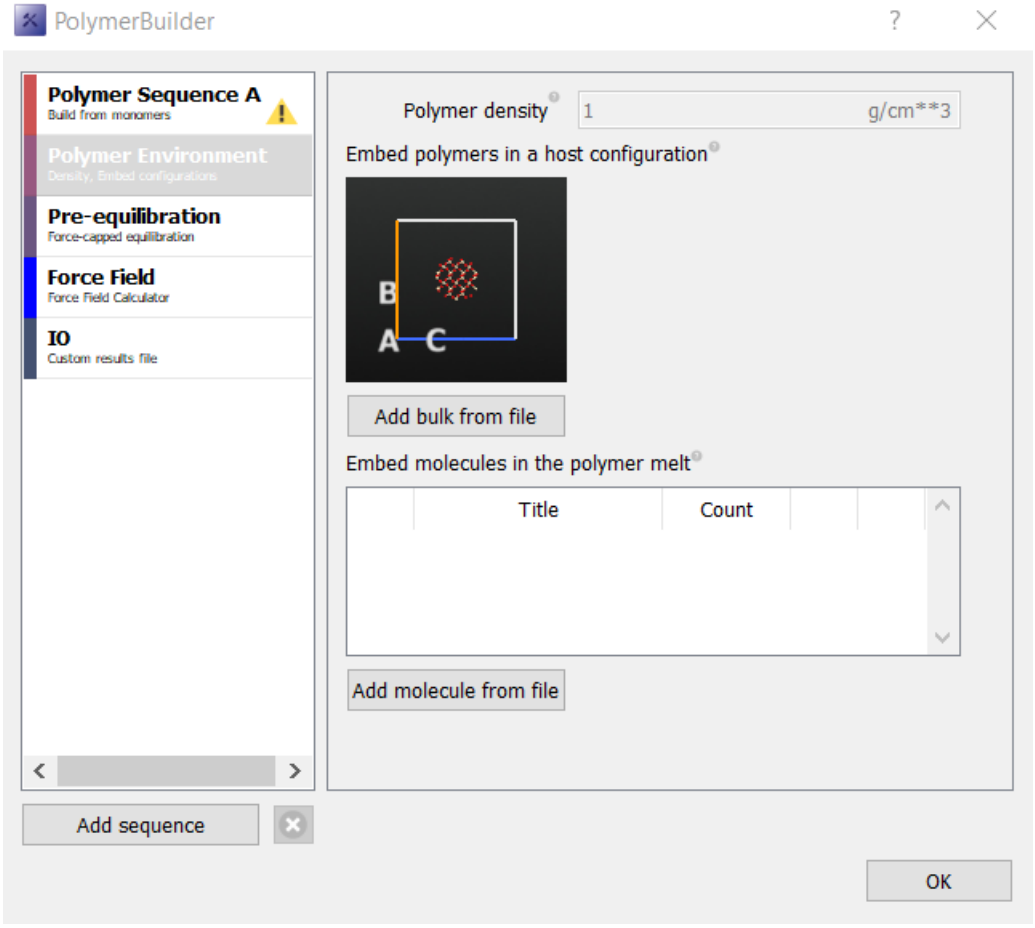
•In the **Polymer Sequance A**, select the `Stylene` in the Monomer Database. And change the number of chains as `10`.

•In the **Polymer Environment**, click `Add bulk from file` button.

You see saved configurations in your project. Import the host configuration here. In this tutorial, download the `15` Å sized SiO_2 nanoparticle configuration in a `35` Å x `35` Å x `35` Å periodic box, `sio2_nanoparticle.hdf5` and use it.

Note: Once you use the host configuration selecting the `Add bulk from file`, `polymer density` is inactive because polymer is packed in the defined periodic box of host configuration.

•Select the `BulkConfiguration_0` of `sio2_nanoparticle.hdf5`. You can see the host configuration on the widget as the below figure.



•In the **Force Field**, change `OPLS` into `Dreiding` force field. Because the new embedded nanoparticle will run using the Dreiding force field without assigning the OPLS force field manually and in the case of SiO_2 nanoparticle, OPLS will be in a trouble not to make a neutral charge in a total configuration.

•Save the output file as `host_nanoparticle_10ps.hdf5`.

•Open the **Editor** and check the script.

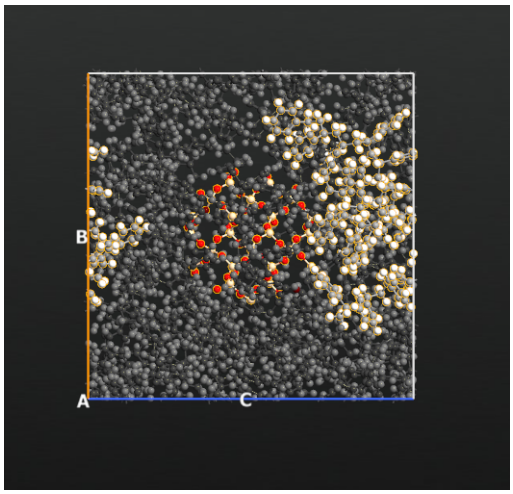
You can see *Host configuration information*.

•Run the job after saving the input file as `host_nanoparticle_10ps.py`.

It takes around 30 minutes on the laptop.

Note: Once the host configuation is large, it takes time to build it even in the MPI process. Polymer builder by polymer Monte Carlo takes a few minutes in your laptop, but force capped molecular dynamics takes time depending on the number of atoms. Such a large system probably needs more steps than default in pre-equilibration to have a reasonable configuration.

The configuration of SiO_2 nanoparticle with 10 *PS* is shown in the below figure.



You will now build nanoparticles in polymer as the embed molecules.

•Open the **PolymerBuilder**.

•In the **Polymer Sequance A**, select the `Stylene` in the Monomer Database. And change the number of chains as `10`.

•In the **Polymer Environment**, click `Add molecule from file` button.

You see saved configurations in your project. But unlike the host configuration, you need a molecular type of configuration.

•Open the downloaded `sio2_nanoparticle.hdf5` in the **Builder**.

It is the `15` Å sized SiO_2 nanoparticle configuration in a `35` Å x `35` Å x `35` Å periodic box. We will remove the periodic box and save as a MolecularConfiguration.

•Change the current configuration into a molecule configuration clicking the icon.

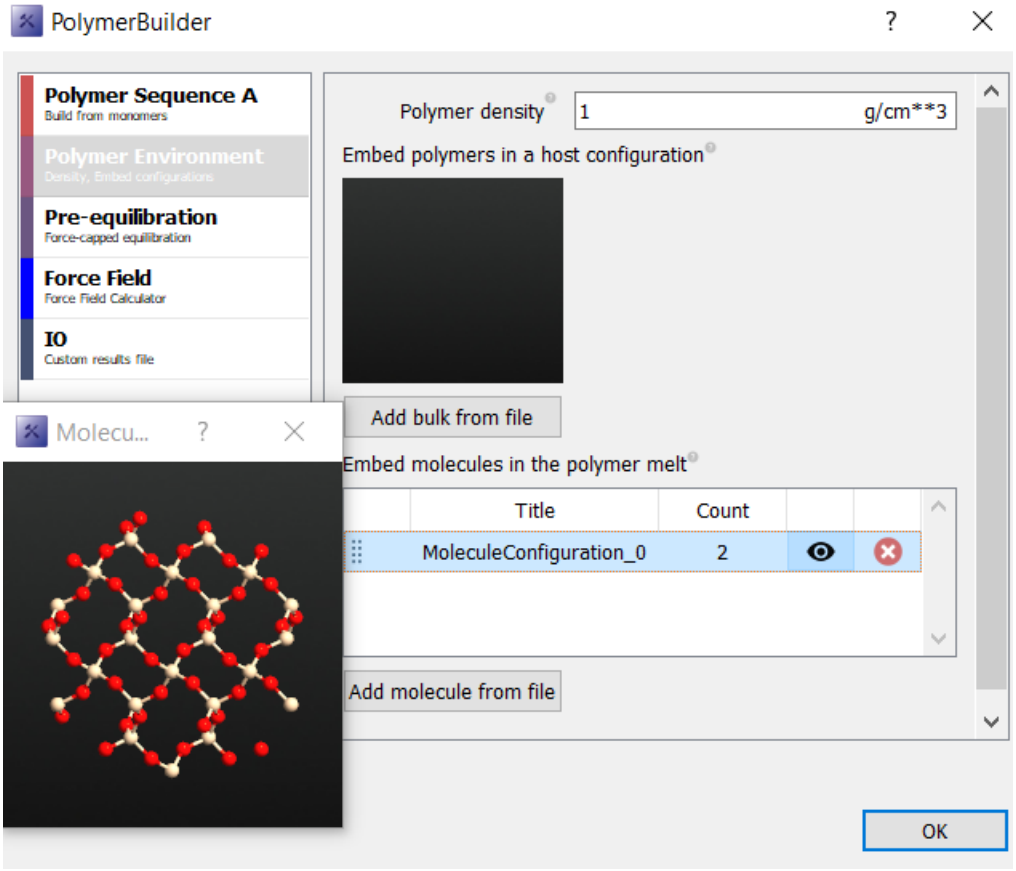
•Save the configuration as `sio2_nanoparticle_molecule.hdf5`.

•Now when you click `Add molecule from file` button again, you see it including `MoleculeConfiguration`.

•Load the `MoleculeConfiguration` in `sio2_nanoparticle_molecule.hdf5`.

•In this case, you will embed 2 nanoparticles. Change the `Count` into `2`.

As the below figure, you can visually check the embed nanaparticle configuration and the number of particles.



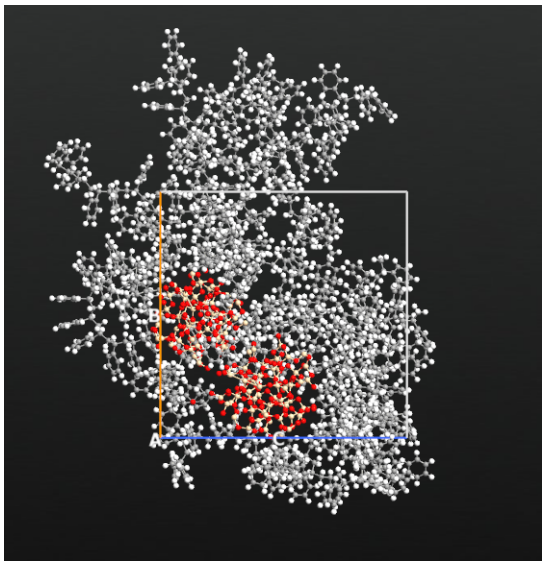
•In the **Force Field**, change `OPLS` into `Dreiding` force field. Because you will not assign the OPLS force field on the nanoparticle manually.

•Save the output file as `2nanoparticle_10ps.hdf5`.

•Open the **Editor** and check the script.

•Run the job after saving the input file as `2nanoparticle_10ps.py`.

It takes around 30 minutes on the laptop. As shown in the following figure, 2 nanoparticles are randomly positioned with polymers. In this case, it is fit to the defined polymer density controlling the periodic box. And nanoparticles and polymers are relaxed by pre-equilibration process.



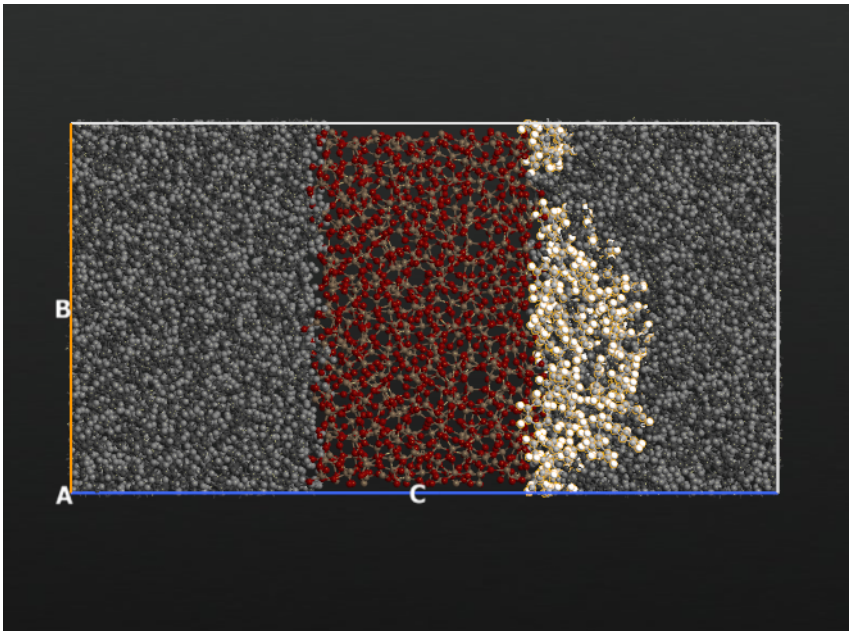
Polymers around a surface

Now you will see an advanced example using the *Poly-stylene* melt with amorphous OH-terminated SiO_2 surface. It is a same procedure to use a host configuration to import the surface configuration as shown in the nanoparticle example. Download the OH-terminated amorphous SiO_2 surface configuration, `sio2_surface.hdf5` and use as a host configuration.

You will build 20 *poly-stylene* chains of 40 monomers per chain with embedded OH-terminated SiO_2 amorphous surface configuration with `25` Å thickness of SiO_2 in about `40` Å x `40` Å x `80` Å sized periodic box as a host configuration.

During the polymer Monte Carlo, the host configuration is fixed to generate 20 *poly-stylene* in a periodic box. After that, Force-capped molecular dynamics will be performed by force field parameters.

It has more than 16,000 atoms. Generation of random polymers by polymer Monte Carlo takes a few minutes on the laptop. But the force-capped molecular dynamics takes a quite long time even in the default condition. Probably you need more steps to get a reasonable configuration in the pre-equilbrium. The below figure shows the 20 *Poly-stylene* melt with amorphous OH-terminated SiO_2 surface with highligted one chain of *Poly-stylene*.



Customized monomers

The Monomer Database of QuantumATK includes several types of monomers. But you may need to design and save customized monomers. You can add customized monomer into the Monomer Database in `/.vnl/databases/monomers` of user home directory.

Original shipped QuantumATK Monomer Database is located in the `/share/nanolab/monomers` of installer directory. You will see some grouping directories such as `Condensation_Monomers`, `Endgroups`, or `Vinyl_Monomers`. When you open one of monomer database (ex. `Tert-Butyl Methacrylate.py`), you see the configuration information with tags. *Add tags* include the information of atom type in a monomer such as `END`, `HEAD`, `TAIL`, `CONNECT`, `GROUP_A` and so on. You can design your own monomer. And add tags and bonds with a correct format and save the python file in `/.vnl/databases/monomers` of user home directory.

We guide the simple way to modify the monomer. This tutorial demonstrates to add `OH` functional group in the `Tert-Butyl Methacrylate` monomer.

In the `/share/nanolab/monomers/Vinyl_Monomers`,

•Drag the `Tert-Butyl Methacrylate.py` into **Builder**.

You see the `Tert-Butyl Methacrylate` monomer on the window.

•Open the *Tags* in the **Selection Tools** plug-in.

You can see the existed tags of `Tert-Butyl Methacrylate` monomer. When you choose one of tags, atom selection will be together. Acoording to this tags, for instance, `HEAD_GROUP_A` and `TAIL_GROUP_A` will finally overlap to formate the polymer. You will modify one of hydrogens not to be effect on the formation of main polymer chain.

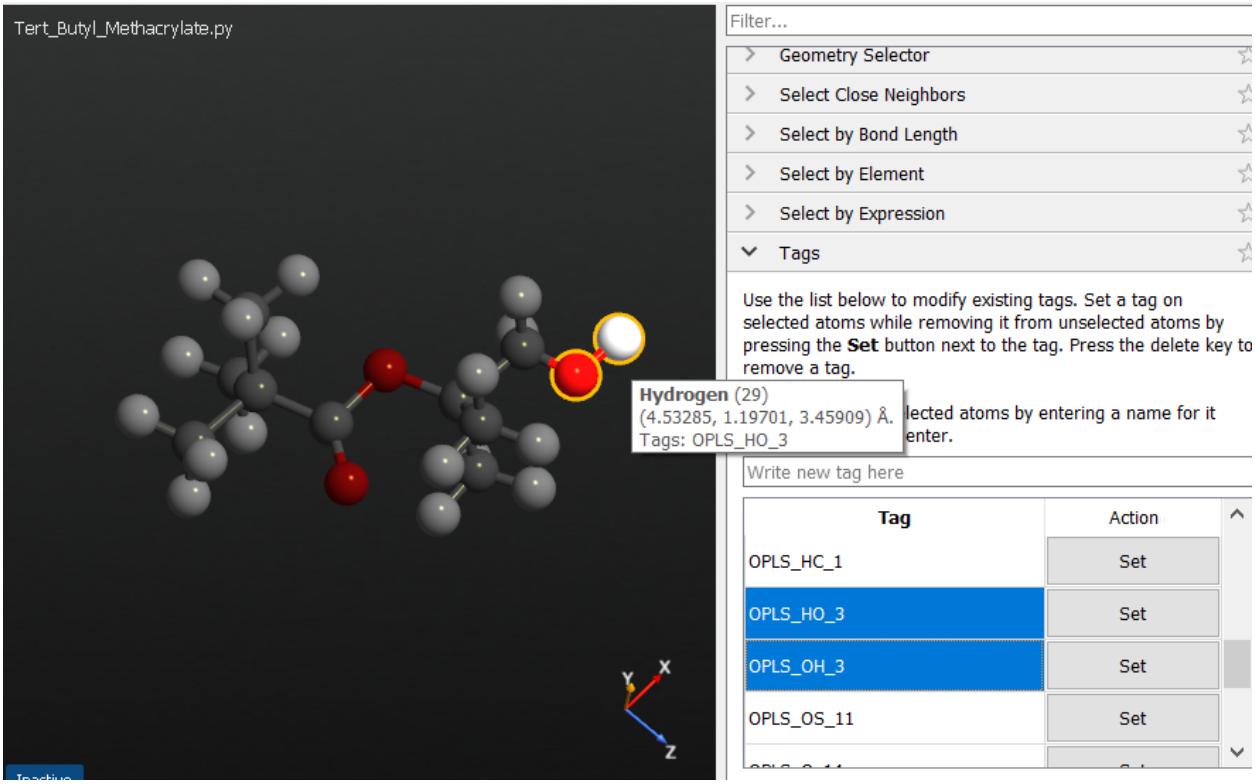
•Change `Hydrogen` of atom number `23` into `Oxygen` atom.

•Click the icon of passivate the configuration with hydrogen.

You will see the `OH` group instead of hydrogen. You need to define the atomic parameter using the `Dreiding` or `OPLS` force field.

•Write new tag in Tags plug-on tool such as O (atom number 23) into OPLS_OH_3, new H (atom number 29) into OPLS_HO_3. And remove or modify the previous tags for OH functional group. For instance, remove the changed hydrogen (atomic number 23) in OPLS_HC_1 tags and modify the carbon (atom number 11) attached OH group into OPLS_CT_11 tag.

It is shown in the below figure.



Add tags should be very careful because you need to consider the polymerization from the monomer. Otherwise force field type is not correct. You can see in detail the Dreiding and OPLS potential parameters of QuantumATK in the *DreidingPotentialBuilder* and *OPLSPotentialBuilder*.

Note: ATKPython has functions of *DreidingPotentialBuilder* and *OPLSPotentialBuilder* that tell the types that you have, and gives a short description of them. Try the function `printTotalTypes()` on the *DreidingPotentialBuilder* and *OPLSPotentialBuilder*. It gives a table for all of the available types. Monomers should have the right tags, then they work with it.

•Open the script using the **Editor** in the Send to.

You will see new tags with OPLS_OH_3 for atom number 23, OPLS_HO_3 for atom number 29, OPLS_CT_11 for atom number 11. And you also add bond information. Atom number 29 needs to make a new bond with atom number 23. You should add it with the format of *Add bonds*.

```
# Add tags
monomer_1.addTags('ENDH_OPLS_CT_4', [0])
monomer_1.addTags('HEAD_CONNECT',   [0])
monomer_1.addTags('HEAD_GROUP_A',   [1])
monomer_1.addTags('H_C',            [20, 21, 22, 24, 25, 26, 27, 28])
monomer_1.addTags('OPLS_CT_11',     [11])
```

(continues on next page)

(continued from previous page)

```
monomer_1.addTags('OPLS_CT_4',      [9, 10, 12, 16])
monomer_1.addTags('OPLS_CT_5',      [0])
monomer_1.addTags('OPLS_CT_8',      [4])
monomer_1.addTags('OPLS_CT_95',     [8])
monomer_1.addTags('OPLS_C_19',      [5])
monomer_1.addTags('OPLS_HC_1',      [ 1,  2,  3, 13, 14, 15, 17, 18, 19, 20, 21, 22, 24,
                                         25, 26, 27, 28])
monomer_1.addTags('OPLS_HO_3',      [29])
monomer_1.addTags('OPLS_OH_3',      [23])
monomer_1.addTags('OPLS_OS_11',     [6])
monomer_1.addTags('OPLS_O_14',      [7])
monomer_1.addTags('TAIL_CONNECT',   [4])
monomer_1.addTags('TAIL_GROUP_A',   [16])
monomer_1.addTags('TAIL_GROUP_B',   [12])

# Add bonds
bonds = [[ 0,  1],
         [ 0,  2],
         [ 0,  3],
         [ 0,  4],
         [ 4,  5],
         [ 4, 12],
         [ 4, 16],
         [ 5,  6],
         [ 5,  7],
         [ 6,  8],
         [ 8,  9],
         [ 8, 10],
         [ 8, 11],
         [ 9, 26],
         [ 9, 27],
         [ 9, 28],
         [10, 20],
         [10, 21],
         [10, 22],
         [11, 23],
         [11, 24],
         [11, 25],
         [12, 13],
         [12, 14],
         [12, 15],
         [16, 17],
         [16, 18],
         [16, 19],
         [23, 29]]
monomer_1.setBonds(bonds)
```

•Save the new monomer with new tags as `Custom_Tert_Butyl_Methacrylate.py` creating the new directory as `Custom` in the `/.vnl/databases/monomers` of user home directory.

Note: If you create a new directory in `/.vnl/databases/monomers`, it will make a grouping with the directory

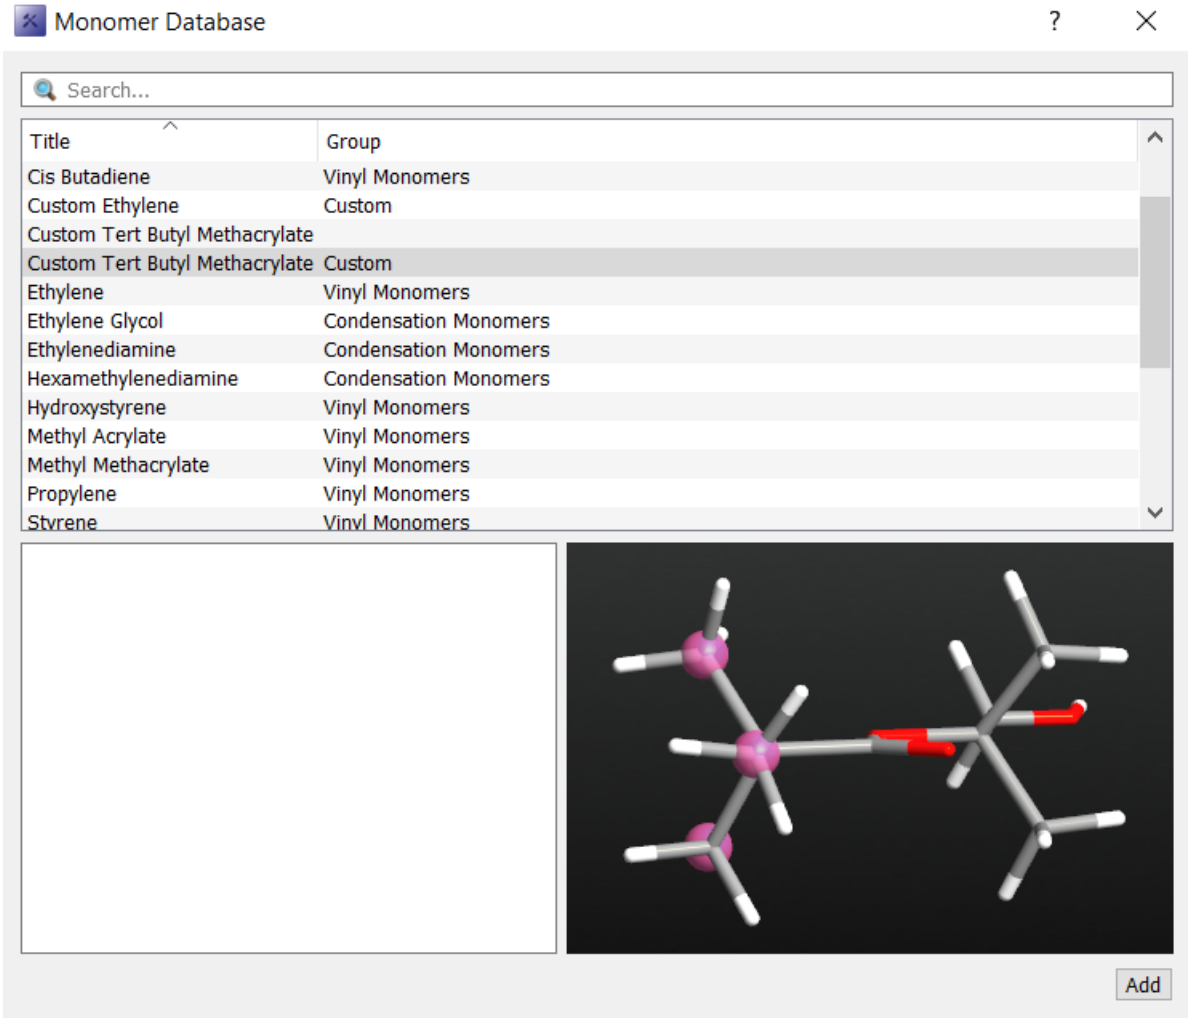
name. After creating a new monomer by user, you need to restart the **Script Generator**.

Now you can load the customized monomer from the Monomer Database in the PolymerBuilder GUI.

•Open the **PolymerBuilder**.

•Click the `Select monomer`.

Now you see the `Custom Tert Butyl Methacrylate` in the momoner database as the below image. When you click it, you also see the configuration indicating how to connect the main chain and `OH` functional group on the widget.



3.11.2 Greens function surface calculations

Version: 2016.0

This tutorial introduces you to a very novel method for computing surface properties: Greens function surface calculations. The central difference to traditional slab calculations is that the surface electronic structure is coupled to the bulk electronic structure through the non-equilibrium Greens function (NEGF) method.

The system you will investigate is a silver (100) surface, for which you will compute the work function. In particular, you will:

•construct the surface configuration;

•set-up and run the Greens function surface calculation;

•analyze the work function and compare to results from traditional slab calculations.

Atomistic models of a surface

This section aims to introduce the Greens function surface configuration, and compare it to the conventional slab model. The two figures shown below illustrate the differences between the two.

The slab consists of a finite number of silver layers, surrounded be vacuum in both directions along the C-axis, so it really has two surface–vacuum interfaces. The Hartree difference potential, ΔV_{H}, is bulk-like in the middle of the slab, but changes near the slab–vacuum interfaces, and becomes constant in the vacuum regions.

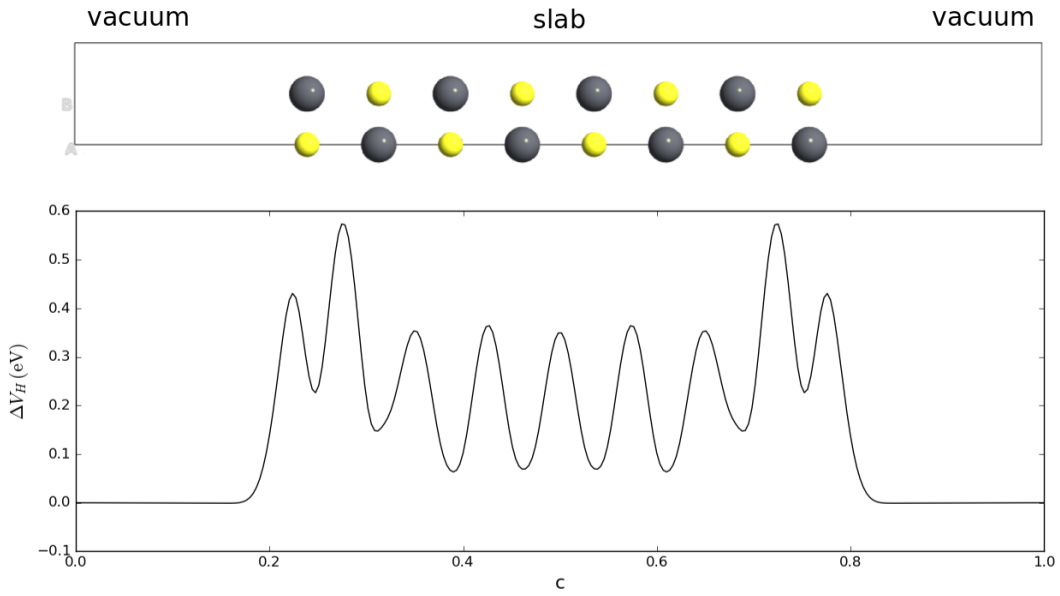


Fig. 3.107: The traditional slab model of a surface is surrounded by vacuum on both sides along the C-direction.

In contrast, the Greens function surface model consists of a single surface region attached to an electrode (a fully periodic bulk). The electronic structure is matched at the electrode–surface boundary using Greens functions. The surface is therefore electronically connected to a bulk substrate, and the surface chemical potential is fixed to that of the electrode.

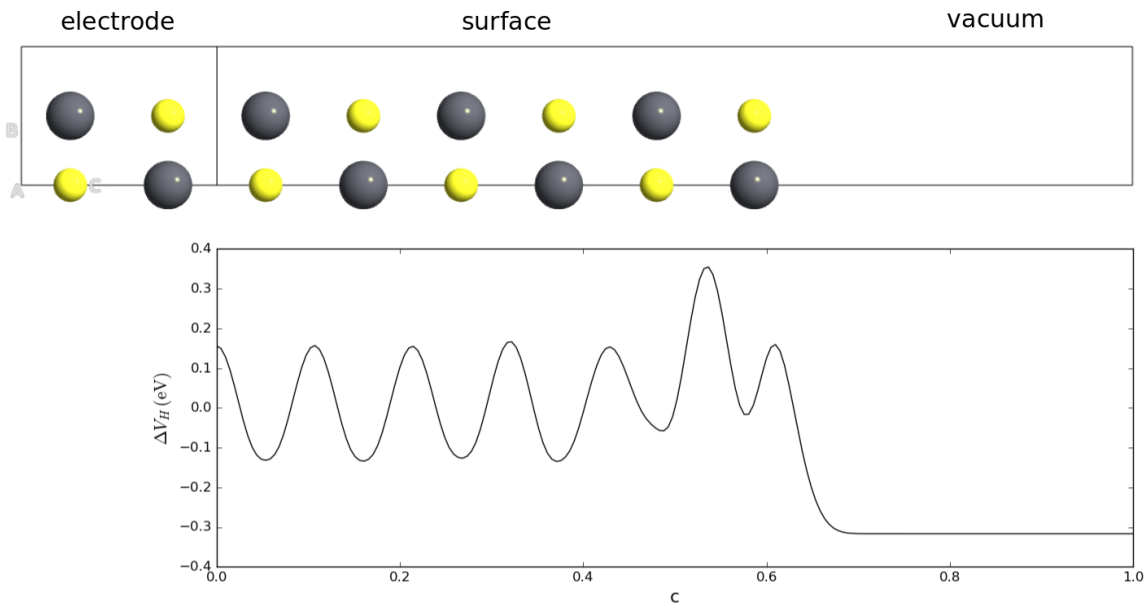

Fig. 3.108: The Greens function surface model has only a single surface–vacuum interface, and is geometrically and electronically connected to a periodic (bulk) electrode.

Advantages of NEGF

Greens function surface calculations have some significant advantages over traditional slab approaches:

- The slab model is a finite system and it therefore has a finite number of electrons. Consequently, when transferring charge from a molecule to the surface (or the other way around), the total number of electrons will change, and therefore the chemical potential of the electrons in the slab also changes. This is a spurious effect, and the Greens function surface model alleviates it completely by coupling the surface to an infinite reservoir of electrons at a fixed chemical potential (the electrode).
- Convergence of computed properties wrt. slab thickness is always an issue, and various corrections are ofte needed to avoid interactions with repeated images of the simulation cell. With the proper choice of boundary conditions, QuantumATK Greens function surface calculations converge very easily wrt. surface thickness, as we shall see later in this tutorial.

NEGF calculation with a single electrode

As already mentioned, the Greens function surface configuration consists of an electrode and a surface region (also called the central region). In the language of QuantumATK, it is therefore a device configuration with a single electrode. As in any QuantumATK device calculation (using NEGF), the calculation proceeds in two steps:

1. The electrode bulk electronic structure is calculated first. This is usually very fast.
2. The NEGF calculation then proceeds to calculating the ground state of the surface region only, given the constraint that the electronic structure at the electrode–surface interface must match.

As illustrated below, three different sorts of boundary conditions are used along the C-direction of the simulation cell. The electrode ensures full periodicity towards the left, while a Dirichlet boundary condition is used at the electrode–surface interface. The Neumann boundary condition is then the natural choice on the right-hand boundary.

Work function of Ag(100)

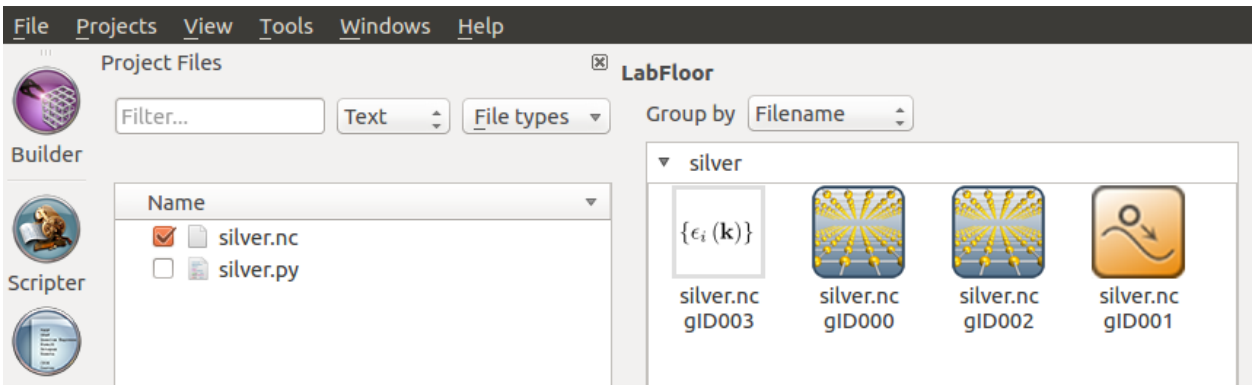
You will now calculate the work function of Ag(100) using DFT and Greens functions. The basic workflow is this:

1. Use the **Builder** to construct the surface configuration from a stress-optimized silver bulk, and specify ghost atoms.
2. Use the **Scripter** to create a script that calculates the ground state, and saves the Hartree difference potential (HDP) and chemical potential.
3. Use the **1D Projector** tool to visualize the HDP.
4. Calculate the work function from the HDP and chemical potential.

Build the surface configuration

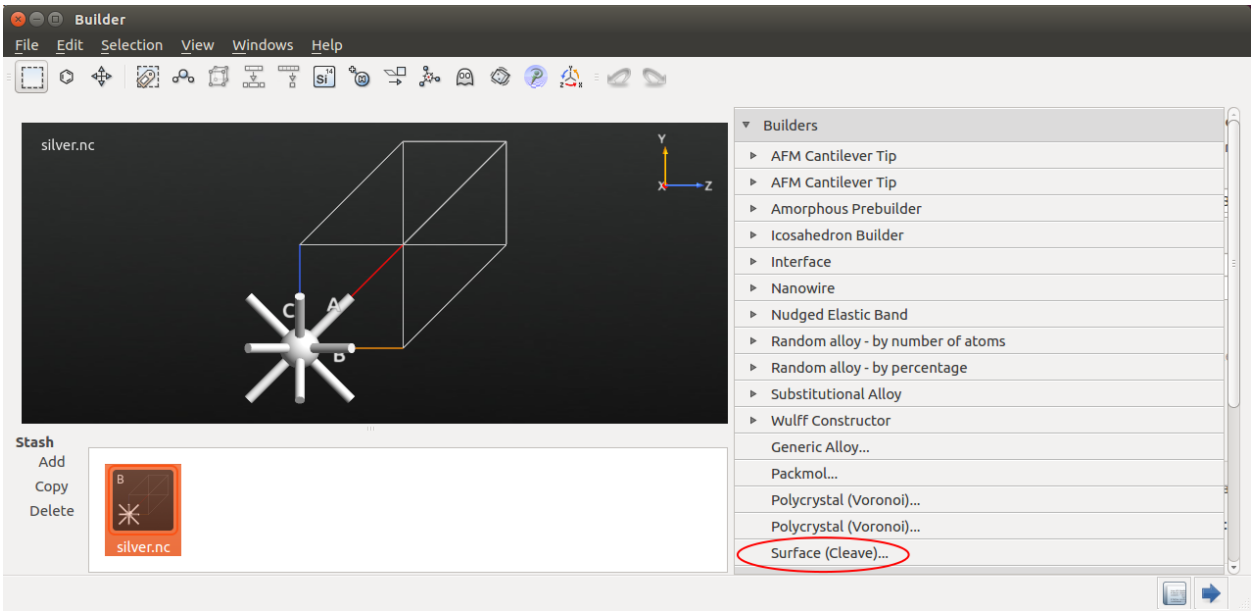
You will first need to cleave a silver bulk configuration along the (100) direction. To this end, you will use a silver bulk optimized at the LDA level using FHI pseudo-potentials and a SingleZetaPolarized basis set.

Create a new **QuantumATK Project**, and download a HDF5 file containing the optimized structure: `silver.hdf5`. Save it in the **Project Folder** such that its contents become visible on the **LabFloor**. You will notice that the silver silver band structure was also calculated – this will prove useful later on. You can also obtain the script used for the calculations: `silver.py`.

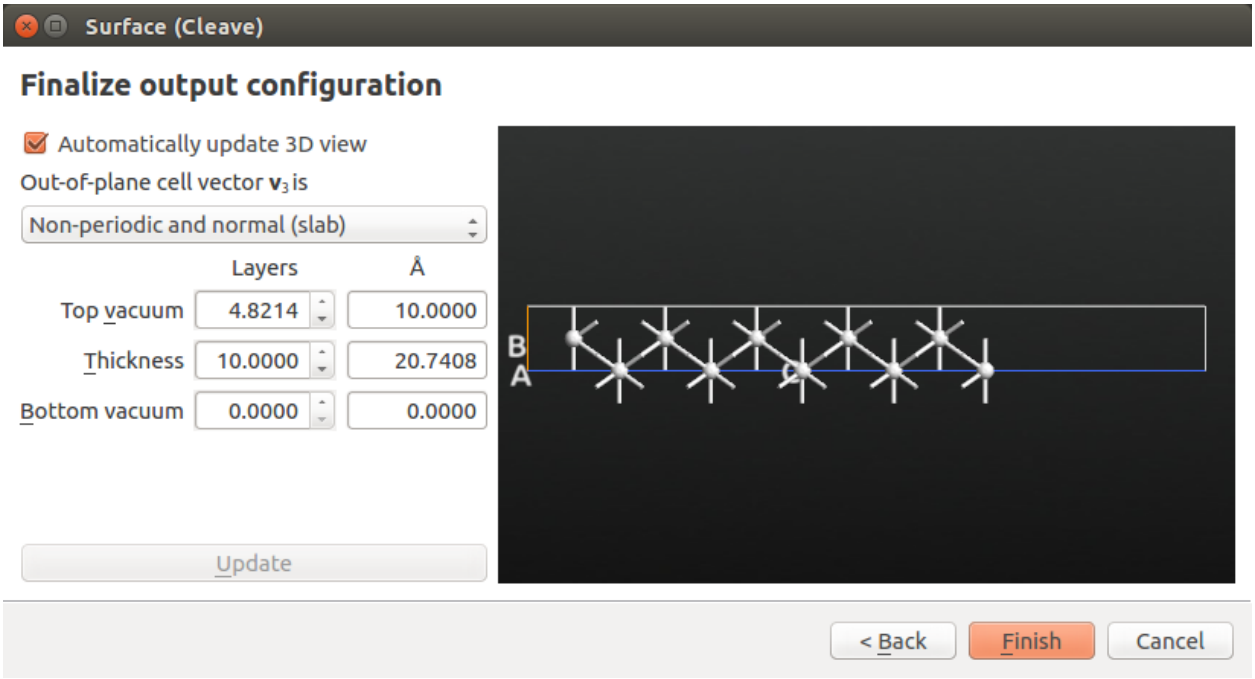


Tip: You may refer to the tutorials *Geometry optimization: CO/Pd(100)* and *Calculate the band structure of a crystal* for more information on how to perform a bulk geometry optimization and a band structure calculation.

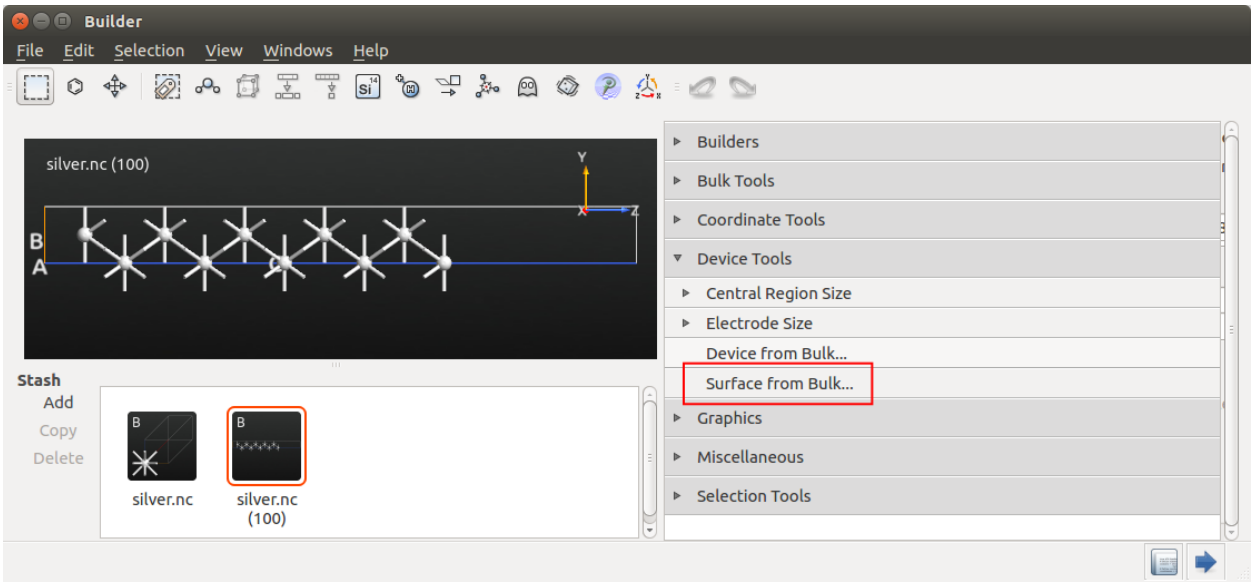
From the LabFloor, transfer the relaxed silver bulk configuration (object id `gID002`) to the Builder and confirm that the optimized LDA-SZP lattice constant is 4.148 Å. Then select the configuration and open the *Builders → Surface (Cleave)* tool.



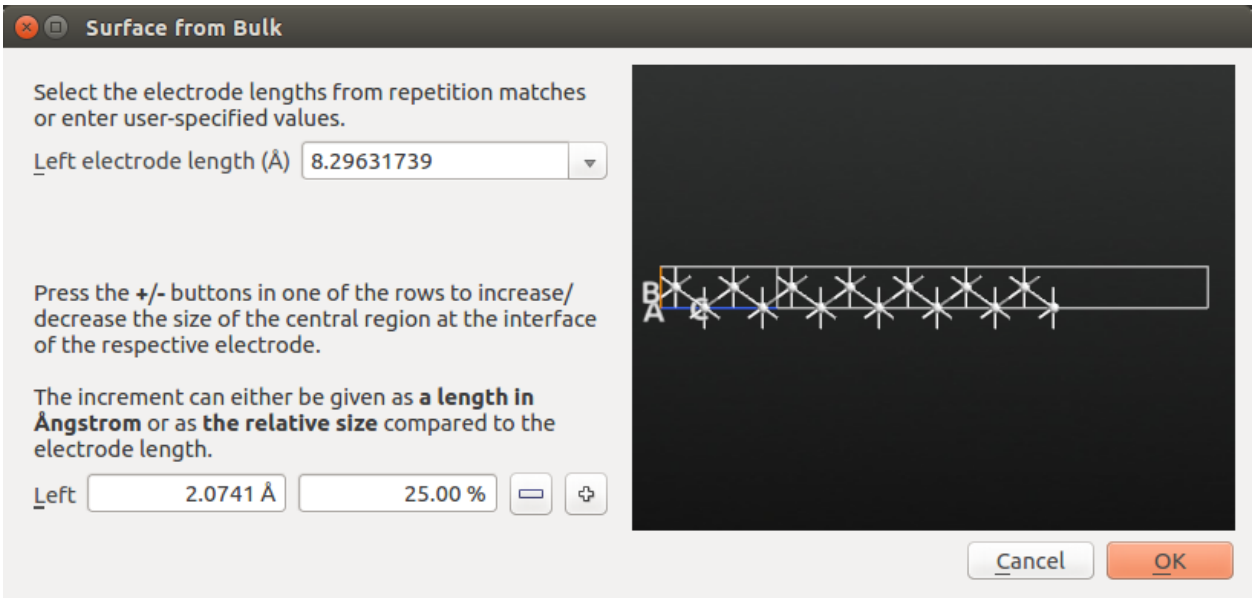
This tool allows you to cleave the silver crystal along the (100) direction: Click *Next* twice, and choose the Non-periodic and normal (slab) output configuration with 10 metal layers, as illustrated below.



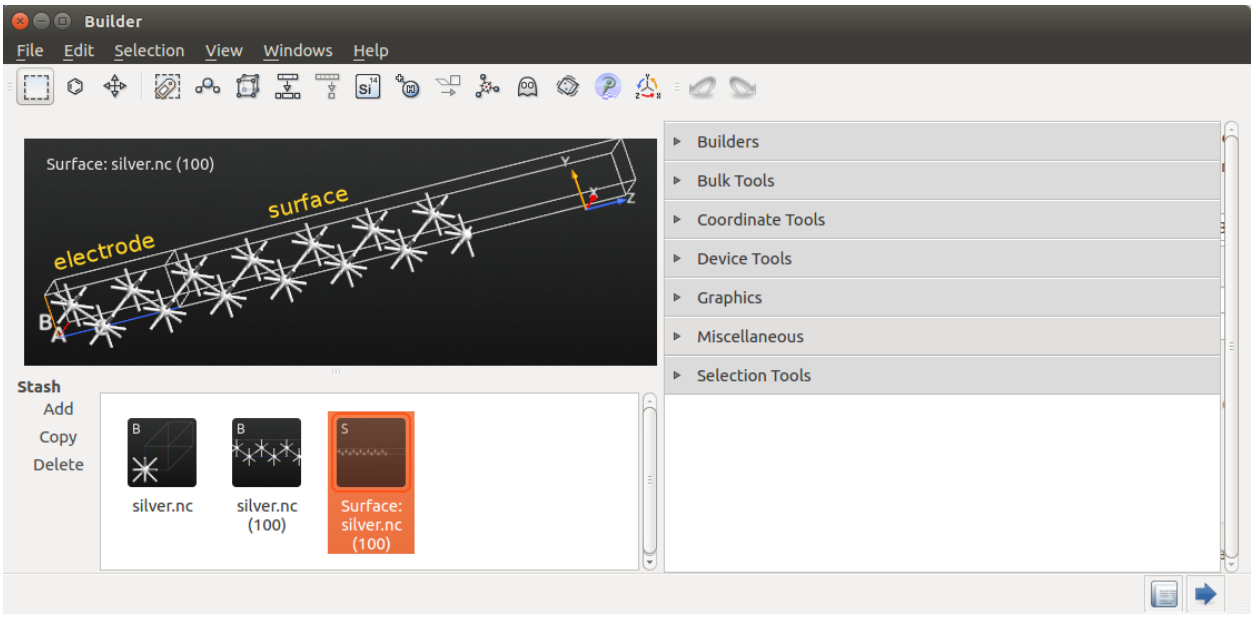
The item *silver.hdf5 (100)* is now in the **Stash**. Select it and use the *Device Tools* → *Surface From Bulk* to create the surface configuration needed for the Greens function surface calculations.



The **Surface from Bulk** widget allows you to select the size of both the electrode and the surface (here denoted the central region). The default electrode length of 8.3 Å will do just fine. Note that you can also change the size if the central region attached to the electrode.



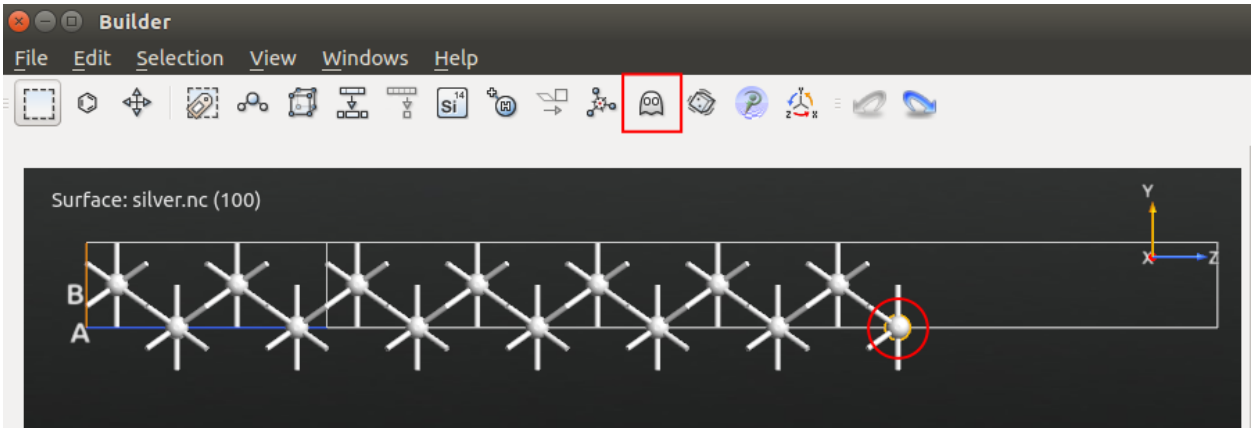
Click **OK** to add the configuration to the Stash. The name of the new item is automatically prefixed *Surface*.



Ghost atom

As discussed in the tutorial *Computing the work function of a metal surface using ghost atoms*, accurate work function calculations with a localized basis set require one or more ghost atoms immediately above the surface. This is most easily accomplished by turning the top-most atom into a ghost atom.

Select the top-most atom as shown in the image below, and click the icon in the top panel bar.



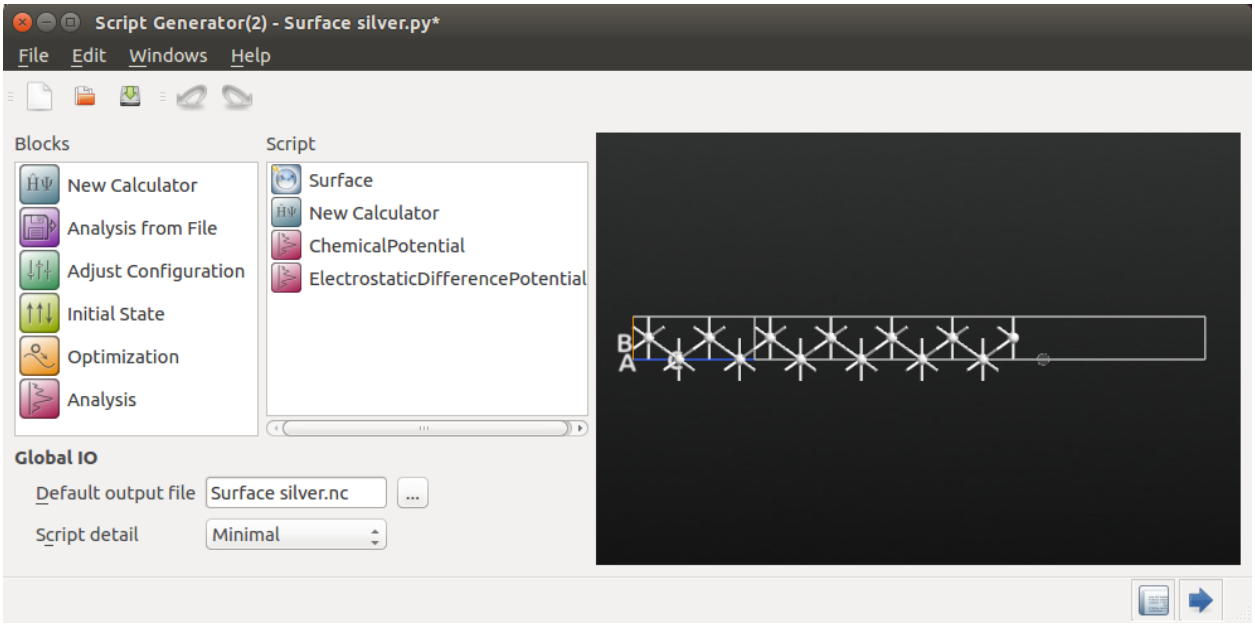
The atom is now designated a ghost atom, i.e. a basis set center with no nucleus.

Transfer the surface configuration to the Script Generator using the icon, and proceed to the next section to set up and run an QuantumATK script for the Greens function surface calculation.

Calculations

The **Script Generator** is a graphical interface for writing an QuantumATK Python script. Add the following blocks to the script by double-clicking them:

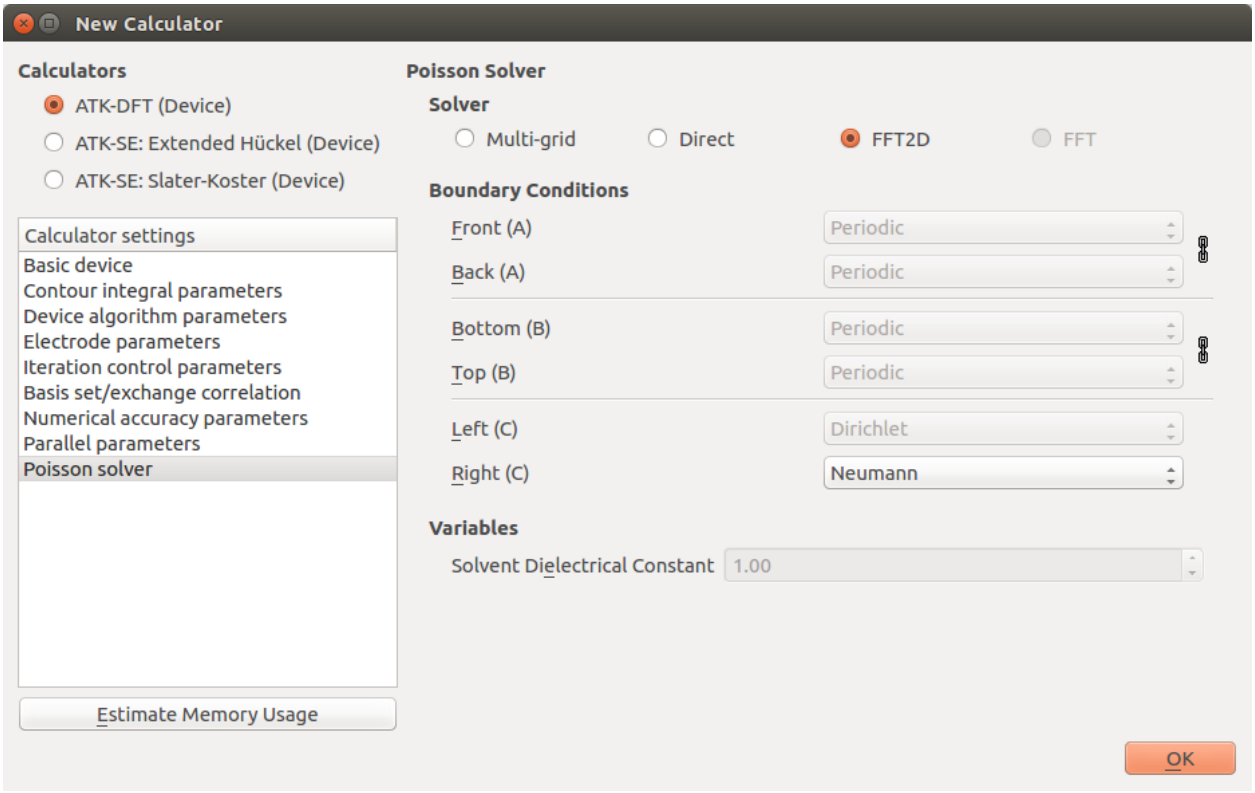
- New Calculator.
- *Analysis* → *ChemicalPotential*.
- *Analysis* → *HartreeDifferencePotential*.



Then double-click the added **New Calculator** block to open it. In the **Basic device** calculator settings, choose LDA exchange-correlation and a 9 x 9 x 100 k-point grid.

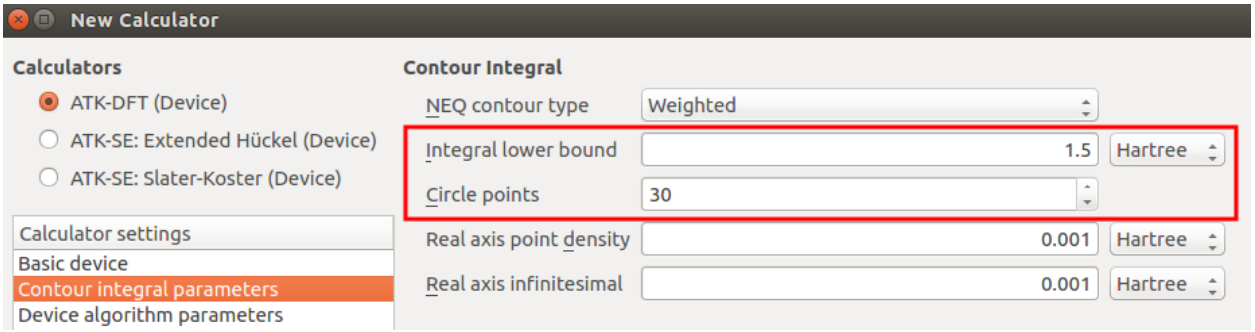
Note: As discussed in detail in the introductory tutorial *Transport calculations with QuantumATK*, it is vital to use a relatively large number of k-points along the C-direction in QuantumATK device calculations, e.g. 100. Importantly, these are only used in the electrode calculation, which is relatively cheap to calculate, and are not used in the main part of the QuantumATK device calculation: The central region is by definition not periodic along C, so it has only a single k-point along C.

Next, navigate to the **Basis set/exchange correlation** settings, and choose the `SingleZetaPolarized` basis set. Lastly, in the **Poisson solver** settings, change the boundary condition on the right-hand C-face to *Neumann*.

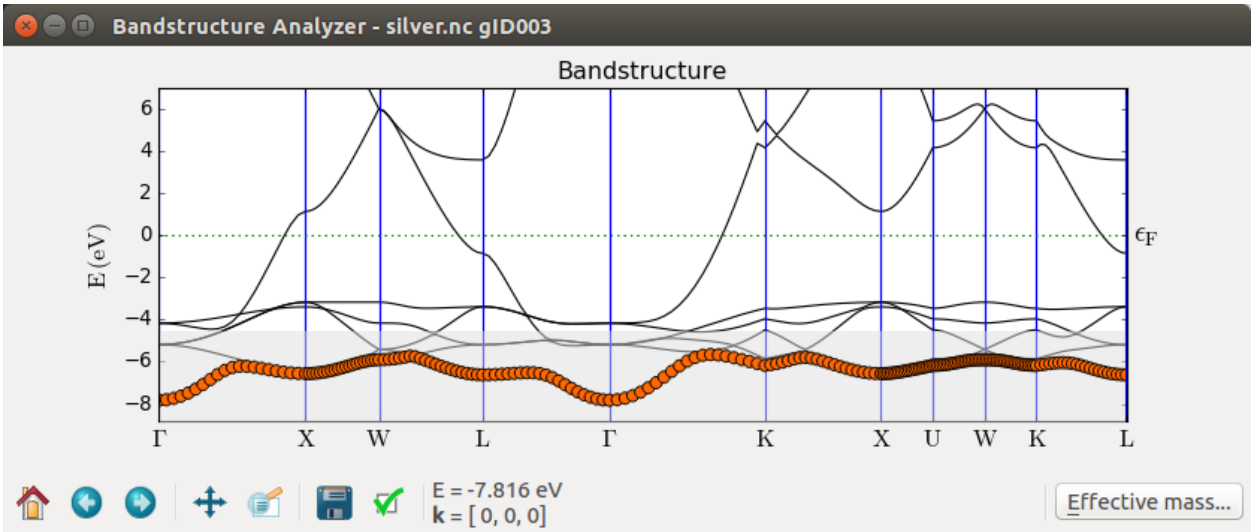


Contour integral

The NEGF method uses a contour integral to evaluate Greens functions. As explained in anothor tutorial (*Finite-bias calculations*), the default values for the settings *Integral lower bound* and *Circle points* may need to be increased if the applied pseudopotentials have deep-lying (semi-core) states.



It is therefore good practice to check the electrode band structure, in order to make sure that the lowest band does not fall outside the lower bound on the contour integral. In the present case, we can use the silver band structure stored in the file `silver.hdf5`, which is illustrated below.



The deepest energy eigenvalue is band is 7.8 eV (0.29 Hartree) below the Fermi level, which is well within the default contour integral energy window (1.5 Hartree below the Fermi level). No need to increase the lower bound, so you should just stick to the default value.

Save the script and run it

Back in the Script Generator main window, change the default output file name `silver_gfs.hdf5` and save the Python script as `silver_gfs.py`. If needed, you can also download the final script: `silver_gfs.py`.

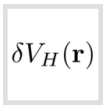
Then execute the script using the **Job Manager** or from a Terminal. The calculation should take about 4 minutes on a laptop.

Analysis

Once the calculation is finished, the HDF5 data file `silver_gfs.hdf5` arrives on the **LabFloor**. It contains the (one-probe) surface configuration with a converged calculator, and the ChemicalPotential and HartreeDifferencePotential (HDP) analysis objects:

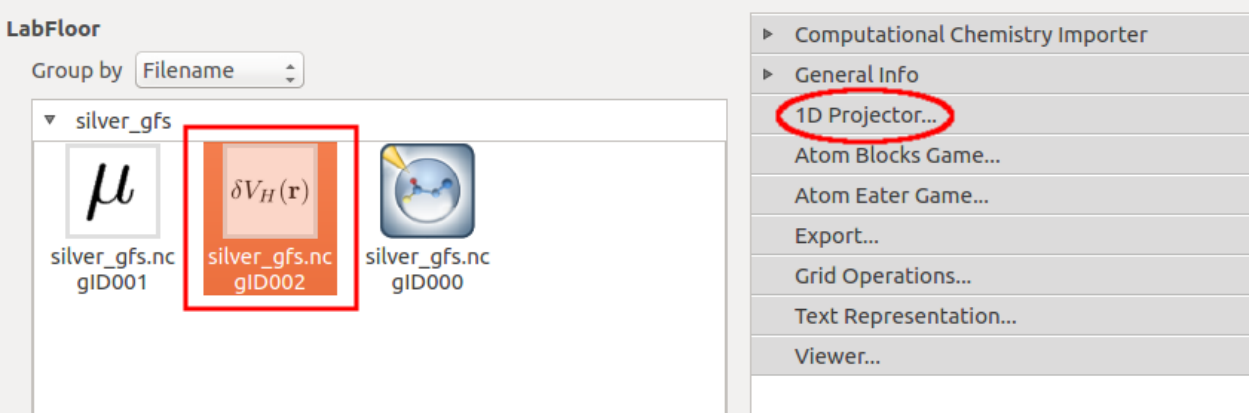
One-probe surface configuration

ChemicalPotential

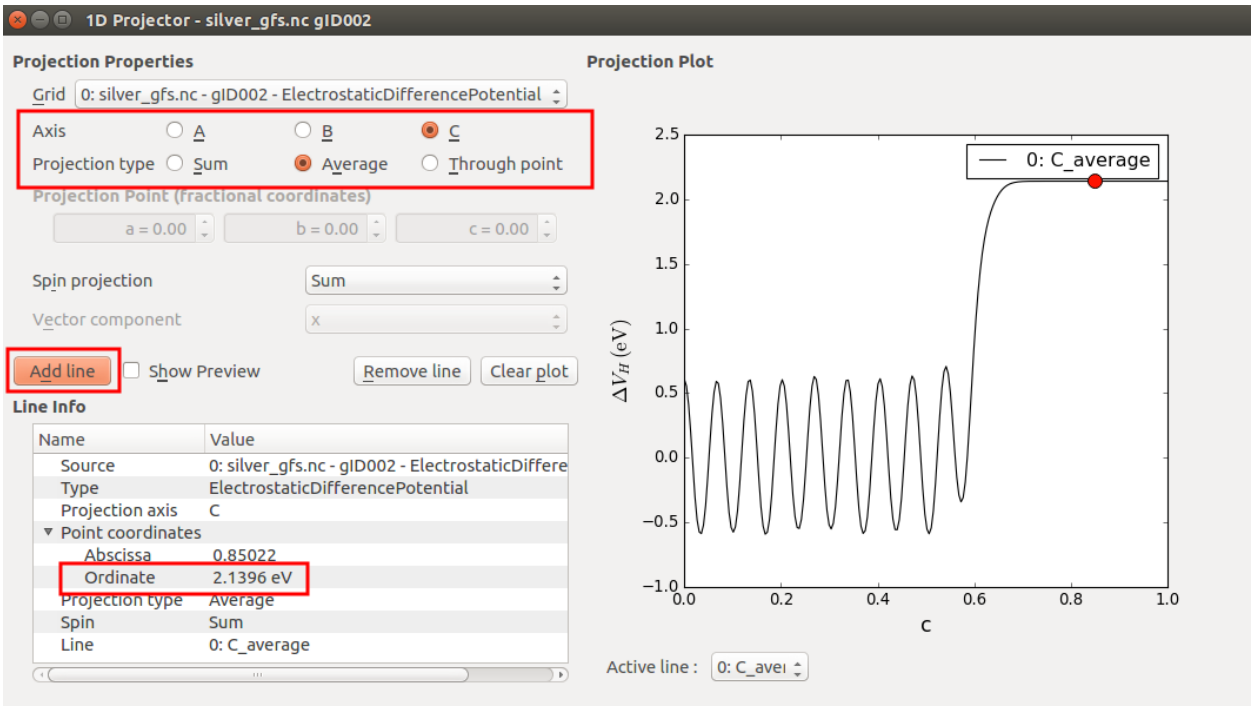


HartreeDifferencePotential

You should first take a look at the Hartree difference potential throughout the surface configuration. Use the mouse to select the HDP item, and then open the **1D Projector** tool from the right-hand plugins panel.



The HDP is represented on a 3D grid, but the 1D Projector allows you to project it onto any unit cell axis. Project the average HDP onto the C-axis in order to get the visualization shown below.

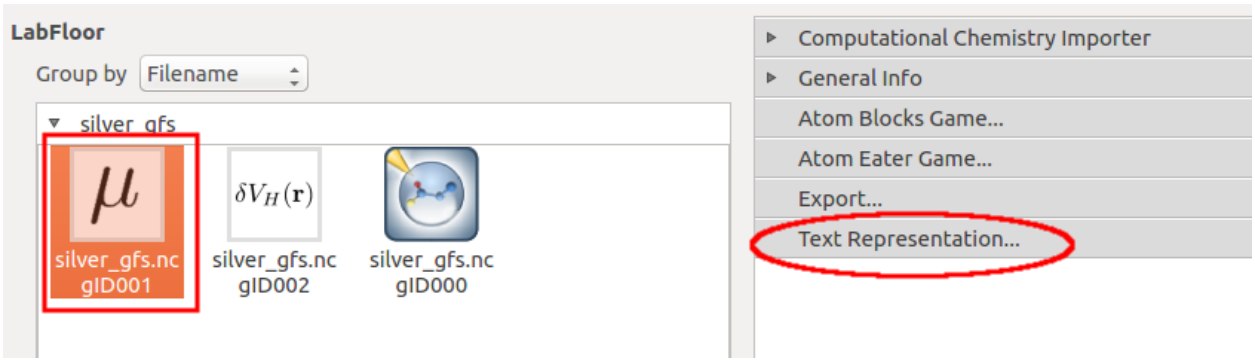


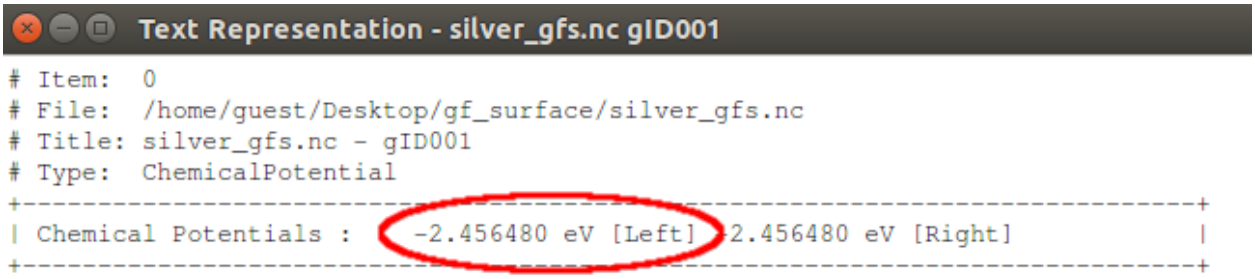
The Ag(100) work function is calculated from the difference between the (constant) Hartree difference potential in the vacuum region and the chemical potential (which in Greens function surface calculations is really the chemical potential of the electrode):

$$\mathrm{WF} = \delta V_{\mathrm{H}}^{\mathrm{c}=1} - \mu$$

By moving the red dot in the projection plot to the far-right end, where c=1, you can read off $\delta V_{\mathrm{H}}^{\mathrm{c}=1}$= +2.14 eV.

Next, use the **Text Representation** plugin to see the value of the chemical potential. You will find that μ= –2.46 eV.





The theoretically predicted work function is therefore 4.6 eV, which is in very good agreement with the experimental value (4.64 eV). Note, however, that the top surface layers were not relaxed. You can easily do this by inserting the
OptimizeGeometry block in the QuantumATK script.

Convergence wrt. metal layers

As a final illustration of the diference between Greens function surface calculations and traditional slab calculations, the figure below shows how the predicted Ag(100) work function converges wrt. the number of silver metal layers. The Greens function calculations are similar to the one done above, but one extra ghost atom is used.

It is quite clear that work functions computed using the Greens function surface model converge much faster than those calculated with the traditional slab model.

If you like, you can reproduce the calculations using the scripts `wf_slab.py` and `wf_surface.py`, and plot the results using `plot.py`.

3.11.3 Polarization

Spontaneous polarization of ferroelectric BaTiO3

Introduction

Ferroelectric (FE) materials have a spontaneous electric polarization that can be reversed by the application of an external electric field. FE materials find applications in capacitors, ferroelectric random access memory (RAM), and more recently in ferroelectric tunnel junction (FTJ) displaying giant electroresistance effects[1][2].

[1] X.Lou, Y. Zheng, and B. Wang, J. Appl. Phys., **111**, 074102, (2012)

[2] A.Chanthbouala, A. Crassous, V. Garcia, K. Bouzehouane, S. Fusil , X. Moya , J. Allibe , B. Dlubak, J. Grollier , S. Xavier , C. Deranlot , A. Moshar , R. Proksch , N. D. Mathur , M. Bibes,and A. Barthélémy, Nature Nanotechnology, **7**, 101, (2012)

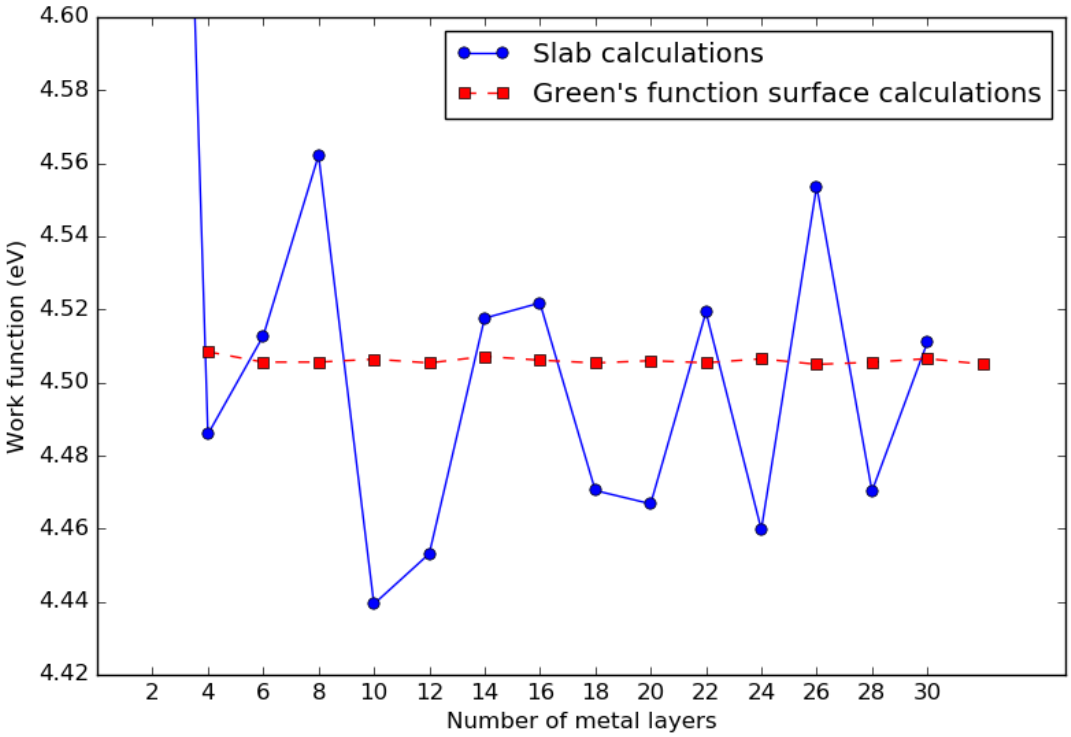


Fig. 3.109: Convergence of calculated Ag(100) work functions wrt. the number of metal layers. Work functions computed using the Greens function surface model converge much faster than those calculated with the traditional slab model. For surface configurations, the number of metal layers includes the two electrode atoms.

One of the most studied FE materials is barium titanate ($BaTiO_3$), which is the topic for this tutorial. Before continuing with the calculations, let us briefly summarize some central theoretical concepts first.

Modern theory of polarization

The theoretical understanding of FE materials is described by the so-called modern theory of polarization[3]. It is common to divide the polarization of a material into electronic and ionic parts. The latter is calculated using a simple classical electrostatic sum of point charges

$$\mathbf{P}_i = \frac{|e|}{\Omega} \sum_\nu Z^\nu_{\mathrm{ion}} \mathbf{r}^\nu,$$

where Z^ν_{ion} and $\mathbf{r}^\nu$ are the valence charge and position vector of atom ν, Ω is the unit cell volume, and the sum runs over all ions in the unit cell.

The electronic contribution to the polarization is obtained as[Page 1453, 3]

$$\mathbf{P}_e = -\frac{2|e|i}{(2\pi)^3} \int_A d\mathbf{k}_\perp \sum_{n=1}^{M} \int_0^{G_\parallel} \langle u_{\mathbf{k},n} | \frac{\partial}{\partial k_\parallel} | u_{\mathbf{k},n} \rangle dk_\parallel,$$

where the sum runs over occupied bands, and where $k_\parallel$ is parallel to the direction of polarization, and $G_\parallel$ is a reciprocal lattice vector in the same direction. The states $|u_{\mathbf{k},n}\rangle$ are the cell-periodic parts of the Bloch functions, $\psi_{\mathbf{k},n}(\mathbf{r}) = u_{n,\mathbf{k}}(\mathbf{r}) e^{i\mathbf{k}\cdot\mathbf{r}}$. The last integral is known as the *Berry phase*. The integral over the perpendicular directions can easily be converged with a few number of k-points. The number of k-points in the parallel direction should be larger, however.

The total polarization is simply the sum of the electronic and ionic contributions,

$$\mathbf{P}_t = \mathbf{P}_i + \mathbf{P}_e.$$

An important finding in Ref.[3] was that the polarization is a multivalued quantity, and in fact forms a lattice. The reason is that the electronic polarization $\mathbf{P}_e$ is determined by the Berry phase, which is only defined modulo 2π. Likewise, the ionic contribution $\mathbf{P}_i$ would attain a different value if all ionic positions were displaced by a lattice constant in either direction.

The polarization is thus a periodic function, and the period is called the polarization quantum, $\mathbf{P}^j_q = \frac{|e|\mathbf{R}^j}{\Omega}$, where $|e|$ is the electronic charge, $\mathbf{R}^j$ is the lattice vector j, and Ω is the unit cell volume.

Given the multivalued nature of the polarization, it is perhaps not surprising that only *differences* in polarization, $\Delta\mathbf{P}$, between two different structures is a well-defined property.

ATK computes and reports the electronic and ionic contributions separately, and also reports the polarization quantum.

Important: Note that the implementation does not work for metallic systems. Usage in 2D systems should be done with thorough testing of the used settings and results.

---

Spontaneous polarization of ferroelectric $BaTiO_3$

The BaTiO3 crystal structure

Barium titanate ($BaTiO_3$) has a tetragonal crystal structure at room temperature, where the unit cell is slightly elongated in the c-direction. An internal stress further shifts the fractional coordinates in the c-direction away from their high symmetry positions. In this tutorial we use the experimental lattice constants and coordinates as obtained from the Inorganic Crystal Structure Database (ICSD) The structure is given in the QuantumATK format below[4]

```
# Set up lattice
lattice = SimpleTetragonal(3.9945*Angstrom, 4.0335*Angstrom)

# Define elements
elements = [Barium, Titanium, Oxygen, Oxygen, Oxygen]

# Define coordinates
fractional_coordinates = [[ 0.      ,  0.      ,  0.      ],
                          [ 0.5     ,  0.5     ,  0.51427 ],
                          [ 0.5     ,  0.5     ,  0.974477],
                          [ 0.5     ,  0.      ,  0.487618],
                          [ 0.      ,  0.5     ,  0.487618]]

# Set up configuration
bulk_configuration = BulkConfiguration(
    bravais_lattice=lattice,
    elements=elements,
    fractional_coordinates=fractional_coordinates
    )
```

Setting up the calculation

You will in this section set up a DFT calculation using the local density approximation (LDA) for the $BaTiO_3$ crystal and calculate the polarization. You will use **QuantumATK** for the calculation, and it is recommended that you go through the Basic QuantumATK Tutorial to be familiar with the basic work flow.

Start up **QuantumATK** and create a new project for this tutorial. Use a new, empty directory. Select the text for the $BaTiO_3$ structure in the python script above and drag it onto the **Script Generator** icon . The tool will interpret the script and open up with the imported geometry

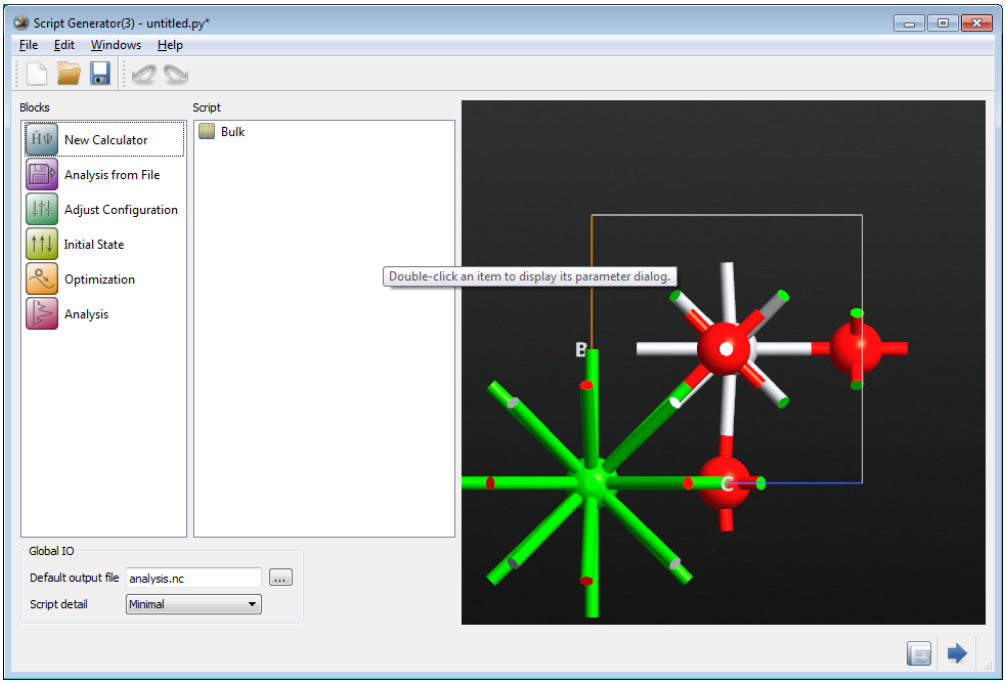
---

Tip: Alternatively you can save the script to a file in the project directory and drag and drop the file to the Script Generator from the **QuantumATK** main window.

Next do the following steps:

- Change the Default output file to `BaTiO3_lda.hdf5`.
- Add a **New Calculator**.

[4] H.Megaw, Acta Crystallographica, **15**, 972, (1962)



•Add *Analysis* → *Polarization*.

Now double-click the **New Calculator** block in the Script panel to open the calculator widget.

Set the k-point sampling to 5x5x5; the other default settings are fine.

The next step is to adjust the settings for the polarization analysis. Double-click the **Polarization** block.

Increase the number of k-points on the diagonal to 20. This is the number of k-points along the lines of integration and needs to be relatively high. You should always check for convergence by comparing calculations with different numbers of k-points. The other k-points with values of 5 correspond to the number of transverse k-points used for averaging over the Brillouin zone. The polarization values converge relatively fast with respect to the number of transverse k-points and we thus use the default value.

You have now finished the script setup. Save the script as BaTiO3_lda.py. Send the script to the **Job Manager** and run the job. After a few minutes the calculation has finished and you can inspect the results.

Analyzing the results

To inspect the calculated polarization reported in the log file, scroll down to the end of the log file and you will find a report as shown below.

```
+-------------------------------------------------------------------------------+
| Polarization                                                                  |

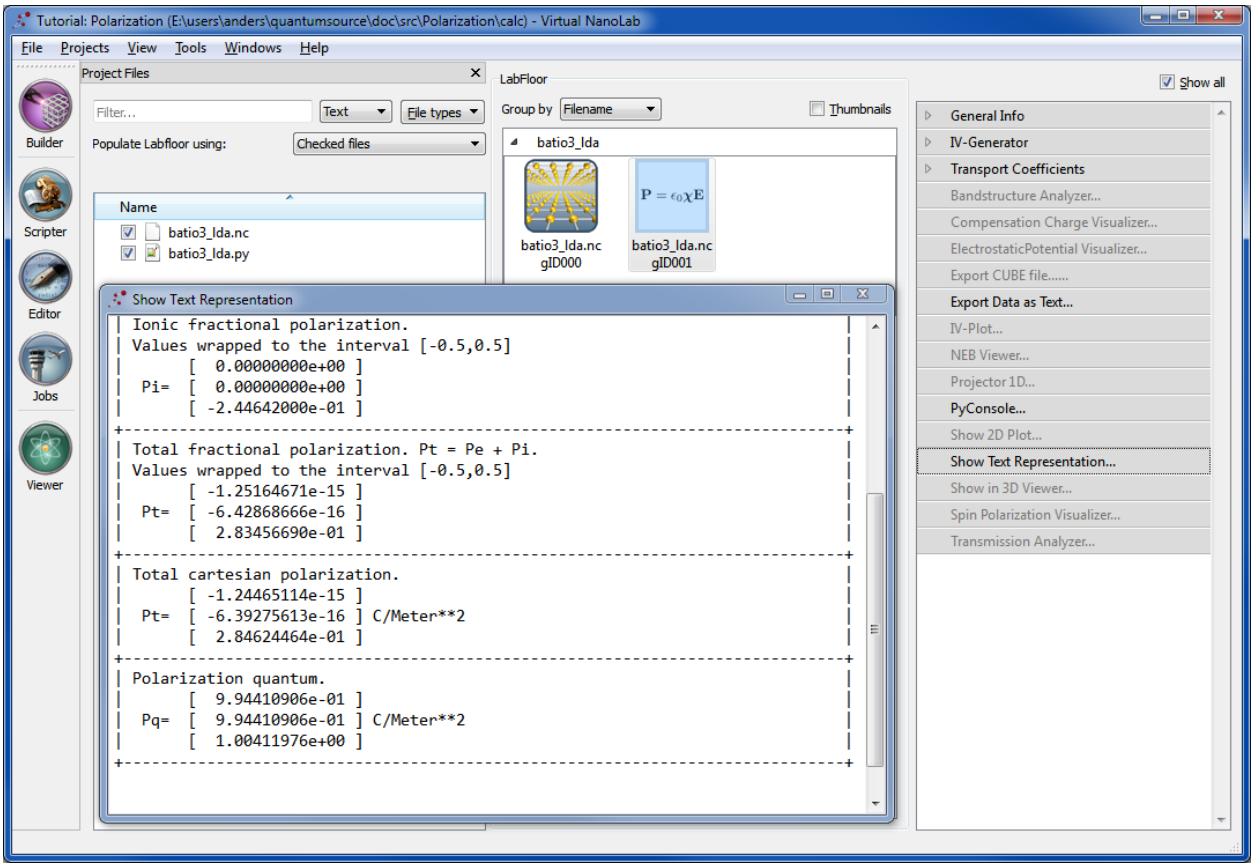
|  Pq=  [  9.94410906e-01 ] C/Meter**2                                         |
|       [  1.00411976e+00 ]                                                    |
+------------------------------------------------------------------------------+
```

Tip: The results can also be inspected by selecting the polarization object in the file BaTiO3_lda.hdf5 on the **LabFloor** and clicking **Show Text Representation**



Notes

The output contains five calculated quantities:

•First, the electronic fractional polarization $\mathbf{P}_e$ is calculated from the Berry phase obtained from the occupied bands, as described in *Modern theory of polarization*. The three values correspond to the x, y, and z directions.

•The second quantity $\mathbf{P}_i$ is the purely ionic fractional polarization $\mathbf{P}_i = \sum_j Z_j^{ion} \tau_j$, where Z_j^{ion} and τ_j are the valence charge and fractional coordinate of of atom j.

•The third quantity, $\mathbf{P}_t$, is the total fractional polarization, which is the sum of the electronic and ionic parts. As discussed in *Modern theory of polarization*, the polarization is a multivalued quantity, and therefore all fractional polarizations are wrapped to the interval [-0.5,0.5], which explains the sign change of the polarization in the z-direction. The sum $\mathbf{P}_e(z) + \mathbf{P}_i(z) = -0.717$ is outside the range and is thus wrapped by adding a fractional quantization quantum (equal to 1), i.e. $\mathbf{P}_t(z) = -0.717 + 1 = 0.283$.

•The fourth quantity is the total polarization $\mathbf{P}_t$ in Cartesian coordinates, expressed in units of C/m^2.

•The fifth quantity is the polarization quantum $\mathbf{P}_q$ introduced in *Modern theory of polarization*. It is relevant that $\mathbf{P}_t$ is small compared to $\mathbf{P}_q$.

According to the modern theory of polarization[3], only the difference in polarization between two configurations is a well-defined property. In order to calculate the spontaneous polarization of tetragonal $BaTiO_3$, it is thus necessary to also compute the polarization of the centrosymmetric, undistorted structure given below:

```
# Set up lattice
lattice = SimpleTetragonal(3.9945*Angstrom, 4.0335*Angstrom)
```

(continues on next page)

(continued from previous page)

```
# Define elements
elements = [Barium, Titanium, Oxygen, Oxygen, Oxygen]

# Define coordinates
fractional_coordinates = [[ 0.0    ,  0.      ,  0.  ],
                          [ 0.5    ,  0.5     ,  0.5 ],
                          [ 0.5    ,  0.5     ,  1.0 ],
                          [ 0.5    ,  0.      ,  0.5 ],
                          [ 0.0    ,  0.5     ,  0.5 ]]

# Set up configuration
bulk_configuration = BulkConfiguration(
    bravais_lattice=lattice,
    elements=elements,
    fractional_coordinates=fractional_coordinates
    )
```

You may repeat the above steps to calculate the polarization for this structure. The results are that all polarization components are zero. The spontaneous polarization of tetragonal $BaTiO_3$, thus corresponds to the values reported above for the distorted structure.

The calculated value for the total Cartesian polarization in the z-direction $\mathbf{P}_t(z) = 0.284$ C/m^2 compares well with the experimental value 0.26 C/m^2[5].

3.11.4 Visualize the LUMO state of a water molecule

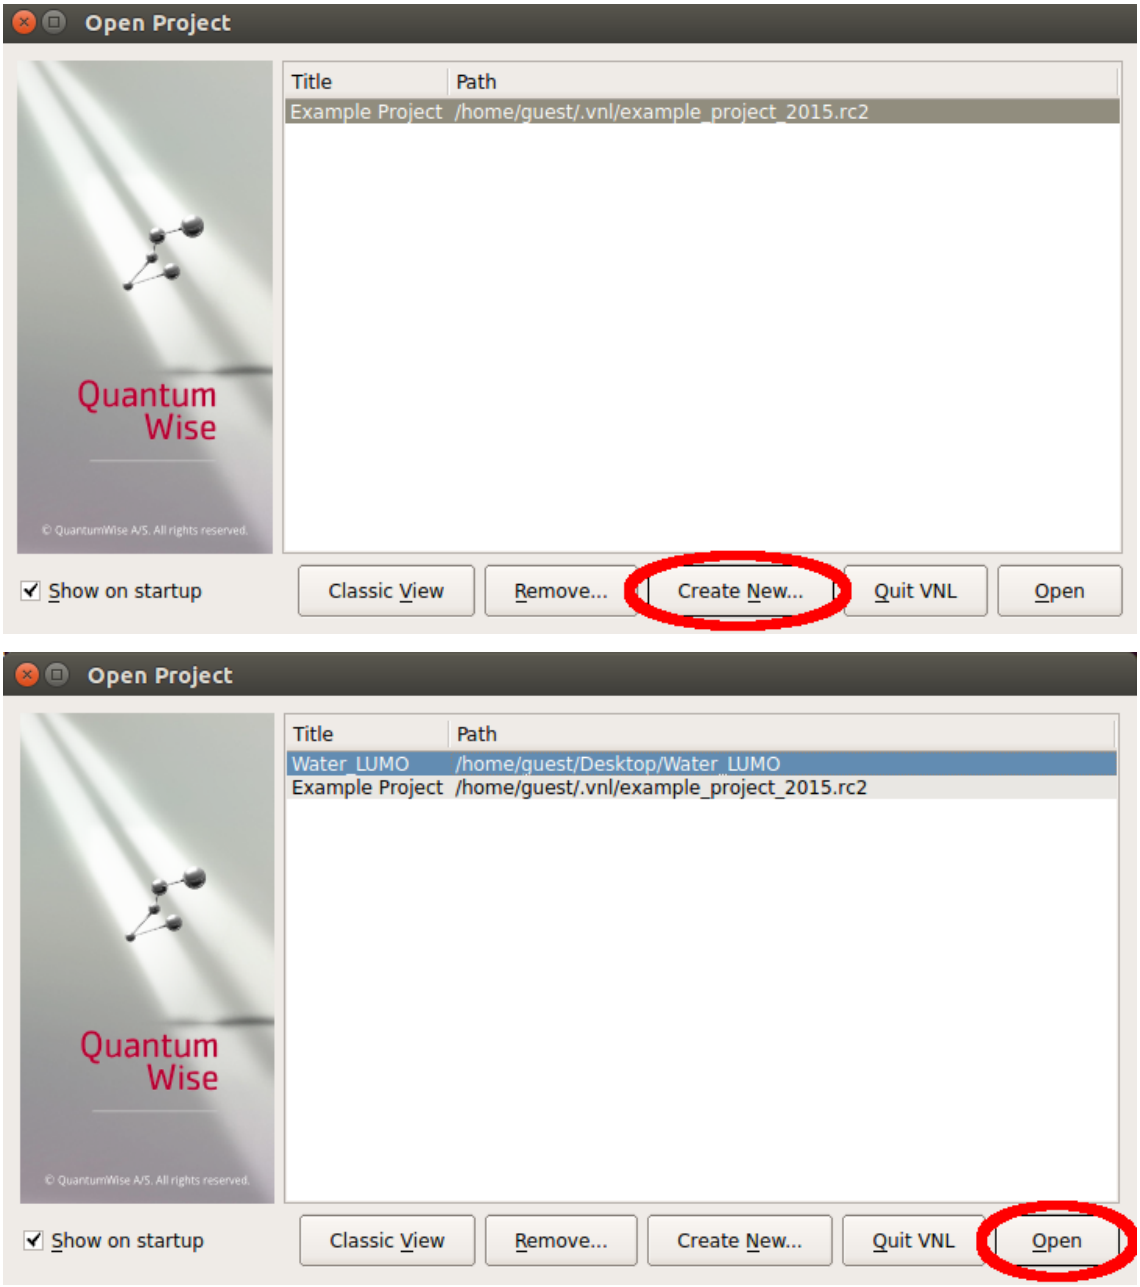
In this tutorial you will learn how to visualize a molecular orbital. As an example, you will visualize the LUMO state of water molecule. Specifically, you will:

- Build the molecule.
- Compute a single point calculation at the DFT level.
- Obtain the molecular eigenenergy spectrum and visualize the LUMO state.

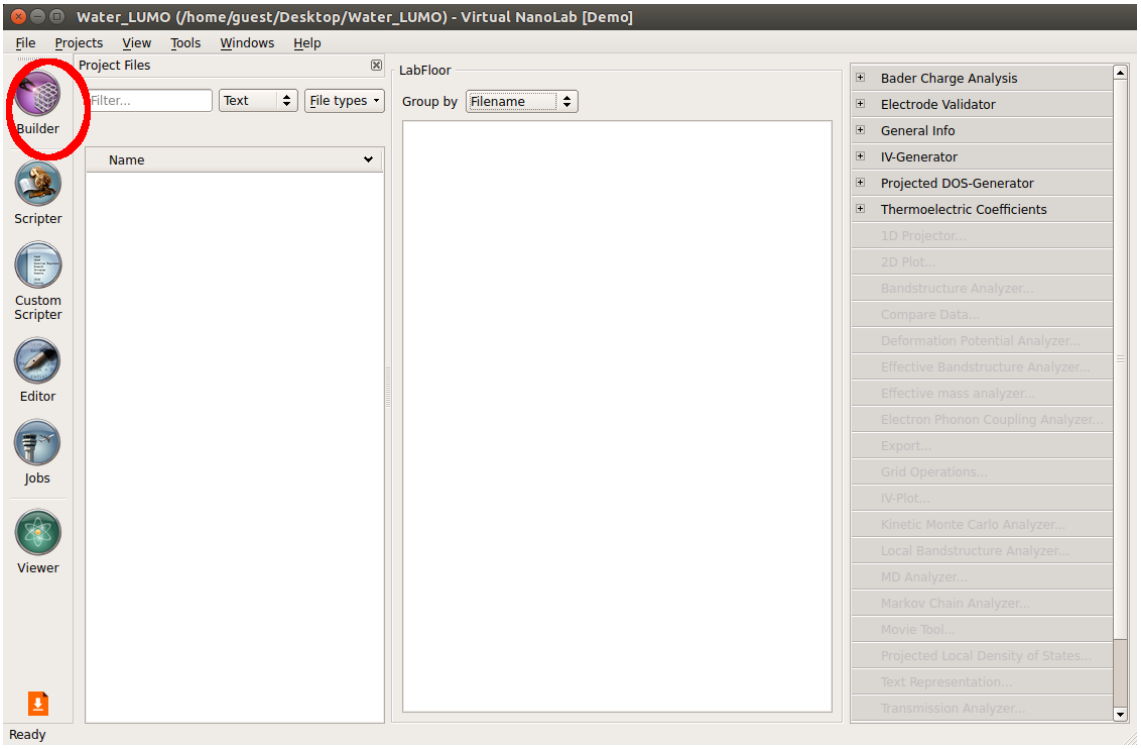
Building the molecule

1. Open **QuantumATK** and create a new project by clicking **Create New**. Give the project a *Title* (here: Water_LUMO), select the folder where data will be stored, then click **OK** and **Open** to start the project.

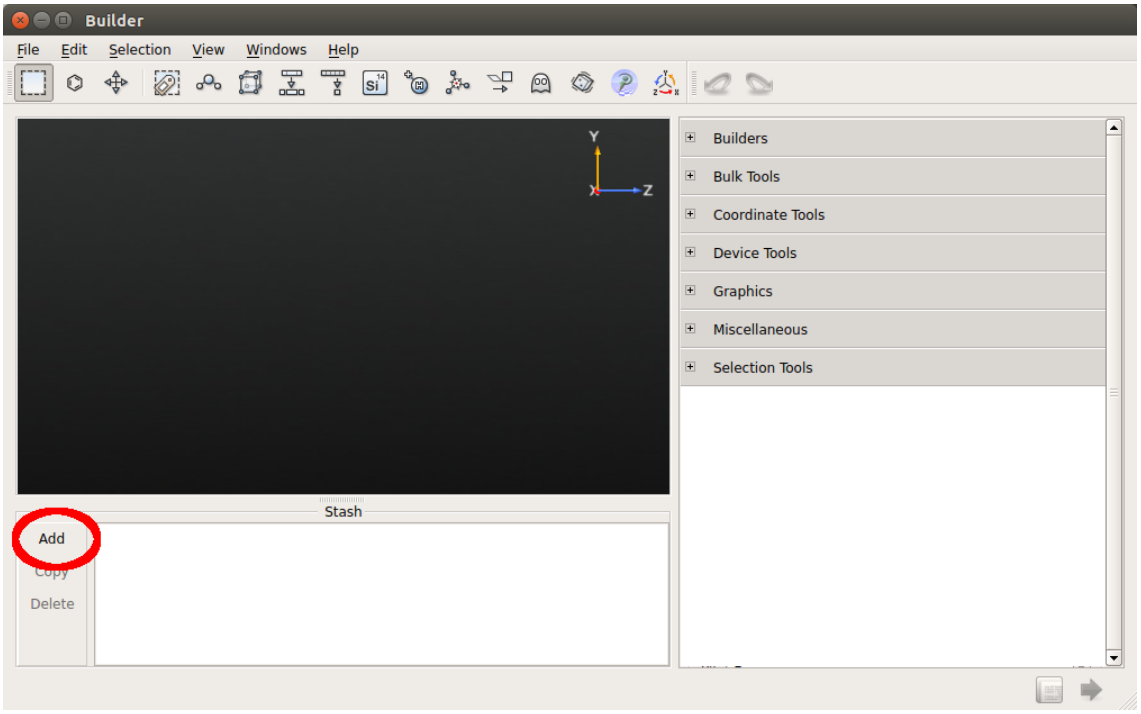
[5] H. Wieder, Phys. Rev. , **99**, 1161, (1955)



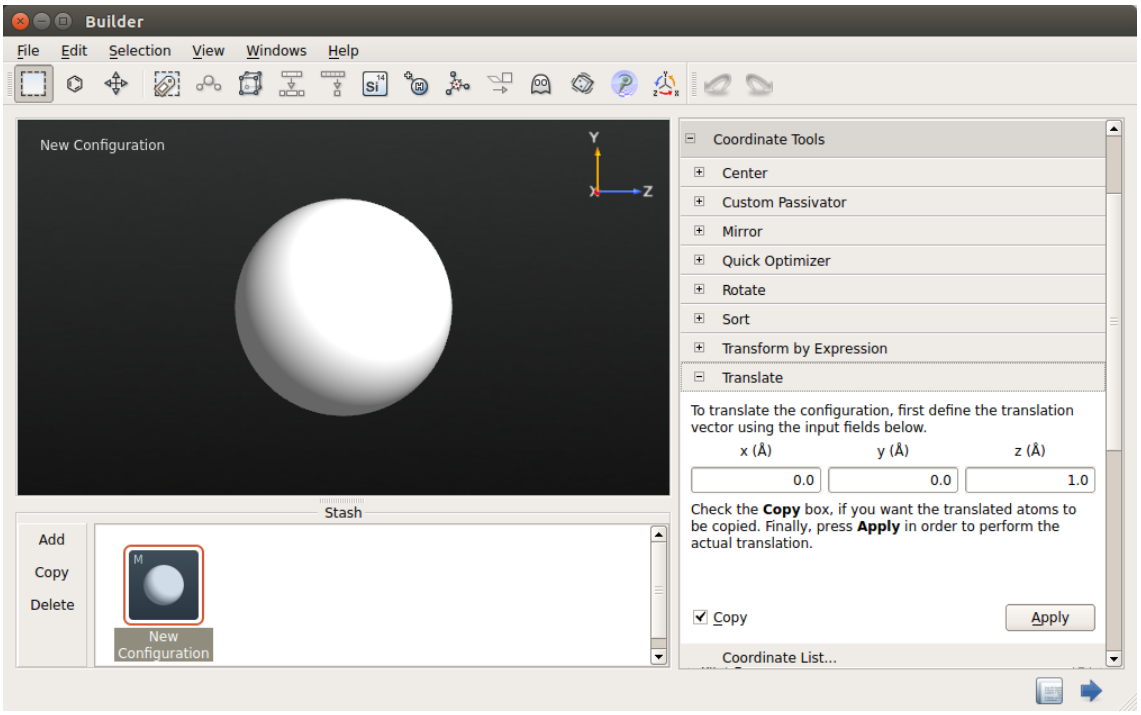
2.In the **QuantumATK** main window, click on the icon to open the **Builder**.



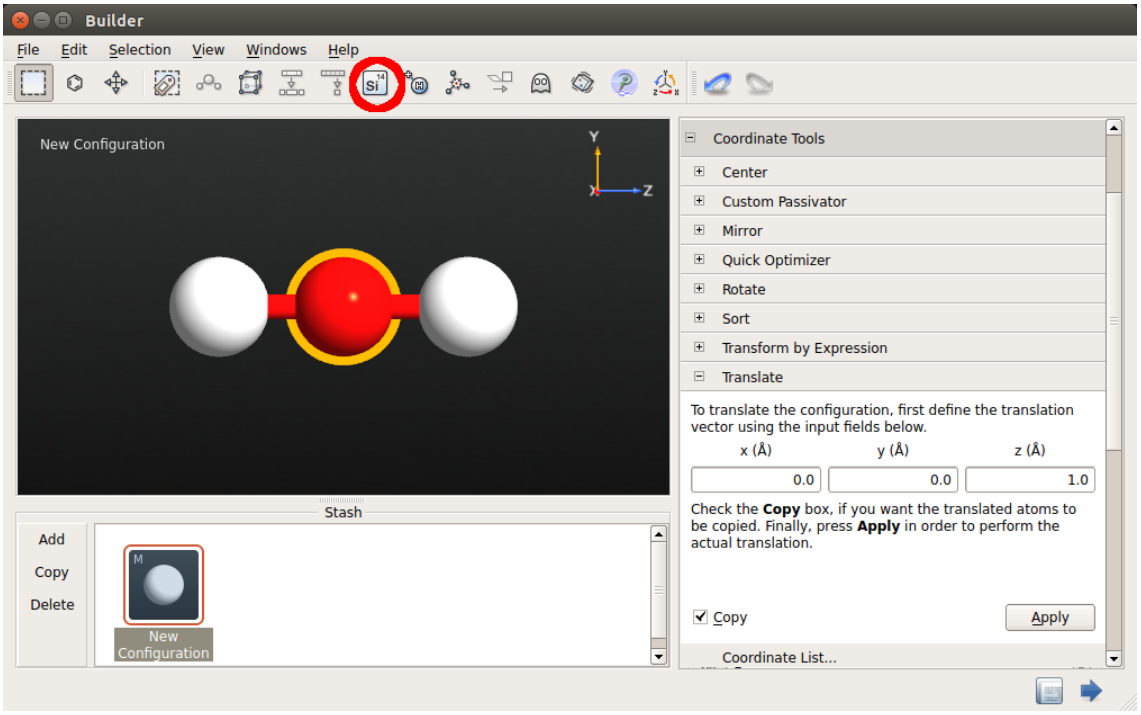
3.Go to the **Stash**, click *Add* → *New Configuration*. A hydrogen atom appears in the **Stash** and in the preview window of the **Builder**.



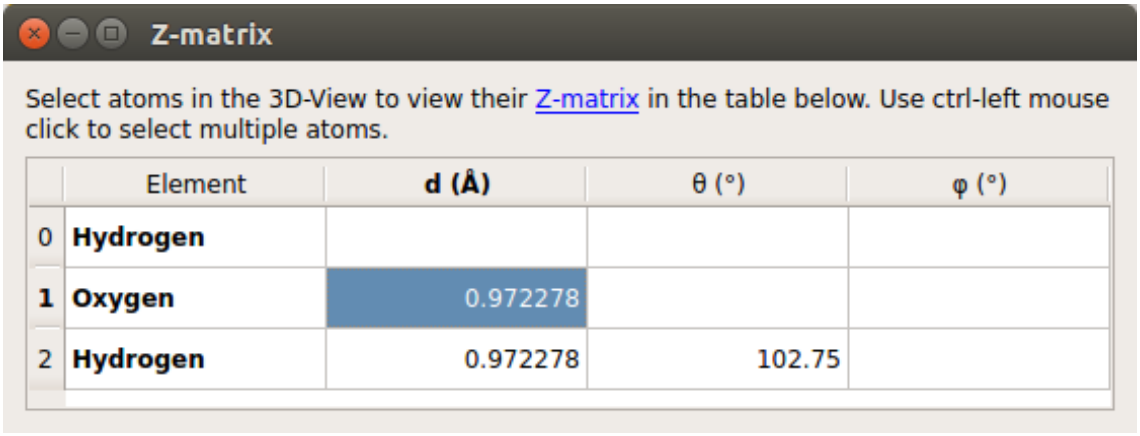
4.Go to *Coordinate Tools* → *Translate*. Tick the **Copy** option, increase Z to 1 Å, and click the **Apply** button twice to add two more hydrogen atoms.

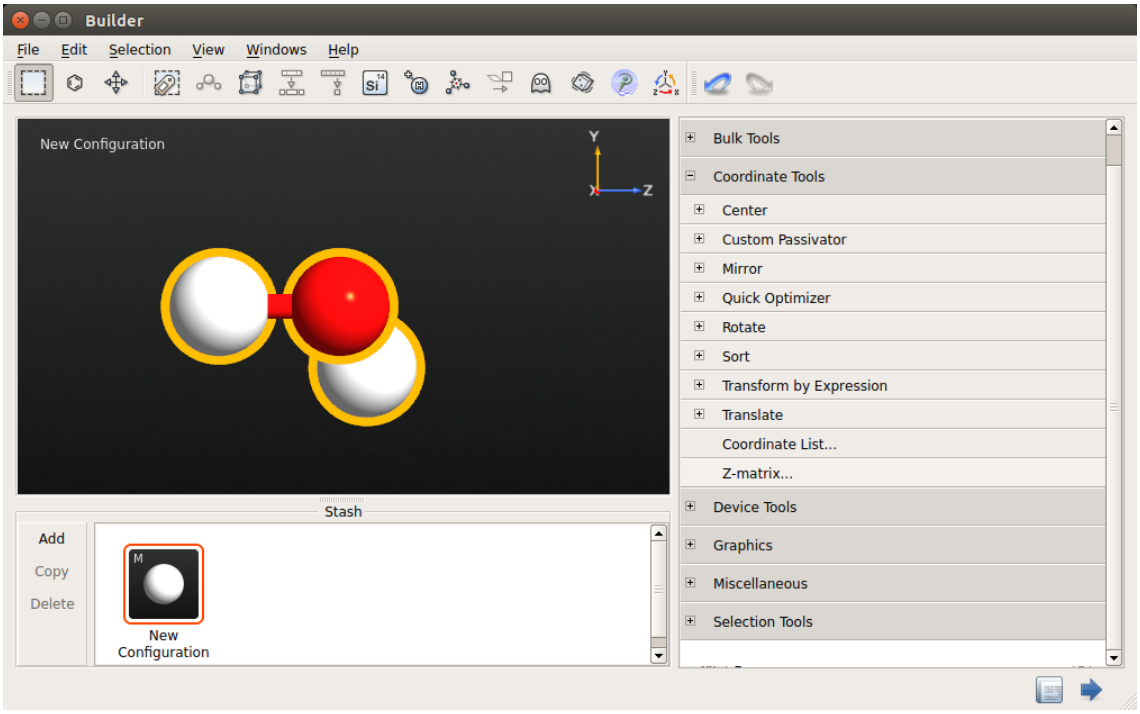


5.Go to the preview window. Press `Ctrl` + `R` to center the view and select the atom in the middle. Use the **Modify Element** tool in the toolbar to change it to oxygen.



6.Select all atoms using the left mouse button while holding down the `Ctrl` button of your keyboard. Go to *Coordinate Tools* → *Z-matrix* and set the distances and angles as shown in the picture below (H-O distance 0.972278 Å and H-O-H angle 102.75 degrees).





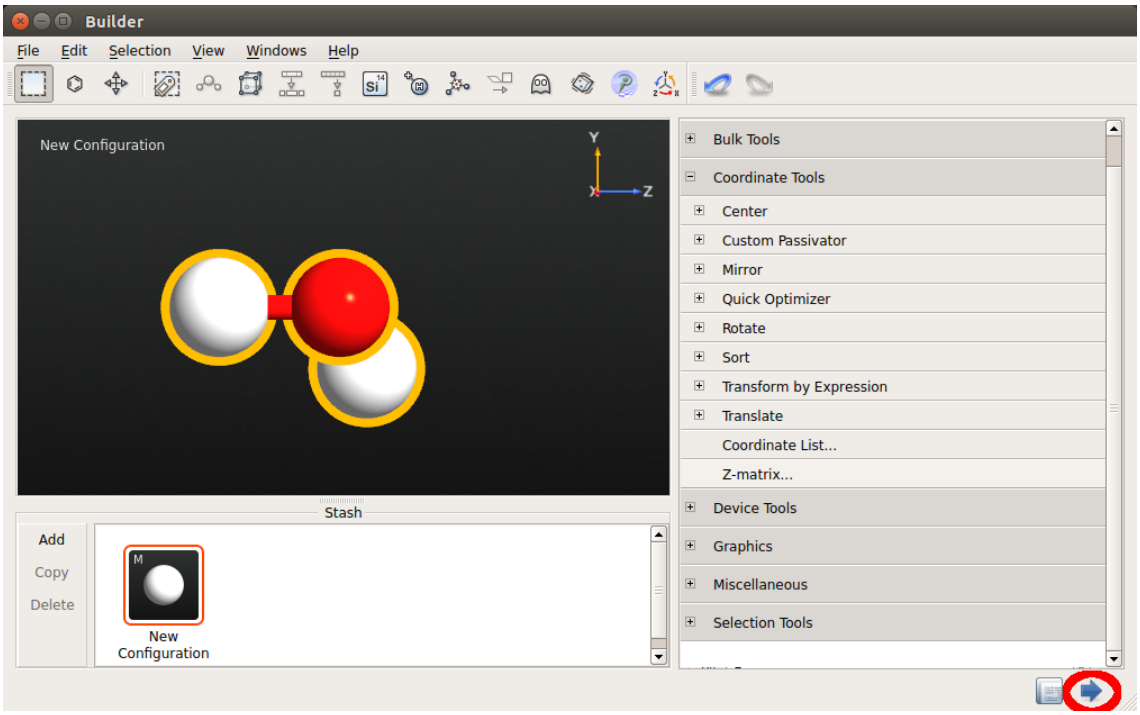
You have now built the water molecule completely from scratch!

Note: It is of course not necessary to always build structures from scratch. Instead, you can import configurations from the **Database**:

- Go to the **Stash** and select *Add* → *From Database*.
- From the menu click *Databases* → *Molecules* and search for *Water* in the search window.
- Select *Water* and add it to **Stash** by double-clicking it or by using the icon.

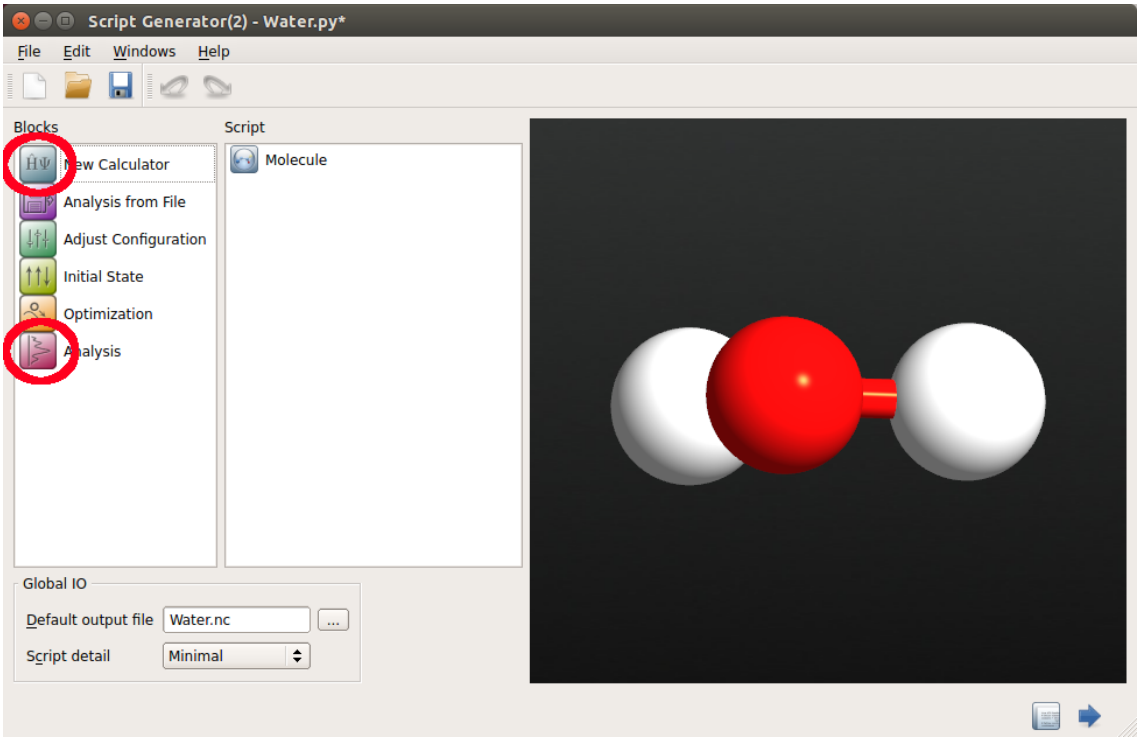
Calculating the LUMO state

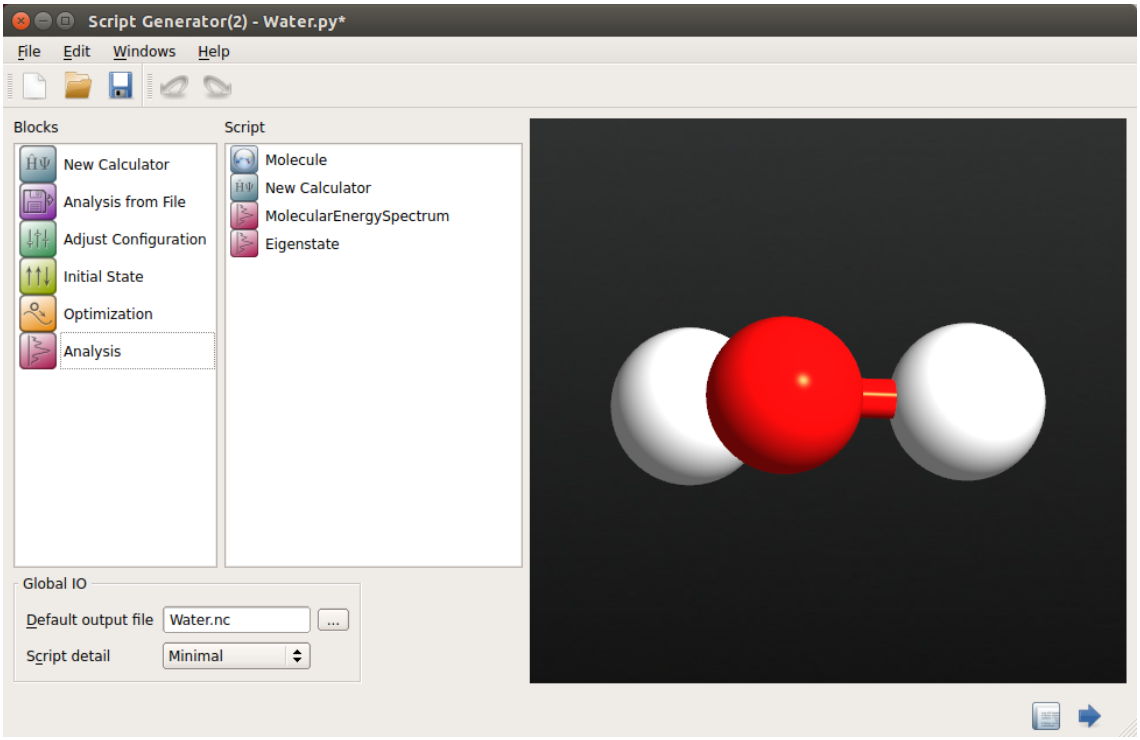
1.In the **Builder**, click in the lower right-hand corner, and select **Script Generator**.



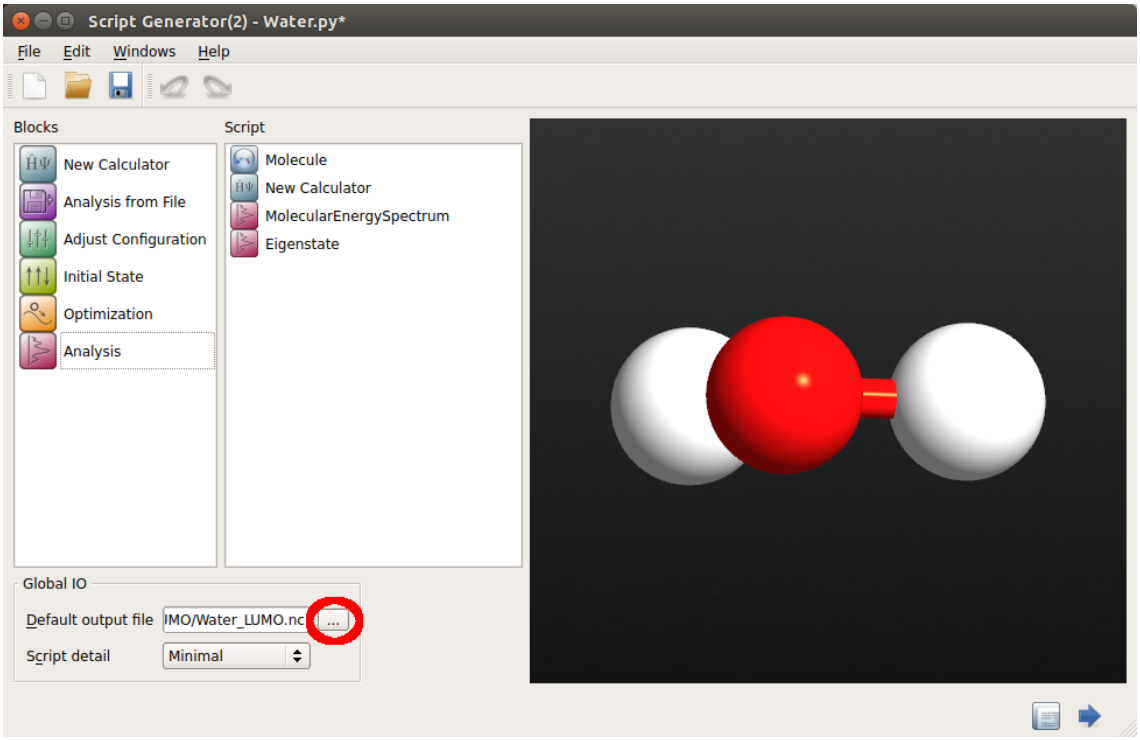
2.In the **Scripter**, add the following blocks by double-clicking the correspoding icons in the Blocks panel on the left-hand side of the screen:

- New Calculator.
- *Analysis → MolecularEnergySpectrum*.
- *Analysis → Eigenstate*.



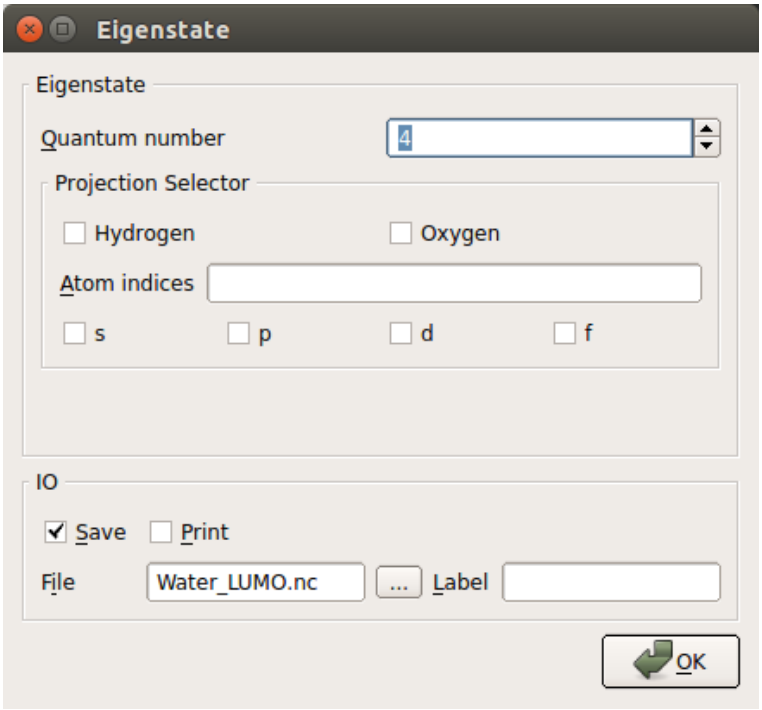


3. Go to **Global IO** and define a suitable location and name of the HDF5 file in which your results will be saved, using the ... button. In this tutorial, save this file as `Water_LUMO.hdf5`:



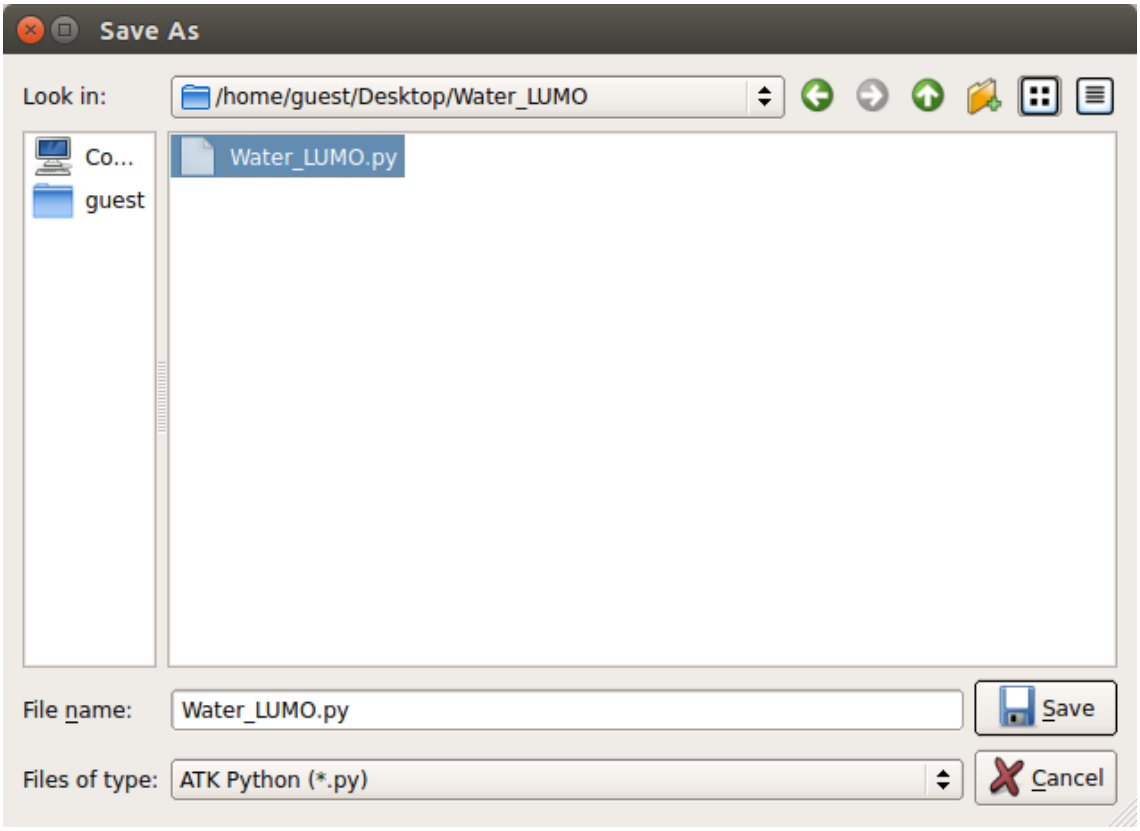
4.Now double-click the **Eigenstate** block and edit it:

•Since water has 8 valence electrons (one for each hydrogen and six for oxygen; the two 1s electrons are part of the pseudocore in QuantumATK), there will be 4 occupied states, each one doubly degenerate since this is a spin-independent calculation. Therefore set the quantum number to 4 for the LUMO state.

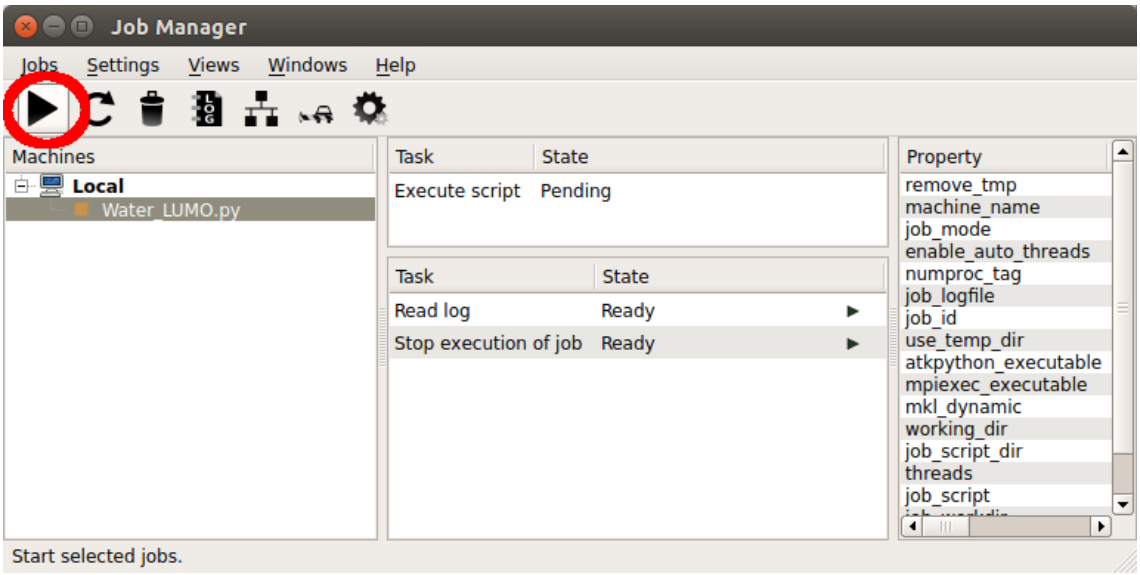


5.To run the calculation, use the **Send to** button to send the script to the **Job Manager**. Then, save the script

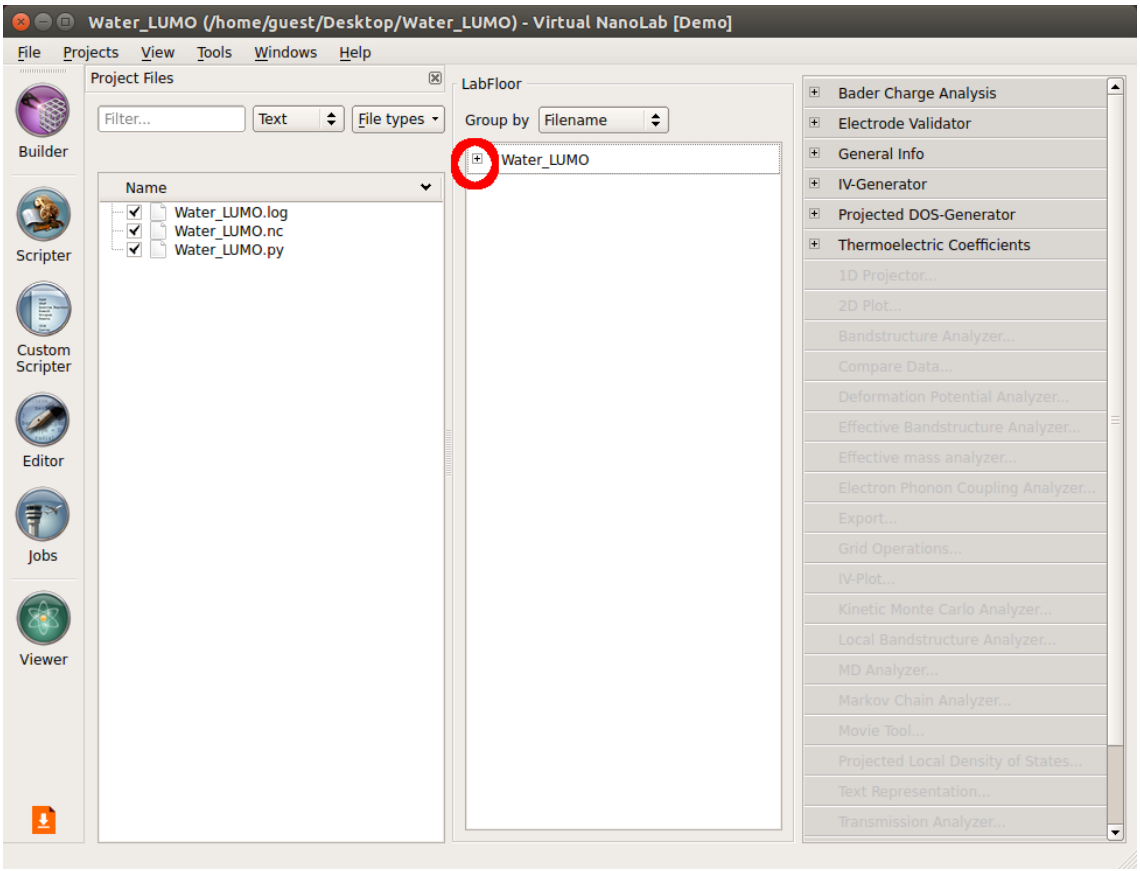
using the window that appears.



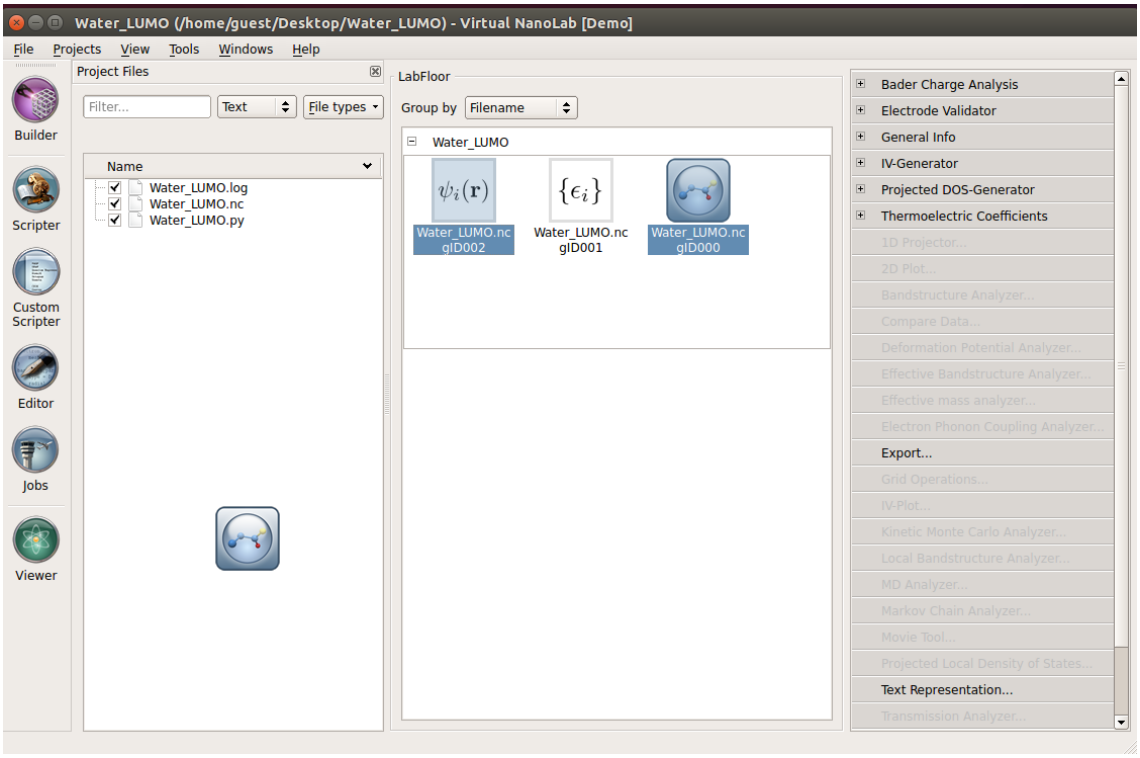
6. When the **Job Manager** opens up, click on the ▶ button to run the script.

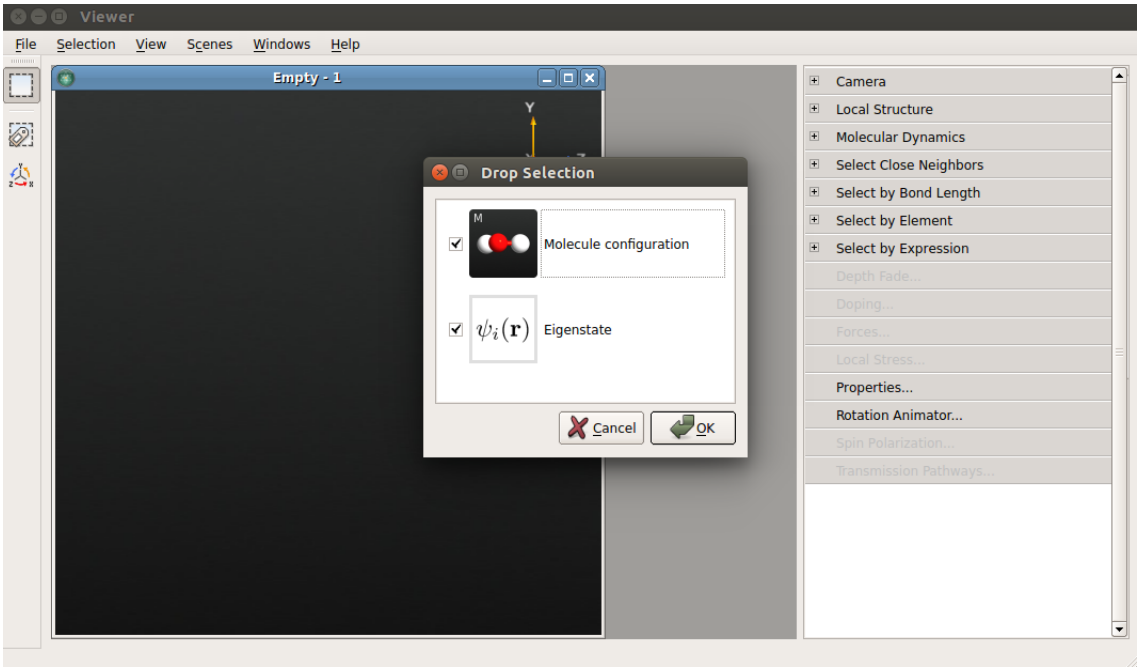


7. When the script has finished (it takes a minute or so), navigate to the **LabFloor** in the **QuantumATK** main window and click on the ⊞ tab of the HDF5 file in order to display the objects contained there.



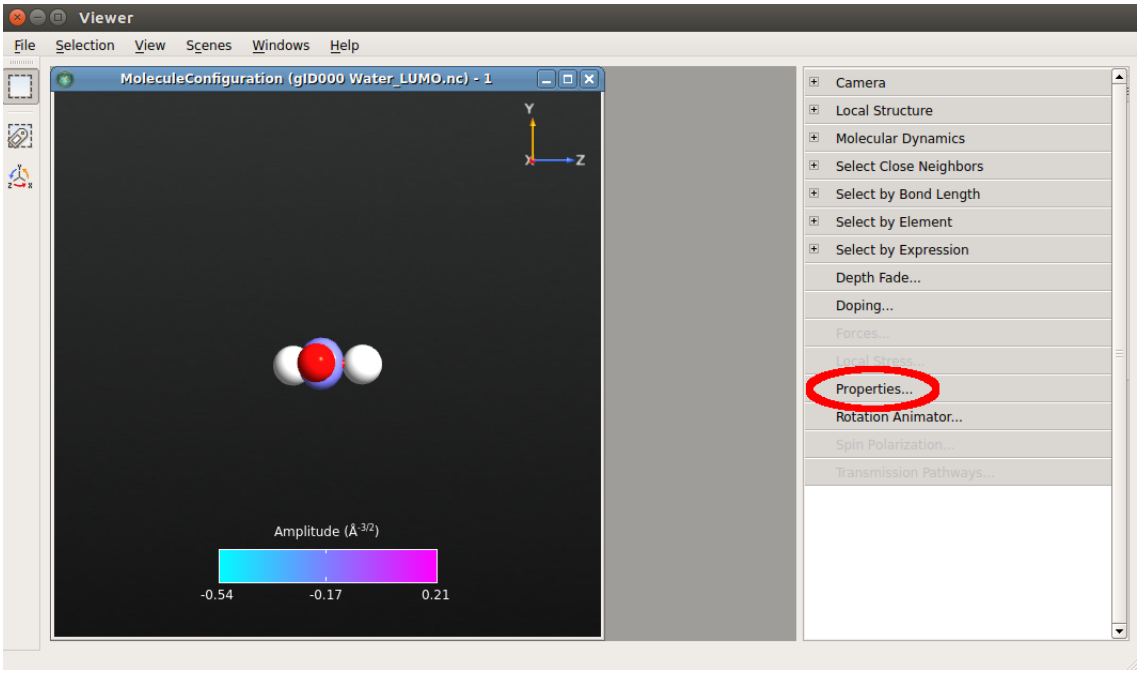
8. Select both the **Eigenstate** and **MolecularConfiguration** objects stored in the HDF5 file (use a left mouse click while holding down `Ctrl`), and drag and drop both objects onto the **Viewer**, which will then pop up.





9.Click **OK**, and click **OK** again in the next window.

10.In the **Viewer**, click on **Properties**.



11. To obtain the same image as below, do as follows:

- Go to *Scene Properties* → *Scene* and uncheck *Compass enabled*.
- Go to *Scene Properties* → *Isosurface* and set the Isovalue to 0.087.
- Go to *Scene Properties* → *Isosurface* and set the Rendering style to Lines.
- Go to *Scene Properties* → *Atoms* and set the atoms and bonds radious to 0.25 and 0.05, respectively.

3.11.5 How to calculate reaction barriers using the Nudged Elastic Band (NEB) method

Version: U-2022.12

Downloads & Links

`Pt_bulk_workflow.hdf5` `relax_initial_and_final_WF.hdf5` `NEB_jump_workflow.hdf5`
`NudgedElasticBand`

In this tutorial you will learn how to calculate reaction barriers for a reaction with well-defined initial and final states. As an example, we will use the diffusion of a single platinum ad-atom on a Pt(100) surface, but the methodology can be used in any situation where you can define an initial and final state of the system, connected by movement of one or more atoms.

Specifically, in this tutorial you will:

- create the Pt(100) surface with a Pt ad-atom;
- create a high-quality initial NEB path and run the NEB calculation;
- analyze the results and compare with the literature.

In order to have more details about the parameters used to construct and optimize the NEB object, you can check the *`NudgedElasticBand`* and `OptimizeNudgedElasticBand` pages in the manual.

Note: The NEB method employed in this tutorial requires the *a priori* knowledge of the initial and final configurations of the reaction, which is often a non-trivial task. However, other powerful methods, such as the Adaptive Kinetic Monte Carlo (AKMC) tool, allow study of reaction barriers in a system from just a user-defined initial state, as shown in *Adaptive Kinetic Monte Carlo Simulation of Pt on Pt(100)*.

Create the initial and final states for the NEB

In this section you will set-up the structure of a Pt ad-atom on Pt(100), which will be used as the initial and final configurations in the NEB calculations. First, you will relax bulk platinum with the chosen calculator to ensure the Pt(100) slab does not have an inherent strain.

Relax bulk platinum

Open **QuantumATK** and create a new project (f.ex. *Pt_Pt100_NEB*). Relax bulk platinum with a **ForceFieldCalculator** using the *EAM_Pt_2004* parameter set and default optimization parameters. This simulation runs in a few seconds. If needed, you can download the workflow for this calculation here: `Pt_bulk_workflow.hdf5`.

Tip: Tutorial on geometry optimization: *Geometry optimization: CO/Pd(100)*

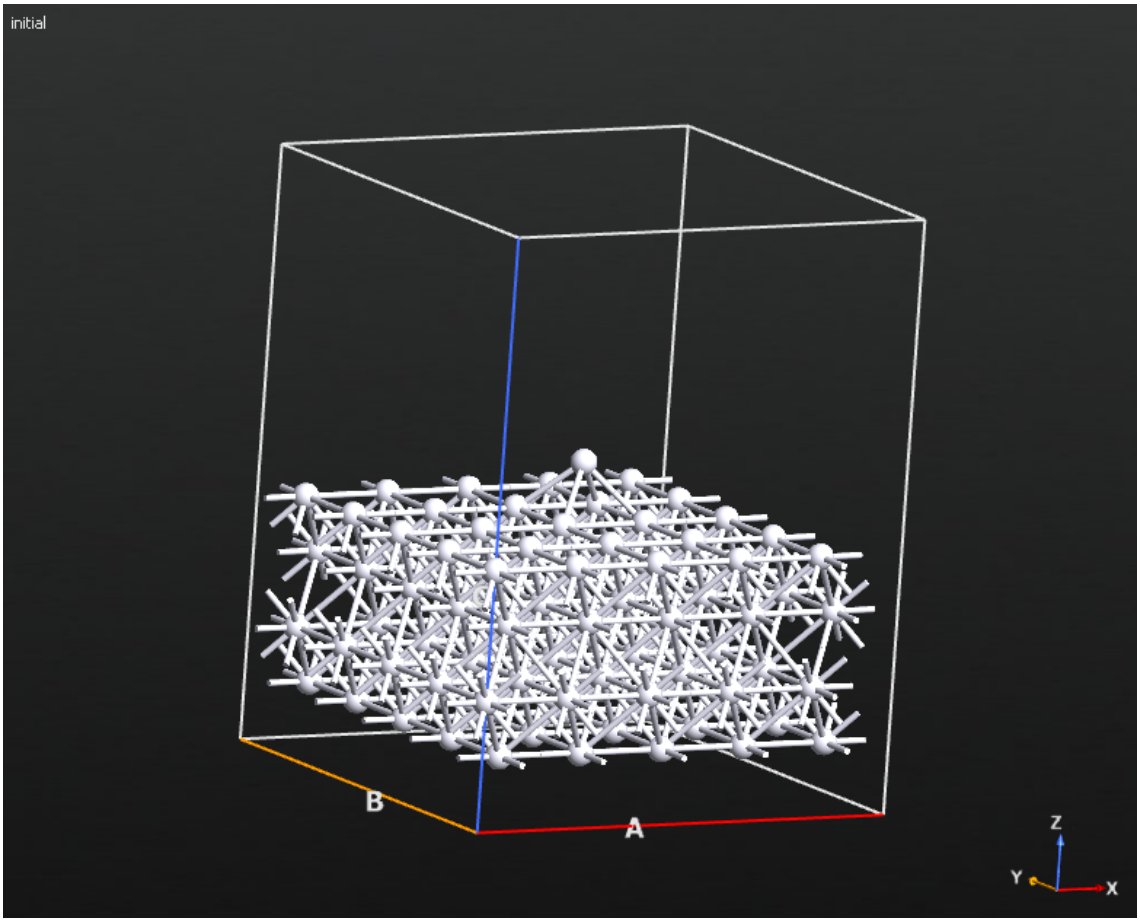
Create the initial state - a Pt(100) surface with a Pt ad-atom

1. Use the relaxed platinum bulk configuration to construct a 5×5 (100) slab with a thickness of 4 layers, using the **Surface (cleave)** tool in the **Builder**.

Tip: A guide to the **Surface (cleave)** tool: *Cleave tool guide*

1. In the **Stash**, right-click with the mouse on the newly created *Pt_bulk (100)* object and select *Duplicate*. Then, right-click on the newly created *Pt_bulk (100) (1)* object and select *Rename* to change its name to *initial*.
2. Click on the icon to open the **Camera** panel, and orient the system along the XY direction.
3. While holding down the `CTRL` button on your keyboard, use the left mouse button to select a square of four Pt atoms of the Pt(100) topmost layer. Then add an extra atom in between them by clicking on the icon.
4. Select the new Pt atom, and click on *Coordinate Tools* → *Translate* in the **Panel plugins** on the right-hand side of the screen. Define the translation vector as 1.6 in the z-direction to move the atom about 1.6 Å above the surface plane.

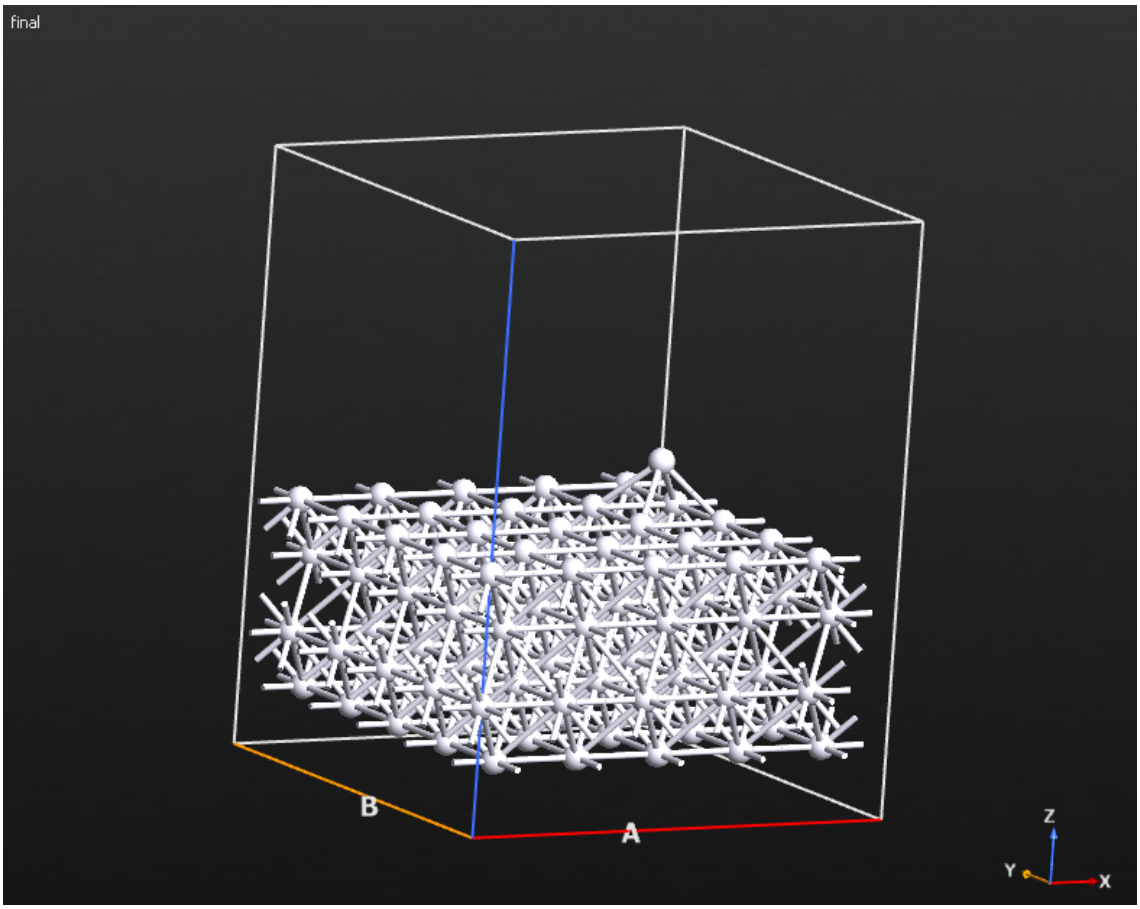
   The structure you have just obtained for a Pt ad-atom on Pt(100) will be used as the initial configuration for the NEB calculations performed in this tutorial.



Create the final configuration for the direct jump process

In this section, you will set up the final configuration for the most direct diffusion process possible for a Pt ad-atom on Pt(100), in which the ad-atom jumps directly between neighboring four-fold hollow sites of the Pt(100) surface.

1. In the **Stash**, duplicate the *initial* configuration and change its name to *final_jump*
2. Select the *final_jump* configuration in the **Stash**, select the Pt ad-atom and click *Coordinate Tools* → *Translate*.
3. In the **Translate Panel**, translate the Pt ad-atom 2.77195 Å in the x or y-direction.
4. In this way, you have obtained the final configuration for the NEB calculation of the direct jump diffusion process.



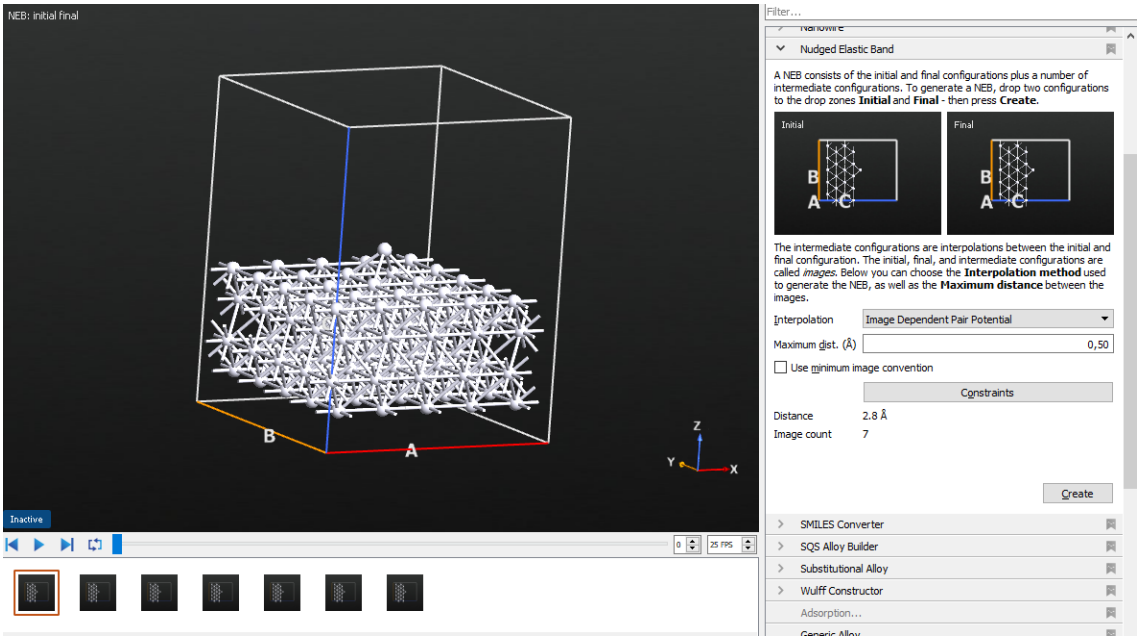
Relax the initial and final configurations

To ensure we get the best possible initial guess for the reaction path between the initial and final states, we need to relax them before constructing it. Use the same calculator as before to relax the two slabs with an ad-atom to a tolerance of *0.01 eV/Å*, and using *FIXED* atom constraints on the bottom two layers of the slab. You can use this workflow to do it: `relax_initial_and_final_WF.hdf5`

Set up and run the NEB calculations

Construct the NEB path

1. In the **Builder**, click on *Builders* → *Nudged Elastic Band* and drag and drop the relaxed *initial* and *final* configurations into the left and right panels.
2. In the **Nudged Elastic Band** panel, set the **Interpolation** to *Image dependent Pair Potential*. Click *Create* to create an object in the **Stash** named *NEB: initial final*, containing the initial and final configurations as well as the interpolated configurations along the reaction path.



Note: The *image dependent pair potential (IDPP)*[1] implemented in **QuantumATK** provides high quality initial guesses for the NEB reaction path compared to the more commonly employed linear interpolation method. For complex reaction paths, the improvement in terms of number of required iterations and speed can be substantial.

Run the NEB calculations

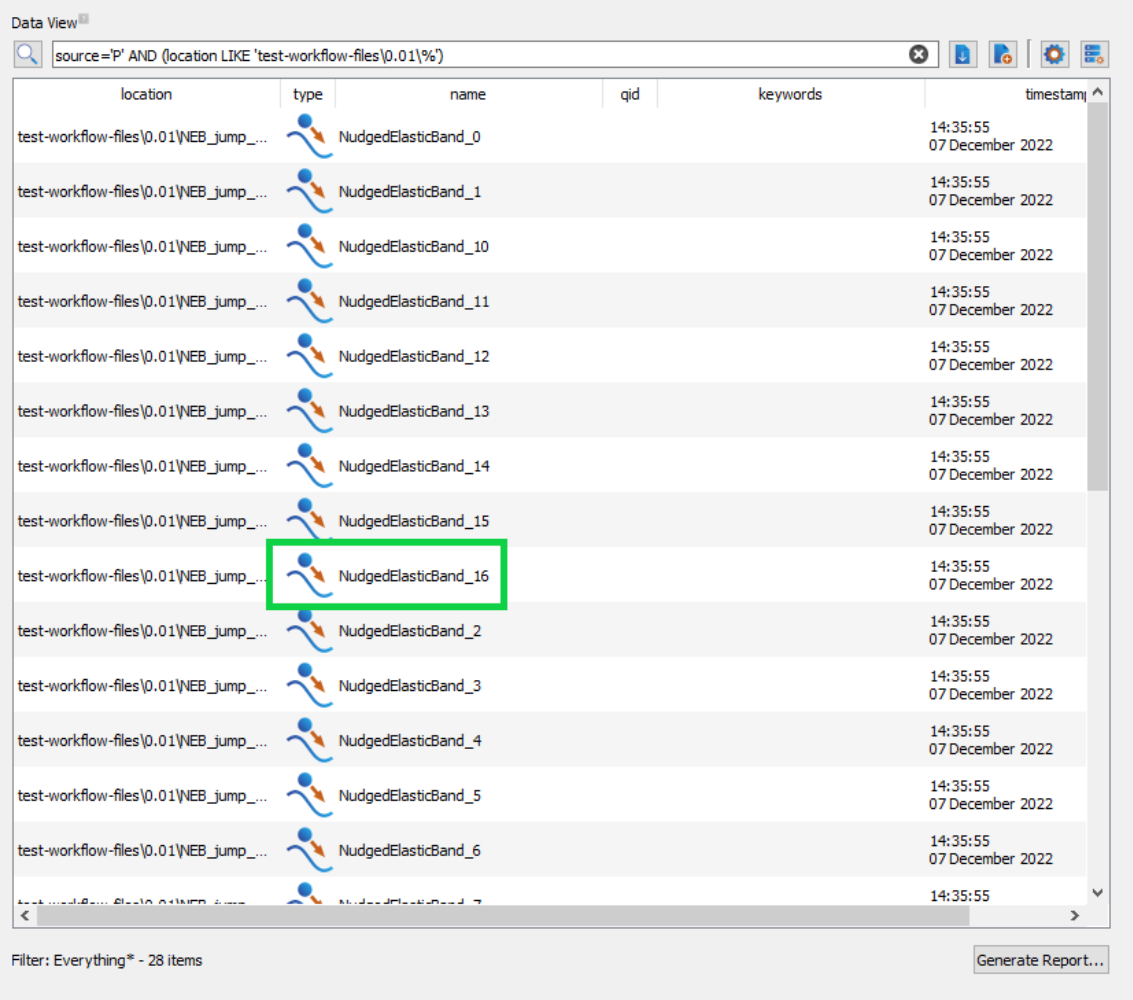
1. Click on the icon and send the *NEB: initial final* configuration to the **Workflow Builder**.
2. In the **Workflow Builder**, change the output **Filename** at the bottom of the middle panel to `NEB_Pt-jump.hdf5`.
3. Add the following blocks to the **Build** panel by double clicking on the corresponding icons in the **QuantumATK** tab in the right-hand panel:
   - Under **Calculators**: *Set ForceFieldCalculator*
   - Under **Optimization and Dynamics**: *OptimizeNudgedElasticBand*
4. Double-click on the *Set ForceFieldCalculator* block and select the *EAM_Pt_2004* parameter set again.
5. Double-click on the *OptimizeNudgedElasticBand* block, set the **Force tolerance** to *0.01 eV/* and set *FIXED* constraints on the bottom two layers.
6. Send the workflow to the **Job Manager** as a script and save the script as `NEB_Pt-jump.py`. This script runs in a few seconds, it can run locally.

   You should now have a workflow identical to this one: `NEB_jump_workflow.hdf5`

[1] S.ăSmidstrup, A.ăPedersen, K.ăStokbro, and H.ăJónsson. Improved initial guess for minimum energy path calculations. *J. Chem. Phys.*, 140:214106, 2014. doi:10.1063/1.4878664.

Analyze the results

Once you have run the NEB calculations for the direct jump diffusion process, many new objects should appear in the **Data View** section of **QuantumATK NanoLab**. There is a `NudgedElasticBand` object for each step in the optimization. They are stored in the file you defined before, here called *NEB_Pt-jump.hdf5*.



1. Select the last NEB trajectory, i.e. the one with the highest number, which contains the optimized NEB path for the direct jump process. Then, double-click on it to open it in the **Movie Tool**.

2. On the left, the **Movie Tool** shows the energy of each image, referenced to the energy of the first image. On the right is the corresponding atomic configuration of each image. You can now see the energy barrier for this diffusion process as the highest point in the plot on the left, and see the corresponding transition state configuration on the right by moving the cursor so the vertical gray line is at the transition state.

Note: As it can be seen in the tutorial at *Adaptive Kinetic Monte Carlo Simulation of Pt on Pt(100)*, the AKMC method finds this path, among others, without any *a priori* knowledge of the potential energy surface of the system.

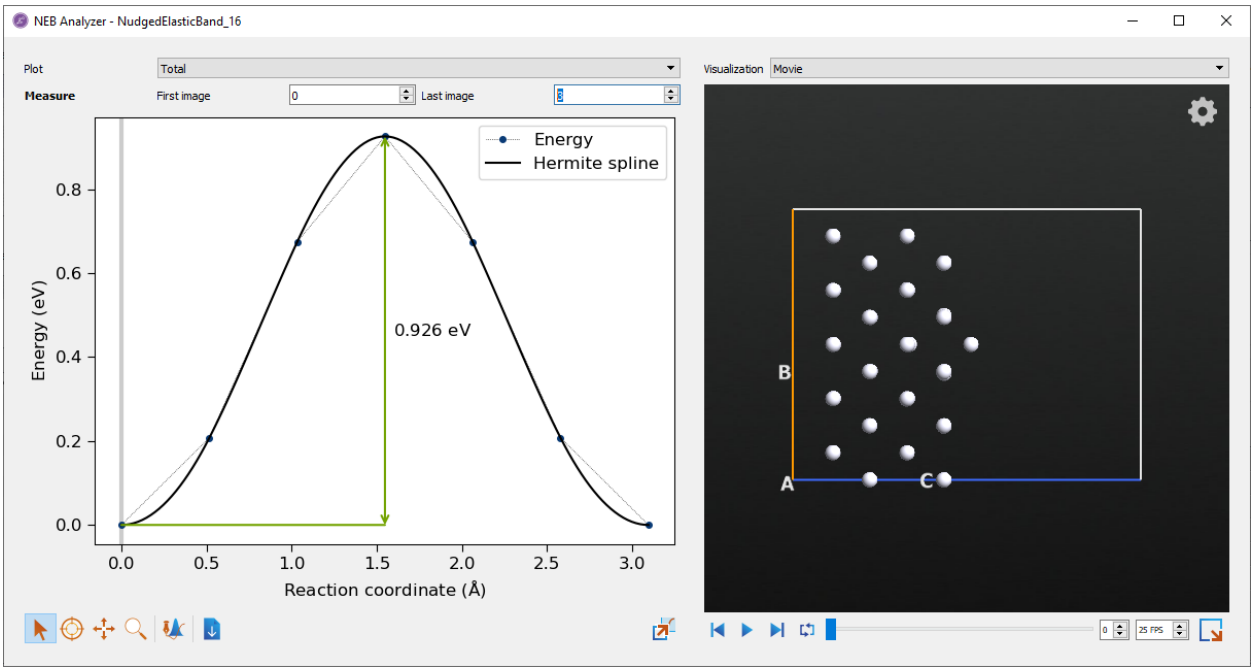


Fig. 3.110: Calculated reaction path for the direct jump diffusion process.

Summary

Throughout this tutorial, you have used a **ForceField** calculator and the **NanoLab** graphical user interface to set up, simulate and analyze the direct jump diffusion path for a Pt ad-atom on a Pt(100) surface. You can also repeat this tutorial with DFT by replacing the **Set ForceFieldCalculator** blocks with **Set LCAOCalculator** blocks, to compare directly with the DFT results reported in the literature[2].

3.11.6 Ammonia inversion reaction barrier using DFTB and NEB

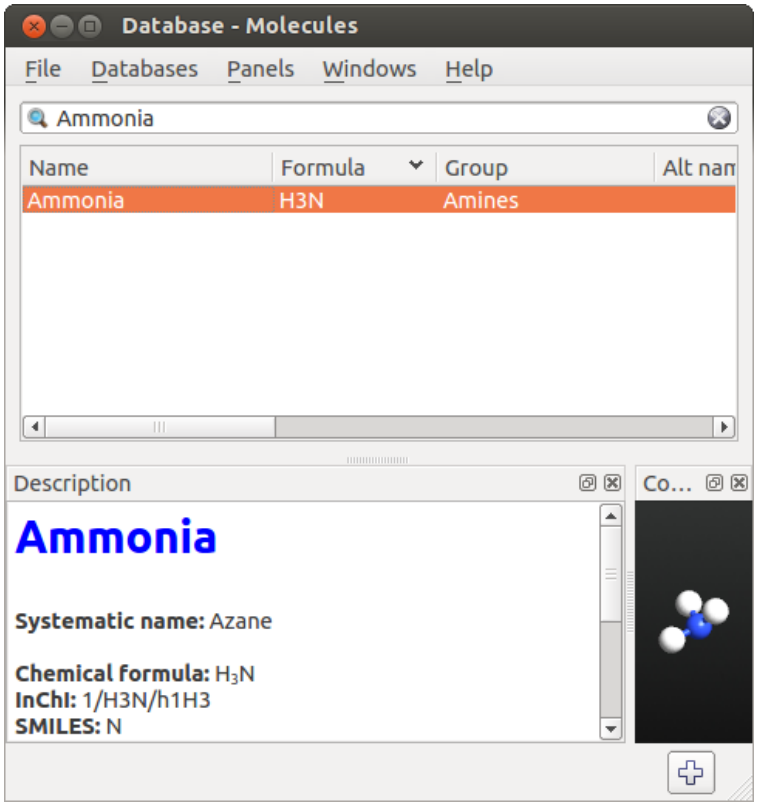
In this tutorial, you learn how to use a Nudged Elestic Band to calculate the reaction path of ammonia inversion. You will use the Density Functional based Tight Binding (DFTB) method (dftb.org) in order to make calculations fast.

Setting up the NEB object

•Open the **Builder** and click *Add* → *From Database*.

•The *Database* tool will open. From the menu, select *Databases* → *Molecules*. Type Ammonia in the search field, and you should see the following:

[2] P.ăJ. Feibelman. Surface diffusion mechanism versus electric field: Pt/Pt(100). *Phys. Rev. B*, 64:125403, 2001. doi:10.1103/PhysRevB.64.125403.

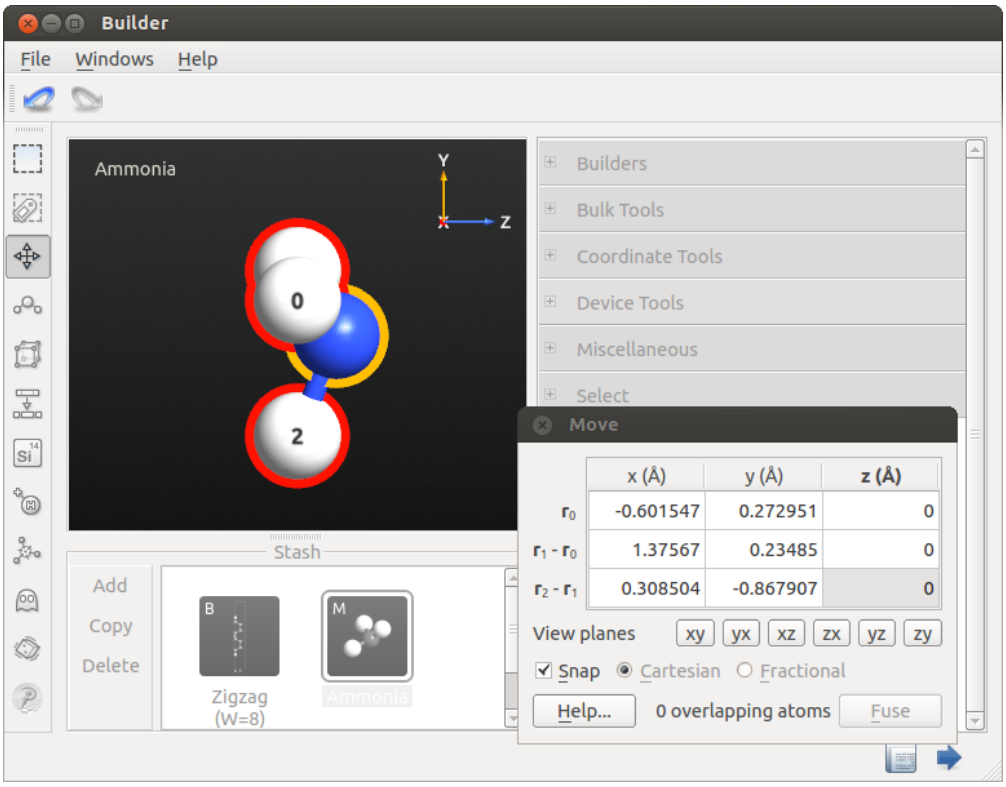


•Double-click the Ammonia entry (or click the icon), and the ammonia molecule will be added to the **Stash**.

Note: When running NEB calculations, it is important to restrict at least a few degrees freedom. What primarily happens in the ammonia reaction considered here, is that the nitrogen atom moves through the hydrogen plane. It is therefore a good idea to keep the hydrogen atom plane fixed when defining the initial reaction path. This can be acheived rather easily, see blow.

•In the **Builder**, activate the **Move Tool** . Select each of the hydrogen atoms as anchor atoms (marked by a red halo); this is the atom you will operate on. Since no atoms were selected when the **Move Tool** was opened, all atoms will simultaneously be selected (marked by a yellow halo); these atoms will be affected by any operation carried out in the **Move Tool**.

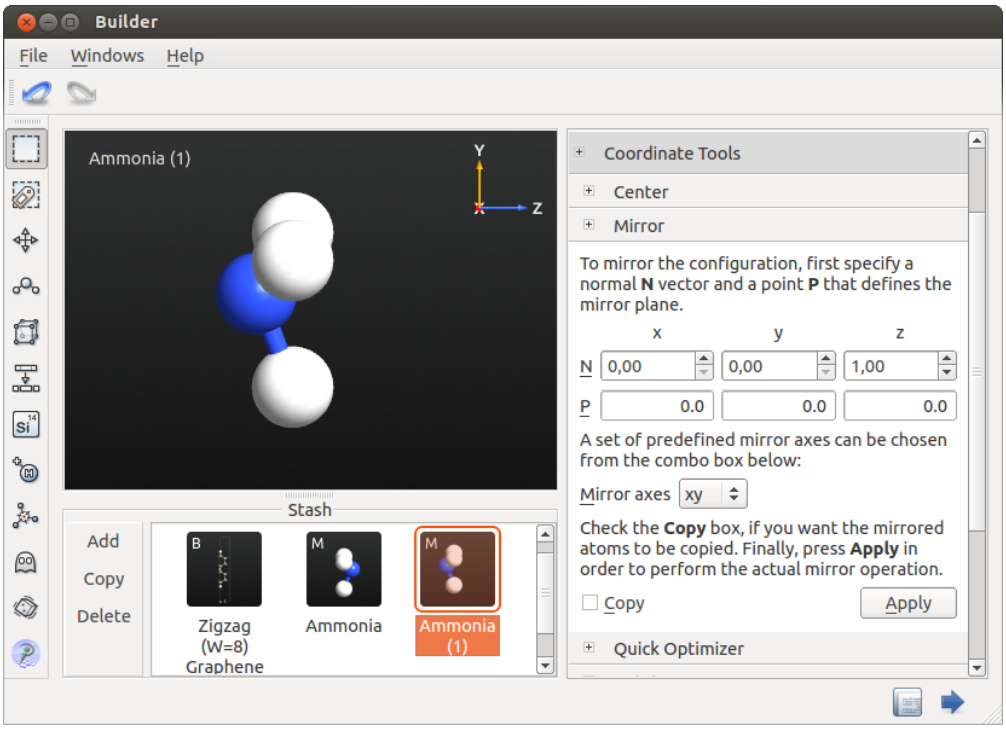
•In the **Move** widget, enter the value 0 for the z coordinate of the atoms, and press **Enter**.



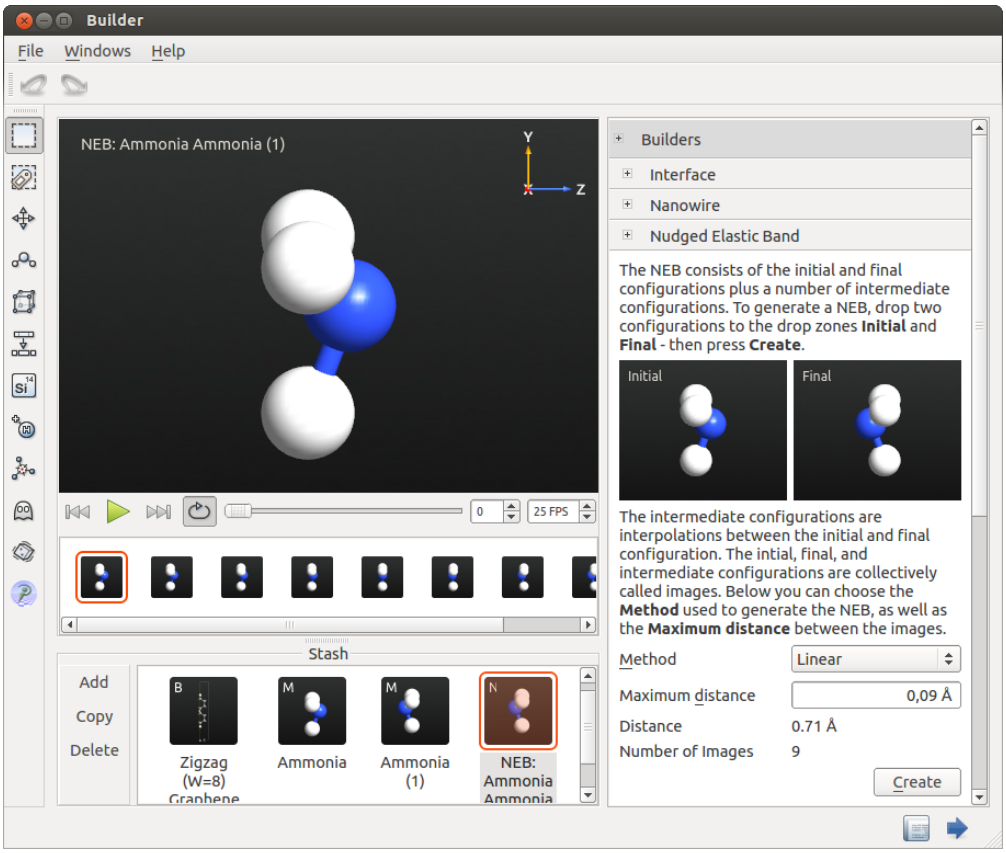
•Close the **Move** tool by closing the widget or clicking the **Select** tool.

•Now ensure that the ammonia molecule is selected on the stash by left-clicking it. Then click the **Copy** button . This adds an additional, identical ammonia molecule to the **Stash**.

•Open the **Mirror** tool from the **Coordinate Tools** in the right tool bar. Ensure that the mirror plane has a normal parallel to the Z axis and contains the origin (this is the default), and press **Apply** to invert the molecule.



- You have now defined the initial and final states of the reaction path. The next step is to set up the NEB configuration by inserting a number of images in-between these states.
- To this end, open the **Nudged Elastic Band** tool under **Builders** from the plugin panel, and drag the two configurations into the *Initial* and *Final* slots.
- Set the maximum distance between images to 0.09 Å in order to have an odd number of images. This is very important, since the reaction path is symmetric. Choose the **Linear** method and press **Create**. The NEB object will now be built and added to the **Stash**.
- Push the **Play** button to see the different configurations that will be used as starting configurations when optimizing the reaction pathway.



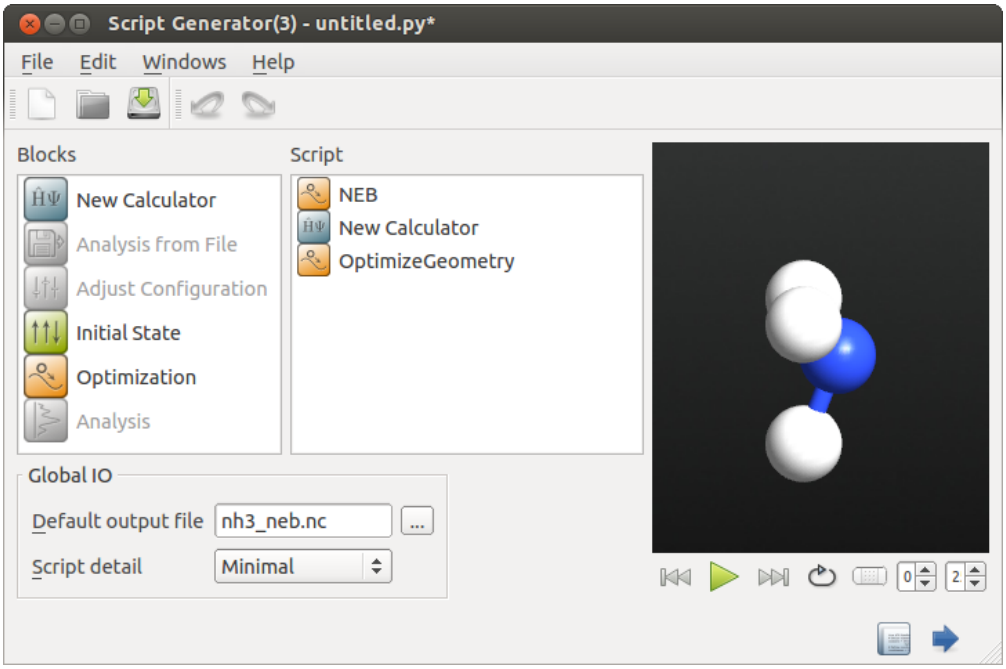
Performing the NEB simulation

To set up the actual calculations, send the NEB object to the **Script Generator** using the **Send To** button .

In the **Script Generator**, add the following blocks:

- **New Calculator**
- **OptimizeGeometry**

and change the default output name to `nh3_neb.nc`.

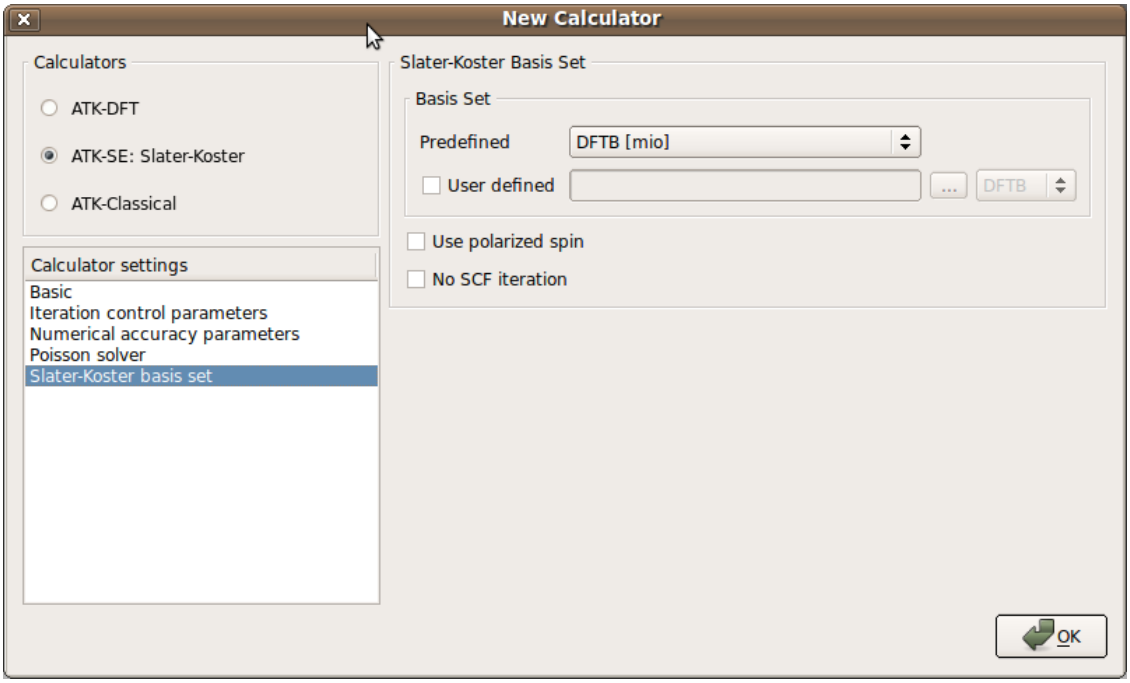


Open the **New Calculator** block and edit it:

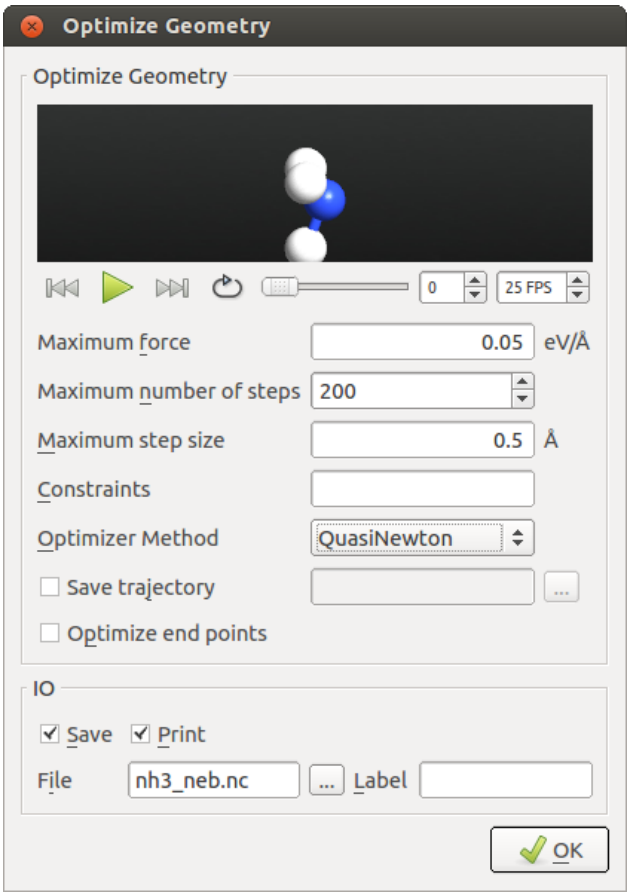
•Select the **ATK-SE: Slater-Koster** calculator.

•Go to the **Slater-Koster basis set** and check that the *DFTB [mio]* basis set is selected.

•Uncheck the **No SCF iteration** box.



Open the **OptimizeGeometry** block, and make sure it looks as shown below.



You are now ready to perform the NEB optimization. Send the script to the **Job Manager** and execute it.

The optimization will take 20-30 minutes depending on your computer.

Note: While most other implementations of the DFTB model use a pointwise electrostatic pair potential interaction model, ATK-SE uses a Poisson solver for calculating the electrostatic interactions. This approach is significantly slower for small systems, like the current ammonia molecule, but faster for large systems, where it scales as $O(N)$ instead of a typical $O(N^2)$ scaling.

The use of a Poisson solver ensures that the DFTB model is equivalent to the other calculators in QuantumATK, and thus can be used for modeling device geometries and allows for using implicit solvent models.

Analyzing the NEB simulation

- Return to the main **QuantumATK** window, and select the file nh3_neb.nc.
- Select the last NEB configuration in the file (the one with the highest ID number).
- Press the **Show configuration** and you will see the calculated energy barrier and the corresponding configurations in the reaction path.
- The reaction path can also be illustrated as an animation by pressing the **Play** button.

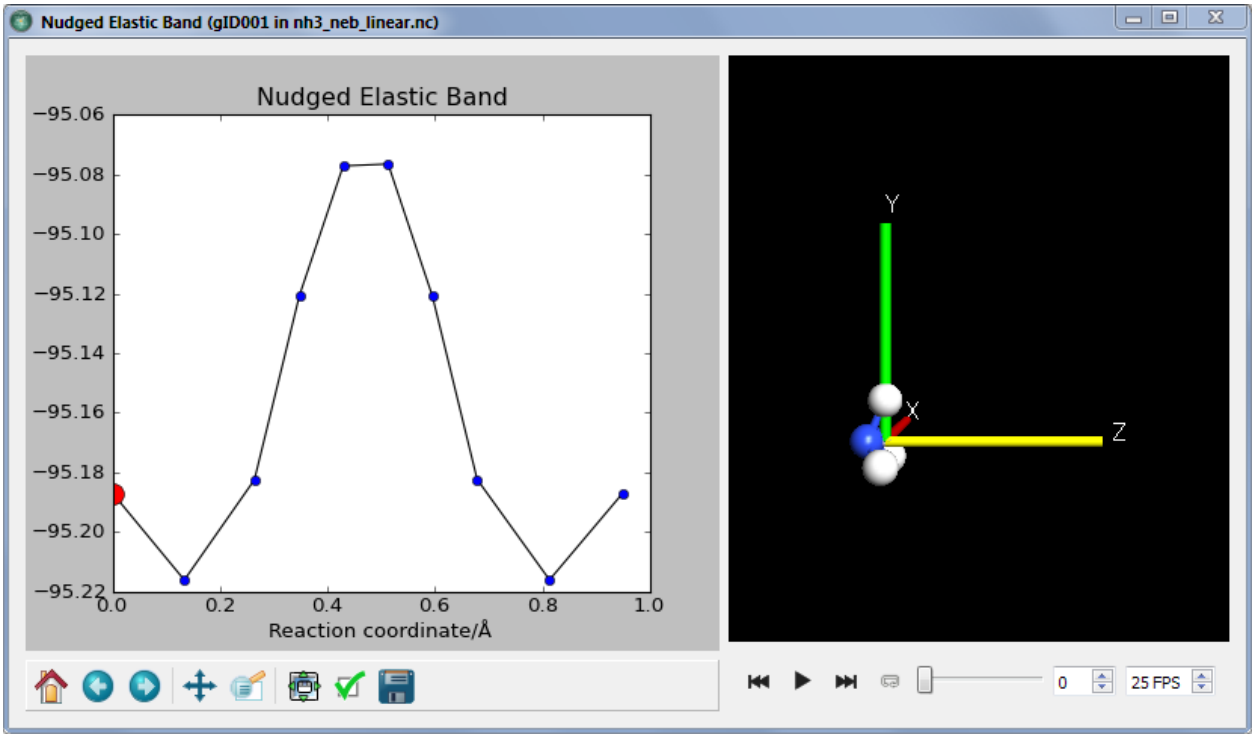


Fig. 3.111: Reaction path of ammonia inversion, computed with the DFTB [mio] method. The end-points were not optimized.

Attention: The obtained reaction barrier is not fully accurate, since the end points were not optimized. This is apparent from the fact that the second image has a lower energy than the end-points. For real studies with the NEB method, the end-points should always be optimized first.

Tip: You can closely inspect an individual optimized configuration in the reaction path by clicking the dots in the reaction paths plot (and stopping the movie).

A recipe for faster calculations

In the calculation above, you used a linear interpolation between the end-points to set up the initial guess for the NEB path. In many cases the linear path is, however, very far from the optimized one. Comparing the movie of the converged result above to the initial NEB path you set up, it can be seen that that the hydrogen atoms need to move out-wards to make room for the nitrogen atom as it passes through the center of the molecule, and then they move back in.

If this behavior could somehow be part of the initial path, one would save some steps in the ionic dynamics, and hence computational time. However, since the initial and final positions of the hydorgen atoms are identical, this cannot be captured by the linear interpolation.

There are, however, other methods for generating the initial path, and some are available in **ATK**.

•Go back to the **Builder**, and the **Nudged Elastic Band** plugin.

•Keep the image distance, but change the **Method** to **Image Dependent Pair Potential**, and create the NEB.

- If you now inspect the initial path, you can see that it already contains this behavior of the hydrogen atoms. This is one of the strengths of the IDPP method[1] for NEB calculations.
- Follow the same procedure as above to run the NEB calculation via the **Scripter**, and you will find that it runs about 30% faster this time, but that results are identical.

Note: The IDPP method is similar to the Halgren–Lipscomb method[2], which is also available in **ATK** (but not suitable for this particular system).

3.11.7 Reconstruction of the Si (100) surface - a geometry optimization study with QuantumATK

Introduction

Although LDA and GGA may not be able to produce a proper band gap in Si (and most other semiconductors), these simple DFT functionals are very capable when it comes to predicting geometrical properties. In this short tutorial we will demonstrate how to use QuantumATK to study the so-called asymmetric dimer reconstruction of a Si (100) surface.

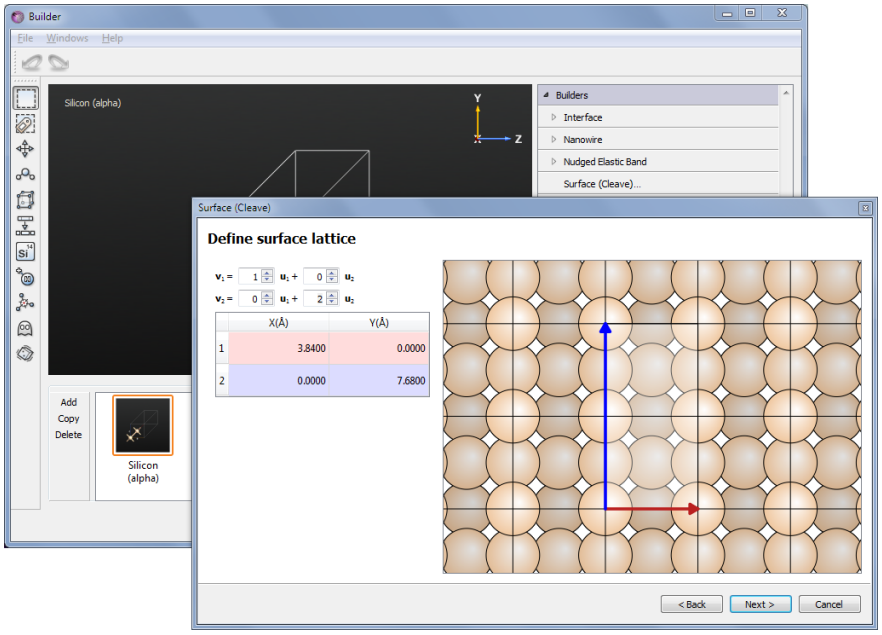
The focus will be on the physics and how to set up the model correctly, rather than how to operate QuantumATK. It will be assumed that you have experience building structures (for instance, cleaving surfaces) and setting up calculations and inspecting the results, and the steps will therefore only be indicated, not explained in any great detail.

Building the geometry

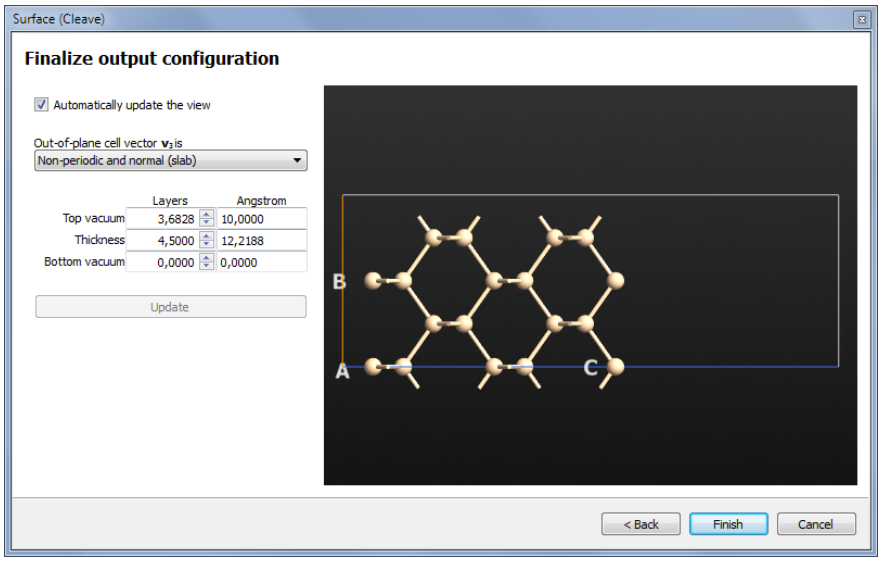
1. Start QuantumATK and open the **Builder**.
2. Add Silicon (alpha) from the Database (*Add* → *From Database*).
3. Open *Builders* → *Surface (Cleave)*.
   - Cleave the structure along 100 by entering the corresponding Miller indices.
   - Since the dimer reconstruction can only occur in a 2x1 supercell, you need to make a larger surface cell than the smallest one. Therefore, on the second page set $\mathbf{v_2} = 2\mathbf{u_2}$.

[1] S. Smidstrup *et al.*, *Improved initial guess for minimum energy path calculations*, J. Chem. Phys. **140**, 214106 (2014) link

[2] T. A. Halgren and W. N. Lipscomb, Chem. Phys. Lett. **49**, 225 (1977)



•On the final page of the Surface tool, choose a Slab configuration with thickness 4.5 layers (the default size of the vacuum is fine).

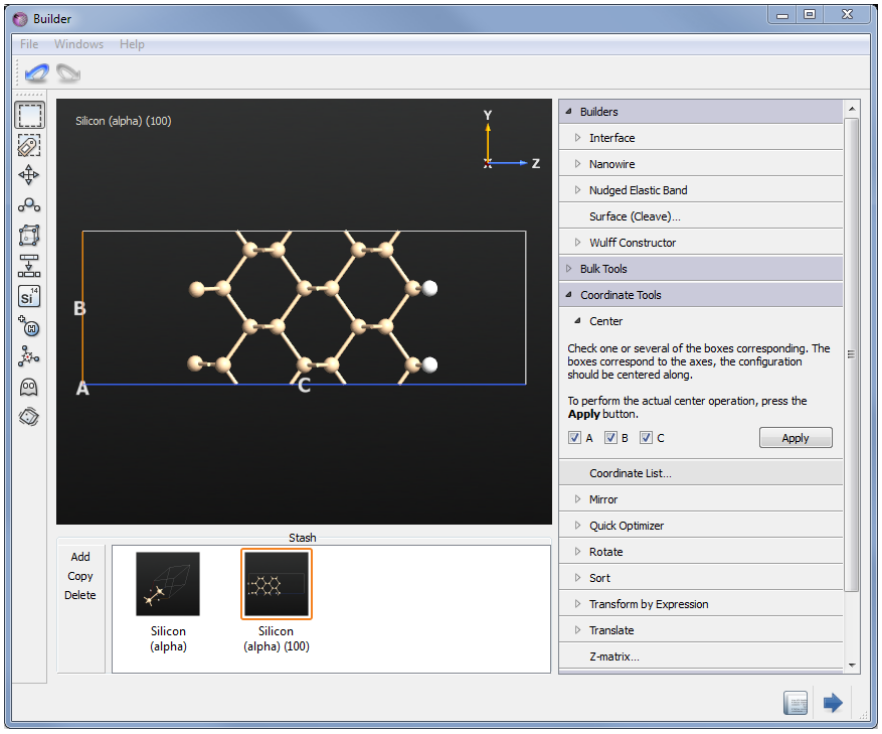


4.Center the structure in all directions (*Coordinate Tools → Center*).

5.Select the two Si atoms with the *smallest* Z-coordinate and add a small random perturbation to their positions by clicking the `Rattle` tool a few times. This is because the completely symmetric state is a meta-stable configuration, and its best to not start the optimization in such a state.

6.Select the two Si atoms with the *highest* Z-coordinate and passivate them to saturate all Si bonds in the structure.

The resulting structure is shown in the picture below.

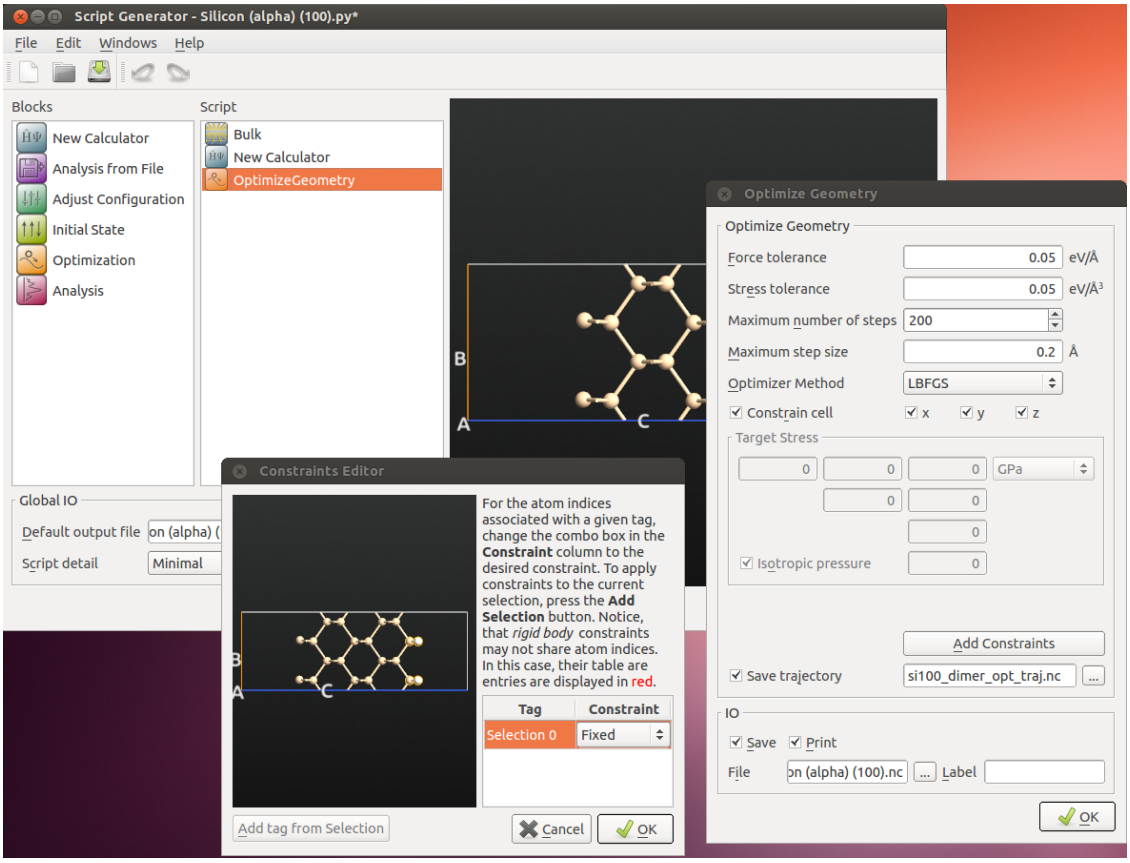


Setting up the calculation

Send the structure to the **ScriptGenerator**.

1. Insert a **New Calculator** block, then an **OptimizeGeometry** block.
2. For the calculator you can keep all parameters at their default except the **k-point sampling**. Set it to 9x9 (of course 1 point is enough in the C direction, since its a slab) - accuracy is important since the difference in energy between the symmetric and asymmetric dimer states is very small[1].
3. For the optimization, constrain the two bottom Si atoms and the 4 hydrogens. It is always important to limit the degrees of freedom in a relaxation if possible, to project out pure translations and rotations.
4. Also, make sure to tick `Save trajectory` and set a name for the trajectory file.

[1] A. Ramstad, G. Brocks, and P.J. Kelly: Theoretical study of the Si(100) surface reconstruction. Phys. Rev. B 51, 14504 (1995)



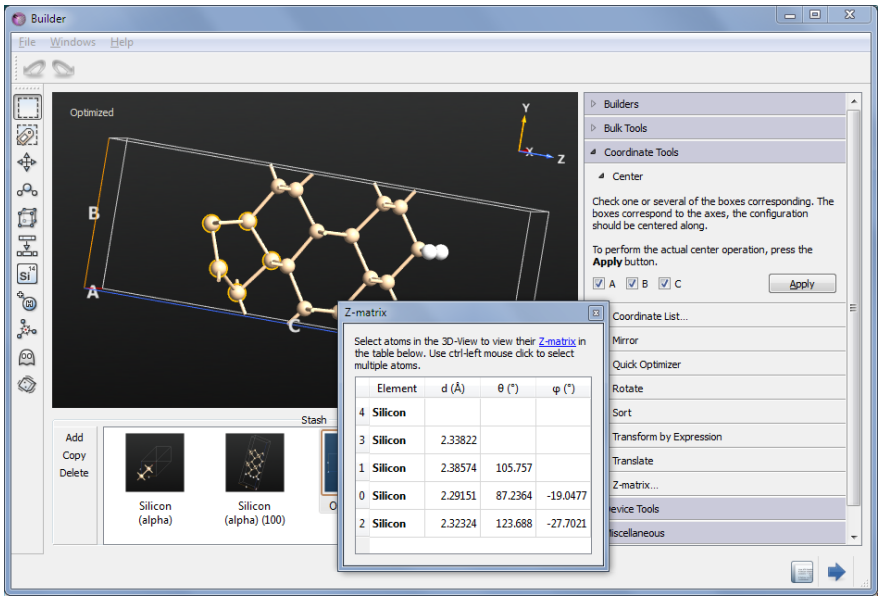
5. Set the name of the output file, and the calculation is ready to be run. Save the script!

   Send the script to the Job Manager, or transfer it to a cluster and run it there. This calculation parallelizes very well, and takes between one and several hours depending on how many MPI nodes it is run on.

Results

When the calculation is done, select the HDF5 file in QuantumATK and inspect the second Bulk configuration, with Id gID001 - this is the optimized geometry.

Drag-and-Drop it on the **Builder** - it is immediately visible that indeed an asymmetric dimer state has been obtained. To display the bond lengths just hoover the mouse over the respective bond - the bond distance will be displayed in the tool tip. To perform measurements of the bond lengths and angles, open *Coordinate Tools* → *Z-Matrix*, and select various atoms in the surface - both for the original and optimized geometry - and compare.



It is also interesting to analyze the relaxation trajectory. Select the LabFloor object in which you have the saved the trajectory, and open it in the **Viewer** to watch a movie of the optimization.

If we plot the total energy and forces for each relaxation step, we see that the total energy is more or less constantly decreasing, as expected from the fact that we use the *LBFGS* algorithm, which indeed is designed to minimize the total energy rather than just following the forces. The following simple script reads the trajectory data and plots the total energy and maximum force for each step:

```
traj = nlread('si_100_traj.hdf5', Trajectory)[0]
energies = []
max_forces = []
for i in range(len(traj)):
    energies.append(traj.imageEnergy(i).inUnitsOf(eV))
    forces = traj.imageForces(i).inUnitsOf(eV/Angstrom)
    force_magnitude = (forces**2).sum(axis=1)**0.5
    max_forces.append(numpy.max(forces))

# Plot the energy and max. force curve using pylab.
import pylab

pylab.figure()
pylab.subplot(2, 1, 1)
pylab.plot(range(len(traj)), energies)
pylab.xlabel('Optimization step')
pylab.ylabel('Energy (eV)')
pylab.grid(True)

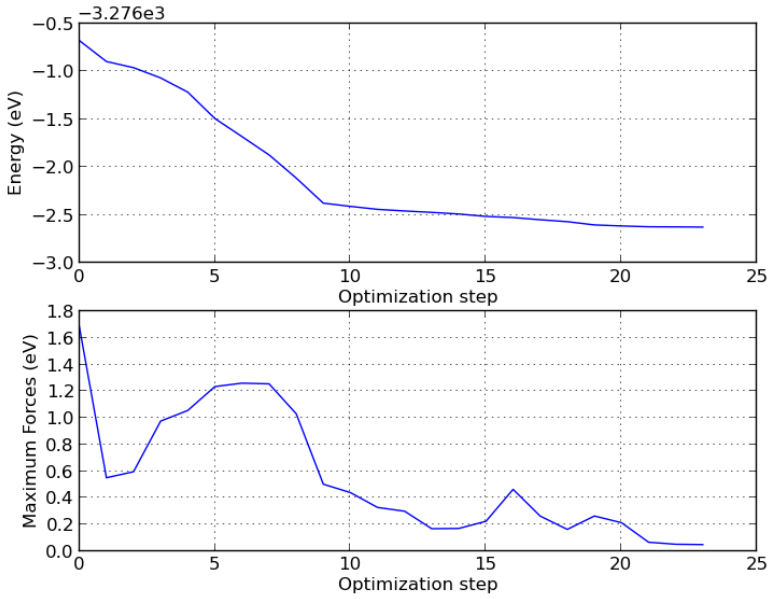
pylab.subplot(2, 1, 2)
pylab.plot(range(len(traj)), max_forces)
pylab.xlabel('Optimization step')
pylab.ylabel('Maximum Forces (eV/Ang)')
pylab.grid(True)
```

(continues on next page)

(continued from previous page)

```
pylab.show()
```

The result may look like the figure below, although the exact curve depends on the exact initial displacement of the top silicon atoms.



From this plot, combined with the trajectory movie, you can learn many things. First of all, note that unless you use a criterion for the forces which is below 0.2 eV/Å, you would be fooled into thinking the symmetric dimer is the minimum, since this state is passed on the way to the asymmetric one! This is also possible to see in the trajectory movie. In fact, although it has not been shown here, it is well known that unless care is taken to have an accurate method (i.e. enough k-points) and even enough vacuum around the slab, the symmetric dimer will be predicted to be the most energetically favorable.

Specifically, the symmetric dimer local minimum is reached around step 13 (see the trajectory picture above), but as the algorithm tries to reduce the total energy further, the forces rise again and the asymmetry starts to appear. After step 15 an asymmetry has been established for real, and the asymmetric dimer is finally formed at around step 20.

You can use the following script to visualize the vertical relaxation of the atomic layers:

```
traj = nlread('si_100_traj.hdf5', Trajectory)[0]
number_of_steps = len(traj)
z_coordinates = []

for i in range(number_of_steps):
    coordinates = traj.image(i).cartesianCoordinates().inUnitsOf(Angstrom)
    # Append all z-coordinates, apart from the fixed bottom layer.
    z_coordinates.append(coordinates[:16, 2].tolist())

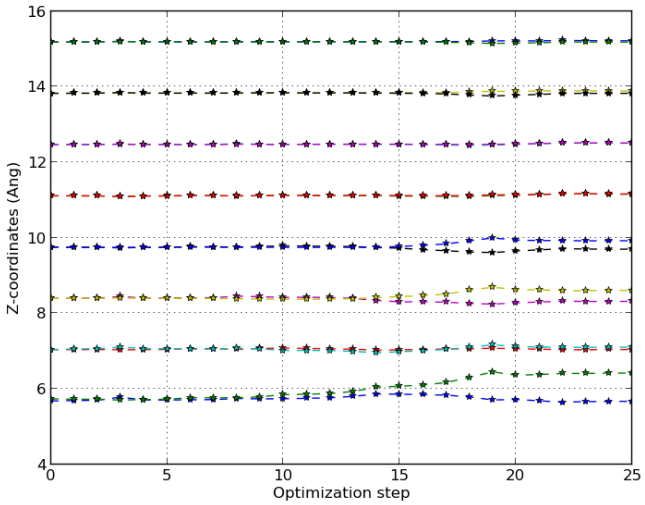
# Convert to numpy array.
z_coordinates = numpy.array(z_coordinates)
# Plot the z-coordinates using pylab.
import pylab
```

(continues on next page)

(continued from previous page)

```
pylab.figure()
# Loop over all unconstrained atoms.
for i in range(16):
    pylab.plot(range(number_of_steps), z_coordinates[:, i], '--*')
pylab.xlabel('Optimization step')
pylab.ylabel('Z-coordinates (Ang)')
pylab.grid(True)

pylab.show()
```



It is important to note that the asymmetry appears as a result of a long-range interaction, which also is why short-range methods like tight-binding or classical potentials are only able to relax the configuration into the symmetric dimer.

Summary

This study has shown how QuantumATK can succesfully predict even a rather complicated geometric reconstruction by using geometry optimization in DFT. The Si 100 surface first forms a symmetric dimer which in turns induces an asymmetry in the electron landscape, under which we again optimize the structure to find the ground state asymmetric structure. The asymmetry is a long-range effect which originates a few layers below the surface where the Si lattice is compressed downwards under the dimer.

3.11.8 Computing the work function of a metal surface using ghost atoms

Version: 2017

In this tutorial you will learn how to compute the work function of a metallic surface using **ATK**. You will create a slab model of Ag (100) surface, use ghost atoms to improve the description of its electronic properties, and use the appropriate boundary conditions to describe correctly the presence of vacuum above it. It is assumed that you have some experience with **ATK**.

Why use ghost atoms?

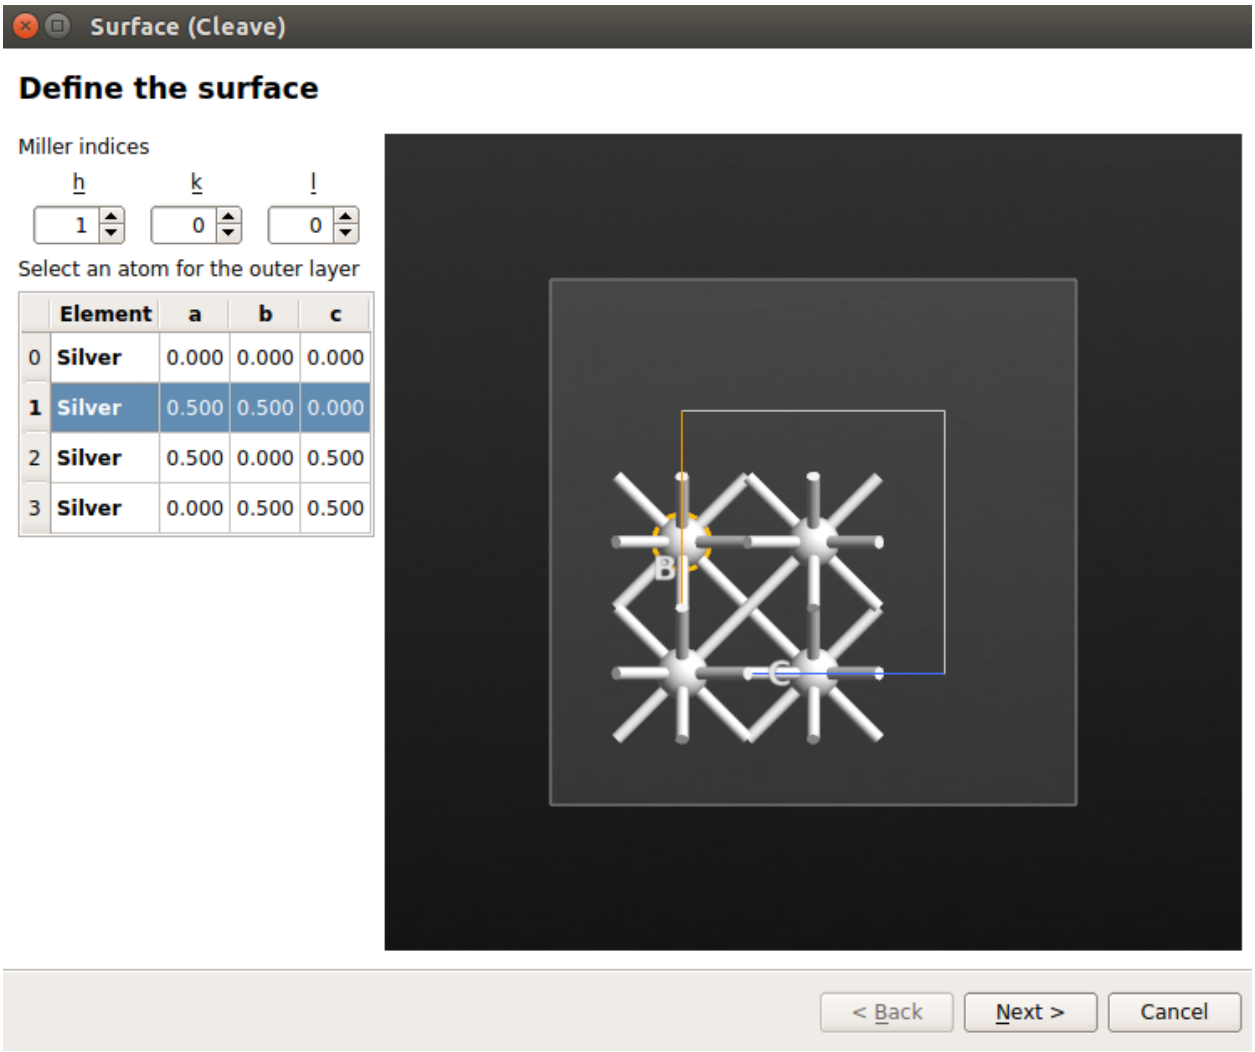
Work function calculations depend critically on accurately simulating the decay of the surface charge density into vacuum, but short-ranged localized basis sets are sometimes not adequate for this. In this case, extra LCAO basis functions are positioned above the surface – these are called ghost atoms.

Setting up the geometry

In this section, you will set up a slab model of Ag(100) surface with ghost atoms, and calculate the work function of the surface.

1. Open **Builder** (icon). Click *Add* → *Add From Database*, find *silver*, and add it to **Stash**.

2. Open *Builders* → *Surface (Cleave)*. Use **Surface (Cleave)** widget to define the surface by cleaving the bulk silver normal to the [100] direction.

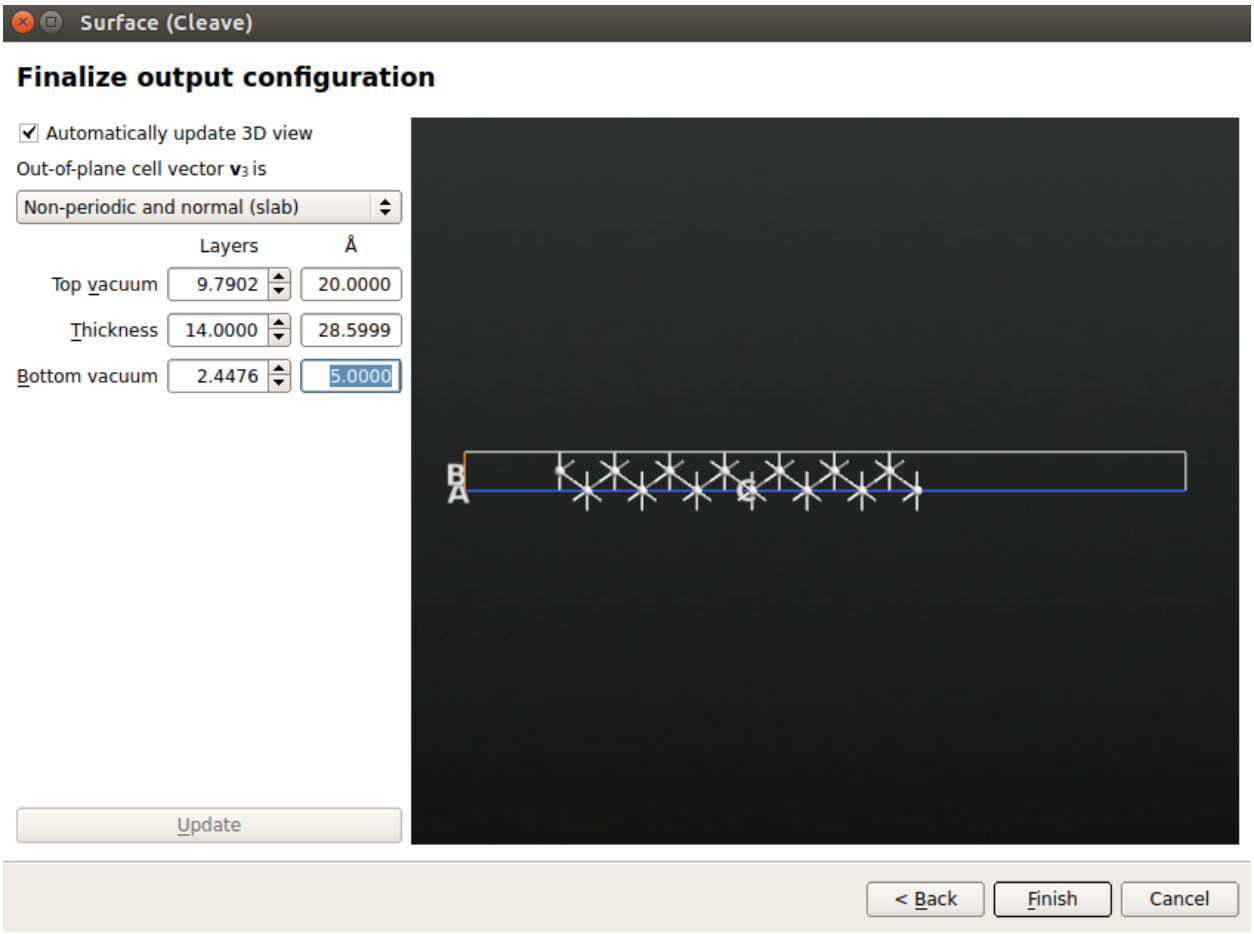


3. Click Next twice. On the final page of the **Surface (Cleave)** widget, set the out-of-plane cell vector $\mathbf{v}_3$ to be *Non-periodic and normal*. Set the rest of the parameters as follows:

- Top vacuum = 20 Å. This large vacuum above the surface ensures that the effective potential has enough space to decay to the vacuum level.

•Thickness = 14 layers.

•Bottom vacuum = 5 Å. This vacuum ensures that no basis functions extend to the bottom edge of the cell (the radius of the basis functions for default silver is 3.7 Å).



Attention: This parameter setting ensures the convergence of work function.

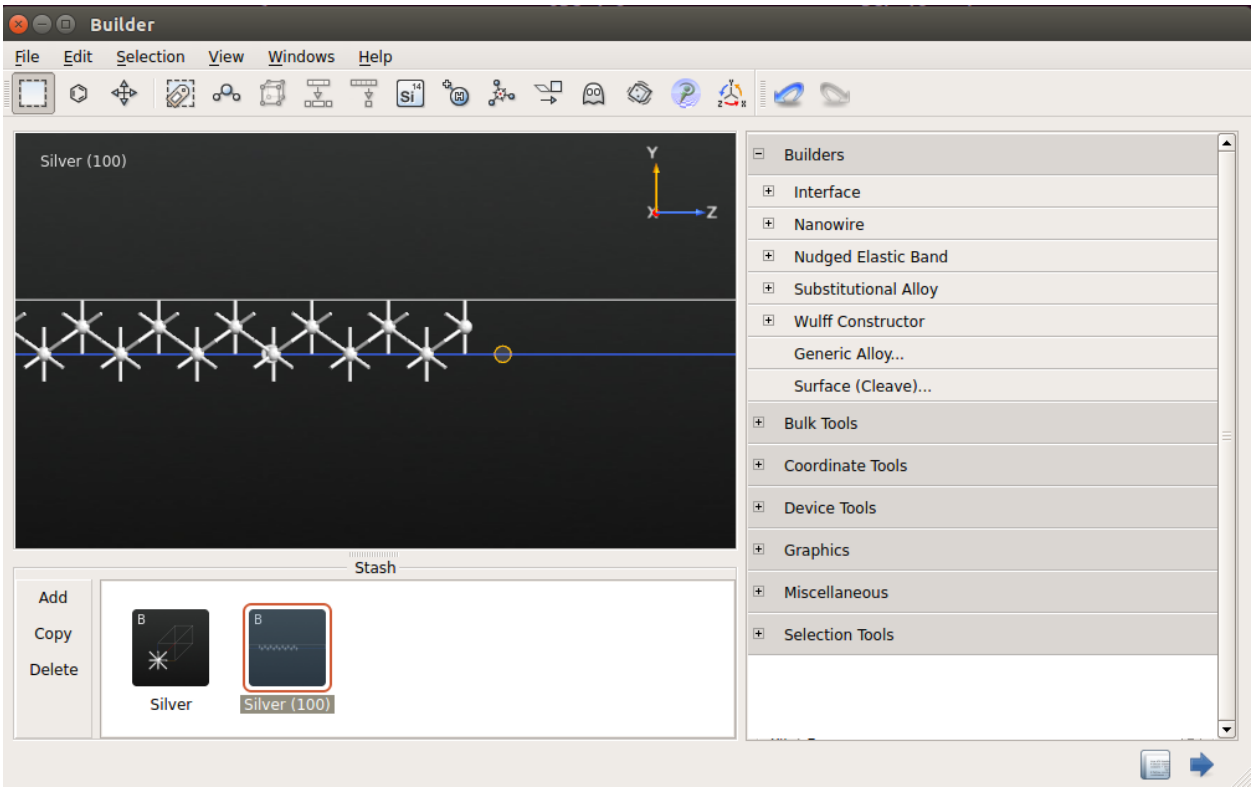
Warning: In the direction normal to the surface, the non-periodicity of the system requires appropriate boundary conditions.

4.Click *Finish*. The surface structure will now appear in **Stash**.

5.To finalize the geometry setup, select the atom with the largest Z coordinate in **Builder** and turn it into a ghost atom by clicking the icon .

6.As a result, the slab consists of 13 layers. The role of the ghost atom on the surface is to describe the smooth decay of electron density in the vacuum.

7.Send the structure to **Script Generator** (icon).



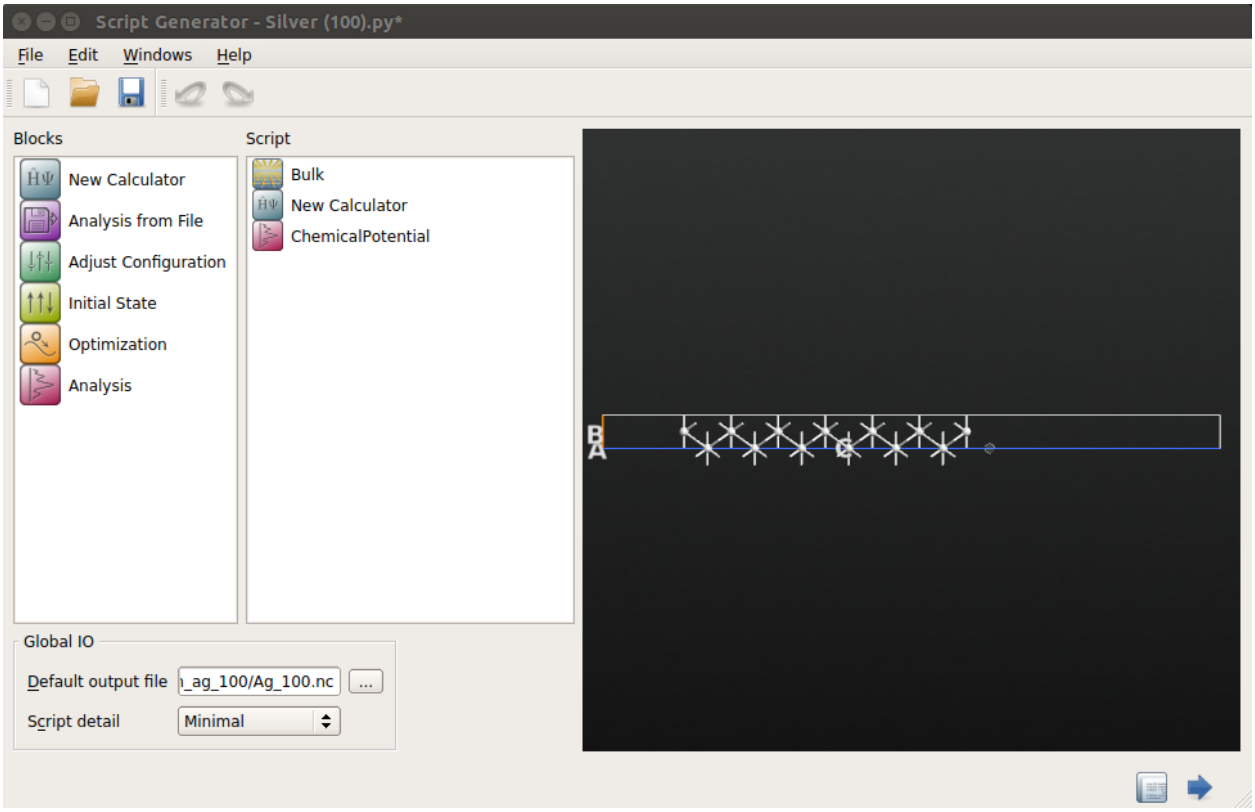
Note: Changing an atom into a ghost atom means setting its potential, e.g., pseudopotential or nuclear charge there, to be zero. The basis functions are, however, still deployed there to describe the electron density. An alternative is to extend the range of the basis functions at every atomic position, although it makes the calculation expensive if the system is not as simple as in this example.

Defining the parameters of the calculation

1. In **Script Generator**, insert a **New Calculator** by double-clicking it in **Blocks** panel. Also, click *Analysis* → *ChemicalPotential* to compute the chemical potential of the slab.

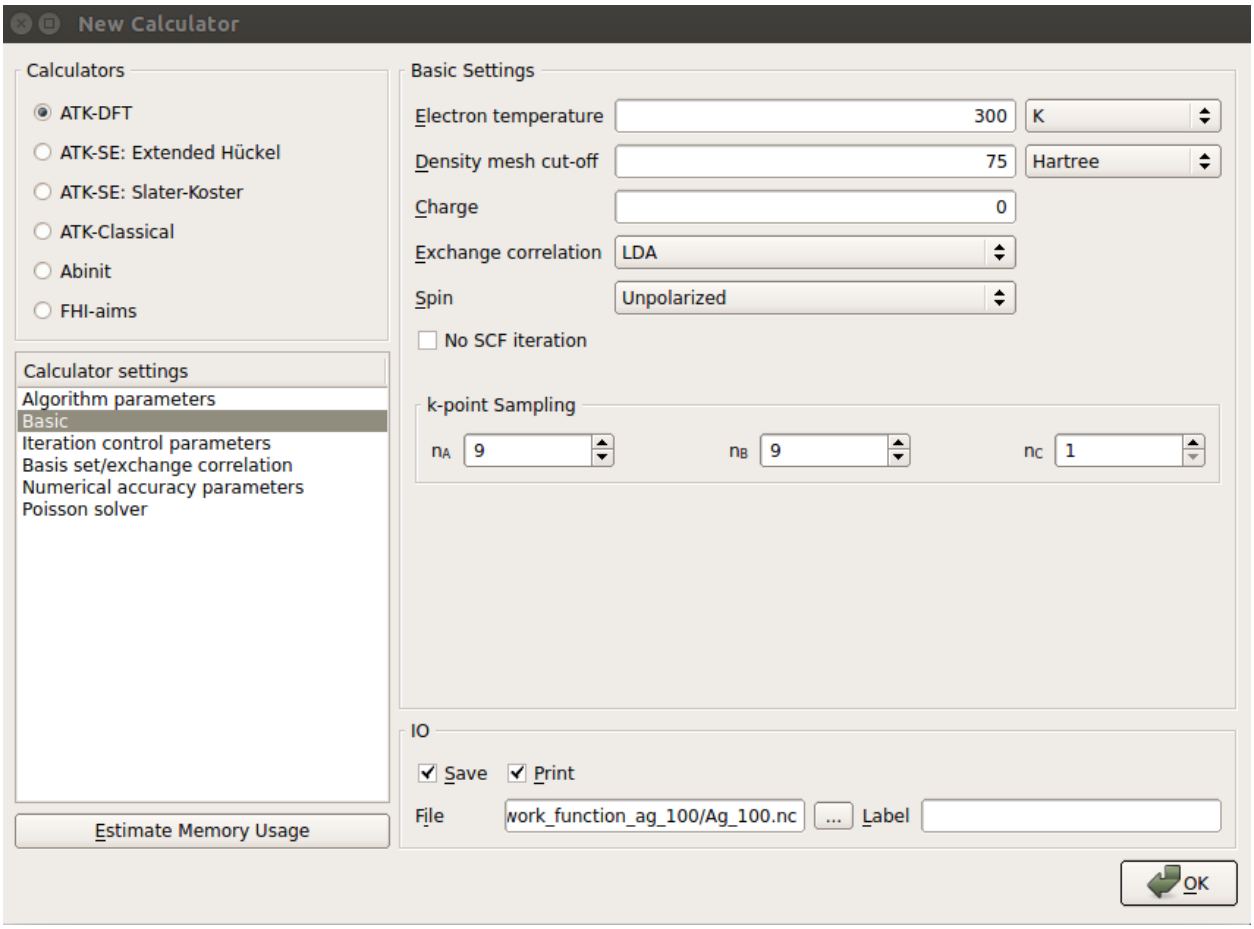
Note: Imposing appropriate boundary conditions at the top and bottom of the slab as shown below makes the chemical potential equal to the work function.

2. Set a suitable file name for the HDF5 file, e.g., *Ag_100.hdf5*.



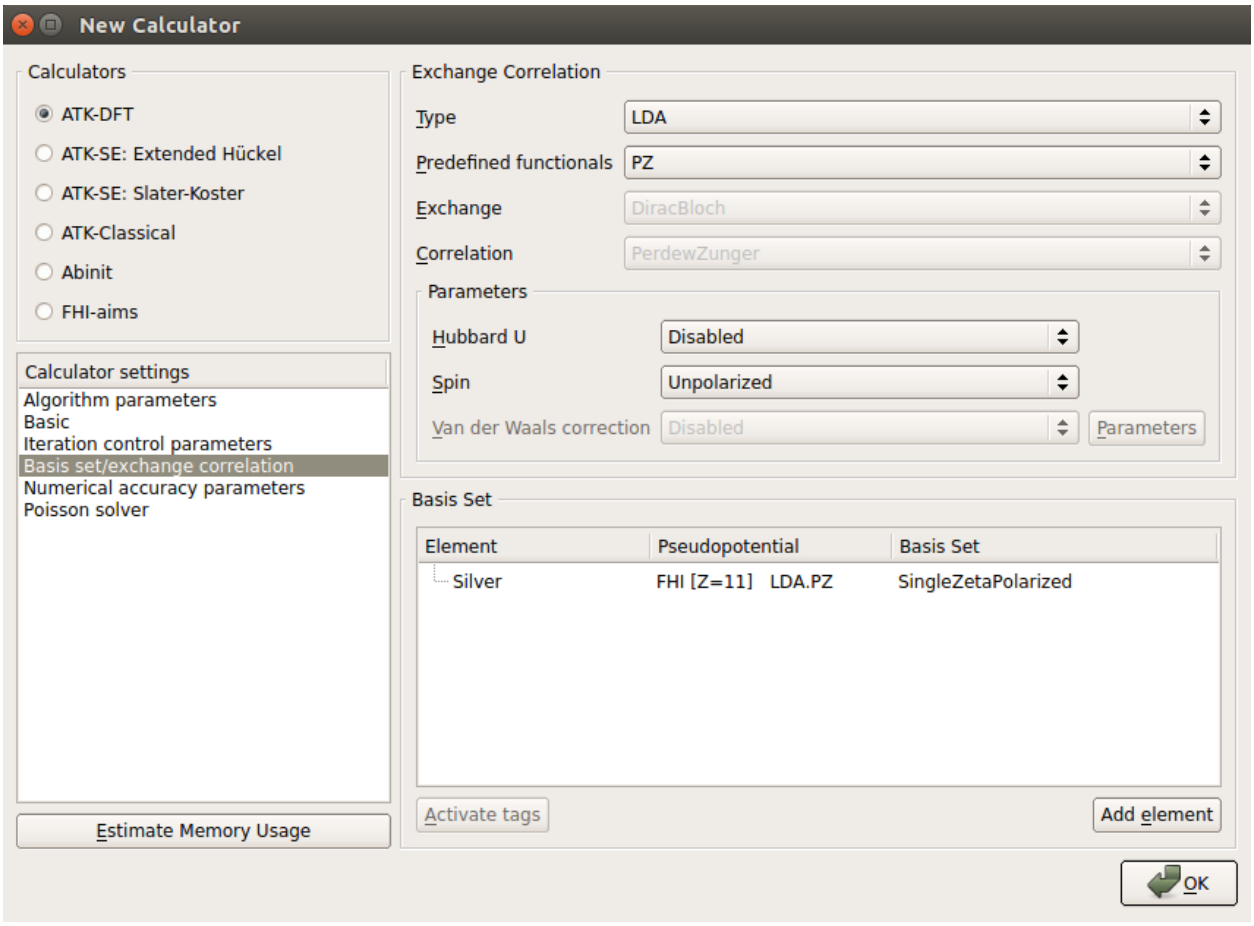
3.Double-click the **New Calculator** in **Script** panel and set the following parameters:

•For accurate description of the electronic structure, set the k-point sampling to be 9x9x1 in *Basic* section of **Calculator settings**



Note: Remember in general to check the convergence of the properties of interest with respect to the fineness of the k-point grid.

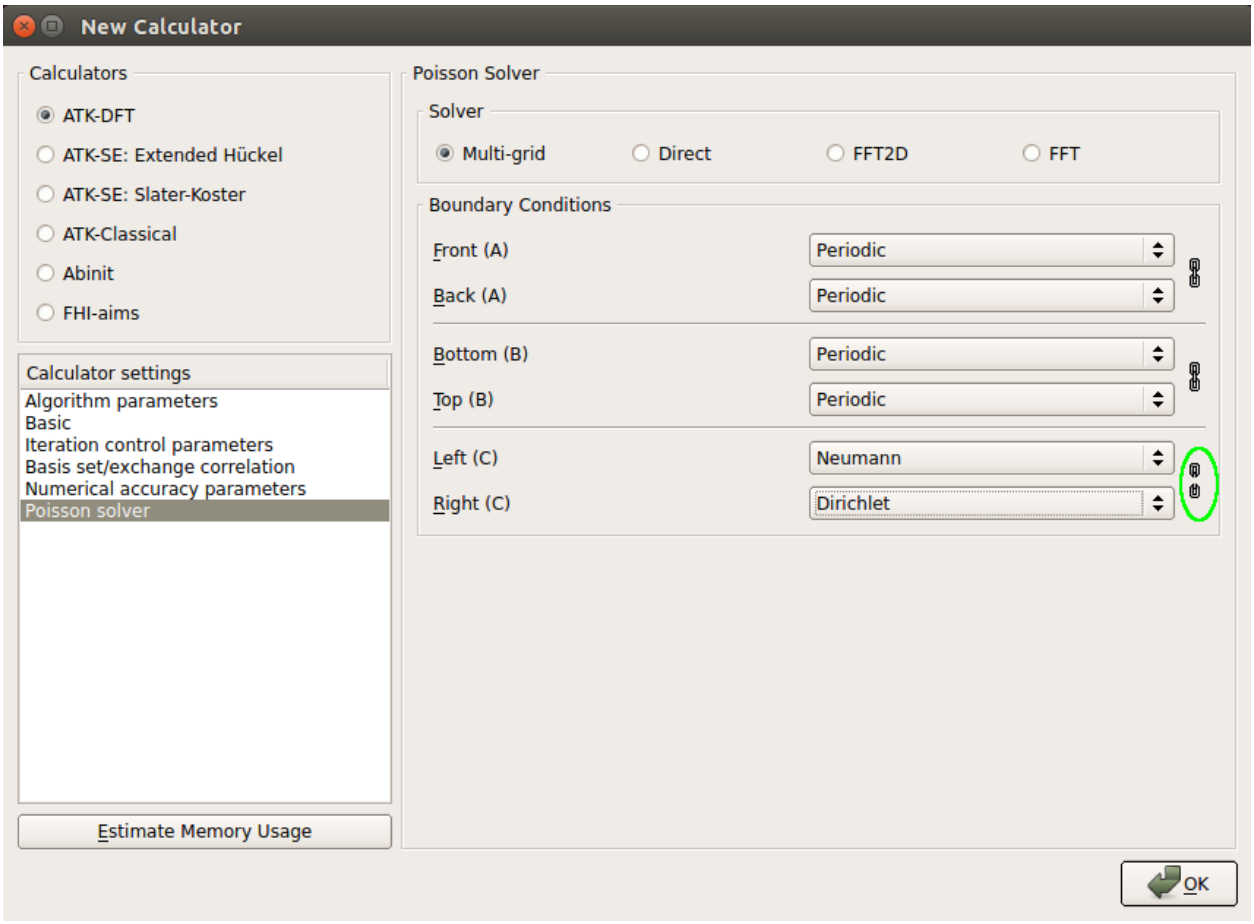
•In *Basis sets/Exchange correlation* section, select *SingleZetaPolarized* for the basis set.



Note: Employing this basis set achieves good accuracy for this slab model with moderate computational effort. For other systems, however, it is not ensured that the use of the same basis set always provides enough accuracy.

Warning: Generally it is not advisable to use the TB09-MGGA to compute the work function, because the TB09-MGGA potential diverges in the vacuum. For the use of TB09-MGGA, the c-parameter should be tuned to obtain a reasonable value of the work function, and correct electronic structure of the material. In the present case, setting c = 0.94 gives WF = 4.44 eV, in excellent agreement with the LDA result (see below). Note that the value of c differs from that calculated self-consistently for bulk Ag, c = 1.31.

•Finally, the most important setting: in *Poisson solver* section, select the Multi-grid Poisson solver. Then, click chain icon (marked in green in the picture below) to unlink the settings of the Left and Right cell boudaries, and set the Neumann boundary condition on the Left boundary, and the Dirichlet boundary condition on the Right cell boundary, respectively.

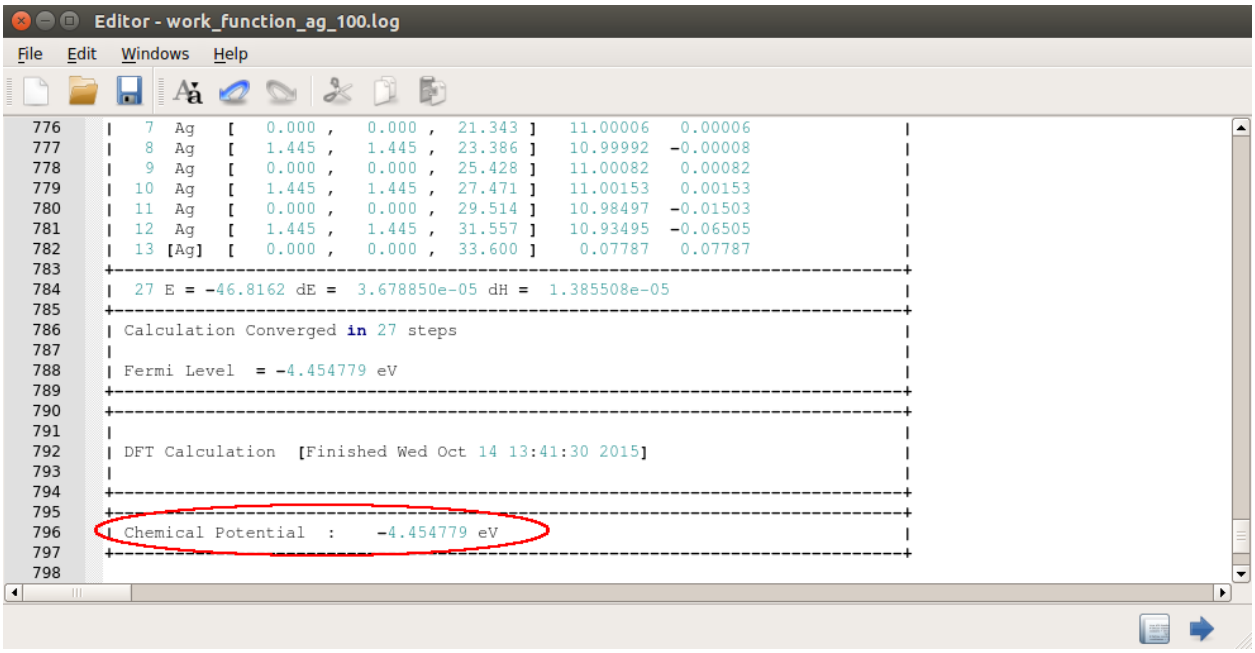


Note: Dirichlet boundary condition determines the Hartree potential to be zero on the right cell boundary, to mimic the presence of vacuum far away from the surface. Because of non-periodicity in the C direction, Neumann condition is used to demand the gradient of the Hartree potential to vanish on the left of the system.

Calculation and analysis

1. Send the structure to **Job Manager** and carry out the calculation. After the calculation, inspect the log file by clicking the button.

2. Around the end of the log file, the chemical potential, or the work function is printed. The value obtained for Ag 100 is 4.45 eV, which lies in the range from 4.22 to 4.81 eV, reported by experiments.



3.Just to demonstrate that with **ATK** it is also possible to get accurate results for other metals, see the comparisons with experiments in the table below:

Table 3.4: Comparison between measured and calculated Work Functions (WFs) for different metal surfaces.

Surface	Measured WF (eV)	WF calculated using the LDA (eV)[Page 1499, 1]
Ag (100)	4.64	4.45
Ag (110)	4.52	4.17[2]
Ag (111)	4.74	4.71
Al (100)	4.41	4.42
Au (100)	5.28	5.38[3]
Ca (100)	2.87	2.85
Cu (100)	4.53-5.10	4.92
Li (100)	2.93	3.14
Nb (100)	3.95-4.87	3.95
Pb (100)	4.25	3.95
Pt (100)	5.12-5.93	5.97
Tl (100)	3.84	3.74
W (100)	4.32–5.22	4.01

[1] All calculations were performed using a DoubleZetaPolarized basis set and a grid of 9x9x1 k-points. The rest of the parameters were set as in the example above. Note that this means that all values are not necessarily converged in these parameters. The surfaces are also not relaxed.

[2] The Ag(110) surface is known to undergo reconstruction; the computed value shown here does not take that into account.

[3] Fortuitously, the calculated work function for gold with SingleZetaPolarized is 5.28 eV.

Comments

•Above we have commented in a few places on the importance of carefully checking convergence in certain numerical as well as geometrical parameters. The work function is quite sensitive to all of them, and so, for convenience, let us summarize the most important ones:

–**Number of slab layers**: for silver, tests show that 13 layers, as we used above, is sufficient, but any smaller number gives different results;

–**Extension of vacuum on both sides**: 20 Å on the right cell boundary, as used in this example, is on the safe side; at least for Ag(100), even just 10 Å is enough;

–**K-point sampling**: 9x9x1 gives reasonable results, but as always with k-point sampling the convergence in this parameter is not a simple monotonous function;

–**Basis set**: for transition metals, polarization orbitals are needed to get correctly shaped atomic functions, and hence we choose *SingleZetaPolarized* for silver. However, for other categories of elements other rules may apply. Independently on the element, the *DoubleZeta* basis set is a good work horse. *DoubleZetaPolarized* is always a safer choice, although it demands a bit more computation time;

–**Exchange-correlation functional**: simple metals are generally well described by LDA, but this is certainly not true for all materials.

•The script can be run in parallel using MPI for a considerable performance benefit, due to the large number of k-points, which is one of the parameters QuantumATK parallelizes well over.

•By comparing the values reported in the table above for the (100), (110) and (111) crystalline faces of Ag, it appears clear that the work function depends on the crystalline face considered.

3.11.9 Tuning the work function of silver by deposition of ultrathin oxide layers

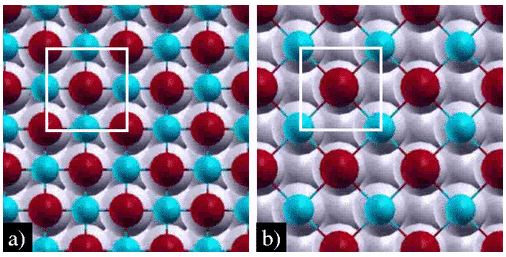
Version: 2015.1

Ultra-thin films of insulating materials deposited on a metal substrate constitute a peculiar class of materials with tunable properties and growing potential in different fields[1][2][3]. In this tutorial, you will learn how to change the work function of a substrate by depositing an overlayer of another material.

[1] Livia Giordano and Gianfranco Pacchioni. Oxide Films at the Nanoscale: New Structures, New Functions, and New Materials. *Accounts of Chemical Research*, 44(11):1244–1252, 2011. doi:10.1021/ar200139y.

[2] Gianfranco Pacchioni. Two-Dimensional Oxides: Multifunctional Materials for Advanced Technologies. *Chemistry - A European Journal*, 18(33):10144–10158, 2012. doi:10.1002/chem.201201117.

[3] Gianfranco Pacchioni and Freund Hajo. Electron Transfer at Oxide Surfaces. The MgO Paradigm: from Defects to Ultrathin Films. *Chemical Reviews*, 113(6):4035–4072, 2013. doi:10.1021/cr3002017.



Note: **Work function tuning** An important consequence of the deposition of a thin insulating film on a metal substrate is the induced change in work function of the metal support, which can be lowered or increased depending on the nature of the interface. Examples of such changes in work function have been reported in the literature. Kelvin probe force microscopy or scanning tunneling microscopy studies of alkali chloride thin films on Au(111) and Ag(100) have shown work function reductions of 0.5–1.2 eV[4][5]. Another work based on field-emission resonance has found for NaCl islands of up to 3 ML (monolayers) a work function reduction of 1.3 eV[6]. Theoretical calculations have predicted a reduction in work function for NaCl, MgO, and other oxides on various metals[7][8][9].

You will here calculate the work function change of a metallic Ag(100) surface as a consequence of depositing 1 to 3 layers of insulating MgO. The procedure to calculate the work function follows the prescription given in the tutorial *Computing the work function of a metal surface using ghost atoms*.

In particular, you will:

1. create and optimize the Ag and MgO bulk structures;
2. construct the Ag(100) and MgO(100) surfaces;
3. create the MgO(100)/Ag(100) interface;
4. set up work function calculations and run them;
5. analyze the results and compare with literature.

Warning: **Computational settings** Throughout this tutorial you will use a particular set of computational settings (mesh cut-off, k-point sampling, basis-set, exchange-correlation, number of metal layers, etc.) which are chosen such that the QuantumATK results can be compared to literature. Always keep in mind, however, that you should check that your results are properly converged with respect to such settings.

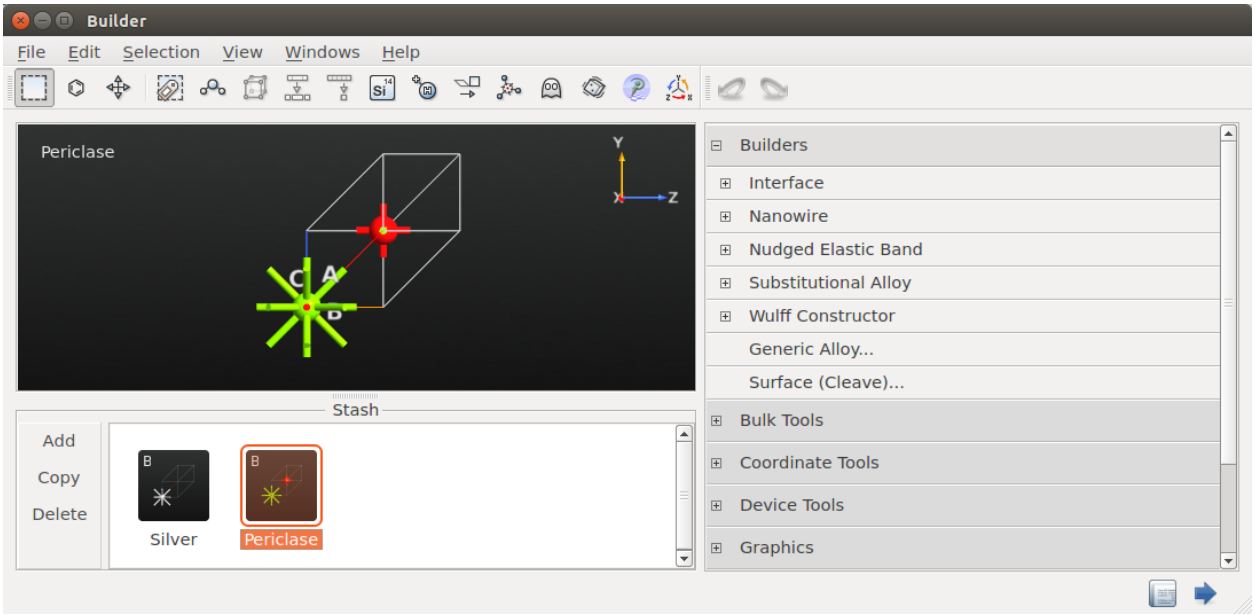
Ag(100) and MgO(100) surfaces

Do the following to build the silver and magnesium oxide bulks:

•Open the **Builder** and click *Add* → *Add From Database*, locate Silver in the database, and add it to the Stash.

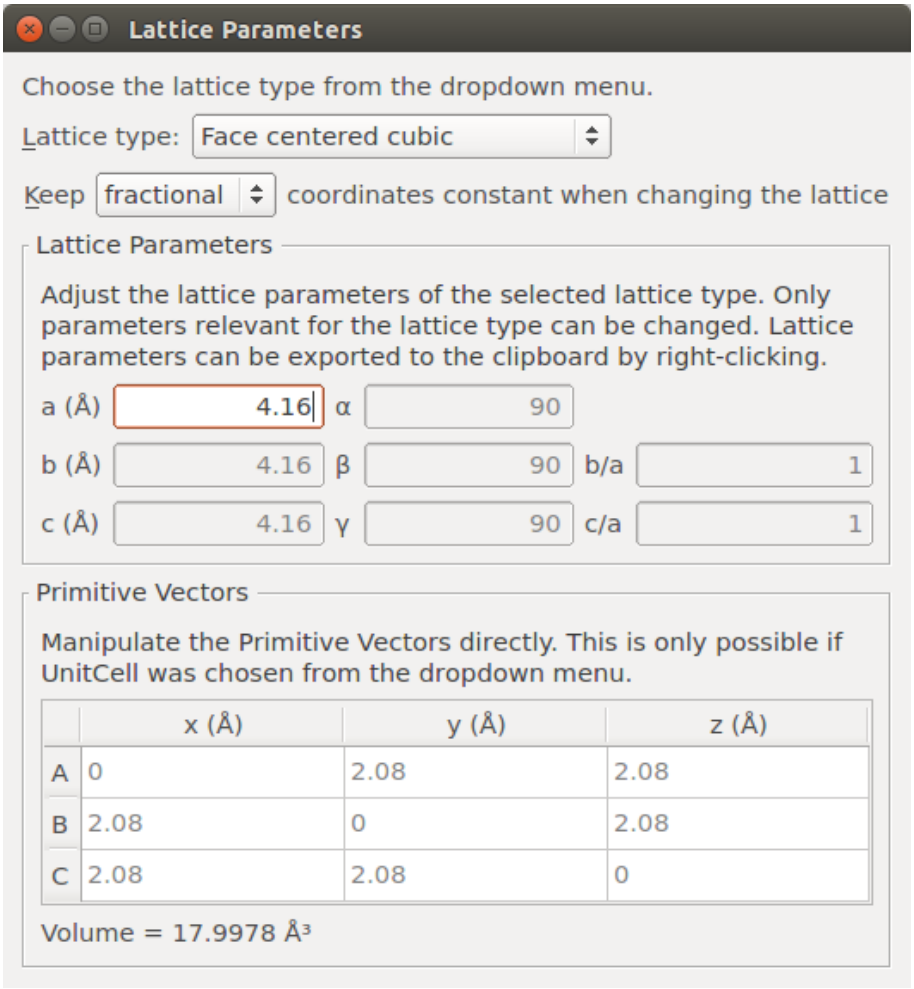
•Also locate MgO and add it to the Stash. You should now have to bulk configurations in the Stash:



You will in this tutorial use the PW91 exchange-correlation functional for DFT simulations, in order to compare to literature results from Prada *et al.*[Page 1501, 9]. The Ag lattice constant is 4.16 Å within PW91, so use this value for the silver bulk configuration:

•Select the Silver Stash item, and open the *Bulk Tools* → *Lattice Parameters* plugin.

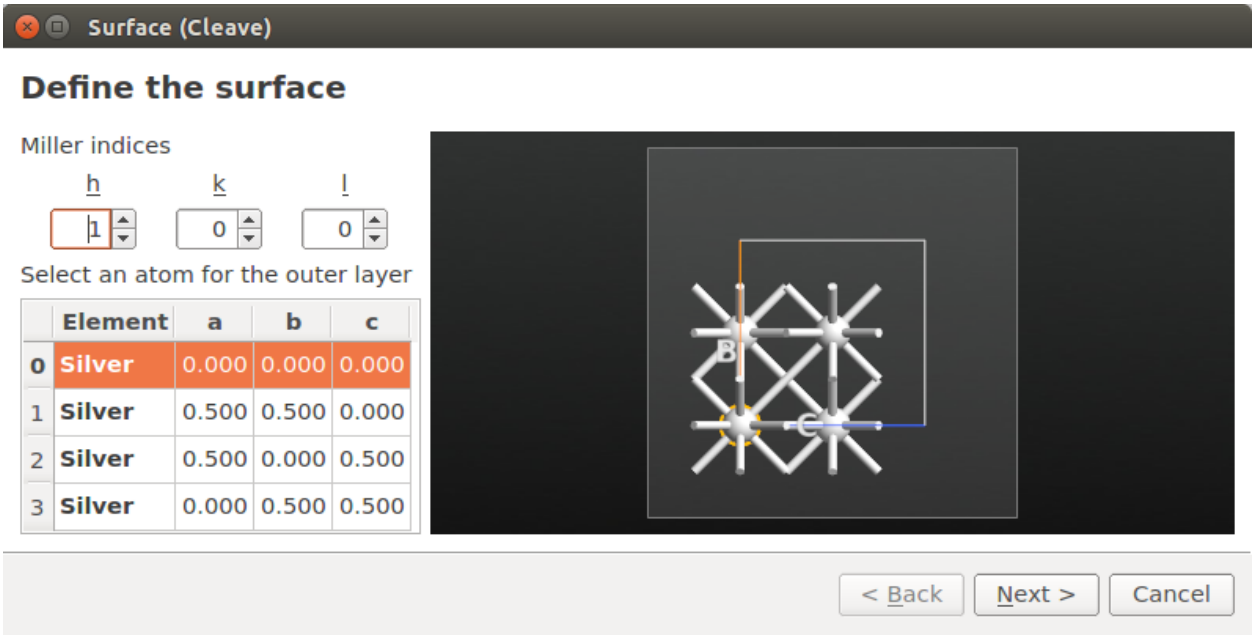
•Make sure fractional coordinates of the atoms are conserved when the lattice is changed, and enter 4.16 Å for the lattice parameter. Close the window.



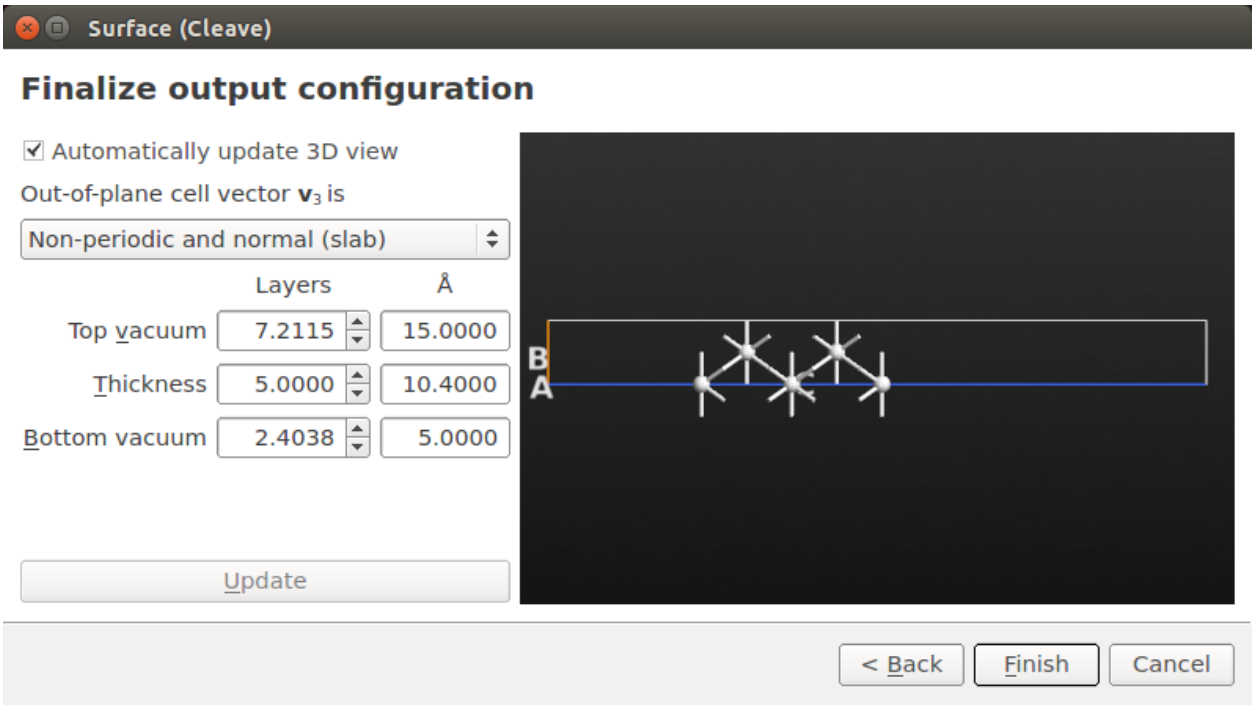
Hint: You could also simply perform a DFT geometry optimization of the silver bulk configuration using PW91 and 11x11x11 k-points, and thereby relax the unit cell. The result of this more general approach would be approximately 4.16 Å for the lattice constant.

Next, create the Ag(100) surface:

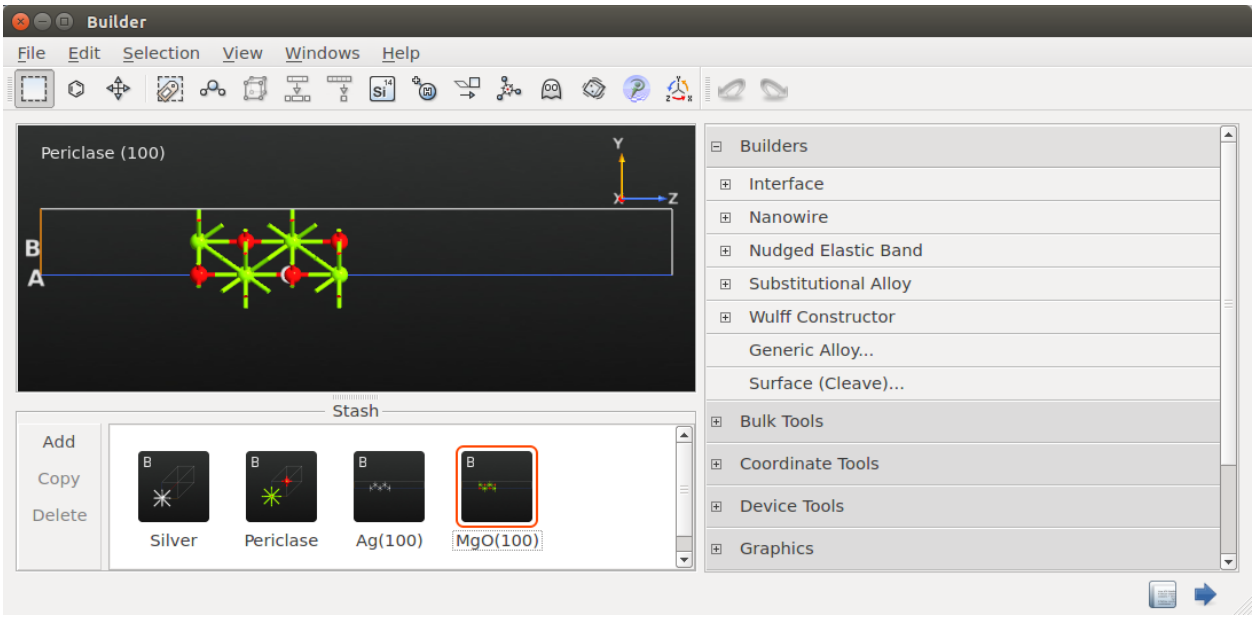
•Use the *Builders* → *Surface (Cleave)* tool to cleave the bulk silver along the [100] direction. Click *Next* twice.



•Choose *Non-periodic and normal (slab)* for the out-of-plane cell vector, and set the slab thickness to 5 layers with 15 Å top vacuum and 5 Å bottom vacuum. The large vacuum ensures that the effective potential can decay smoothly to zero above the slab.



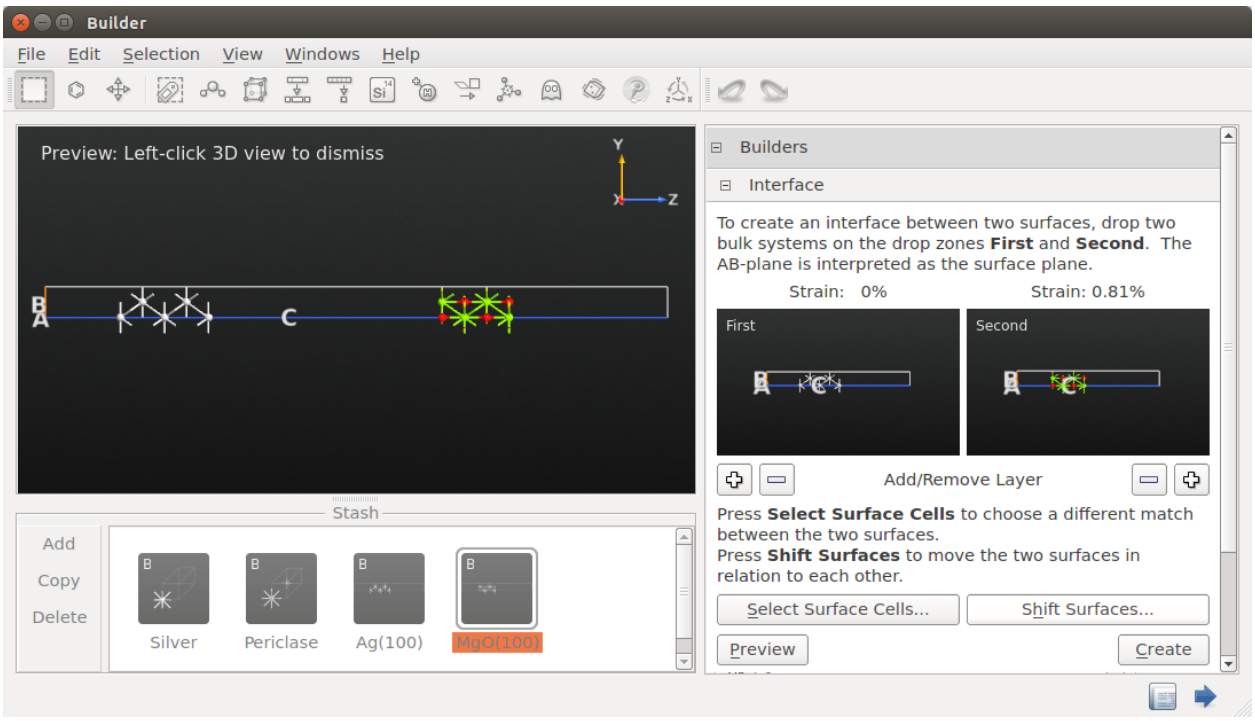
Follow the same steps to create a 4-layer MgO(100) surface, and then rename the two new Stash items to Ag(100) and MgO(100), respectively.



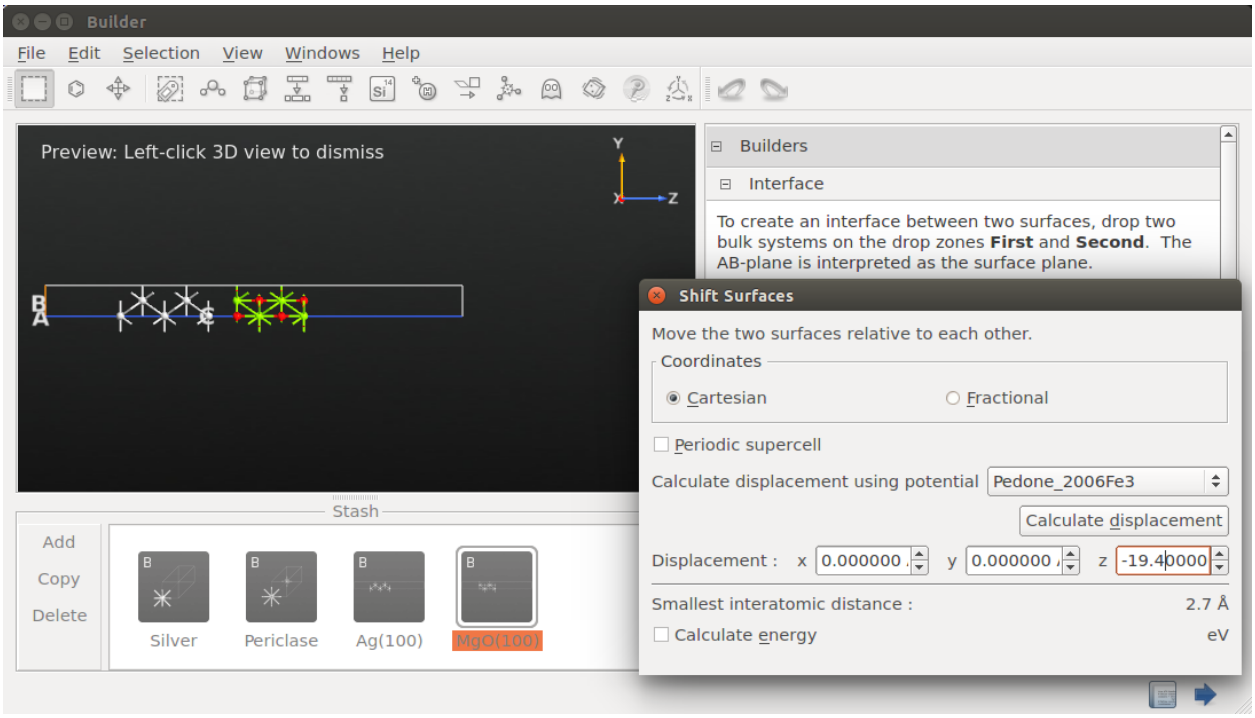
Ag/MgO interface

You should now use the *Builders* → *Interface* plugin to create the Ag(100)/MgO (100) interface:

•Open the Interface plugin, and drag and drop the Ag(100) and MgO(100) configurations into the two drop zones. Notice that the *Second* surface (MgO) is automatically strained slightly, 0.81%, such that it matches the *First* surface (Ag):



•The Ag–MgO separation is way too large. Click the **Shift Surfaces** botton and enter a displacement along z of -19.4 Å in order to move the MgO(100) slab closer to the Ag(100). The interface separation should now be 2.7 Å. Note that an O atom is in an on-top position relative to an Ag atom, so you do not have to shift the MgO slab in the xy plane:



•Close the Shift Surfaces window and click *Create* to add the interface to the Stash.

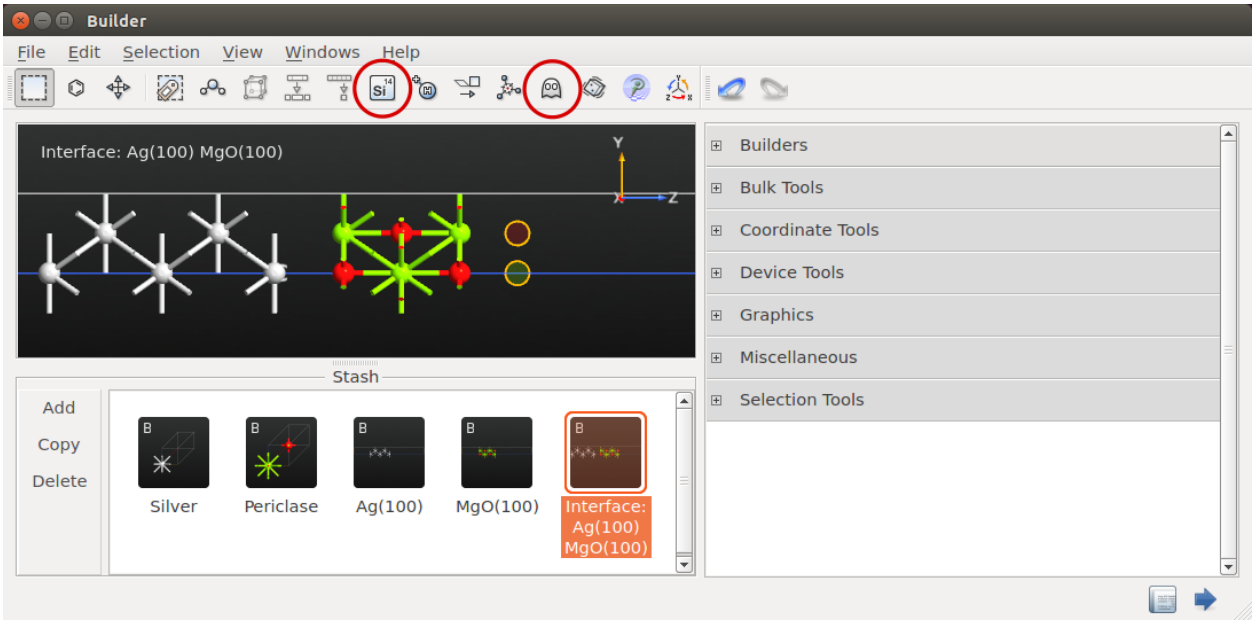
Tip: You can learn more about the Interface Builder in the Technical Notes on *Interface Builder*.

DFT calculations

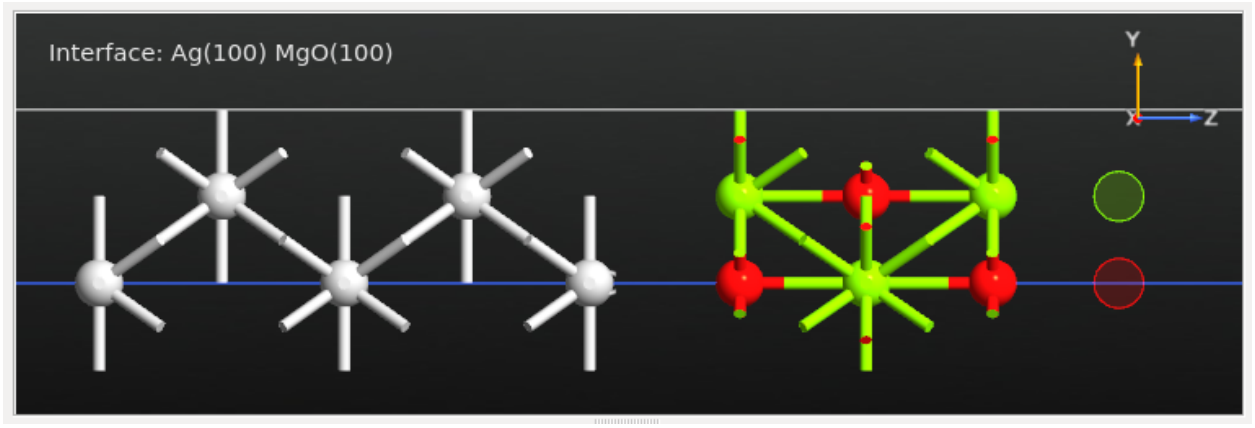
As explained in the tutorial *Computing the work function of a metal surface using ghost atoms*, you will need to add ghost atoms above the surface or interface. Work function calculations require a very good description of the charge density extending into the vacuum, and ghost atoms offer exactly this.

Adding ghost atoms

•Select the outermost O and Mg surface atoms (two atoms in total) and click the icon in the tool bar at the top of the Builder window:



•Next, swap the identity of the two ghost atoms, such that the O ghost atom is above the surface O atom and likewise for Mg. You can simply select a (ghost) atom and use the Si icon encircled in the image above to select from the periodic table.

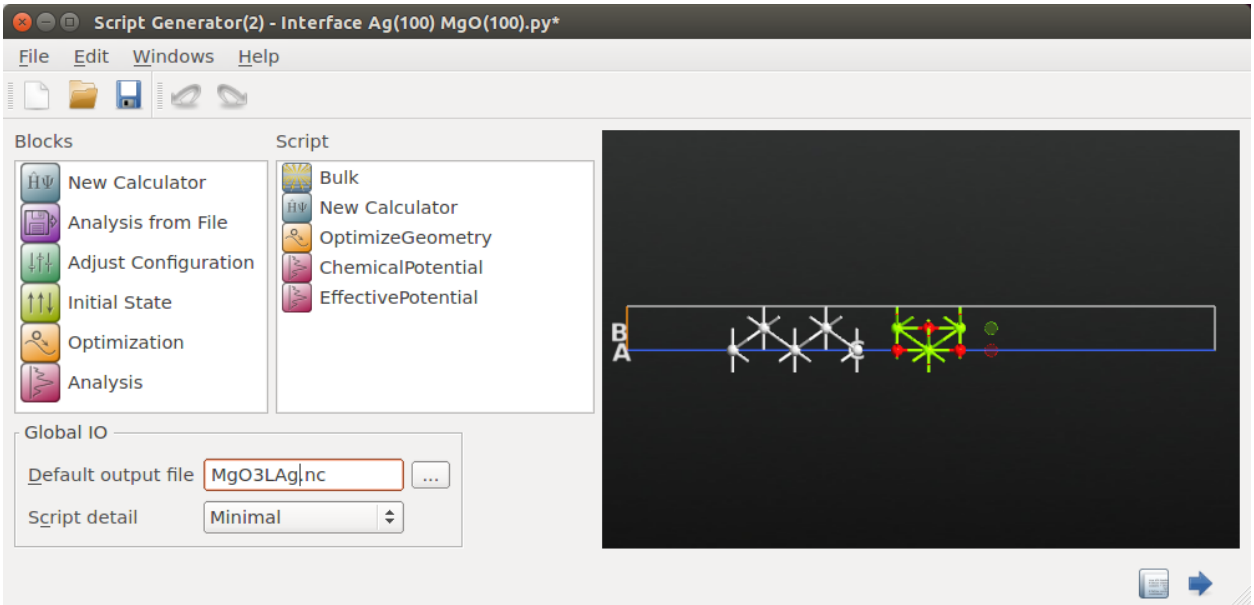


•Finally, send the configuration to the **Script Generator** .

ATK-DFT calculations

The work function is identified as the chemical potential when the effective potential is zero on the cell boundary above the surface. A Dirichlet boundary condition (BC) is used to enforce this. You will also compute the effective potential in order to inspect it visually. Set up the required DFT calculations in the following manner:

•Change the default output name to `MgO3LAg.nc` and add four blocks to the script: New Calculator, Optimize-Geometry, ChemicalPotential, and EffectivePotential.



•Open the New Calculator block and set the following parameters:

–*k-point Sampling*: 11x11x1;

–*Iteration Control*: Tolerance = 10^{-5} Hartree;

–*Exchange Correlation*: GGA.PW91;

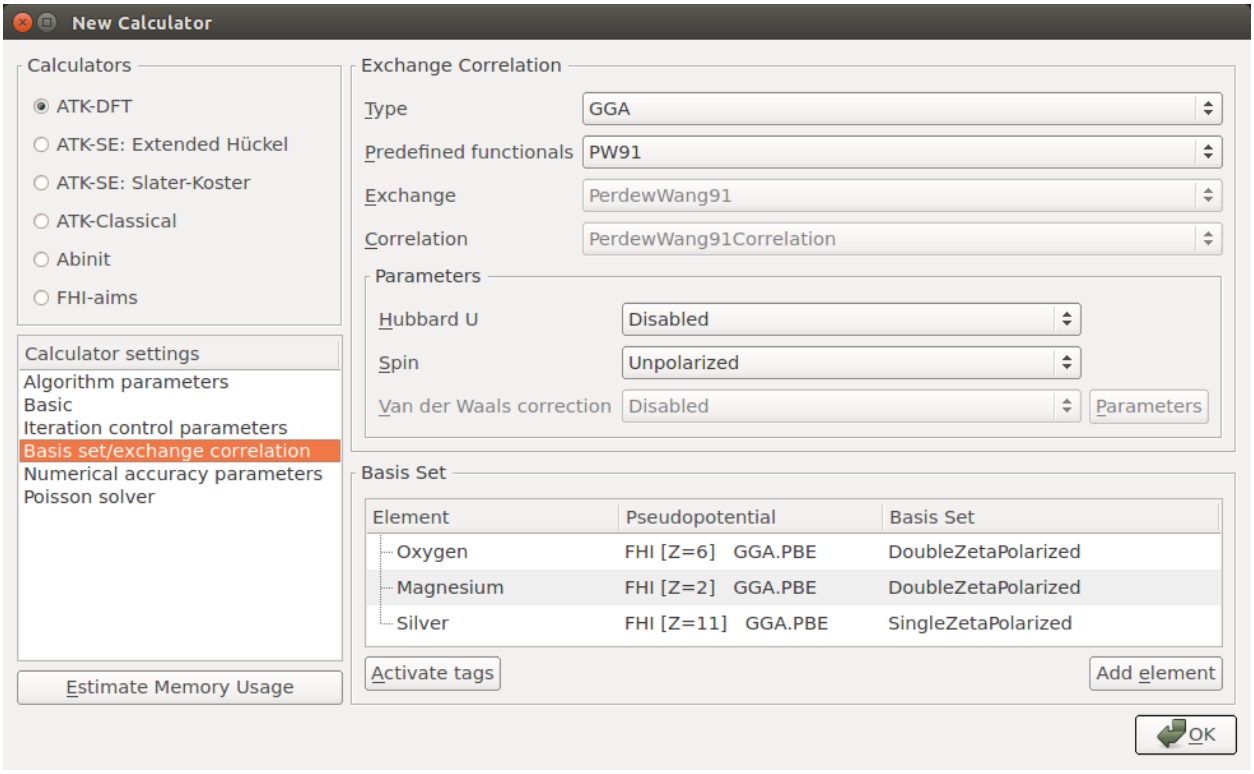
–*Basis set*: DoubleZetaPolarized for O and Mg, SingleZetaPolarized for Ag;

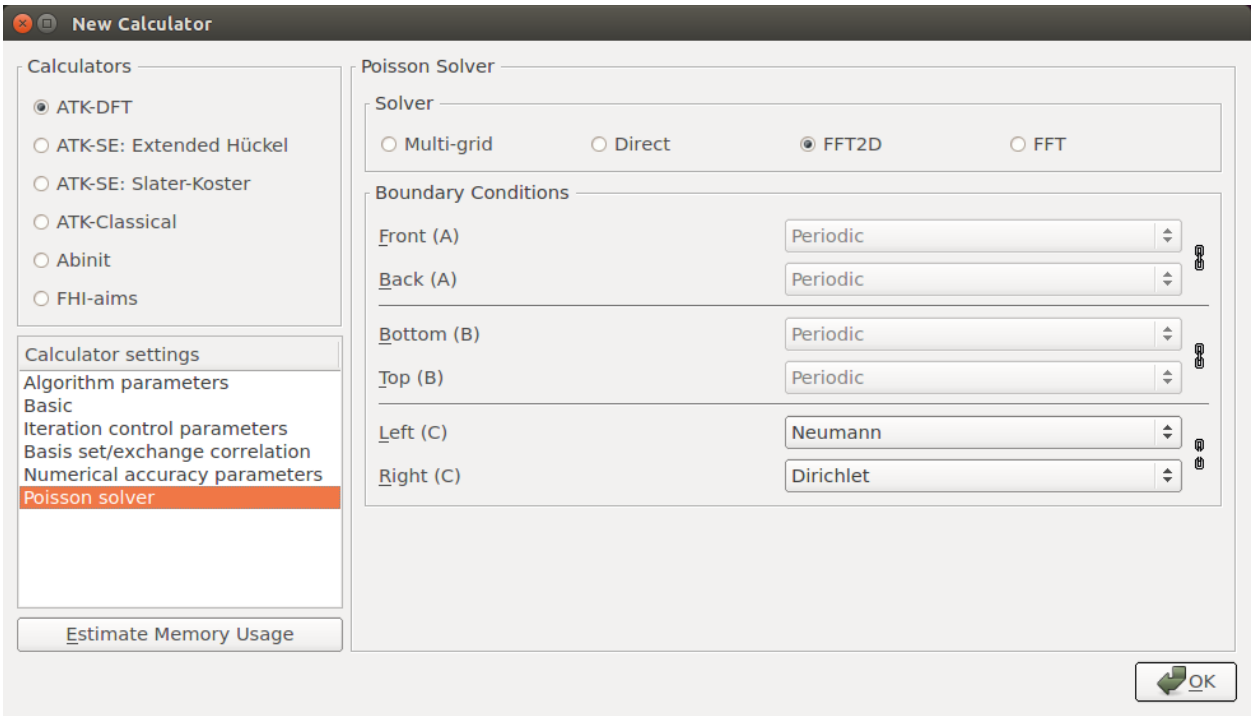
–*Poisson solver*:

∗choose the FFT2D solver,

∗select a Neumann BC on the left C face,

∗select a Dirichlet BC on the right C face.



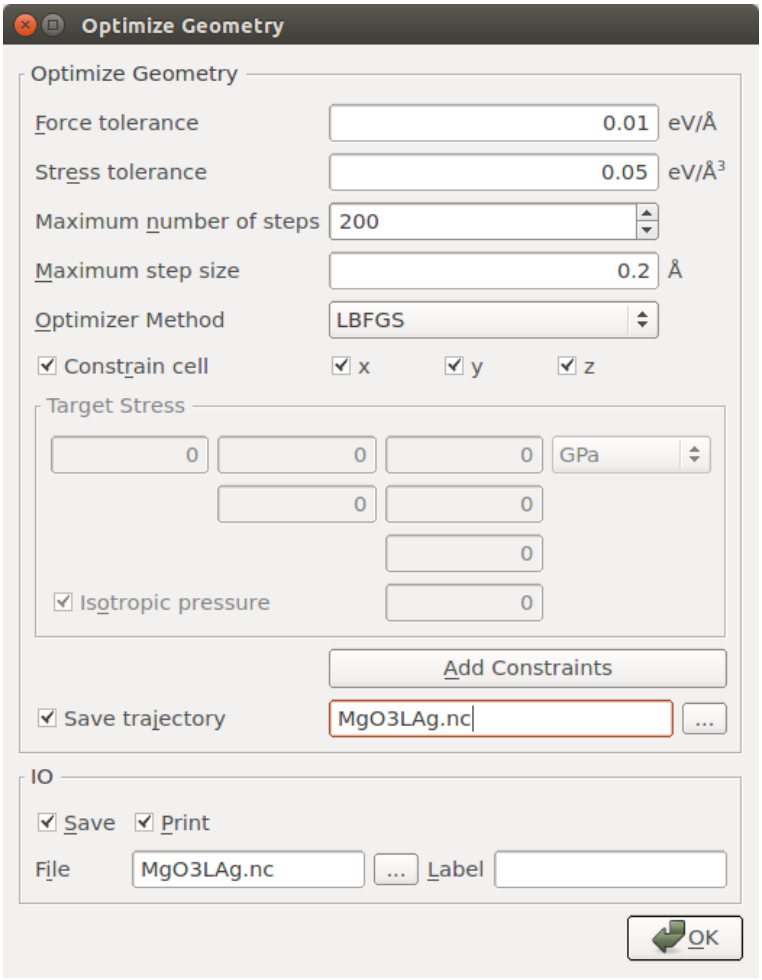


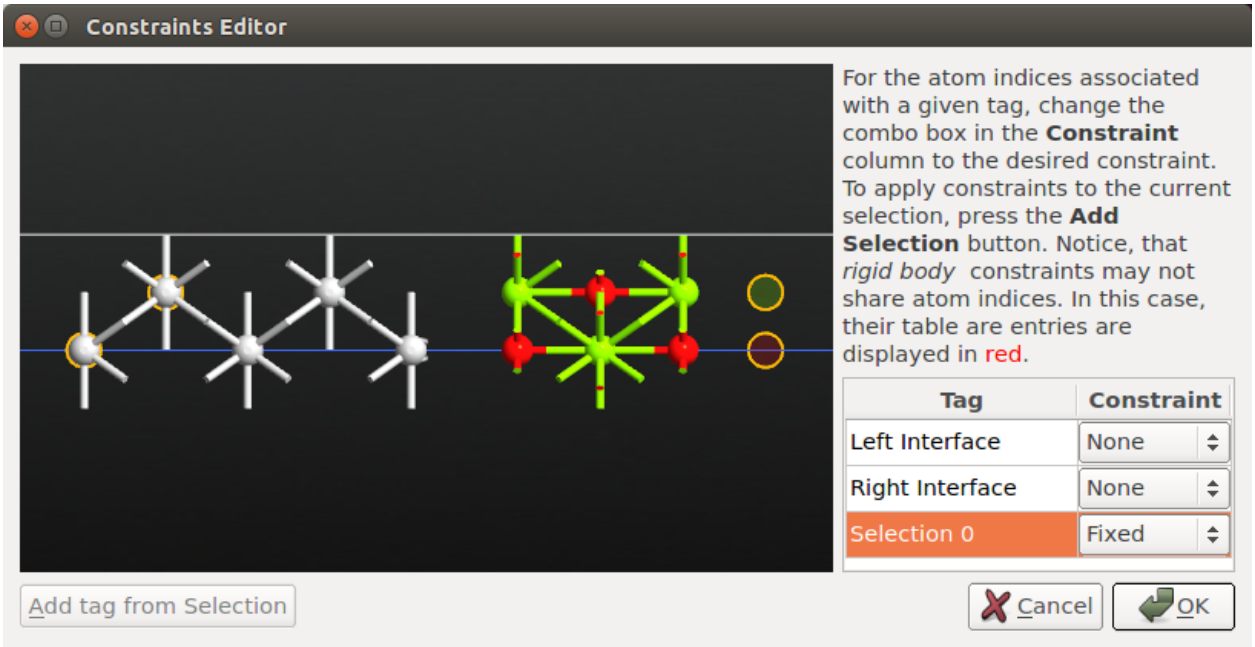
•Next, open the OptimizeGeometry block and edit it. In particular, make sure to constrain the bottom of the Ag(100) slab and the ghost atoms during the optimization:

–Decrease the force tolerance to 0.01 eV/Å.

–Tick *Save trajectory*, and enter `Mg03LAg.nc` as the file name.

–Click **Add Constraints** and select the bottom two Ag atoms and the two ghost atoms. Then click *Add tag from selection* and choose a *Fixed* constraint for that group (Selection 0).

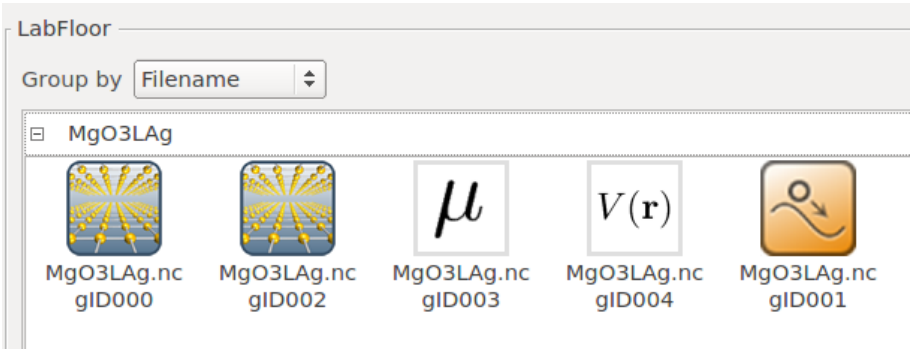




•Save the script as `MgO3LAg.py` and execute it using the **Job Manager** . If needed, you can also download the final script here: `MgO3LAg.py`. It should only take about five minutes to finish if executed in serial on a modern laptop. This can be reduced to 2.5 minutes if executed in parallel with 4 MPI processes.

Analyzing the results

The OptimizeGeometry, ChemicalPotential and EffectivePotential objects should now have appeared on the QuantumATK **LabFloor**:



OptimizeGeometry **ChemicalPotential** **EffectivePotential**

Try to select the OptimizeGeometry object and visualize the relaxation trajectory by clicking the **Viewer** plugin on the right-hand side of the LabFloor. Click to start the video. Confirm that the constrained Ag and ghost atoms are indeed fixed during relaxation.

Work function

Select the ChemicalPotential object and click the **Show Text Representation** plugin to read off the calculated chemical potential of -2.99 eV.

The work function for this 3 layer MgO on Ag(100) is therefore 2.99 eV, which is in a very good agreement with the calculated value of 2.96 eV reported in the literature by Prada *et al.*[Page 1501, 9].

You can also create the 2L-MgO/Ag(100), 1L-MgO/Ag(100) and the Ag(100) systems following the steps described above. Another approach is to use the relaxed 3L-MgO/Ag(100) configuration as a starting point for the other systems. This will reduce the number of BFGS steps needed for relaxing those systems, and thereby save computational time.

For example, to create the 2L-MgO/Ag system and calculate the work function:

•Locate the relaxed 3L-MgO/Ag(100) configuration on the LabFloor. It has object ID *glD002*.

•Transfer it to the Builder and rename it `MgO2LAg`.

•Delete the two O and Mg ghost atoms, and convert the new surface O and Mg atoms to ghost atoms.

•Swap the Mg and O ghost atoms as described above.

•Send the configuration to the **Scripter** and set up the calculation as descibed above.

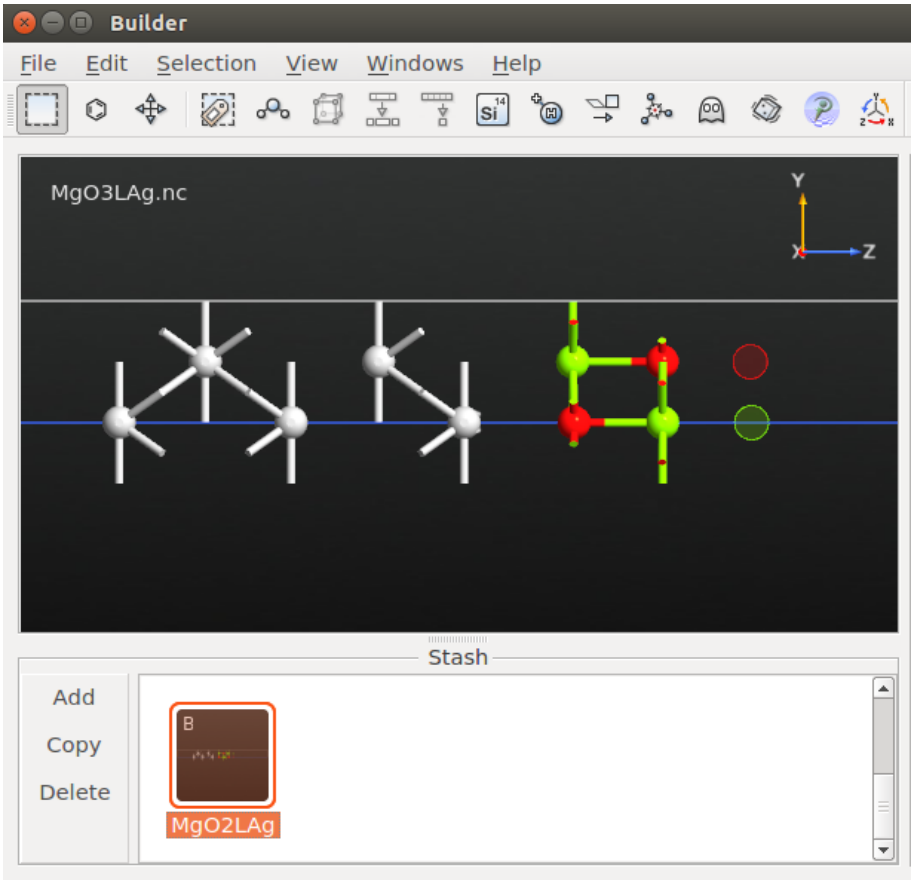


Table 3.5: Table: Calculated PW91 work functions (eV). The corresponding work function difference wrt. to clean Ag(100) is reported in parenthesis.

	QuantumATK	Pada *et al.*[Page 1501, 9]
Ag(100)	4.22	4.23
1L-MgO/Ag	3.31 *(-0.91)*	3.29 *(-0.94)*
2L-MgO/Ag	2.97 *(-1.25)*	2.95 *(-1.28)*
3L-MgO/Ag	2.99 *(-1.23)*	2.96 *(-1.27)*

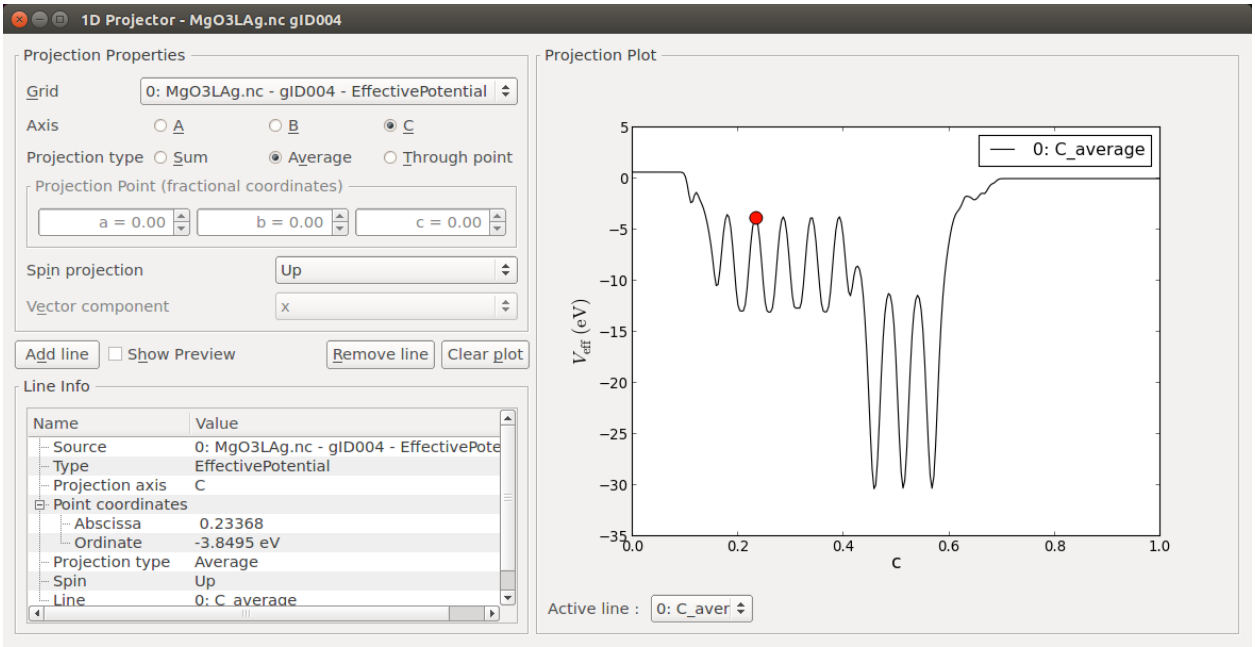
The scripts needed to calculate all the work functions in the table column labelled QuantumATK may be downloaded here: `Ag100.py`, `MgO1LAg.py`, `MgO2LAg.py`, `MgO3LAg.py`.

Tip: The table above shows excellent agreement between QuantumATK and literature (VASP) work function calculations. However, results may change if the computational settings change. For example, a SZP basis set was used for the Ag atoms – a DZP basis set may give slightly different results. The type of pseudopotentials used may also affect results, and more ghost atoms may be needed in some cases.

Effective potential

You have used a particular set of boundary conditions for the work function calculations – Neumann on the left C face, and Dirichlet on the right C face. You can now use the **1D Projector** plugin to visualize the average effective potential in the calculations:

- Select the EffectivePotential object on the LabFloor, and click the 1D Projector plugin.
- Select to project along the C axis using the *Average* projection type, and click **Add line** to plot the projection:



The effective potential is clearly different in the Ag(100) and MgO(100) regions. Moreover, the effect of the two different BCs are quite clear from the value and slope of the potential in both ends of the supercell:

- The Neumann BC on the left C face has imposed a zero slope of the effective potential on the boundary, but does not constrain the actual value of the potential on the boundary.
- On the contrary, the Dirichlet BC on the right C face has forced the effective potential to zero on the boundary, and the slope just happens to be approximately zero in the vacuum region.

1D Projector plugin

Common QuantumATK grid objects

BlochState, EffectivePotential, Eigenstate, ElectronDensity, ElectronDifferenceDensity, ElectrostaticDifferencePotential, ExchangeCorrelationPotential, ExternalPotential, LocalDeviceDensityOfStates, TransmissionEigenstate, ElectronLocalizationFunction.

The 1D Projector can be used to project all sorts of 3D grid data onto a 1D representation. This is very useful for visualization purposes, and works for a wise range of QuantumATK grid objects (see the box).

Several options are available in the plugin widget:

Grid
You can open the projector tool with multiple objects selected on the LabFloor, to plot them next to each other. Here

you choose which one to plot.

Axis
Choose along which direction you want to project your 3D data grid.

Projection type
Sum or average all the data in the plane perpendicular to the selected direction. You can also simply plot the single values along a line passing through a particular projection point.

Projection point
Specify, in fractional coordinates, the projection point to be used in case the projection type *Through point* is selected.

Spin projection
In case of spin polarized calculations, collinear or non-collinear, you can select the specific spin projection.

Add line
Once the options above are specified, click this button to plot your projection in the window on the right-hand side. You can add more projections to the same plot.

Remove line
Select one line in the Projection Plot window and click to remove the line from the plot.

Clear plot
Remove all lines from the plot.

Line Info
Some useful information about the currently selected plot line/point are shown. Note that the plot is interactive. Click on any point of the plot to print the corresponding information.

Projection Plot
Right-click to zoom, customize or export data to file.

3.11.10 Calculating Reaction Rates using Harmonic Transition State Theory

Introduction

In this tutorial, you will learn to use **QuantumATK** for calculating reaction rates using the nudged elastic band (NEB) method and harmonic transition state theory (HTST). These two techniques are a powerful combination that allow researchers to model solid-state reactions (or more generally any rare event dynamics). Typically, reactions in the solid state are too slow to efficiently study with molecular dynamics (MD) simulations. HTST, on the other hand, takes a statistical mechanics approach to computing the reaction rate. Therefore, in constrast to MD simulations, the amount of computational work required to calculate a reaction rate is independent of the timescale of the reaction.

Theory

HTST[1] is derived from a more general formalism known as transition state theory (TST)[2][3]. TST works by defining a transition state (a hyperplane) that separates the reactant from the products. Then the reaction rate is calculated as the probability of finding the system at the transition state relative to the entire reactant state, multiplied with the rate of crossing from the reactant region to the product region at the transition state. In general, TST is difficult to use, because it requires a definition of the transition state hyperplane. Additionally, calculating the probability of being at the

[2] Henry Eyring. The Activated Complex in Chemical Reactions. *The Journal of Chemical Physics*, 3(2):107–115, 1935. doi:10.1063/1.1749604.

[3] ArthurăF. Voter and JimmieăD. Doll. Transition state theory description of surface selfdiffusion: Comparison with classical trajectory results. *The Journal of Chemical Physics*, 80(11):5832–5838, 1984. doi:10.1063/1.446610.

transition state requires evaluating the full partition function of the transition state region and the reactant region, which is computationally prohibitive when using density functional theory, and challenging even for fast classical potentials.

TST can be made a more practically useful theory by making two simplifying assumptions. The first is that saddle points on the potential energy surface represent bottle neck regions that separate reactant from product configurations. This solves the issue of determining the hyperplane in TST by defining it as the hyperplane normal to the unstable direction at the saddle point. The second is that the potential energy surfaces around the reactant configuration and the saddle point are locally harmonic (quadratic). This allows for a second order Taylor series expansion of the potential energy surface at those points and the resulting configuration integrals needed in TST are now closed-form expressions. The combination of these two assumptions is called HTST.

HTST is a good approximation for many solid-state reactions, because the energy barriers are often large compared to the average kinetic energy in the system ($k_{\mathrm{B}}T$). This is important because it ensures that the system reaches a local equilibrium between reactive events. If the barriers are relatively small compared to the thermal energy, then there are dynamical correlations in the trajectory. This means that the history of the trajectory is an important factor in determining the reaction rate and would require the use of a more sophisticated statistical model. Another reason that solid-state reactions are described well by HTST is that the harmonic approximation is often valid. Near the saddle points the potential energy rises rapidly and creates a small bottleneck region, however, in some soft systems (e.g. conformation changes in a protein) the potential energy is relatively flat in the region around the saddle point and is not well characterized by harmonic expansion of the saddle point.

The first step in using HTST is to find the saddle point associated with the reaction in question. There are a number of techniques that can be used, but here we will use the NEB. NEB optimization can be performed in such a way that one of the images converges to a saddle point (as opposed to all the images being evenly spaced along the reaction coordinate). This is called climbing image NEB (CI-NEB) and an optimized CI-NEB should have a saddle point as its highest energy image.

Once the saddle point has been obtained the following formula is used to calculate the reaction rates:

$$k_{\mathrm{HTST}} = \frac{\prod_i^{3N} \nu_i^{\mathrm{R}}}{\prod_i^{3N-1} \nu_i^{\mathrm{S}}} \exp\left[-\left(E^{\mathrm{S}} - E^{\mathrm{R}}\right)/k_{\mathrm{B}}T\right]$$

where N is the number of atoms; ν_i^{R} and ν_i^{S} are the stable (real valued) normal mode frequencies at the reactant and saddle point (the $3N-1$ at the saddle is due to there being exactly one imaginary frequency at the saddle); E^{R} and E^{S} are the energies at the minimum and saddle point; k_{B} is Boltzmanns constant; and T is the temperature.

The functional form of HTST is analogous to the empirically derived Arrhenius rate law:

$$k_{\mathrm{Arrhenius}} = A \exp\left[-E_{\mathrm{a}}/k_{\mathrm{B}}T\right].$$

The pre-exponential factor, A, in the Arrhenius rate law corresponds to the ratio of the product of the vibrational modes at the minimum over the product of the stable vibrational modes at the saddle in HTST. This can be interpreted as an attempt frequency, i.e. the number of times per second that the system vibrates along the reaction direction.

The activation energy, E_{a}, in the Arrhenius rate law is defined as the difference in energy between the saddle and minimum in HTST. The exponential term represents the Boltzmann probability that a vibrational along the reaction direction will overcome the barrier and continue into the product state.

Thus, the HTST rate equation can be interpreted as:

$$k_{\mathrm{HTST}} = [\text{Attempt Frequency}] \cdot [\text{Probability of Success Per Attempt}]$$

Note: In most systems, the prefactor does not change significantly (ca. a factor of 10) from reaction to reaction. However, the exponential term (the Boltzmann probability of the system being at the transition state) can easily span 10 orders of magnitude. This is because most solid-state reactions are thermally activiated processes, whose rate primary depends upon the energy barrier.

Despite the small contribution of the prefactor to the difference in rate between different mechanisms it can be more computationally expensive to compute than the energy barrier.

It is thus recommended to experiment with the system to see if it is neccessary to compute the prefactor every time. In reactions involving light atoms (first two rows of the period table) the prefactor is often in the order of 10^{14} Hz, while for heavier metal atoms it may be as small as 10^{11} Hz. These frequencies are related to a typical vibrational period in these systems, which primarily depends on the atomic mass.

Modeling Pt Adatom Diffusion on Pt(100)

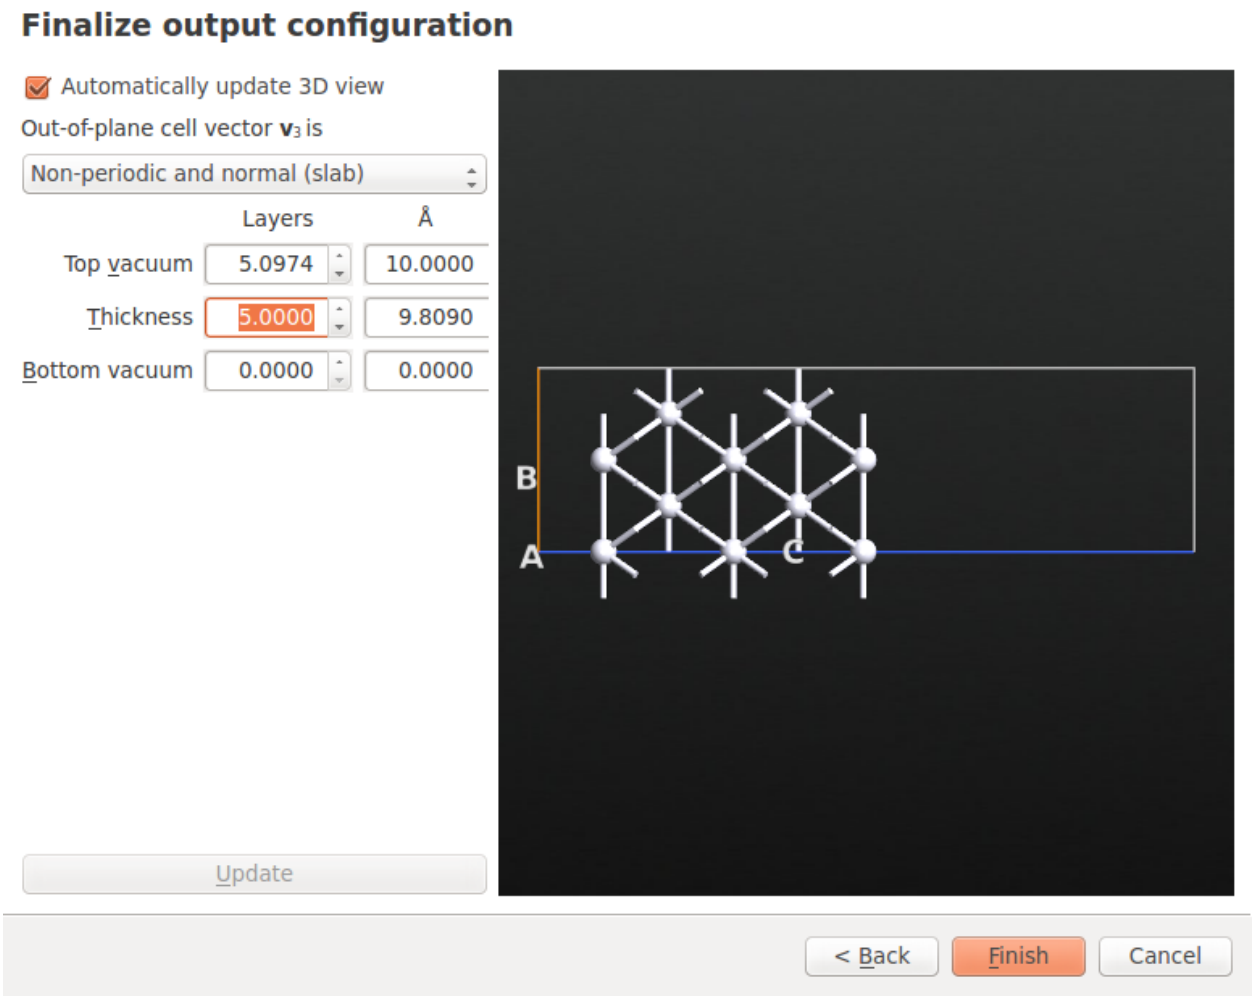
As an model system we will examine Pt adatom diffusion on a Pt(100) surface. There are at two well known mechanisms for adatom diffusion on this surface. The first is the hop mechanism where the adatom directly moves to an adjacent hollow site. The second is the exchange mechanism where the adatom exchanges places with a surface atom and displaces it into an adjacent hollow site.

There are several interesting things we will learn from this system. The first is that although DFT and classical potentials often agree about equilibrium properties, where the classical potentials have been fit, the agreement is often quite bad near saddle points. Often saddle points describe bond breaking and bond formation steps that can be particularly challenging to describe in many classical potentials, especially those potentials that make use of explicit angle terms as is often used to describe Si and C bonding. The second is that what may initially look like a simple one step reaction sometimes actually involves multiple steps. It is not uncommon to encounter a relatively unstable reaction intermediate between the chosen initial and final geometries. This will be an important point to understand since, formally, HTST only describes elementary single step reactions.

Constructing the Pt(100) surface

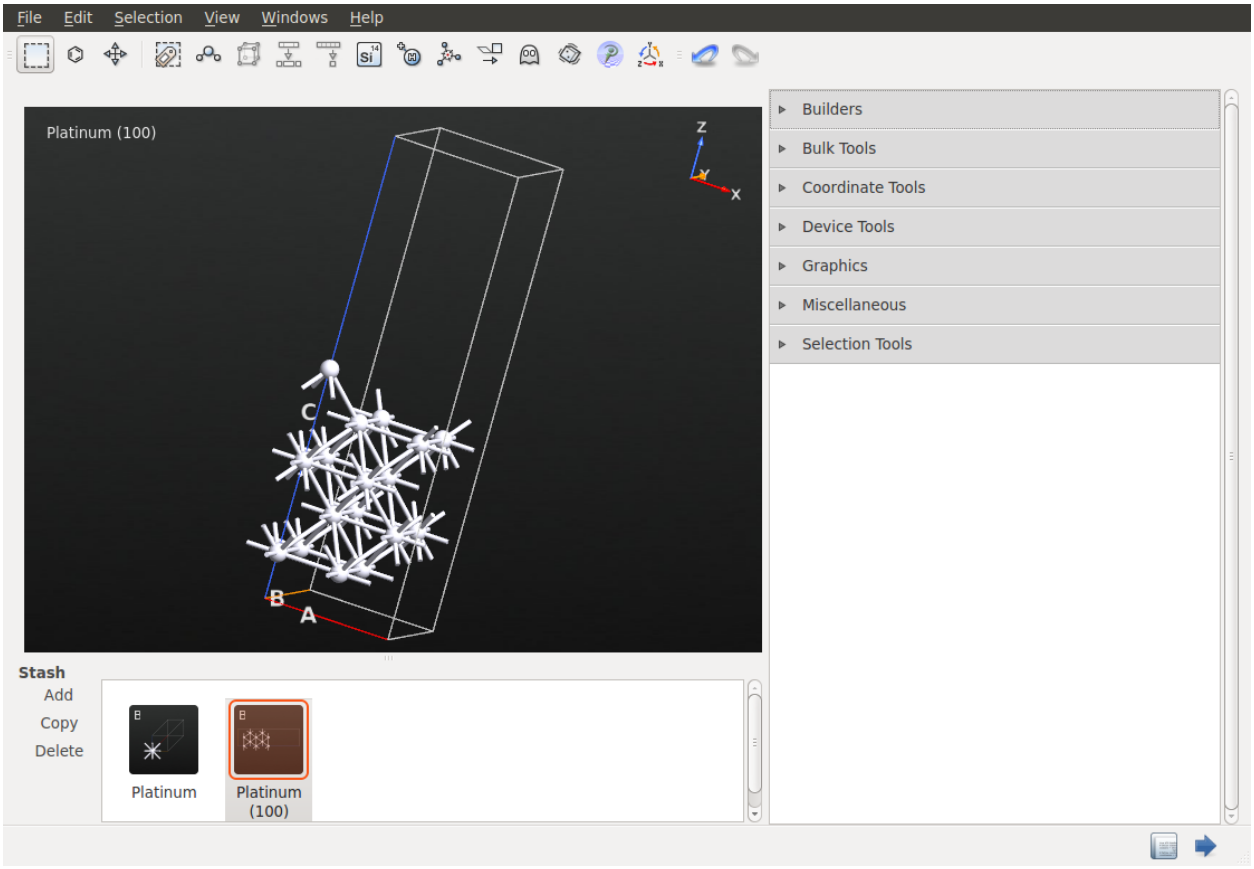
In the **Builder** click *Add* → *From Database* and then search for platinum. A list of structures containing platinum will appear, scroll through them to find Platinum and double click on it.

Then click *Builders* → *Surface (Cleave)* and set the Miller indices to (100) and click *Next*. Create a 2x2 surface lattice and click *Next*. Then choose the Out-of-plane cell vector to be *Non-periodic and normal (slab)*, set the thickness to 5 layers, and click *Finish*.



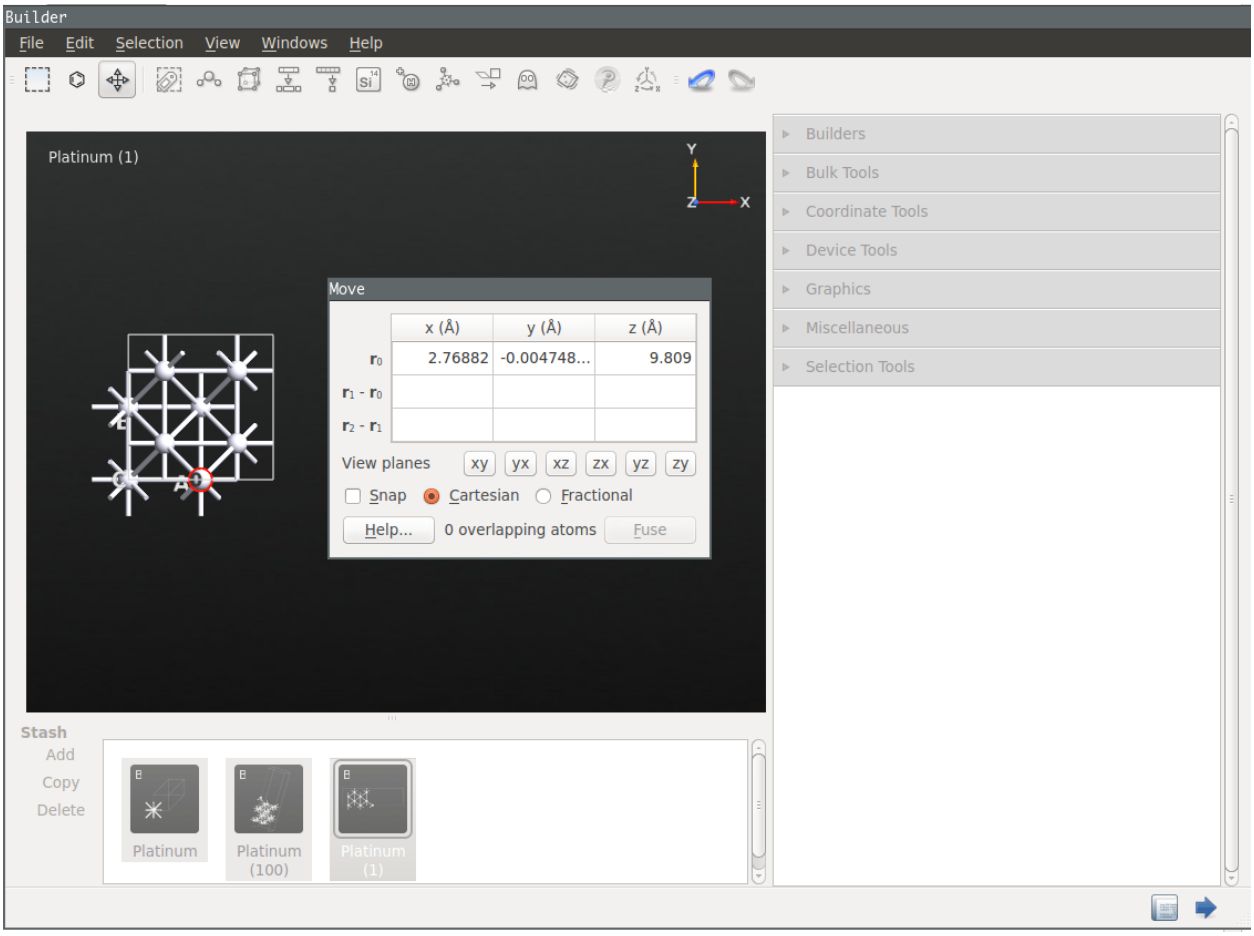
For later visualization it is nice to center the slab model in the x-y plane. To do this click *Coordinate Tools* → *Center*, uncheck the *C* direction and click *Apply*.

Delete all but one of the atoms in the 5th layer. The remaining atom will be the diffusing adatom in the NEB calculation.



Constructing the NEB Configuration

Make a copy of the configuration by clicking the *Copy* button in the **Stash**. Double click on the new configuration. Now select the adatom and click on the move tool in the toolbar and drag the adatom to and adjacent hollow site. This is easiest to do if you first camera view plane to the XY plane.



Click *Builders* → *Nudged Elastic Band* and drag both configurations from the stash to the *initial* and *final* drop zones. Click on *Constraints* and select the bottom most layer. Click *Add tag from Selection*, then change the constraint type from *None* to *Fixed* and click *OK*. Change the NEB method from *Linear* to *Image Dependent Pair Potential*. In this case, as few as 5 images should work well, since it is a relatively simple reaction coordinate. Set the *Maximum distance* to 1 Å and click *Create*.

Right click on the NEB configuration in the *Stash* and select *SendTo* → *Script Generator*.

Optimizing the NEB and Calculating the HTST Rate

Double click on *New Calculator* in the *Blocks* list to add a calculator to the *Script*. Now double click on the just added *New Calculator* in the *Script*. Change the k-point sampling to be 3x3x1 and the *Exchange correlation* function to *GGA*. Then click *OK*.

Double click on *Optimization* → *OptimizeGeometry* in the *Blocks* list and the double click on *OptimizeGeometry* in the *Script* list. Change the *Force Tolerance* to 0.01 eV/Å. Then click *Add Constraints*, select the bottom most layer of atoms, click *Add tag from Selection*, and change the constraint type from *None* to *Fixed*. Check the *Climbing Image Method* check box as well as *Optimize end points*.

It is crucial that a CI-NEB calculation is performed. If a regular NEB optimization is used then the images will be equally spaced along the reaction coordinate. This means that there will most likely not be an image at the saddle point. While, a converged CI-NEB calculation should have a saddle point as the highest energy image.

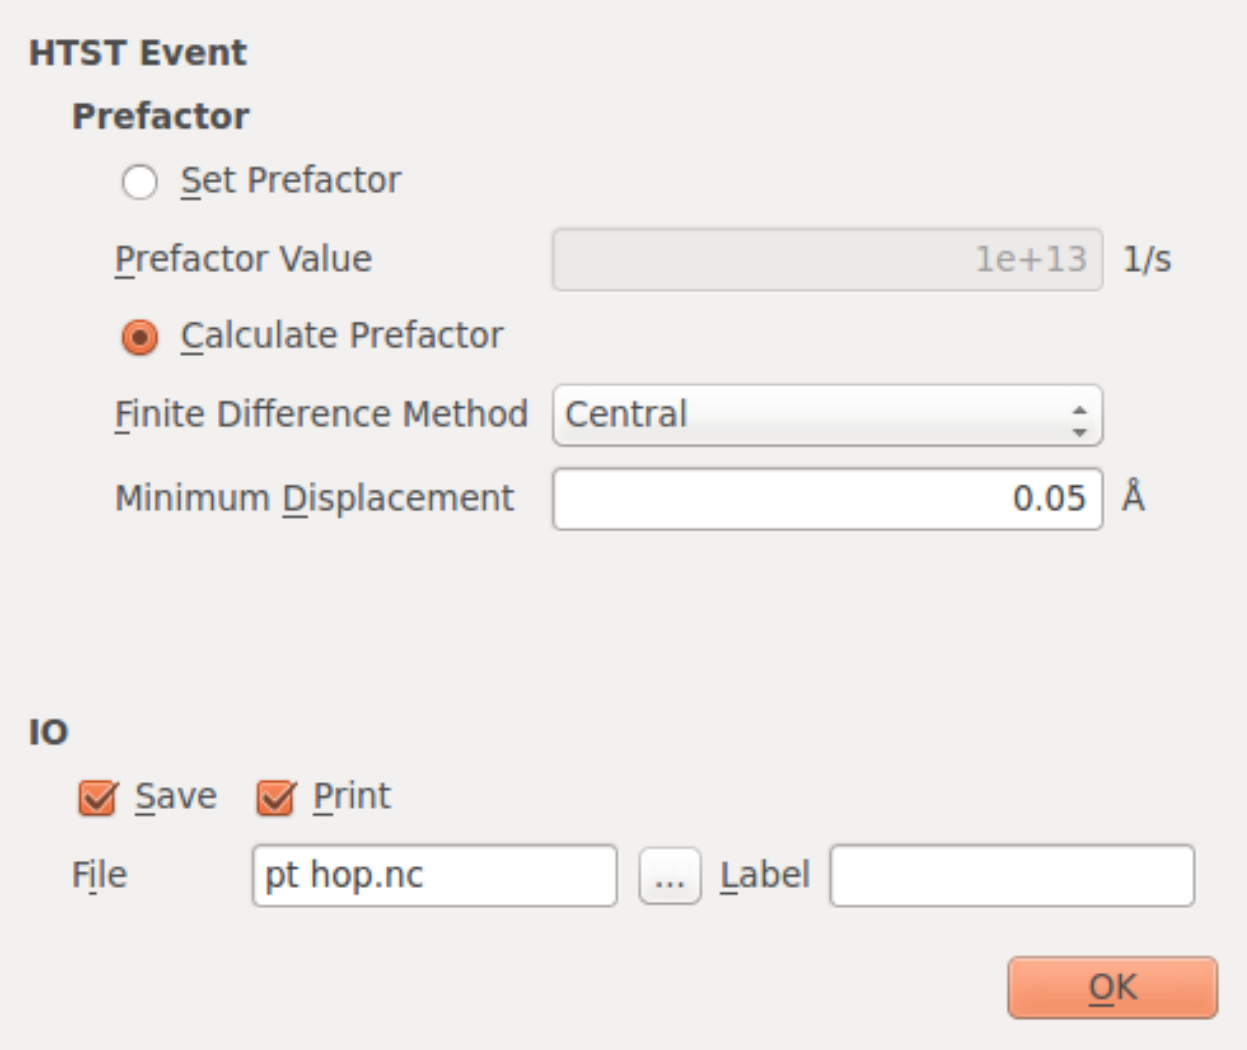
Note: In this tutorial, we are optimizing the NEB end points and the intermediate images in one step. This works fine

for this simple case where the endpoints are close to their optimized geometries, however, it is typically a good idea to break this process up into three steps:

1. Optimize the initial end point.
2. Optimize the final end point.
3. Create the NEB configuration from the optimized endpoints and optimize it.

This approach allows you to analyze and verify the optimized end points to ensure that the geometry optmization did not significantly alter them.

Double click on *Analysis* → *HTSTEvent* in the *Blocks* list then double click on the *HTSTEvent* in the *Script* list. There are two options for determining the prefactor in the HTST rate equation (see the first equation in the introduction).



The first way to calculate the prefactor is to calculate the dynamical matrix for a subset of the atoms in the system. The atoms included in the calculation are those that move by by more than the *Minimum Displacement* parameter along the reaction coordinate along with their nearest neighbors (as determined using covalent radii). The second method is to simply set the prefactor to a known value.

Change the default output file `pt hop.nc`. Then either save the script and run it with *atkpython* or send it to the **Job Manager** to run it.

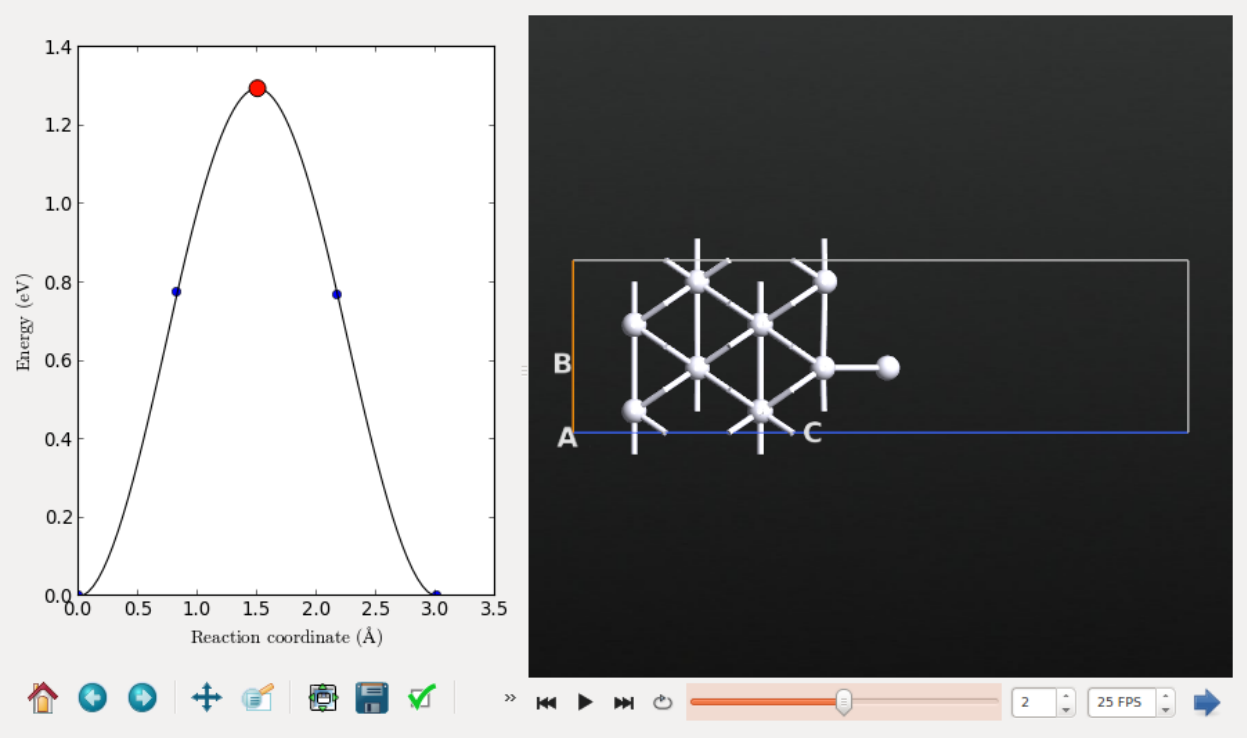
The calculation may take a couple of hours depending upon your hardware and the number of MPI processes used.

Note: It is possible that the highest energy image of the converged CI-NEB calculation will not be a first order saddle point. This will be detected when the frequencies at the saddle point are calculated. An error message will be printed to the log and the calculated frequencies will be printed. There are a number of reasons why this may occur:

1. The NEB optimization did not converge. Consider increasing the maximum number of steps in the optimization and double checking the input geometries to be sure that the initial guess is reasonable.
2. The NEB optimization may have converged, but the force tolerance is too large. Try making the force tolerance smaller. A good value for many systems is 10^{-2} eV/Å, but it may sometimes be required to use 10^{-3} eV/Å.
3. If negative frequencies at the saddle still persist, then it is possible the NEB has converged to a second-order saddle point (i.e. a saddle point with two negative frequencies). In this case you should try to build a different initial guess for the NEB configuration to see if it will converge to the correct first-order saddle point.

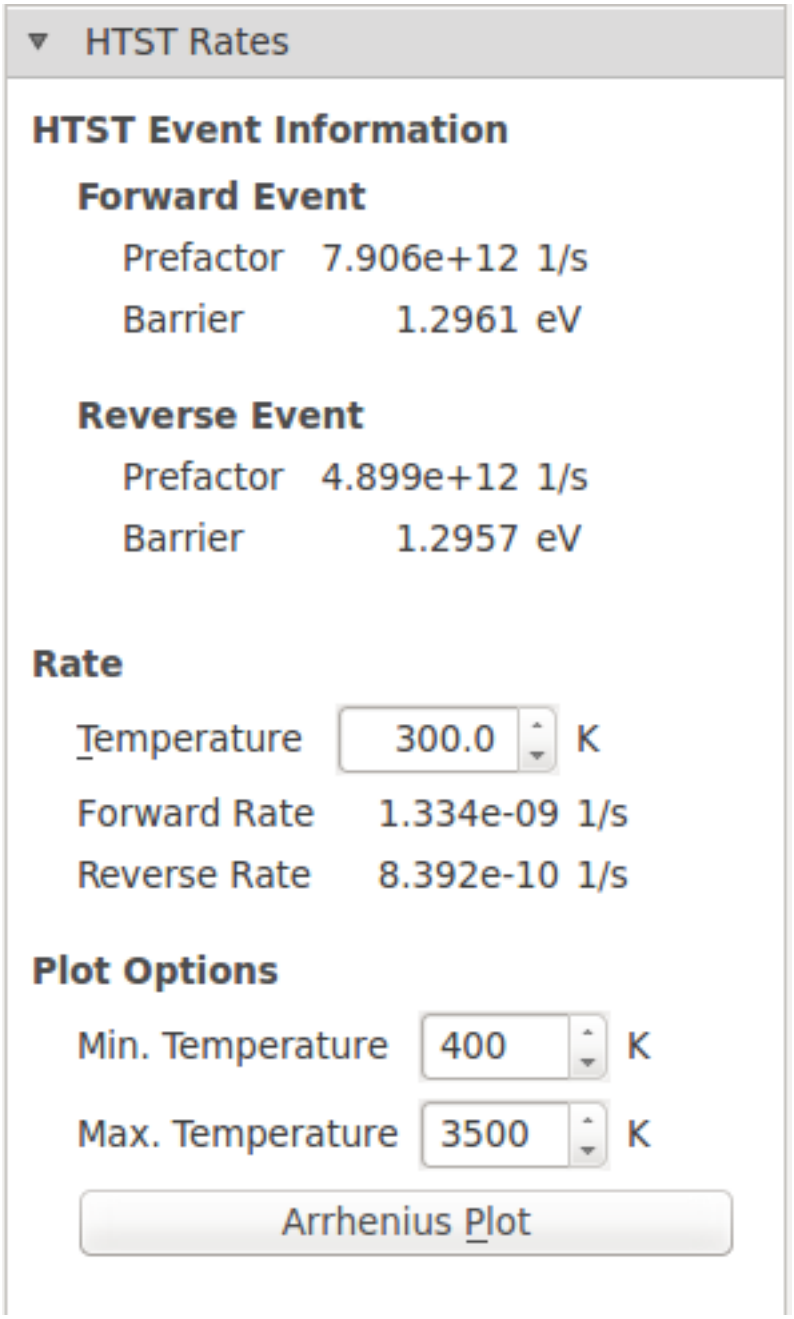
Analyzing the Results

After the calculation finishes the file `pt hop.nc` should contain the initial and converged NEB configurations, as well as the HTSTEvent. Click on the second NEB configuration and click on the *Movie Tool* in the panel on the right.



The potential energy curve shows that the barrier is about 1.3 eV. The movie of the reaction visualizes the expected hopping process. There is a single barrier between the initial and final state. Close the *Movie Tool* window. Select the HTSTEvent object on the LabFloor and click the *HTST Rates* plugin in the panel on the right.

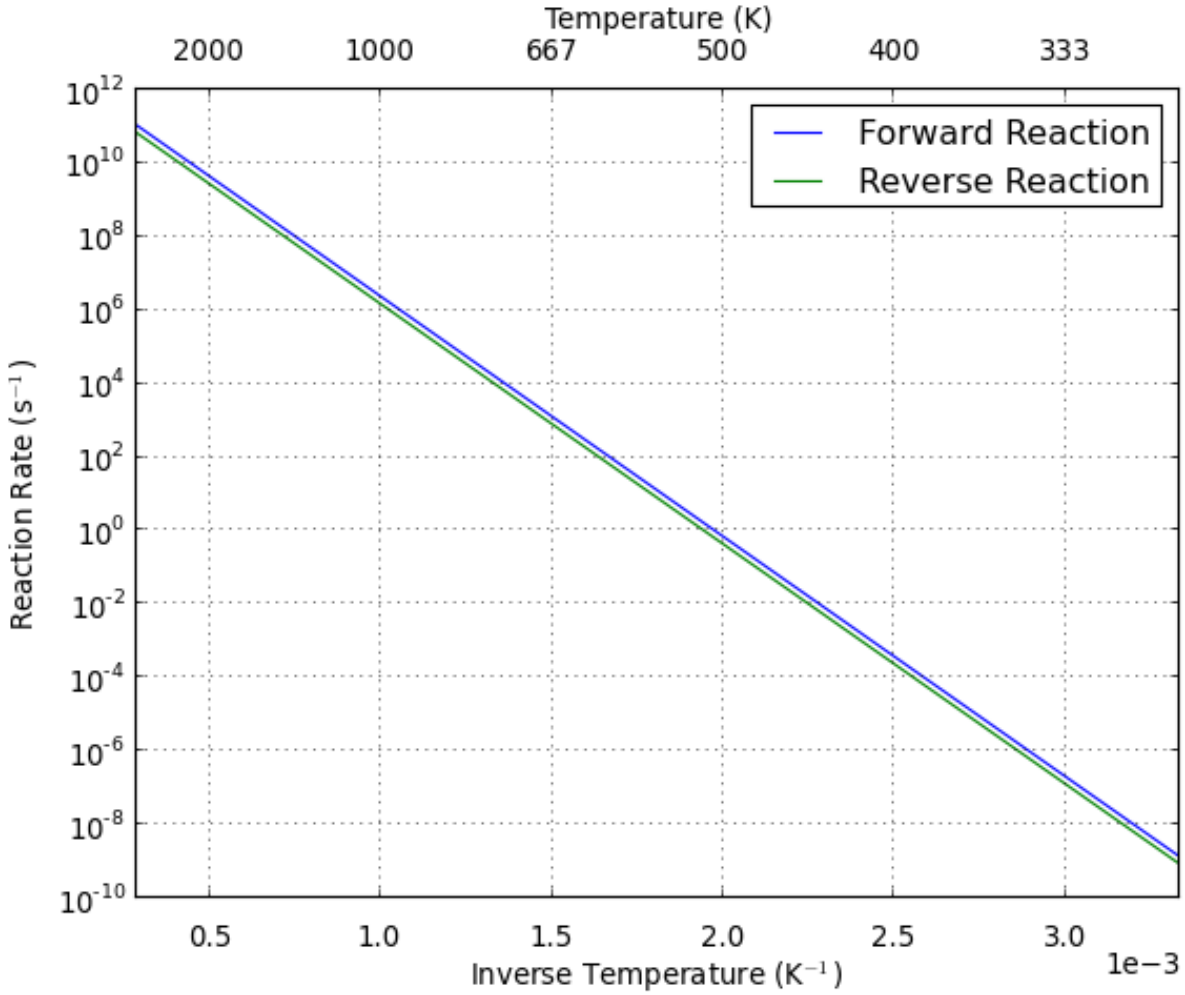
Information about about the reaction such as the barriers and prefactors are shown. The rate can be calculated at any temperature by changing the temperature value, which is 300 K by default.



The forward and reverse barrier and prefactor should be identically theoretically, however, in practice they are not. This is due to small differences in the NEB endpoint geometries since each was minimized from a slightly different starting structure. Also, since this is an ATK-DFT calculation, translational symmetry is not perfectly preserved due to the eggbox effect. This effect describes the relationship between the real-space grids used to represent the charge density and potentials and the positions of the atoms. These grids will be aligned differently with different atoms thus breaking the translational symmetry. The effect is very small for the total energy in this case (< 1 meV), but is more pronounced for the prefactor, where it differs by a factor of 1.6. These errors can be minimized by increasing the *Density mesh cut-off* in the ATK-DFT calculator settings, but it increases the computational cost of the simulation and may not be necessary to get meaningful results.

It is also possible to make an Arrhenius plot to show the temperature dependence of the HTST rate. An Arrhenius plot is the $\log(\text{rate})$ vs $1/T$. When the temperature dependence is plotted this way, the plots will always be straight lines. The slope of the line is $-\Delta E/k_{\text{B}}$ and the y-intercept is the prefactor. From the plot it is easy to interpret that the

prefactor is the maximum possible rate predicted by HTST.

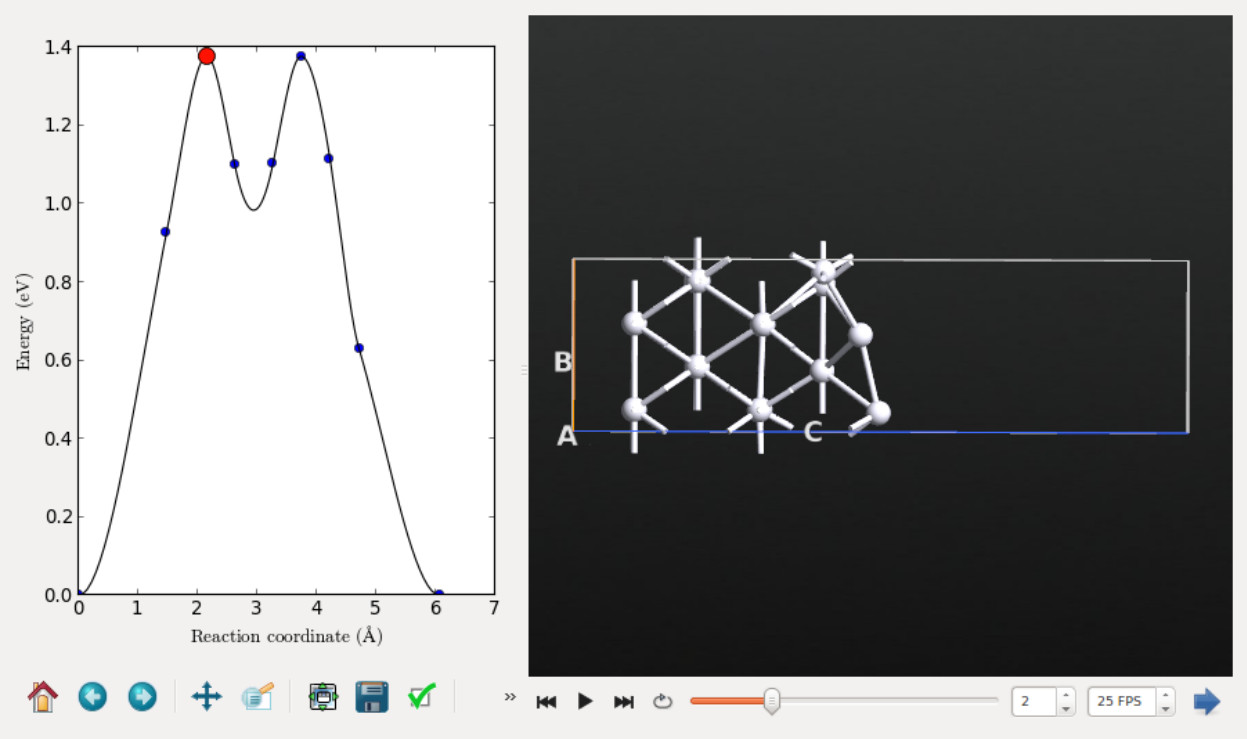


The reaction rate for Pt diffusion via the hopping mechanism is extremely slow at room temperature. The average time between reactions (the inverse of the rate) is on the order of centuries. However, at 600 K we can expect the reaction to occur tens of times per second.

Calculating the Rate for Multiple Elementary Reaction Steps

The exchange mechanism for Pt adatom diffusion on Pt(100) is an interesting case study, because it does not proceed via a single elementary reaction like the hop mechanism does. Details for setting up the calculation are given in another *tutorial*, but the results of the calculation and how to understand the reaction using HTST will be explained here.

The converged CI-NEB calculation shows the following reaction coordinate diagram:



Here you can see that there are two saddle points and thus two reaction steps. The first barrier is about 1.4 eV and the second barrier is about 0.35 eV. Calculating the HTST rate for this reaction would involve splitting the calculation up into two separate NEB configurations to determine the rate constants for each step of the reaction.

Depending on what you are trying to model, it can often be a reasonable approximation to ignore the intermediate state. For example, at 600 K the initial reaction step has a rate of about 1.7 Hz, while the second step has a reaction rate of about 1 GHz ($10^{12}\exp[-0.35eV/600Kk_{\mathrm{B}}]$). Therefore, it may be reasonable to ignore the reaction intermediate.

A more careful study would involve running a kinetic Monte Carlo simulation to determine the kinetics of the system. As soon as more than one reaction step is involved, the reaction kinetics will no longer strictly obey a first order rate law, even if it is often a valid approximation.

3.11.11 Calculation of Formation Energies

In this tutorial you will learn how to calculate cohesive and defect formation energies of different systems by total energy calculations. In particular, three examples are shown:

1. GaAs bulk;
2. Ga vacancy in GaAs;
3. Oxygen vacancy on a MgO surface.

Formation energy calculations (or cohesive energy)

In **ATK** you can easily calculate the formation energy (or cohesive energy) of your system from conventional total energy calculations. In particular, you can calculate the formation energy from the total energy of your system and the total energy of its constituent parts:

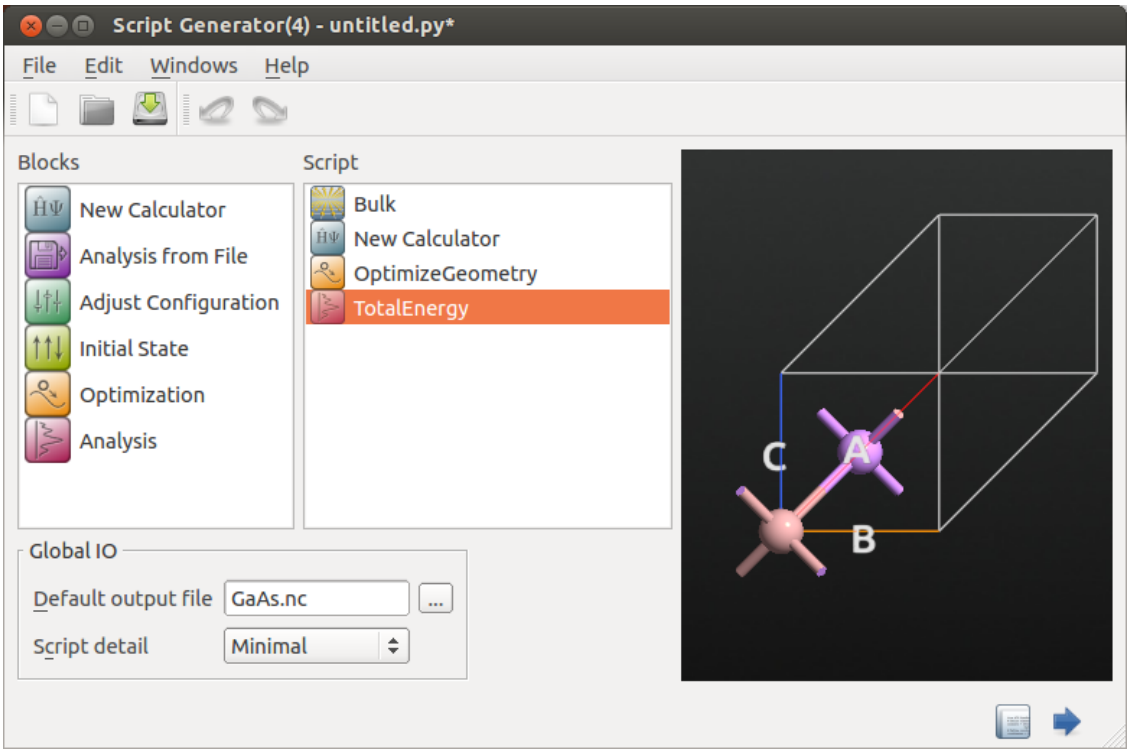
$$E_{form} = E_{tot} \Sigma_x E_{tot}(x). \tag{3.14}$$

E_{form} represents the energy required to dissociate the material into its individual components, x. You should pay particular attention when you choose the reference systems for your individual components, which could be bulk or gas phases.

Note:

- E_{form} is calculated from electronic structure calculations and does not take into account thermal and zero point energy terms (vibrational contributions).
- You may need well converged calculations (mesh cut-off and k-points).
- Remember to normalize the total energy you get by the number of atoms which compose your system.
- Pay attention to spin polarization. In particular if your reference system is a molecule with particular spin state, e.g. O_2.

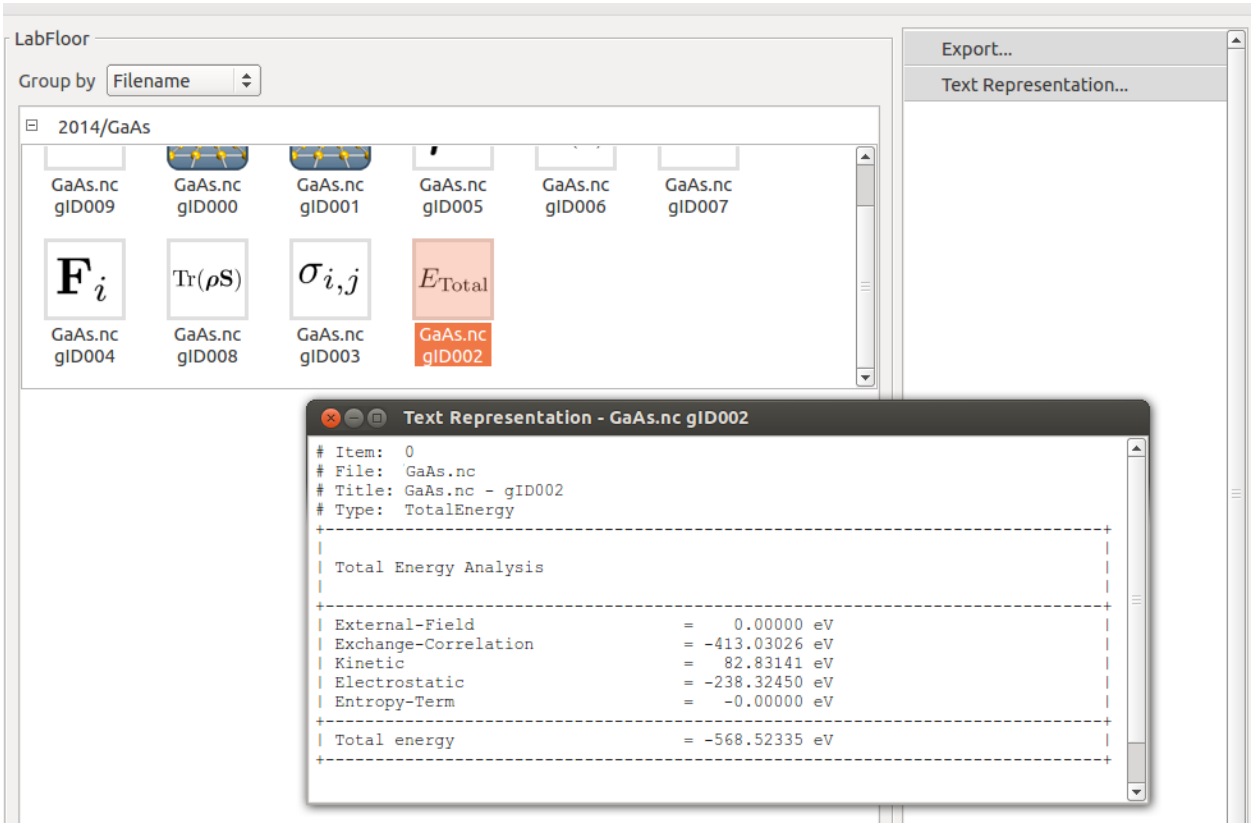
In order to calculate the total energy of your system, from the **Scripter** add a **GeometryOptimization** block and a **TotalEnergy** analysis:



Note: For a detailed explanation of each energy terms contained in the **TotalEnergy** analysis in **ATK-DFT** and

ATK-Huckel for bulk and device configurations, see the notes in *TotalEnergy*.

You can read the total energy of your system, in eV, in your log file and by analyzing the **TotalEnergy** object on the **LabFloor** using the **Text Representation** tool:



Cohesive energy of a bulk system

Let us take the simple example of a bulk system, GaAs, where you can take the bulk phases as reference systems for its individual components, Ga and As.

In this case you can calculate the formation energy of bulk GaAs from Ga and As bulk:

$$E_{form}^{\mathrm{GaAs}} = E_{tot}^{\mathrm{GaAs}} - E_{tot}^{\mathrm{Ga}}/n_{\mathrm{Ga}} - E_{tot}^{\mathrm{As}}/n_{\mathrm{As}},$$

where n_{Ga} and n_{As} are the number of atoms in the Ga and As bulk unit cells, respectively.

Results

With LDA and the FHI DoubleZetaPolarized basis set you will get E_{form}^{GaAs} = -0.6645 eV (exp: -0.73 eV[1]). The negative sign means that 0.6645 eV are gained when forming GaAs from Ga and As bulk.

[1] El-Mellouhi F. and Mousseau N. Self-vacancies in gallium arsenide: An ab initio calculation Physical Review B 7, 125207 (2005)

Attention: The choice of the pseudopotentials and basis set can be crucial for formation energy calculations, and it very much depends on the elements included in your system.

In this particular case, the Ga element and its components are more sensitive to the pseudopotential and basis set definition.

In QuantumATK the HGH and OMX pseudopotentials are also available.

By using the HGH pseudopotentials (Tier 4 basis set) for the calculation of the formation energy of GaAs, you will get E_{form}^{GaAs} = -0.76 eV, in very good agreement with the reported experimental value[Page 1527, 1].

Note: You can apply the same methods for other systems, such as molecular crystals. In this case, the terms $\Sigma_x E_{tot}(x)$ in the equation above corresponds to the total energies of the isolated molecules forming the crystal.

Attention: Be aware that you may need to apply the counterpoise correction to account to the basis set superposition error depending on the basis set. For more details please refer to the *Including the D2 dispersion correction* tutorial.

Note: You can also calculate the molecule formation energy from the total energy of your molecule and the total energy of the isolated atoms forming the molecule. Remember that especially in this case you should run spin-polarized calculations. Be also aware of DFT limitations in describing isolated species, e.g. O atom for the calculation of O_2 formation energy[2].

Defect formation energy calculations

By using the same approach you can calculate defect formation energies from total energy calculations.

Ga vacancy in GaAs

Consider a GaAs crystal with a Ga vacancy. The defect formation energy can be calculated from:

$$E_{form} = E_{tot}^{\mathrm{Ga}_{1-x}\mathrm{As}} E_{tot}^{\mathrm{GaAs}} + x \cdot E_{tot}^{\mathrm{Ga}}, \tag{3.15}$$

where $E_{tot}^{\mathrm{Ga}_{1-x}\mathrm{As}}$ is the total energy of GaAs containing x gallium vacancies, E_{tot}^{GaAs} is the total energy of the perfect GaAs crystal, and E_{tot}^{Ga} is the total energy of bulk Ga.

Note: Besides the usual parameters to check for convergence you should also pay attention to the cell size which is directly related to the defect concentration.

[2] Wang L. et al. Oxidation energies of transition metal oxides within the GGA+ U framework Physical Review B 73, 195107 (2006)

Results

For LDA and FHI DoubleZetaPolarized basis set the **ATK-DFT** formation energy of a gallium vacancy in a 216 atoms GaAs unit cell is 3.15 eV (compared to 2.9 eV in[Page 1527, 1]).

Surface O vacancy on MgO(100)

Finally, let us take the example of an oxygen vacancy on a MgO(100) surface. In this case your reference system is either O_2 in the gas phase or a single oxygen atom. The corresponding formation energies are reported in the table below for a 3x3 MgO(100) surface.

	Formation energy (eV)	
	1/2 O_2	O_2
ATK-PBE	6.82	10.36
ATK-PBE - ghost atom	6.61	10.16
VASP PW91[3]	6.32	9.48

Depending on the extension of your basis set you may need to include the BSSE correction as explained in the *Including the D2 dispersion correction* tutorial. In this case, the first term in Equation (3.15) is the total energy of the vacancy configuration with the atom that form the vacancy as ghost atom (ATK-PBE - ghost atom in the table), instead of actually removing them from the configuration.

References

3.11.12 Elastic constants

QuantumATK provide a very simple way to set up and execute calculations of the **elastic constants for arbitrary bulk configurations**. The method is generalized and can easily be used with density functional theory (ATK-DFT), semi-empirical methods (ATK-SE), or classical potentials (ATK-ForceField). In this tutorial, you will learn how to calculate elastic constants with QuantumATK.

Note: In a bulk solid, the elastic constants relate the linear response of the stress tensor σ to an external strain ε on the system. The elastic constants thereby describe the directional stiffness of the material under specific types of deformations. More general moduli, such as bulk, shear, or Youngs modulus, can also be calculated.

All of these quantities characterize the mechanical properties of a solid. In addition, elastic constants and moduli are often employed as fitting observables for parameterization of classical potentials.

---

[3] Giordano L. et al. F and F+ Centers on MgO/Ag(100) or MgO/Mo(100) Ultrathin Films: Are They Stable? J. Phys. Chem. C 112, 3857 (2008)

Methodology

The stress and strain tensors are always symmetric 3x3 matrices, and they can therefore be expressed more compactly as 6-vectors, using the so-called **Voigt notation**:

$$\boldsymbol{\sigma} = (\sigma_{xx}, \sigma_{yy}, \sigma_{zz}, \sigma_{yz}, \sigma_{xz}, \sigma_{xy}),$$

and

$$\boldsymbol{\varepsilon} = (\varepsilon_{xx}, \varepsilon_{yy}, \varepsilon_{zz}, 2\varepsilon_{yz}, 2\varepsilon_{xz}, 2\varepsilon_{xy}).$$

The linear response of the stress vector to a given strain vector can then be written as

$$\boldsymbol{\sigma} = \boldsymbol{C} \cdot \boldsymbol{\varepsilon},$$

where the symmetric 6x6 matrix $\boldsymbol{C}$ contains the **elastic constants**.

Depending on the crystal symmetry, the number of independent entries in $\boldsymbol{C}$ can be reduced further. For instance, in a cubic crystal only three entries, C_{11}, C_{12}, and C_{44}, are independent:

$$\begin{pmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_3 \\ \sigma_4 \\ \sigma_5 \\ \sigma_6 \end{pmatrix} = \begin{pmatrix} C_{11} & C_{12} & C_{12} & 0 & 0 & 0 \\ C_{12} & C_{11} & C_{12} & 0 & 0 & 0 \\ C_{12} & C_{12} & C_{11} & 0 & 0 & 0 \\ 0 & 0 & 0 & C_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & C_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & C_{44} \end{pmatrix} \cdot \begin{pmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \varepsilon_3 \\ \varepsilon_4 \\ \varepsilon_5 \\ \varepsilon_6 \end{pmatrix}$$

To obtain the elastic constants, one should apply small deformations, η, to the simulation cell along selected strain vectors, and calculate the resulting stress vectors. The linear stress contribution is obtained by fitting the $\sigma_i(\eta)$ curves of each Voigt stress component and for every strain vector. The independent elastic constants are then calculated as the least-squares solution to a linear system of equations, taking the crystal symmetry into account.

Note: For the calculation of elastic constants, QuantumATK employs the Lagrangian strain and stress tensors instead of the corresponding physical tensors.

To minimize the number of stress calculations, QuantumATK uses the Universal Linearly-Independent Coupling Strain (ULICS) vectors (Ref.[1]). For each strain vector, typically three deformations ($-\eta$, 0, $+\eta$), centered at the reference configuration ($\eta = 0$), are applied.

Important: For configurations with more than one atom in the cell, the atomic positions of each strained cell must be **optimized** before the stress is calculated; QuantumATK automatically takes care of this. You should however ensure that the cell vectors (and atomic positions) of the reference configuration are well optimized **before** starting the calculation of the elastic constants.

---

[1] R.ăYu, J.ăZhu, and H.Q. Ye. Calculations of single-crystal elastic constants made simple. *Computer Physics Communications*, 181(3):671–675, 2010. doi:10.1016/j.cpc.2009.11.017.

Calculating elastic constants using classical potentials

You will now perform an elastic constant calculation based on classical potentials, using **ATK-ForceField**. The advantage of of classical potentials, apart from the calculation speed, is that that most properties, such as energies, forces and stress, are smooth functions of the coordinates. This makes calculation of elastic constants particularly robust with respect to the setting sused for calculating the strain.

Two examples will be considered:

- A bulk silicon crystal, using the Stillinger–Weber potential[2].
- SiO_2 α-quartz, using the Pedone2006 Fe2 potential[3].

Bulk silicon

Open the QuantumATK **Builder** and use *Add* → *From Database* to add Silicon (alpha) to the Stash. Then send the configuration to the **Script Generator** and do the following:

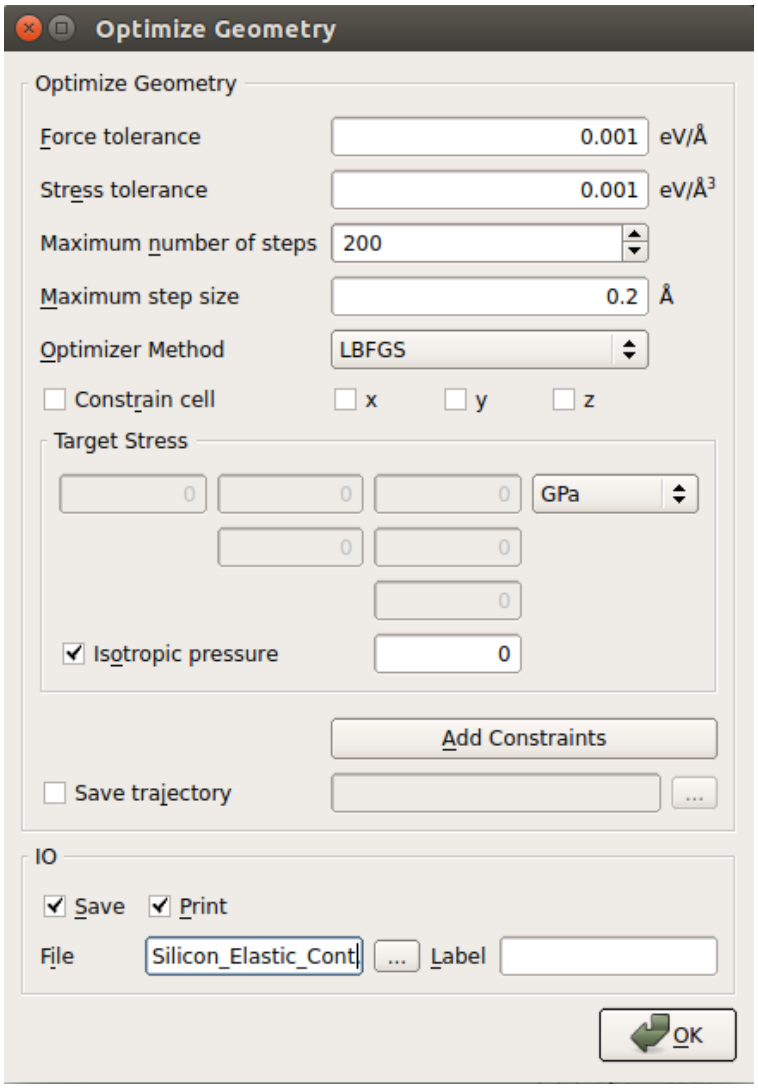
- Add a New Calculator block.
- Select **ATK-ForceField** and the Stillinger_Weber_Si_1985 potential.

Note: For QuantumATK-versions older than 2017, the **ATK-ForceField** calculator can be found under the name **ATK-Classical**.

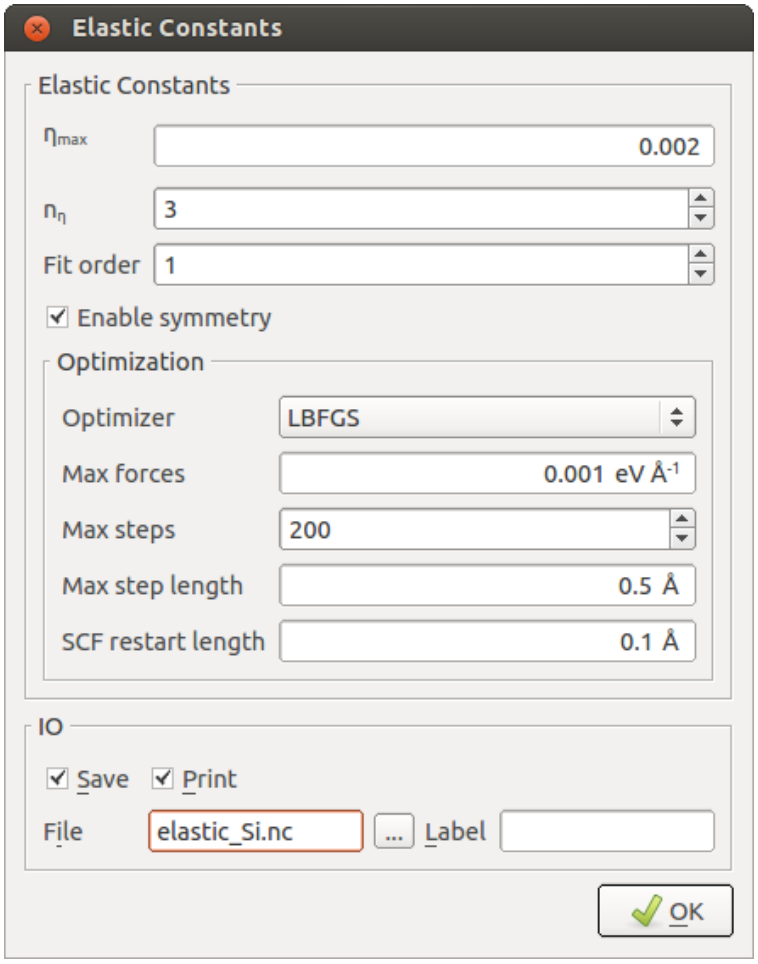
- Add a *Optimize* → *OptimizeGeometry* object to the script and edit it:
  - select sufficiently accurate settings for maximum force and maximum stress, e.g. 0.001 eV/Å for the force and 0.001 eV/Åsup:*3* for the stress;
  - uncheck the Constrain cell check box to enable optimization of the cell vectors;
  - select **LBFGS** as the optimizer method.

[2] F.ăH. Stillinger and T.ăA. Weber. Computer simulation of local order in condensed phases of silicon. *Phys. Rev. B*, 31:5262–5271, Apr 1985. doi:10.1103/PhysRevB.31.5262.

[3] Pedone Alfonso, Malavasi Gianluca, Menziani M.ăCristina, N.ăCormack Alastair, and Segre Ulderico. A New Self-Consistent Empirical Interatomic Potential Model for Oxides, Silicates, and Silica-Based Glasses. *The Journal of Physical Chemistry B*, 110(24):11780–11795, 2006. doi:10.1021/jp0611018.



•Back in the Scripter, add an *Analysis* → *ElasticConstants* block Open the block to set up the analysis.



The first set of parameters and options refer to the stress/strain calculation:

Parameter: η_{max}
Specifies the maximum deformation magnitude applied to the cell. A sufficiently large value should be chosen to achieve a significant variation in stress, but small enough to remain essentially within the linear regime. The default value of 0.002 is in most cases a good choice. Elastic constants calculated with classical potentials are in general not too sensitive to this parameter.

Parameter: n_η
Specifies the number of intermediate deformations between $-\eta_{max}$ and $+\eta_{max}$ for every strain vector. A higher value, together with a higher-order fit (as specified by the next parameter), may help to filter out possible non-linear contributions, but also increases the number of calculations that need to be performed. The default value is 3 and usually works well.

Parameter: ***Fit order***
Specifies the highest polynomial order in the stress vs. η fitting procedure, which should be smaller than n_η. For evaluation of the elastic constants, only the linear contribution is used.

Option: ***Enable symmetry***
Allows QuantumATK to detect the crystal symmetry and calculate only the independent constants for this lattice symmetry. Otherwise, all 21 constants of the upper triangle of the $\boldsymbol{C}$ matrix are treated as independent.

The remaining settings are related to the force optimization (of the atomic coordinates) that can be invoked before the stress of each strained system is calculated:

Option: ***Optimizer***

Sets the optimizer method. If you select None, no force optimization is carried out before the stress is calculated, which is the fastest, but least accurate option. If there is only one atom in the unit cell, there is no need for an optimization of the internal coordinates and the optimizer is **automatically disabled**.

Parameters for force and stress minimization
The remaining parameters control the optimizer setttings. These options are in fact the same as in the Optimize-Geometry object. While most of these parameters are only relevant in special cases, the Max forces parameter should be chosen sufficiently accurate. The default value of 0.005 eV/Å (which is 10x lower than the usual default in QuantumATK) represents a good balance between accuracy and efficiency. Since the example at hand uses fast ATK-ForceField calculations, you can easily afford to reduce this value even further to 0.001 eV/Å to achieve a higher precision.

Execute the calculation by sending the script to the **Job Manager**, again using the button. You may be asked to save the script again. Click the button to start the job. It takes around five seconds to finish on a laptop.

Analysis of the results

You can find information about the calculation and results in the *log file**. As you see, QuantumATK has correctly recognized the cubic symmetry of the FCC silicon crystal and calculates only the three independent elastic constants:

```
+-------------------------------------------------------------------------------+
| Calculating elastic constants for the given bulk configuration                |
+-------------------------------------------------------------------------------+
| Detected space group number:    227                                           |
| Detected lattice symmetry:      Cubic                                         |
| This lattice symmetry has 3 independent elastic constants:                    |
| C11  C12  C44                                                                 |
+-------------------------------------------------------------------------------+
```

The elastic constants matrix is printed at the bottom of the log file, and is in excellent agreement with literature results using the Stillinger–Weber potential[4]:

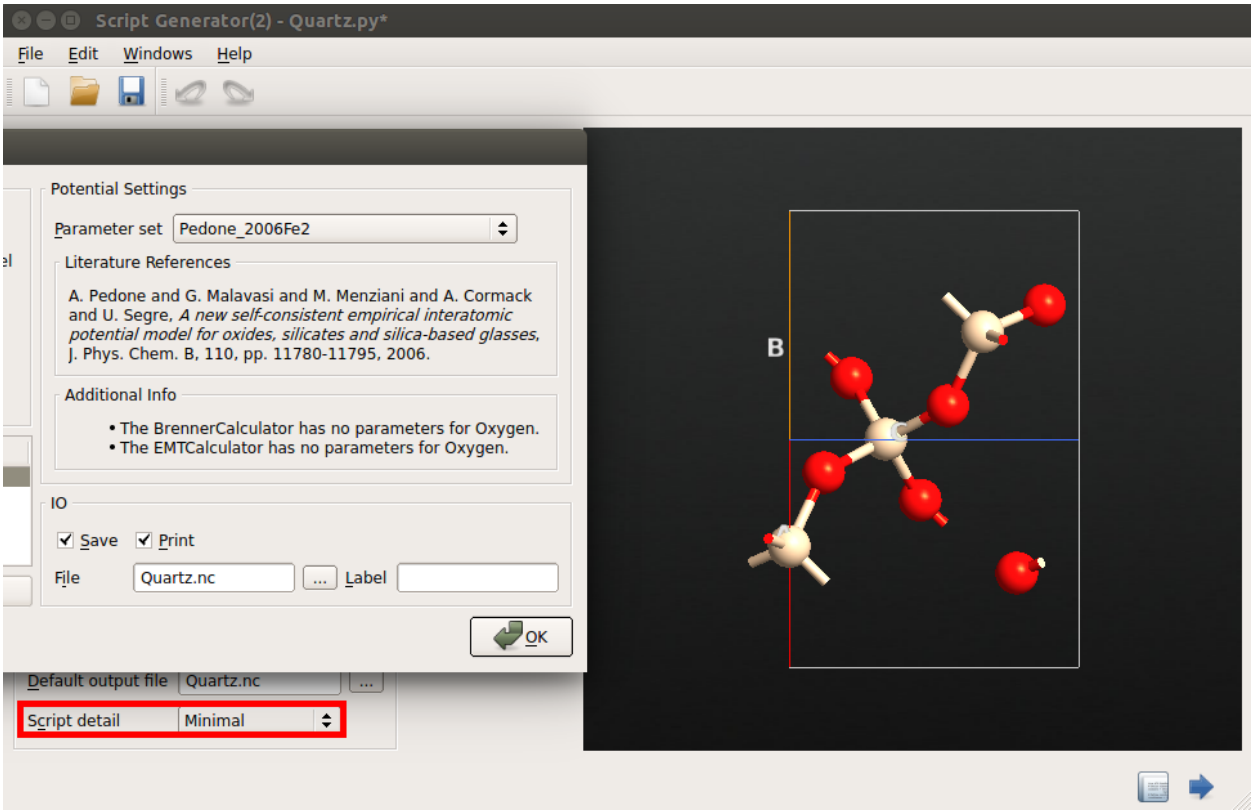
$$C_{11} = 151.4\,\mathrm{GPa}, \quad (3.16)$$
$$C_{12} = 76.4\,\mathrm{GPa},$$
$$C_{44} = 56.4\,\mathrm{GPa}.$$

Tip: The log file also records more detailed analysis of the elastic constant matrix. It contains the elastic compliance matrix, which is the inverse of the elastic constants matrix. More general moduli, such as bulk, shear or Youngs modulus, are also calculated from the elastic constants. Be aware tha there are three different definitions of bulk and shear modulus, according to the slightly different formulae from Voigt and Reuss. All of them are listed in the log output for comparison.

[4] E.ăRoger Cowley. Lattice Dynamics of Silicon with Empirical Many-Body Potentials. *Phys. Rev. Lett.*, 60:2379–2381, Jun 1988. doi:10.1103/PhysRevLett.60.2379.

SiO_2 quartz

You can use the same method to compute the elastic properties of more complex crystals, such as SiO_2 α-quartz. Follow the same steps above and select the Pedone2006_Fe2 potential , which is from Ref.[Page 1531, 3].



Accurate long-range electrostatics

After setting up the script in the Script Generator, change the **Script Detail** setting in the Global IO field from Minimal to Show defaults, and transfer the script to the Editor in order to make one small modification. In the calculator block, you will find that all the pair potentials are now individually listed and added to the potential set (this is a result of the Show defaults setting).

The Pedone potential includes long-range electrostatic interations. You can manually increase the cutoff distance for these interactions (`r_cut`). To achieve a high accuracy of the stress calculation, you should change this parameter from the default of 9.0 Å to a larger value of 15 Å, to account for the long-range nature of the Coulomb potential:

```
potentialSet.setCoulombSolver(CoulombDSF(r_cut=15.0*Angstrom, alpha = 0.2))
calculator = TremoloXCalculator(parameters=potentialSet)
calculator.setInternalOrdering("default")
```

This will affect the speed of the calculations, but since the elastic constants calculation does not involve extensively long simulations, you will hardly notice it.

Results

Performing the calculation will give the following results:

```
+-------------------------------------------------------------------------------+
| Elastic Constants in GPa                                                      |
+-------------------------------------------------------------------------------+
|    86.55       8.71      11.16     -18.36       0.00       0.00              |
|               86.55      11.16      18.36       0.00       0.00              |
|                         106.67       0.00       0.00       0.00              |
|                                      49.41       0.00       0.00              |
|                                                  49.41     -18.36              |
|                                                             38.92              |
+-------------------------------------------------------------------------------+
```

Due to the rhombohedral symmetry, there are six independent constants, $C_{11}, C_{12}, C_{13}, C_{14}, C_{33}$ and C_{44}. All values reproduce very well the results of the original publication, Ref.[Page 1531, 3].

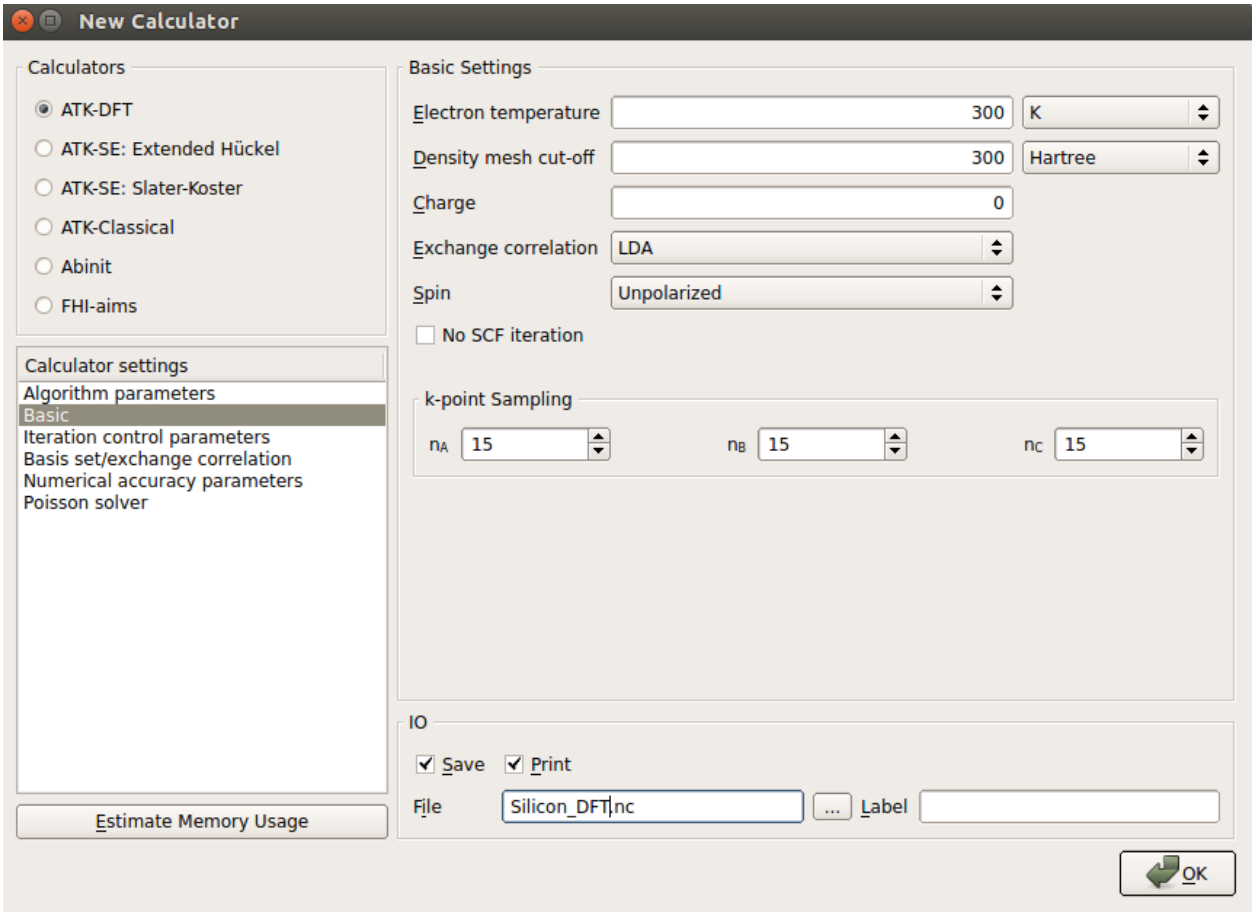
Calculate elastic constants using DFT

Finally, you will perform a calculation of the elastic constants of silicon using density functional theory. The framework outlined above can be used again – you just need to replace the calculator such that is uses **ATK-DFT with GGA exchange correlation**.

Use again the Builder to create the silicon structure and send it to the Script Generator. Add the **New Calculator** , **OptimizeGeometry** and **ElasticConstants** blocks.

To obtain numerically precise stress differences between the strained conformations, we generally have to employ some slightly tighter calculator settings than the defaults:

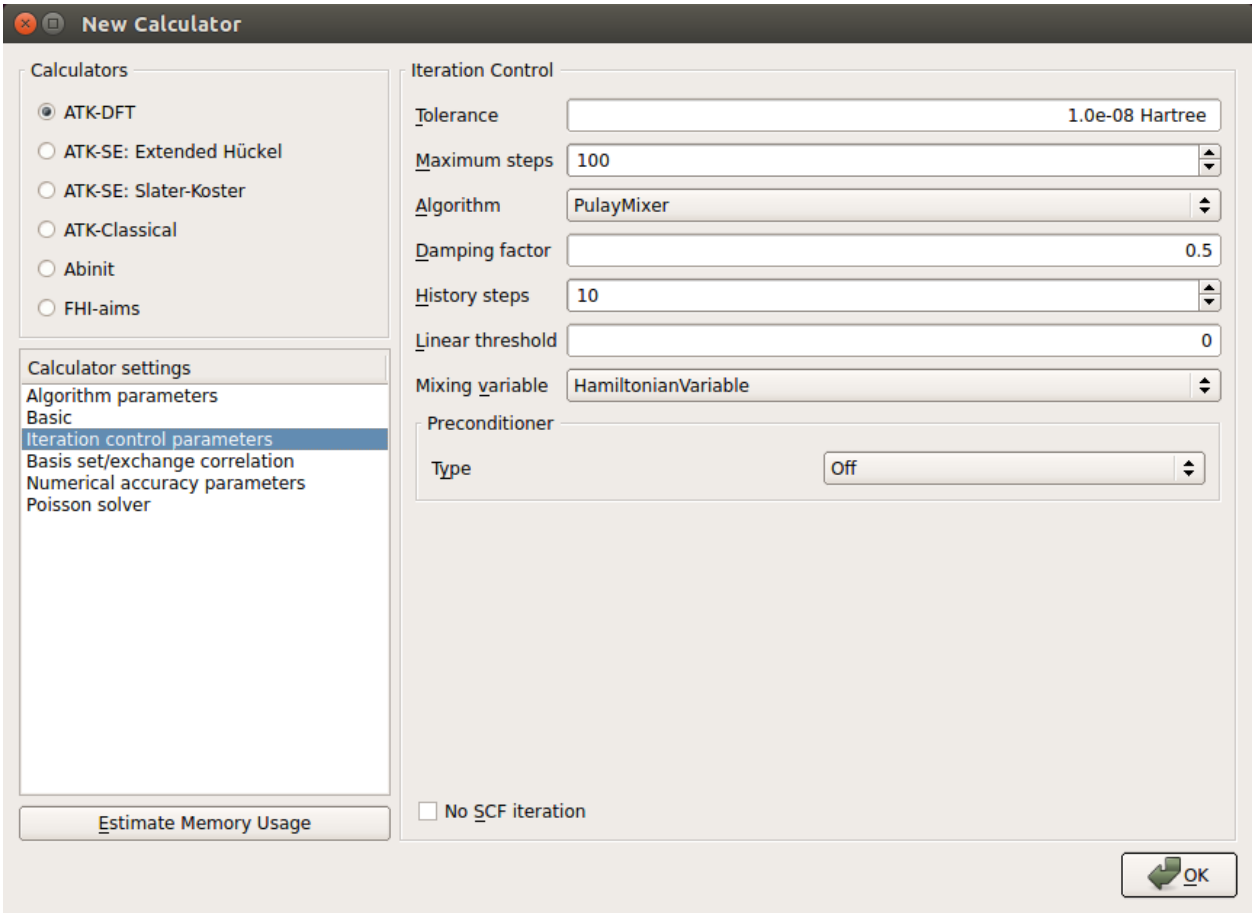
- Choose **ATK-DFT** as the calculator, and set the following parameters in **Basic**:
  - set the grid mesh cut-off to 300 Hartree;
  - set k-point sampling to 15x15x15.



•In the **Iteration control parameters** tab:

–set the tolerance parameter to 1.0e-08;

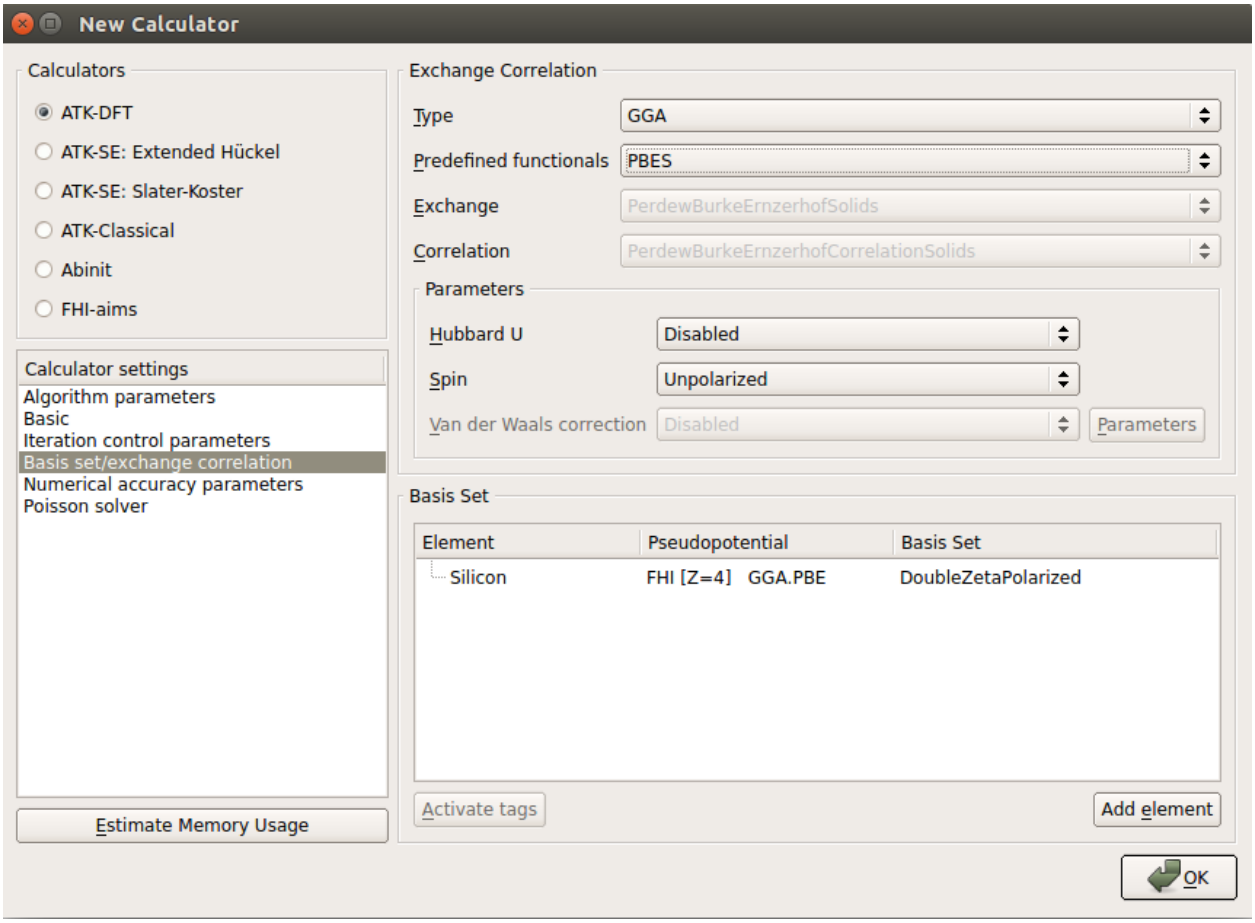
–set the damping factor to 0.5 and the number of history steps to 10.



- In the **Basis set/exchange correlation** tab use the PBEsol functional, which offers very reliable DFT predictions of bulk moduli and related quantities:

  – choose **GGA** for the exchange-correlation type;

  – select in **PBES** in the list of predefined functionals;



The settings in the **OptimizeGeometry** and **ElasticConstants** blocks should be almost identical to the ones chosen for the classical potentials, except that the η_{max} value in the **ElasticConstants** settings should be 0.003 (which means that a larger strain will be employed, resulting in a more pronounced change in the stress).

This calculation takes only about 10 minutes to finish. The calculated elastic constants are

```
+-------------------------------------------------------------------------------+
| Elastic Constants in GPa                                                      |
+-------------------------------------------------------------------------------+
|   161.02      65.22      65.22       0.00       0.00       0.00              |
|              161.02      65.22       0.00       0.00       0.00              |
|                        161.02       0.00       0.00       0.00              |
|                                    75.68       0.00       0.00              |
|                                               75.68       0.00              |
|                                                          75.68              |
+-------------------------------------------------------------------------------+
```

The results are in reasonably good agreement with the experimental values, Ref.[5], which are listed below:

$$C_{11} = 167.4\,\text{GPa} \tag{3.19}$$
$$C_{12} = 65.2\,\text{GPa}$$
$$C_{44} = 79.6\,\text{GPa}$$

3.11.13 Geometry optimization: CO/Pd(100)

Version: 2015.1

In this tutorial you will learn how to do a geometry optimization using *Fixed* and *Rigid* constrains on the atoms. As an example, you will study adsorption of the CO molecule on a Pd(100) surface. You will use the ATK-DFT calculator engine and a standard GGA functional.

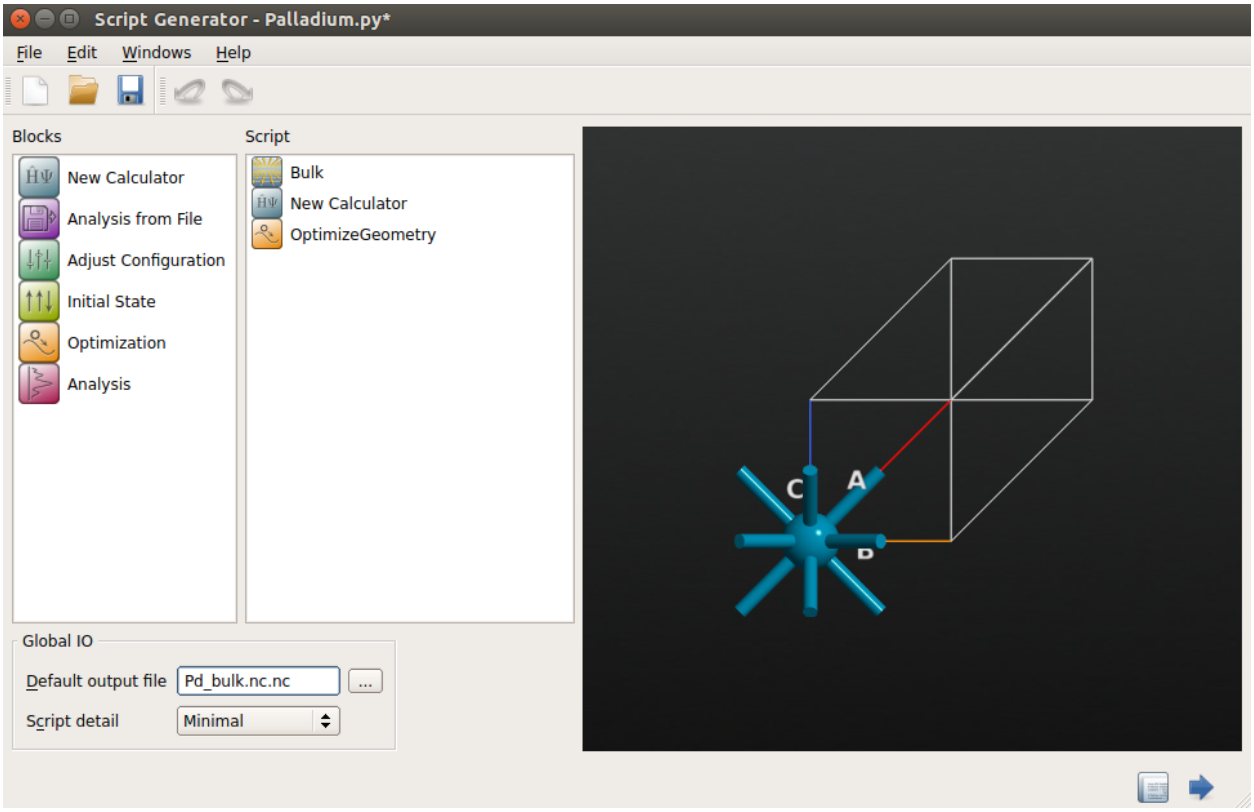
Specifically, you will:

1. optimize the bulk palladium crystal;
2. cleave the bulk to create the Pd(100) surface and relax it;
3. adsorb the CO molecule in the surface, and relax the system in two steps;
   1. first apply *Rigid* constraints on atoms during an initial relaxation;
   2. then apply *Fixed* constraints on the bottom Pd atoms in a final optimization.
4. lastly, relax the CO molecule and calculate the adsorption energy.

Bulk palladium

Create a new project called Pd100_CO and open the **Builder** .

- Use *Add* → *From Database* to import the Pd bulk to the Stash and send the configuration to the **Script Generator** using the send to button .
- In the Script Generator, add the **New Calculator** and **OptimizeGeometry** blocks to the script by double-clicking them, and change the default output file name to `Pd_bulk.hdf5`.



•Double-click the **New Calculator** block and set the following parameters in the window that opens up:

–*k-point sampling*: 9x9x9;

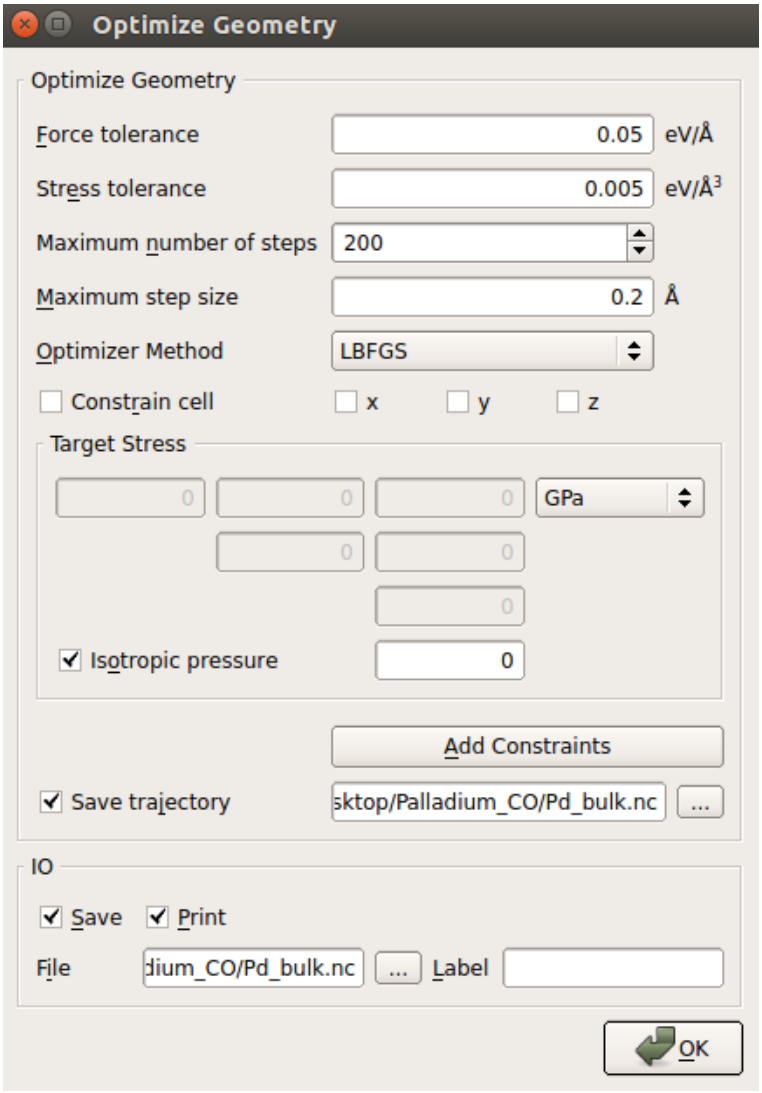
–*exchange-correlation*: GGA-PBE functional.

•Open the **OptimizeGeometry** block, and set the parameters as shown in the image below. In particular:

–enable stress relaxation by unticking *Constrain cell*;

–decrease the stress tolerance to 0.005 eV/Å^3;

–save the relaxation trajectory by ticking *Save trajectory* and enter `Pd_bulk.hdf5` for the trajectory file name.

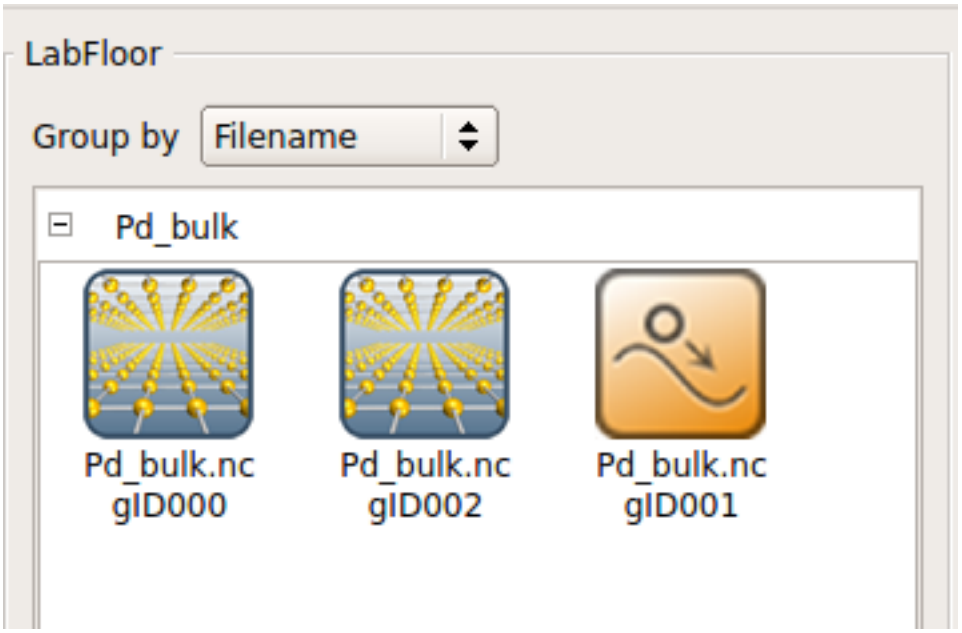


Tip: It is usually a good idea to save the trajectory file. In case your geometry optimization is interrupted you can simply restart it from one of the latest images in the trajectory. If you would like to know more about how to restart a stopped calculation, check out the tutorial *Restarting a stopped calculation*.

•Click *OK* and the OptimizeGeometry window will close.

•The script is now finished. Send it to the **Job Manager** using the button. Save the script in the window that appears and run the calculation. It will take a few seconds. If needed, you can download the script here: `Pd_bulk.py`.

Once the bulk relaxation is finished, the calculation output will appear on the LabFloor. The bulk configurations with IDs *glD000* and *glD002* are the initial and final structures, respectively, while the relaxation trajectory has ID *glD001*.



You can drag and drop these objects to the **Viewer** to visualize them. In the Viewer, you can check the lattice constant by hovering the mouse on the cell boundaries. You could also check the lattice constant in the newly formed log file.

In the following, you should of course use the relaxed bulk structure, *glD002*.

Build the Pd(100) surface and relax it

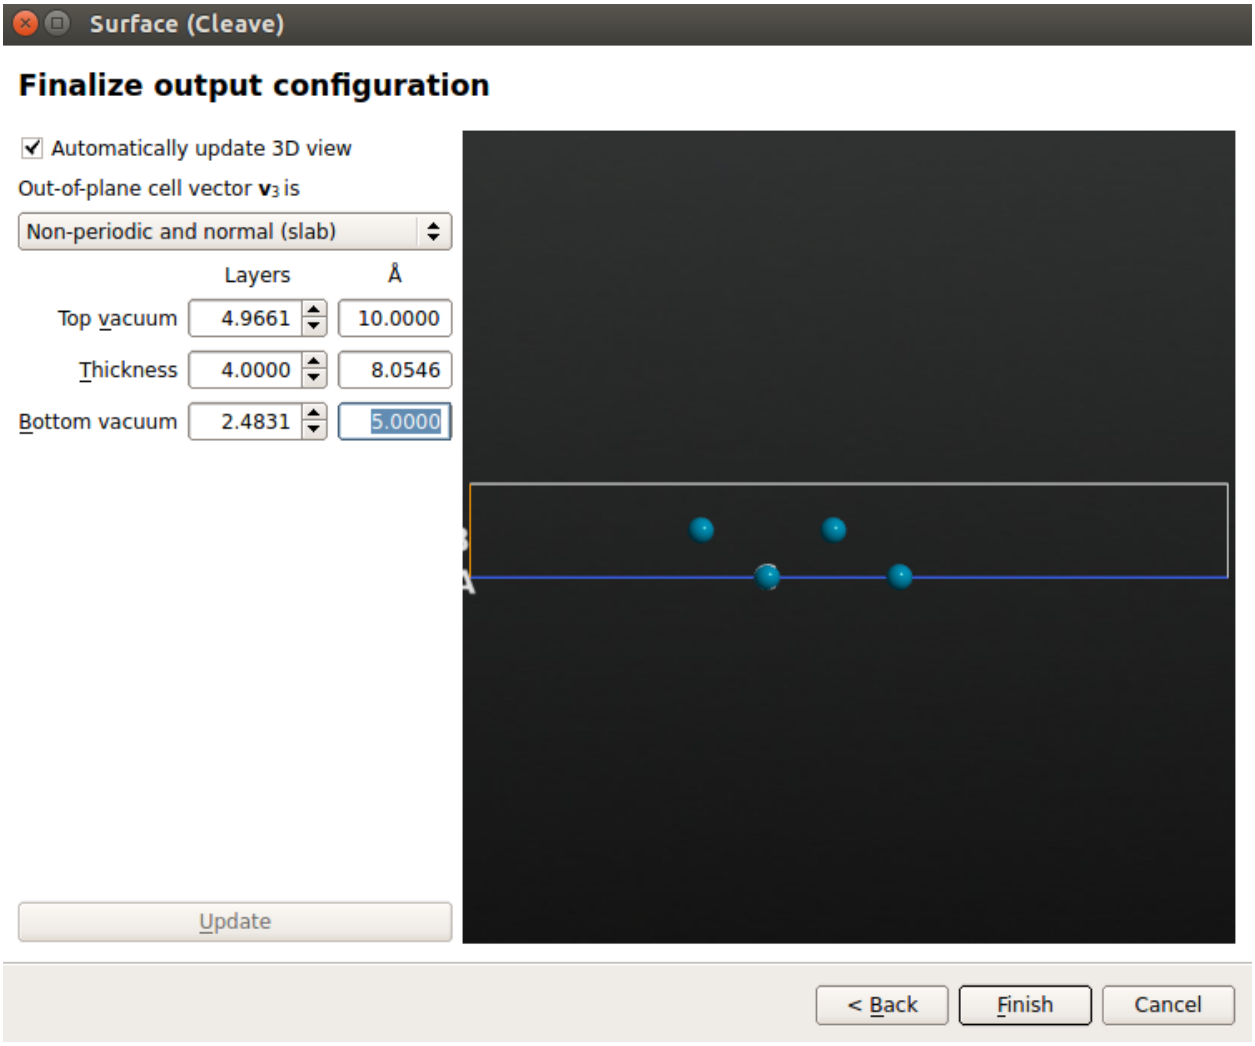
•Drag and drop the relaxed bulk configuration to the **Builder** .

•Open the *Builders* -→ *Surface (Cleave)* plug-in.

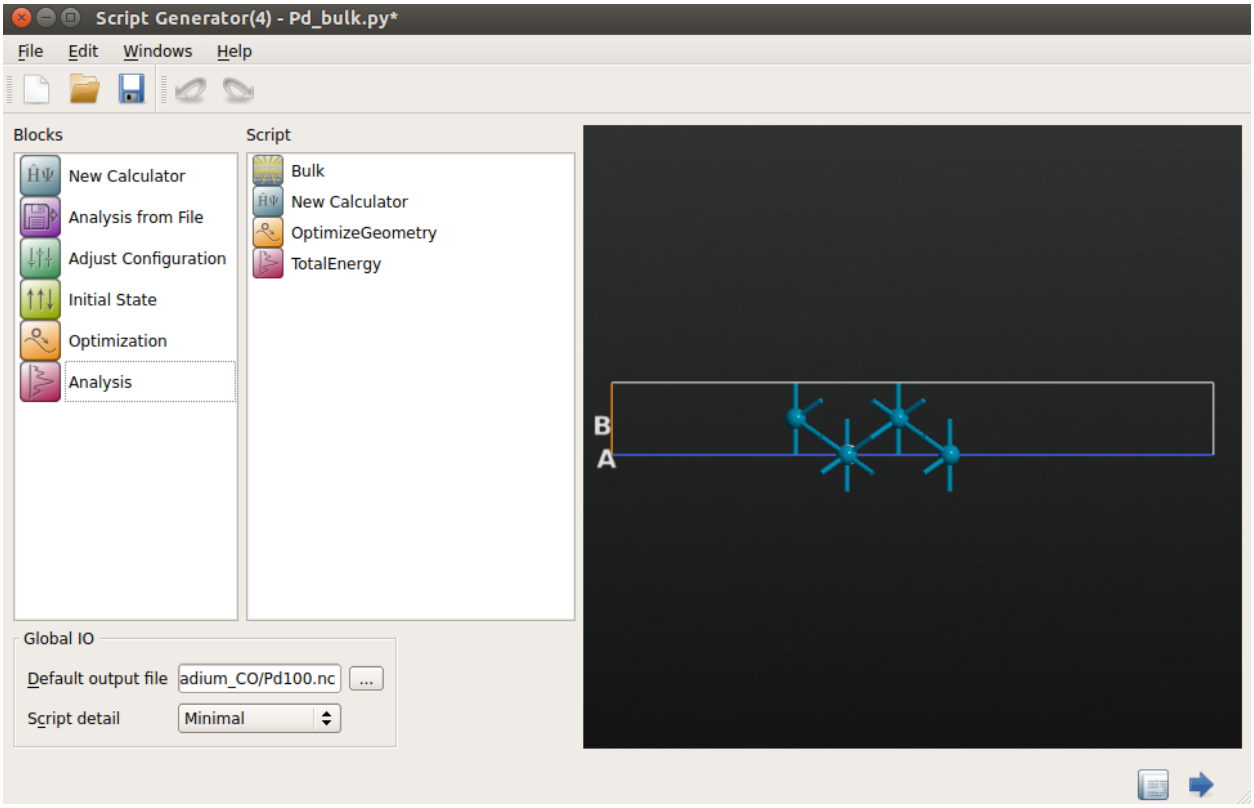
•Keep the default Miller indices and click *Next*.

•Keep the default 1x1 surface lattice and click *Next*.

•Choose a *Non-periodic* and *normal (slab) out-of-plane cell vector*, 4 slab metal layers, and 10 Å and 5 Å for the top and bottom vacuums, respectively. Click *Finish* to build the surface.



•Send the slab structure to the **Script Generator** and add the **New Calculator**, **OptimizeGeometry** and **TotalEnergy** blocks to the script, and set the default output file name to `Pd100.hdf5`.

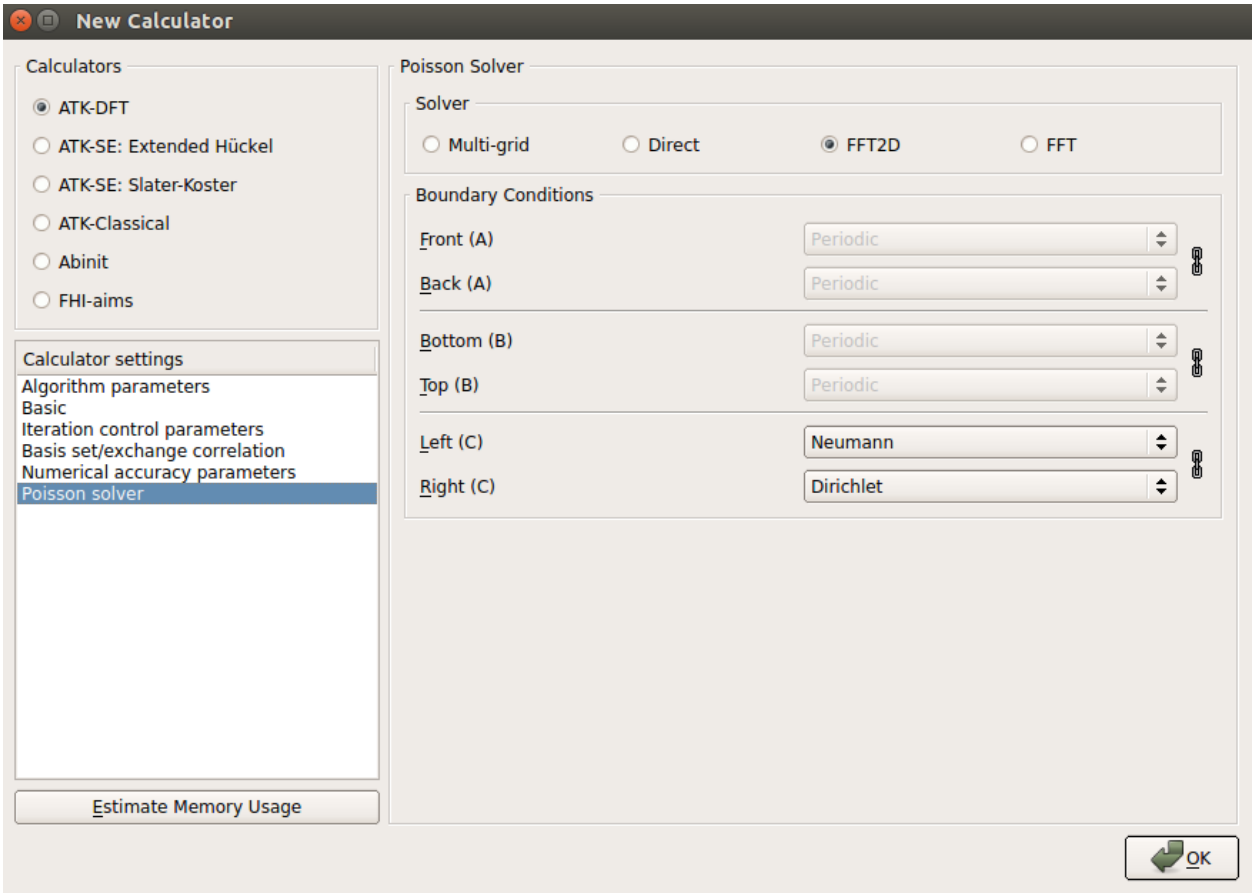


•Choose the following set of calculator parameters:

–*k-point sampling*: 9x9x1 k-points;

–*exchange-correlation*: GGA-PBE;

–*FFT2D Poisson solver* with *Neumann* boundary conditions under the slab and *Dirichlet* boundary conditions above the slab:



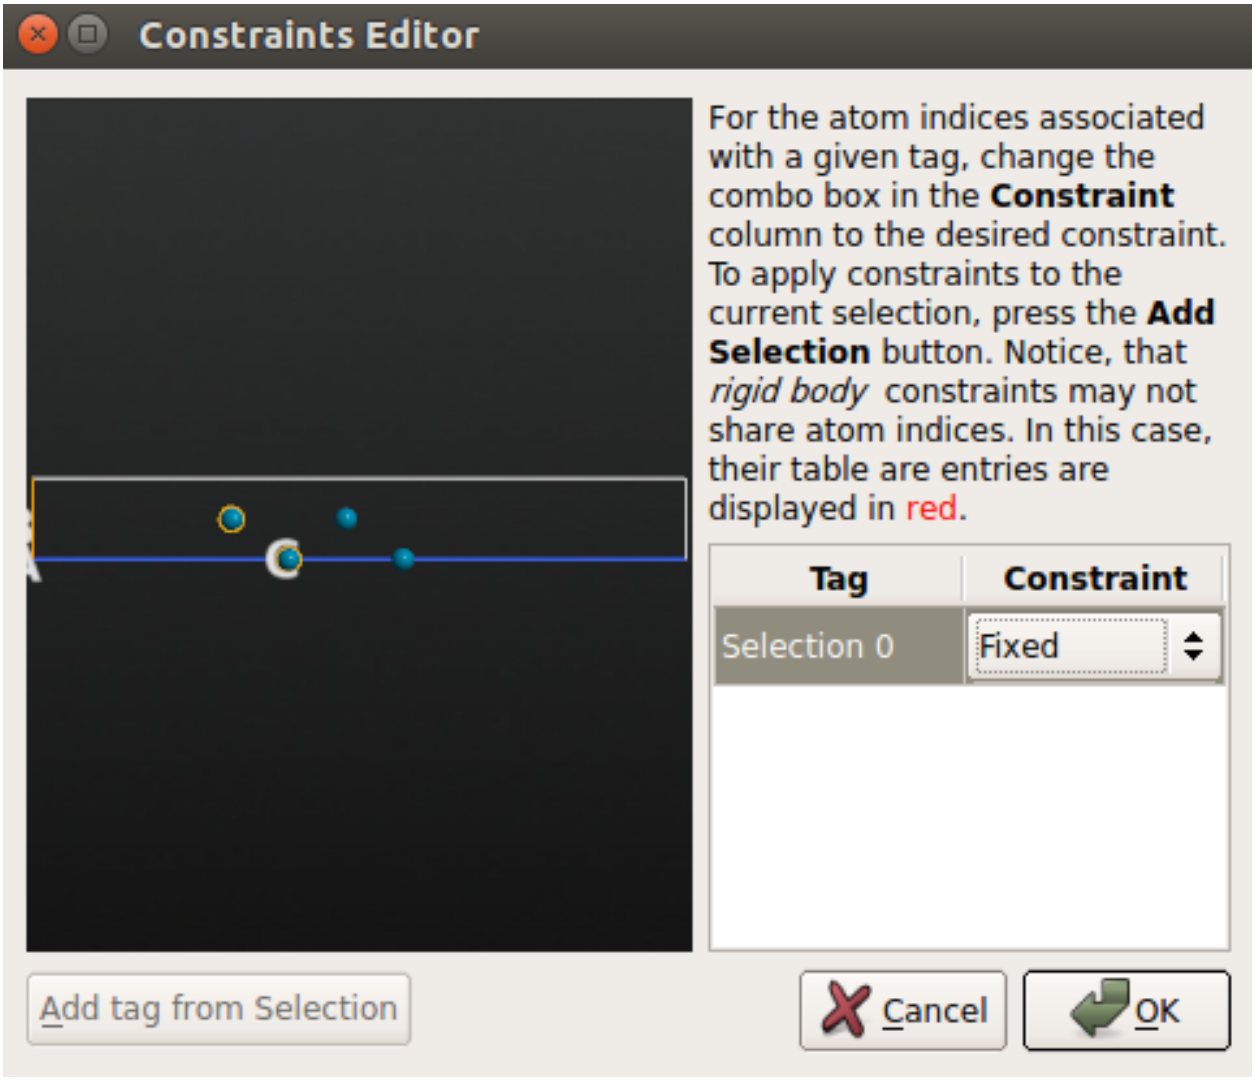
Note: This particular set of boundary conditions along the C direction of the simulation cell is appropriate for slab calculations, where the vacuum above the slab could in principle extend to infinity.

•Open the **OptimizeGeometry** block and set it up for force relaxation:

–save the trajectory to `Pd100_traj.hdf5`;

–click **Add Constraints** to open the Constraints Editor;

–use the mouse to select the bottom two layers of the Pd(100) surface and click *Add tag from selection*. Those two atoms are now tagged Selection 0. Then choose the *Fixed* constraint for the Selection 0 group.



•There is nothing to edit in the **TotalEnergy** block, so the script is now finished. Save it as `Pd100.py` and execute it using the **Job Manager** . The calculation will take roughly one minute. If needed, you can download the script here: `Pd100.py`.

Once the Pd(100) surface has been geometry optimized, the results will appear on the **LabFloor**. You can again visualize the relaxation trajectory using the **Viewer** .

Tip: You can check the total energy of the relaxed Pd(100) surface by selecting the TotalEnergy object and clicking on the **Text Representation** plugin. The energy is also printed in the log file.

Relax the CO/Pd(100) system

The next step is to add the CO molecule to the surface and relax the system. You should use the CO/Pd(100) structure available here: `CO_Pd100.py`. If needed, you can learn how to add a molecule to a surface from the tutorial *Building molecule–surface systems: Benzene on Au(111)*.

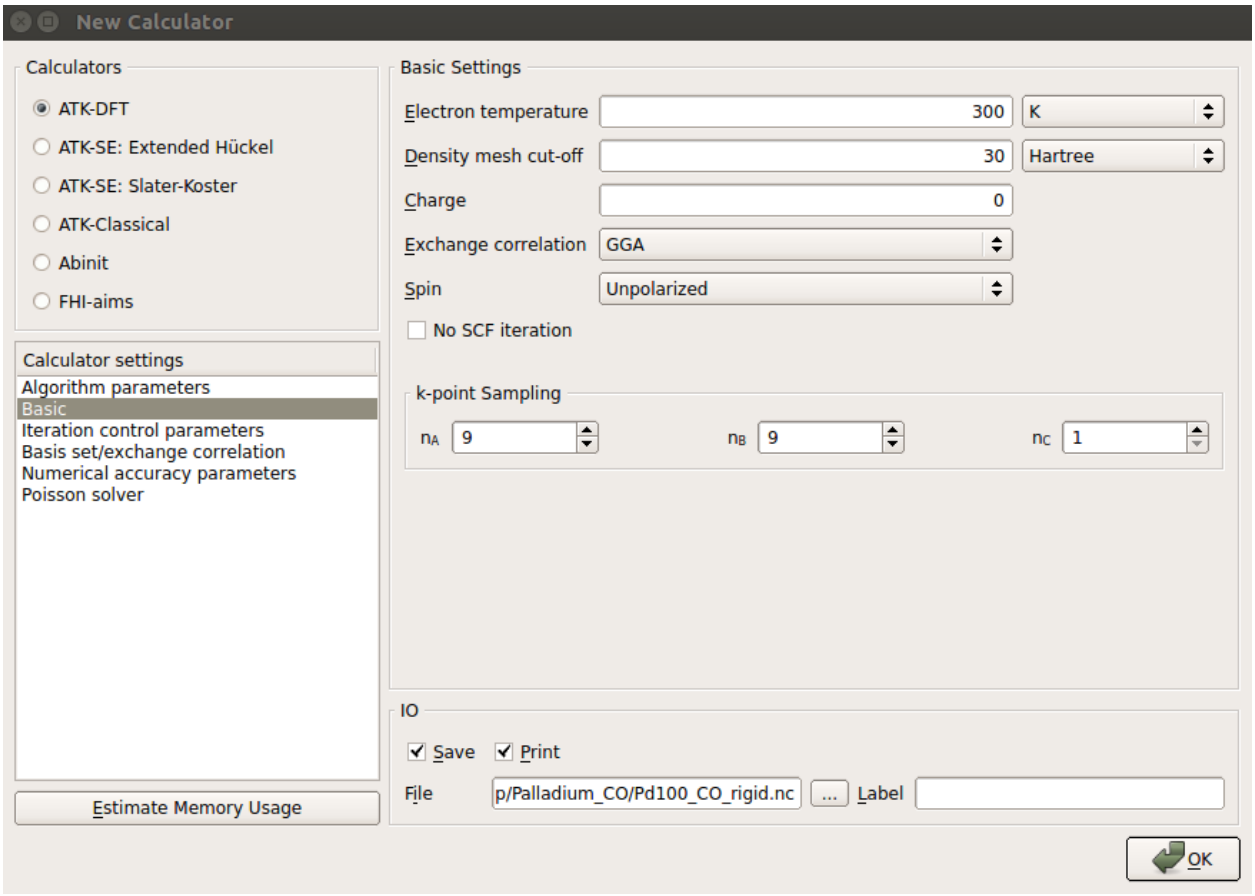
As mentioned in the introduction, you will relax the CO/Pd(100) configuration in two steps:

1. use a *Rigid* constraint for CO and *Fixed* constrain for the surface, together with a relatively low electron density mesh cut-off, in order to get a quick idea of where the CO will be adsorbed;
2. the final relaxation step does not constrain the CO molecule and just fixes the bottom of the Pd(100) slab.

Rigid relaxation

Transfer the provided CO/Pd(100) configuration (`CO_Pd100.py`) to the **Script Generator** and add the **New Calculator** and **OptimizeGeometry** blocks. Enter `Pd100_CO_rigid.hdf5` for the default output file name, and then edit the script:

- In the **New Calculator** block, use the same settings as for the Pd(100) relaxation in the previous section, but decrease the density mesh-cut off to 30 Hartree.

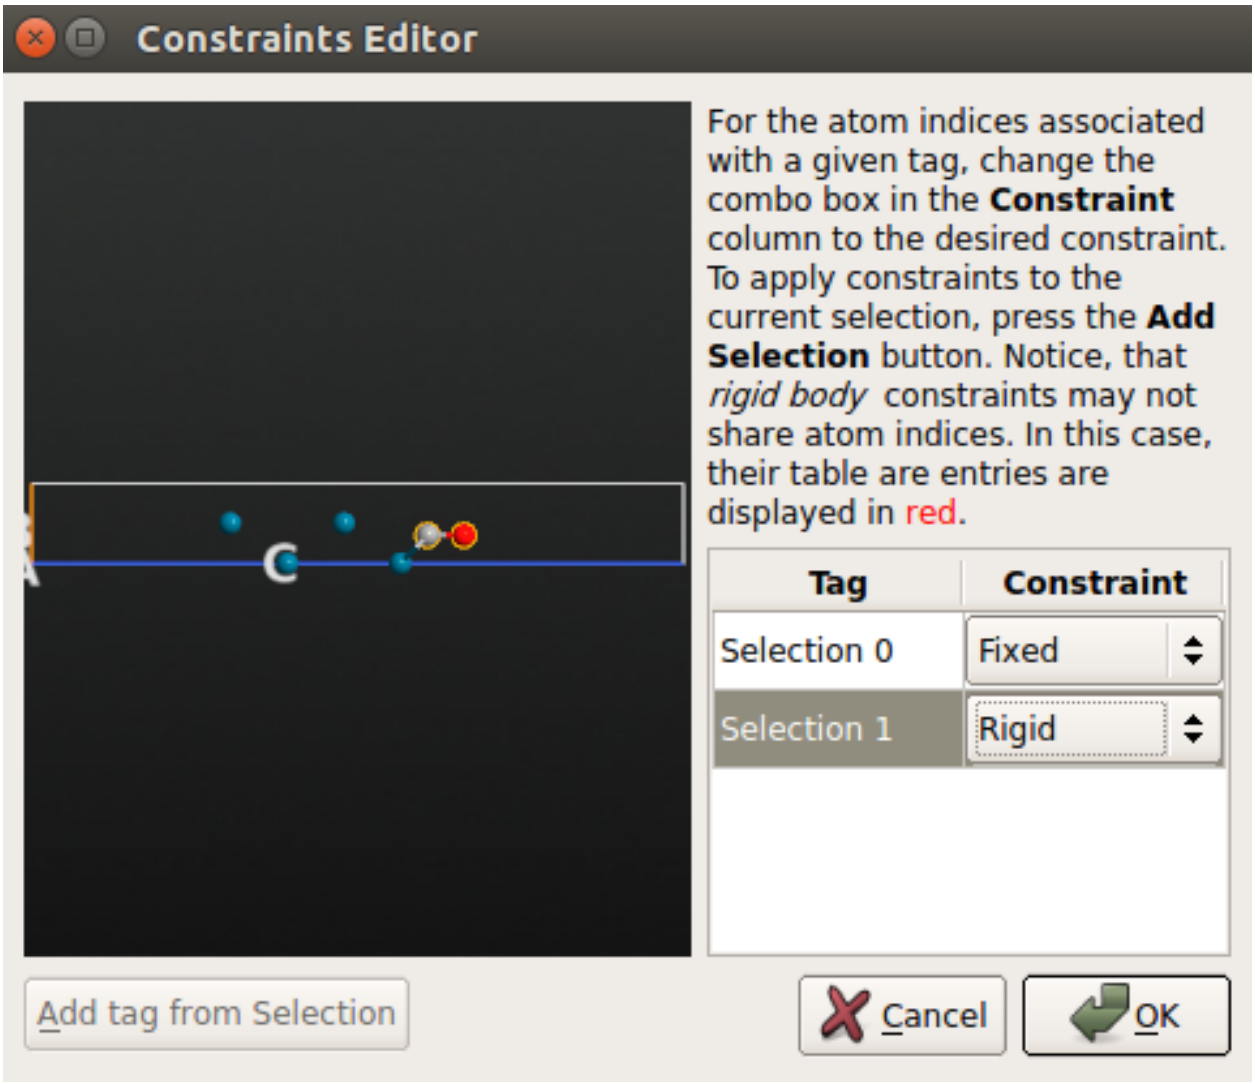


- Set up the **OptimizeGeometry** block similarly to the one used for Pd(100), but choose a slightly different set of

constraints:

–select the *Fixed* constraint for all atoms in the metal slab;

–select the *Rigid* constraint for the CO molecule (add the C and O atoms to the group Selection 1).



Note: The Rigid constraint on a group of atoms causes those atoms to move like a rigid body during force optimization.

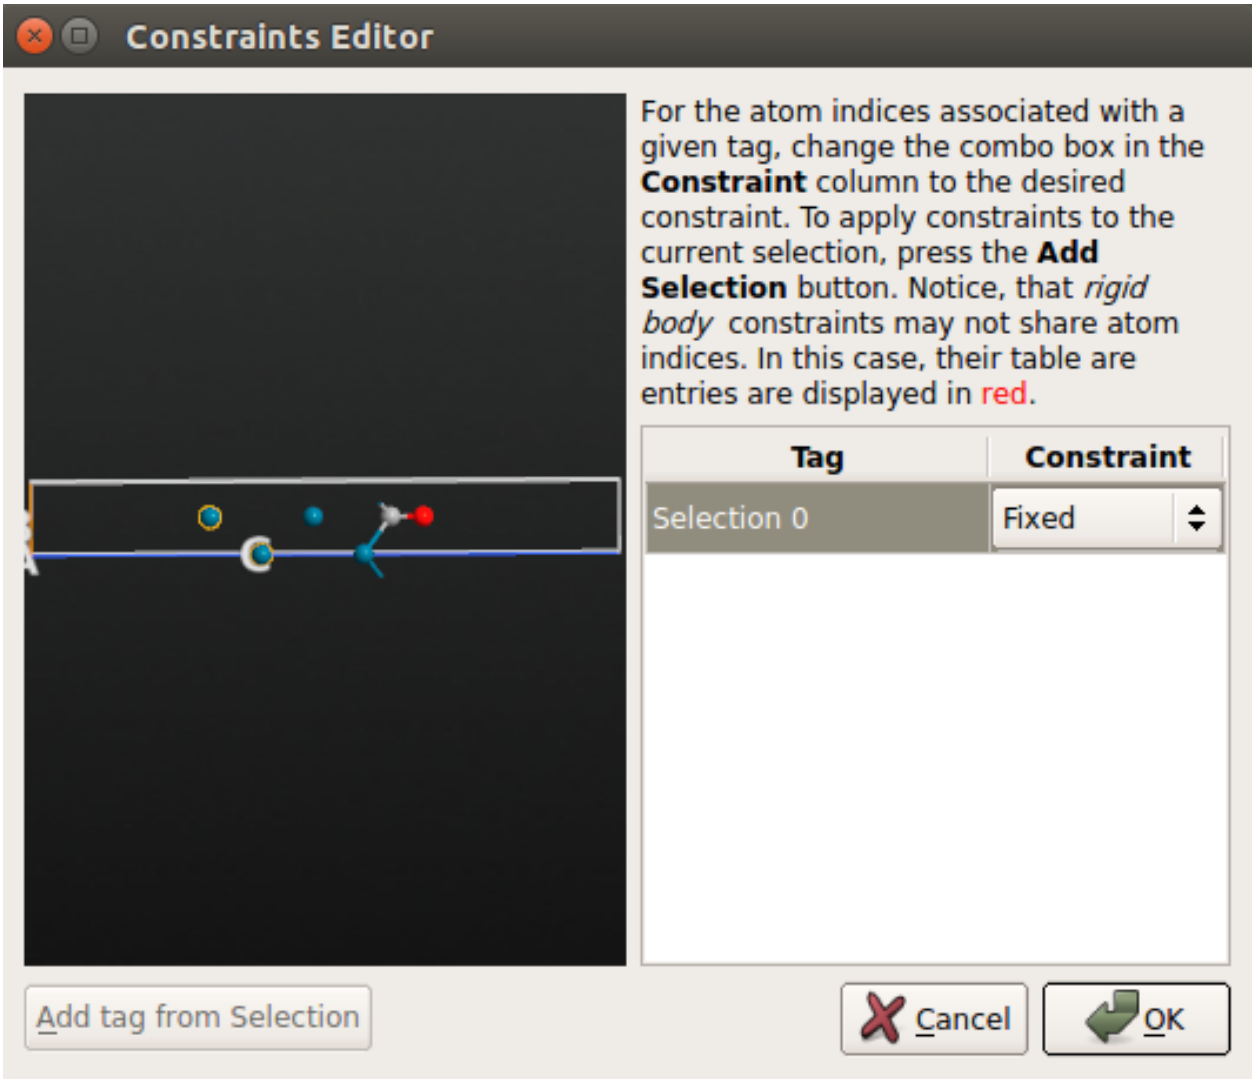
•Save the script as `Pd100_CO_rigid.py` and run it using the **Job Manager**. The simulation should take roughly 5 minutes if executed in serial. You can download the script here: `Pd100_CO_rigid.py`.

Important: If you take a look at the trajectory, you will see that the CO molecule has moved slightly away from its initial position, but the C–O bond length has not changed, and the molecule has not rotated. This is how the rigid constraint works.

Final relaxation

You will now perform the final geometry optimization of the CO/Pd(100) structure, starting from the result of the previous step.

- Send the configuration with ID *glD002* in `Pd_CO_rigid.hdf5` to the **Scripter**, and enter `Pd_CO.hdf5` for the default output file name.
- Once again, add the **New Calculation**, **OptimizeGeometry** and **TotalEnergy** blocks, and edit them similarly to what you did in the previous section. This time, however, use a 75 Hartree mesh-cutoff for the ATK-DFT calculator, and use only a *Fixed* constraint for the bottom two Pd atoms:



- Save the script as `Pd_CO.py` and execute it using the Job Manager or in a Terminal. The calculations should take about 20 min in total, but can of course be quicker if run in parallel on more CPUs. The script is also available here: `Pd100_CO.py`.

Tip: You can actually use the **Viewer** tool to monitor the progress of the geometry optimization while the

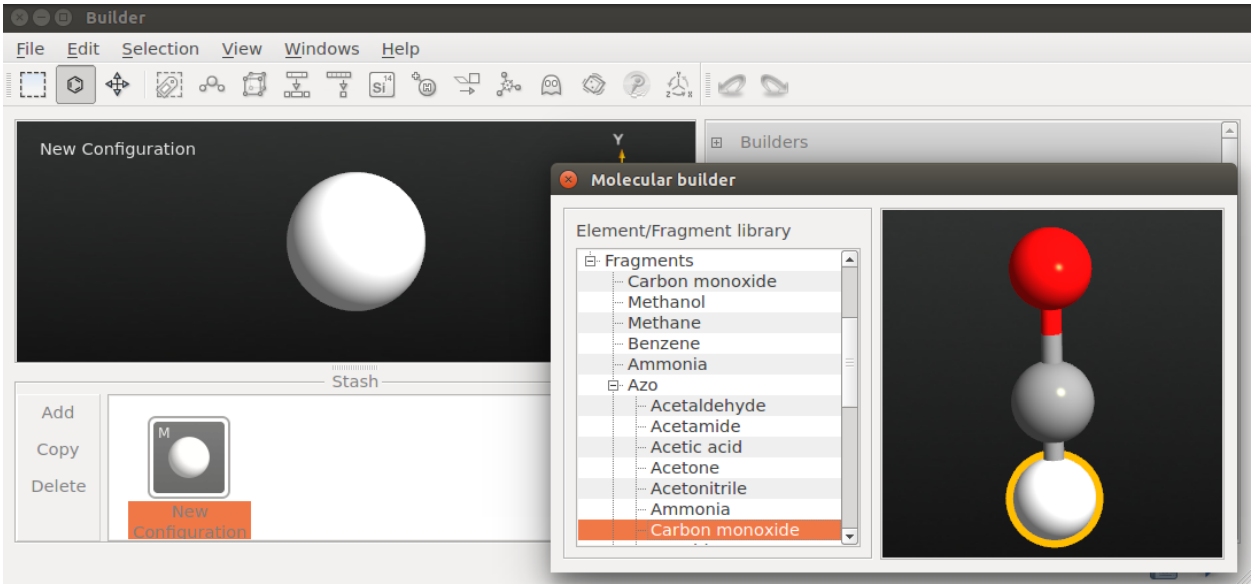
calculation is running. The trajectory object is continuously updated as new relaxations steps are taken.

When the calculation has finished you should have a look at the full relaxation trajectory, and see how the CO molecule has moved from a position around the hollow adsorption site on the Pd(100) surface to a bridge site between two Pd surface atoms:

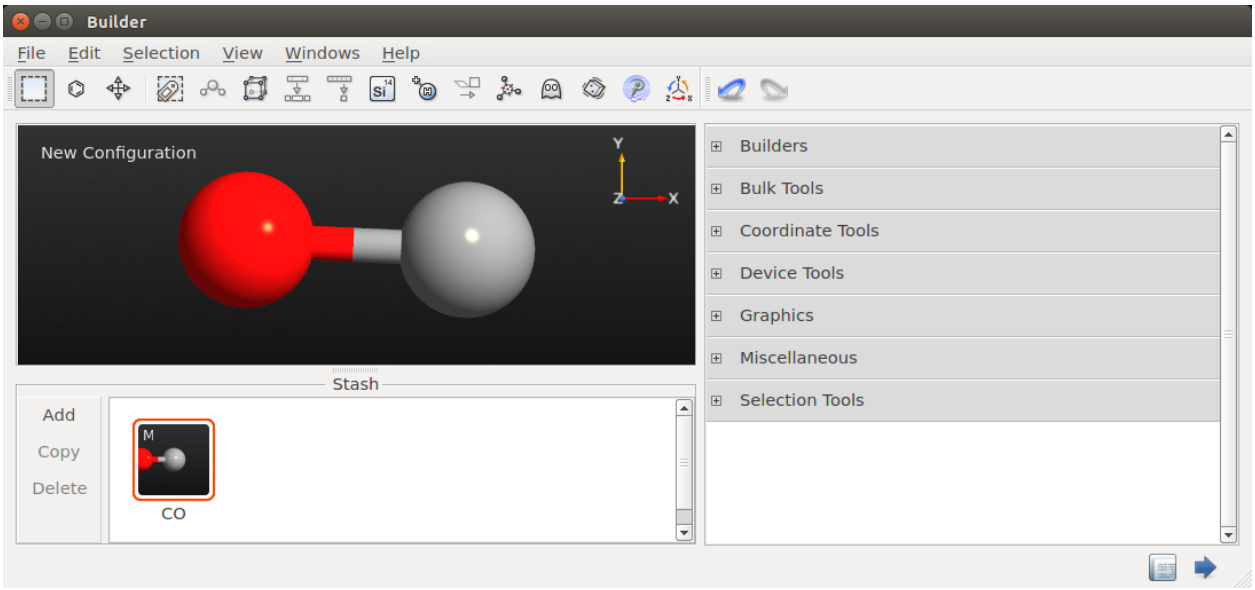
Relax the CO molecule

In order to calculate the CO adsorption energy on Pd(100) you also need to relax the isolated CO molecule. We can obtain it following the next steps:

- go to the **Builder** and add a new configuration using *Add* → *New Configuration*;
- click the **Molecular Builder** tool and click *Fragments* → *Carbon monoxide* in the panel that opens up;



- next, click the hydrogen atom in the `New Configuration` Stash item to substitute it for the CO fragment, close the Molecular Builder window, and rename the Stash item to `CO`.



Tip: For more details about how to use the **Molecular Builder**, you can check out this tutorial: *Molecular builder*.

Now you just need to relax the CO atomic coordinates and compute the total energy. Send the structure to the **Script Generator** and add the **New Calculator**, **OptimizeGeometry** and **TotalEnergy** blocks. Enter `CO.hdf5` for the default output file name, and then edit the blocks a bit:

- **New Calculator**: Choose the GGA-PBE functional;
- **OptimizeGeometry**: You may want to save the trajectory or decrease the force tolerance, but its not mandatory;

Save the script as `CO.py` and run the calculation – it should be very fast. The script is also available for download: `CO.py`.

You will find that the C–O bond length relaxes to 1.143 Å, which matches experiments very well.

Adsorption energy

You are now ready to calculate the CO/Pd(100) adsorption energy at a full monolayer coverage, ΔE, which is of course given by total energy differences:

$$\Delta E = E_{\text{products}} - E_{\text{reactants}} = E_{\text{Pd(100)/CO}} - E_{\text{Pd(100)}} - E_{\text{CO}}$$

You can use the **Text Representation** plugin to see all three total energies and then calculate ΔE, or you can use a script to do it: `adsorption_energy.py`.

The adsorption energy, calculated using PBE and the FHI pseudopotentials with a DZP basis set, is ΔE = –1.97 eV. However, this number is affected by the so-called basis set superposition error, so you should proceed to the next section to correct for this.

Counterpoise correction

The basis set superposition error (BSSE) is due to the incompleteness of the LCAO basis set, and can have a significant impact on energy differences between different sub-systems. As explained in a tutorial (*DFT-D and basis-set superposition error*), the superposition of Pd and CO basis sets in the CO/Pd(100) system can give rise to an artificial lowering of the total energy because the Pd(100) and CO sub-systems can borrow basis functions from each other. The result is a too large adsorption energy.

The standard approach to neutralize the BSSE is to apply a so-called counterpoise correction. In QuantumATK, this is done using the `counterpoiseCorrected`.

You should therefore calculate the counterpoise (CP) corrected total energy for the CO/Pd(100) system in order to compute the CP corrected adsorption energy:

$$\Delta E^{\mathrm{CP}} = E^{\mathrm{CP}}_{\mathrm{Pd(100)/CO}} - E_{\mathrm{Pd(100)}} - E_{\mathrm{CO}}$$

Use the script shown below (can be downloadad here: `Pd_CO_cp.py`). The script reads in the previously relaxed CO/Pd(100) configuration and the calculator that was used, and creates a new calculator that applies the CP correction. The configuration is then relaxed and the total energy is calculated.

Run the script using the Job Manager or in a Terminal. It should perform 4 very small relaxation steps, and finish within 10 minutes. The CP correction will increase the total energy of the CO/Pd(100) system, resulting in an adsorption energy of ΔE^{CP} = –1.68 eV.

3.11.14 Modeling Vacancy Diffusion in $Si_{0.5}$ $Ge_{0.5}$ with AKMC

Version: 2017

Downloads & Links

initial-structure.py adding-akmc.py

In this tutorial, we will model vacancy diffusion in a $Si_{0.5}$ $Ge_{0.5}$ alloy using the Adaptive Kinetic Monte Carlo method (AKMC). AKMC is an algorithm for performing Kinetic Monte Carlo (KMC) simulations on-the-fly without having to have a predefined set of states and reaction mechanisms. The reaction mechanisms are determined by locating saddle points on the potential energy surface and then using Harmonic Transition State Theory (HTST) to calculate the reaction rate. You can learn more about the AKMC method in this tutorial: *Adaptive Kinetic Monte Carlo Simulation of Pt on Pt(100)*.

Note: For typical MD simulations, it is impractical to model more than a couple of hundred nanoseconds. However, by using AKMC, we will be able to model the dynamics of the system on a longer time scale. This is because the KMC simulation describes the dynamics of the system as transitions between states that – once found – can be computed very quickly.

Obtaining an Initial Structure

In order to generate the initial $Si_{0.5}$ $Ge_{0.5}$ alloy structure, we will use the *Builders* → *Substitutional Alloy* in the **Builder**, implemented in the **ATK 2015** version. If you have an older version, you can use this script instead: `initial-structure.py`.

1. Open the **Builder**.

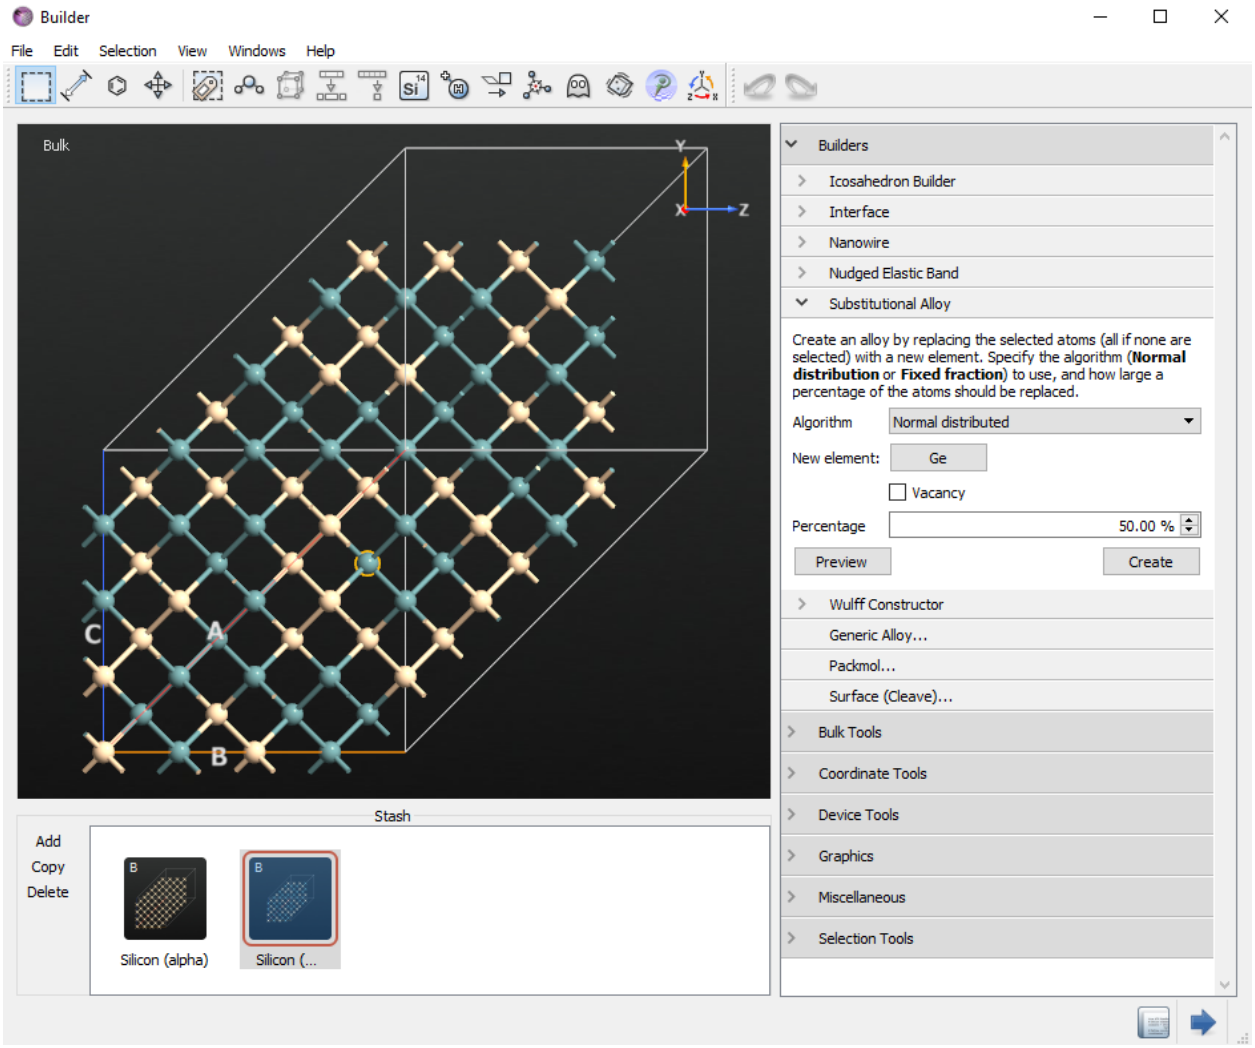
2. Using *Add* → *From Database*, add the Silicon (alpha).

3. Click the *Bulk Tools* → *Repeat*, set A = 4, B = 4, C = 4, and press the *Apply* button.

4. Select the *Builders* → *Substitutional Alloy*.

5. Use the default to substitute 50 percent of Si with Ge.

6. Click the *Create* button.



You now see the initial alloy in the main window of the **Builder** and in the **Stash**. It might be different from the one shown here, as the alloy is randomly created. We make one Si vacancy in the initial structure. In this case, we delete one yellowish Si behind blue-colored Ge at the front site. You can make one Si vacancy randomly.

Now we will optimize the initial structure.

1. Send the initial configuration to the **Script Generator** by clicking the button.

2. Add **New Calculator** and **OptimizeGeometry** blocks.

3. Change the output name to `alloy.hdf5`.

4. Double-click the **New Calculator** block and select the *ATK-Classical* calculator and choose the *StillingerWeber_SiGe_1995* Parameter set.

5. In the **OptimizeGeometry** block, set the Force tolerance to 0.01 eV/Å.

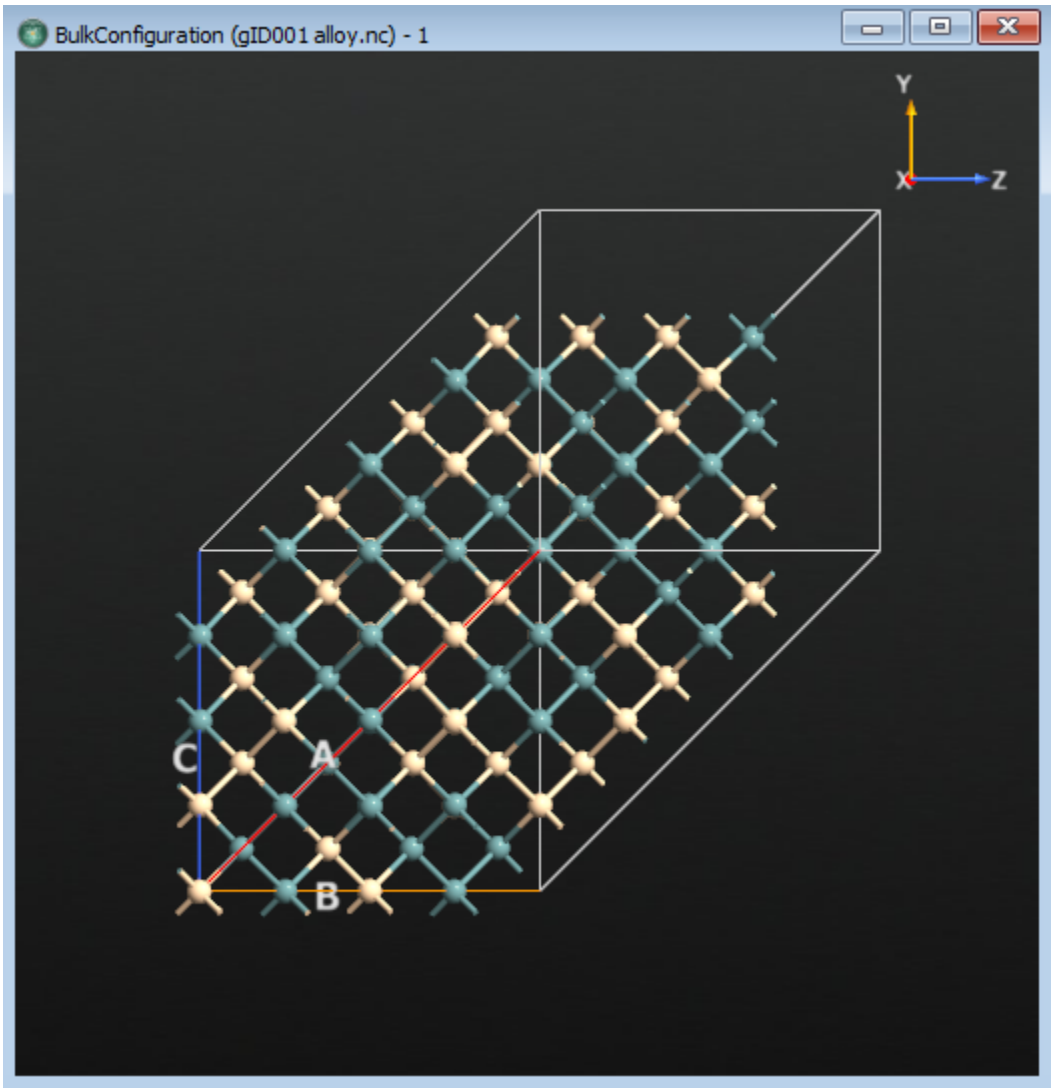
6. Send the script to the **Job manager** by clicking the button.

You can also download and use the script `initial-structure.py`. This script generates a silicon supercell and then

randomly replaces Si atoms with Ge atoms in order to achieve a 50:50 ratio and then creates a Si vacancy as shown below.

Run the script either by dragging it from the main **QuantumATK** window and dropping it on the **Job Manager**, or directly through the terminal.

Now you have generated a 4x4x4 supercell of SiGe with one vacancy, calculated the optimized geometry and saved the structure to `alloy.hdf5`. Note that this is a very small system, useful only for illustrative purposes. You will need a larger system for scientifically valid modelling. You can visualize the structure in **QuantumATK** by selecting the *gID0001* object from the alloy in the **LabFloor** and drag and drop it on the **Viewer**. The result is shown below.



There is a vacancy in the structure, but it is difficult to see. You will perform a *LocalStructure* calculation to see which atoms do not have the typical diamond-like packing.

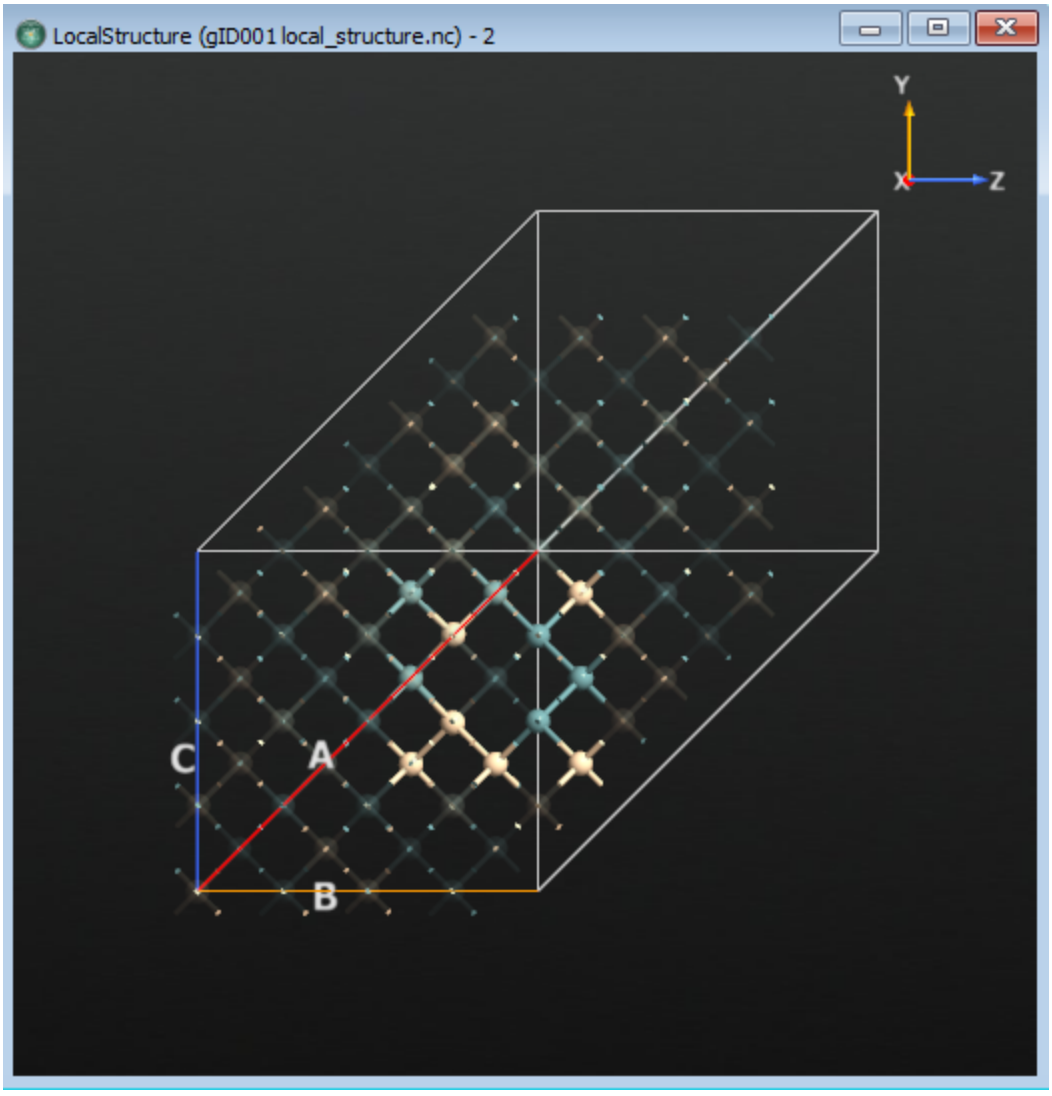
1. Drag the *gID0001* object from the **LabFloor** to the **Scripter**.

2. In the **Scripter**, double click on *Analysis* → *LocalStructure*.

3. Choose the default output file to be `local_structure.hdf5`.

4. Send the script to the **Job Manager** using the button and run the calculation. It should take no more than a minute.

Now you can get a better look at the structure around the vacancies. From the main window, open the **LocalStructure** item in the **Viewer** and expand the **Local Structure** panel in the sidebar. Select *Diamond-like*. Now all of the atoms that are not near the vacancies, and thus have the ideal crystal structure, have been selected. Open the **Properties** dialog and in the **Atoms** tab and change the opacity to 0.1 for the selected atoms. This will highlight the atoms near the vacancies, by making the others almost transparent. The result is shown in the figure below. Note the obvious vacancy in middle of the cluster.



Running the AKMC Simulation

Now that you have an optimized initial structure, you can run the AKMC simulation. Drag `alloy.hdf5` from the main **QuantumATK** window to the **Script Generator**. The **New calculator** will be automatically loaded in the Scripter. Starting from **ATK 2017**, AdaptiveKineticMonteCarlo is implemented in the **Scripter**. If you have an older version, you can download the script `adding-akmc.py` and append the contents in the **Editor** instead of following the steps below.

Add the *Optimization* → *AdaptiveKineticMonteCarlo* block.

1. Double click **AdaptiveKineticMonteCarlo**.
2. In the *Saddle Search* section, set the *Number of searches* to 100.
3. Go to the *Optimization* section, and press the *Atomic Constraint Editor* button.
   - Select one atom as far away as possible from the vacancy
   - Press the *Add tag from Selection* button
   - Change from None to *Fixed* for Constraint.
   - Press the *OK* button.
4. In the *Molecular Dynamics* part, set the *temperature* to 1200 K.

Note: If you look at the **Help** button on the AdaptiveKineticMonteCarlo widget, settings and definitions are introduced in detail. Higher number of searches and higher confidence give us more accuracy, but is also computationally more expensive.

---

5. Save the output file as `akmc.hdf5`.

Tip: When you see the AKMC script (either from the **Scripter** or in `adding-akmc.py`), it enables a restart of the simulation, by reusing the existing files if they exist. For a detailed description of the parameters for the AKMC object, please see the tutorial: *Adaptive Kinetic Monte Carlo Simulation of Pt on Pt(100)*.

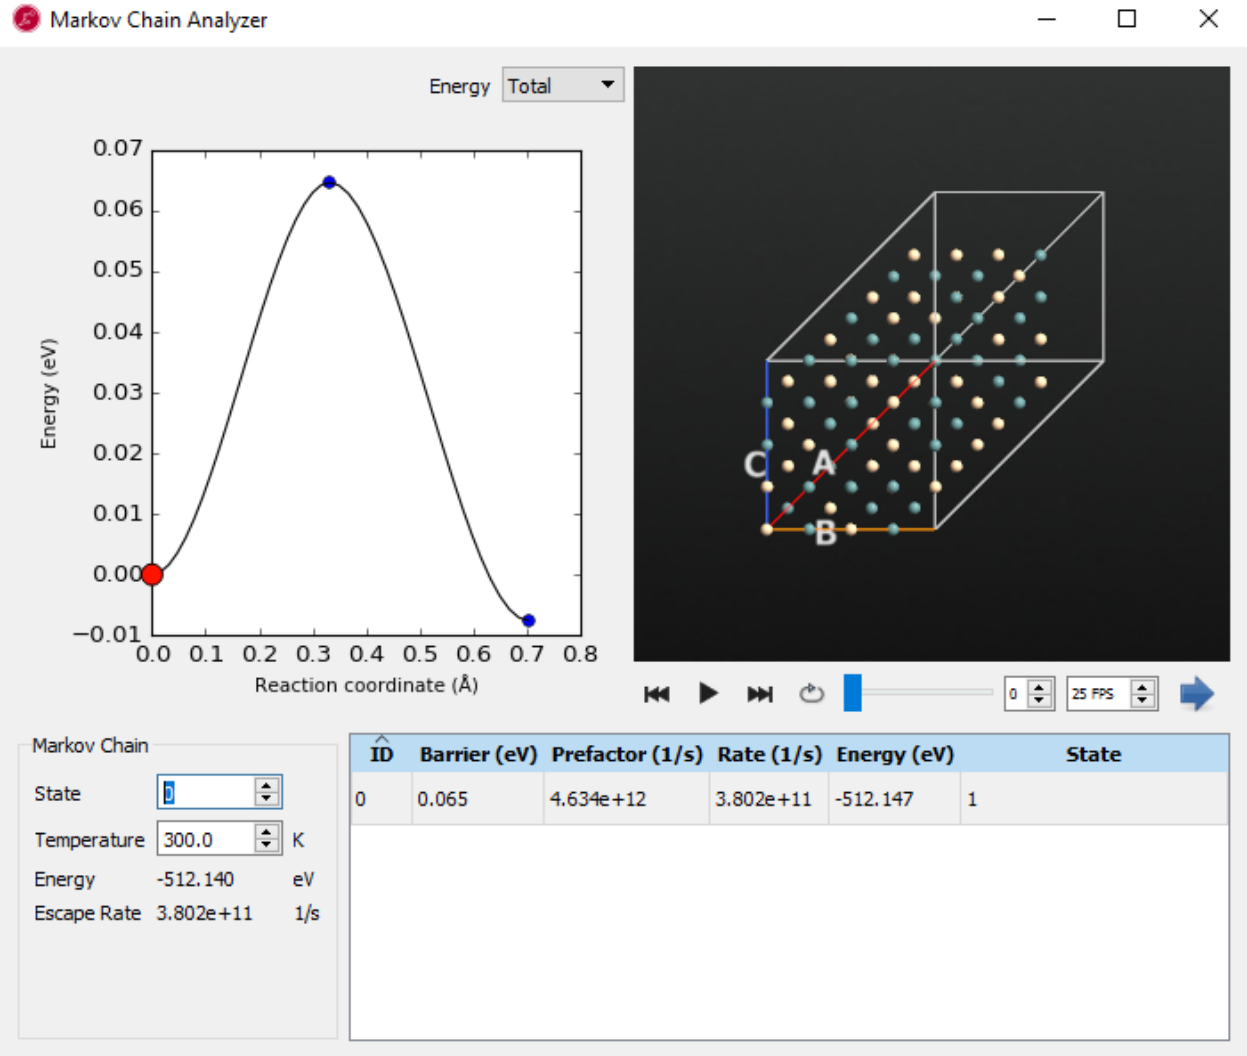
Now run the script. Running the script should take no more than half an hour on a desktop machine. At the end, you will have a *MarkovChain* object stored inside the `akmc_markov_chain.hdf5` file as well as a *KineticMonteCarlo* object stored inside the `akmc_kmc.hdf5` file. The *MarkovChain* object stores all of the states (configurations) that were found during the simulation as well as the connectivity between them. It can be used to calculate the full rate matrix for the whole system.

Note: Due to the random elements in these methods, you might not have exactly the same results as those analyzed here. If you want to follow the analysis exactly, you can download the files used in creating the tutorial here: `akmc_kmc.hdf5`, `akmc_markov_chain.hdf5` and `akmc_log.hdf5`

Select the *gID000* object in the `akmc_markov_chain.hdf5` file on the **Labfloor**, and click the **Markov Chain Analyzer** in the right panel.

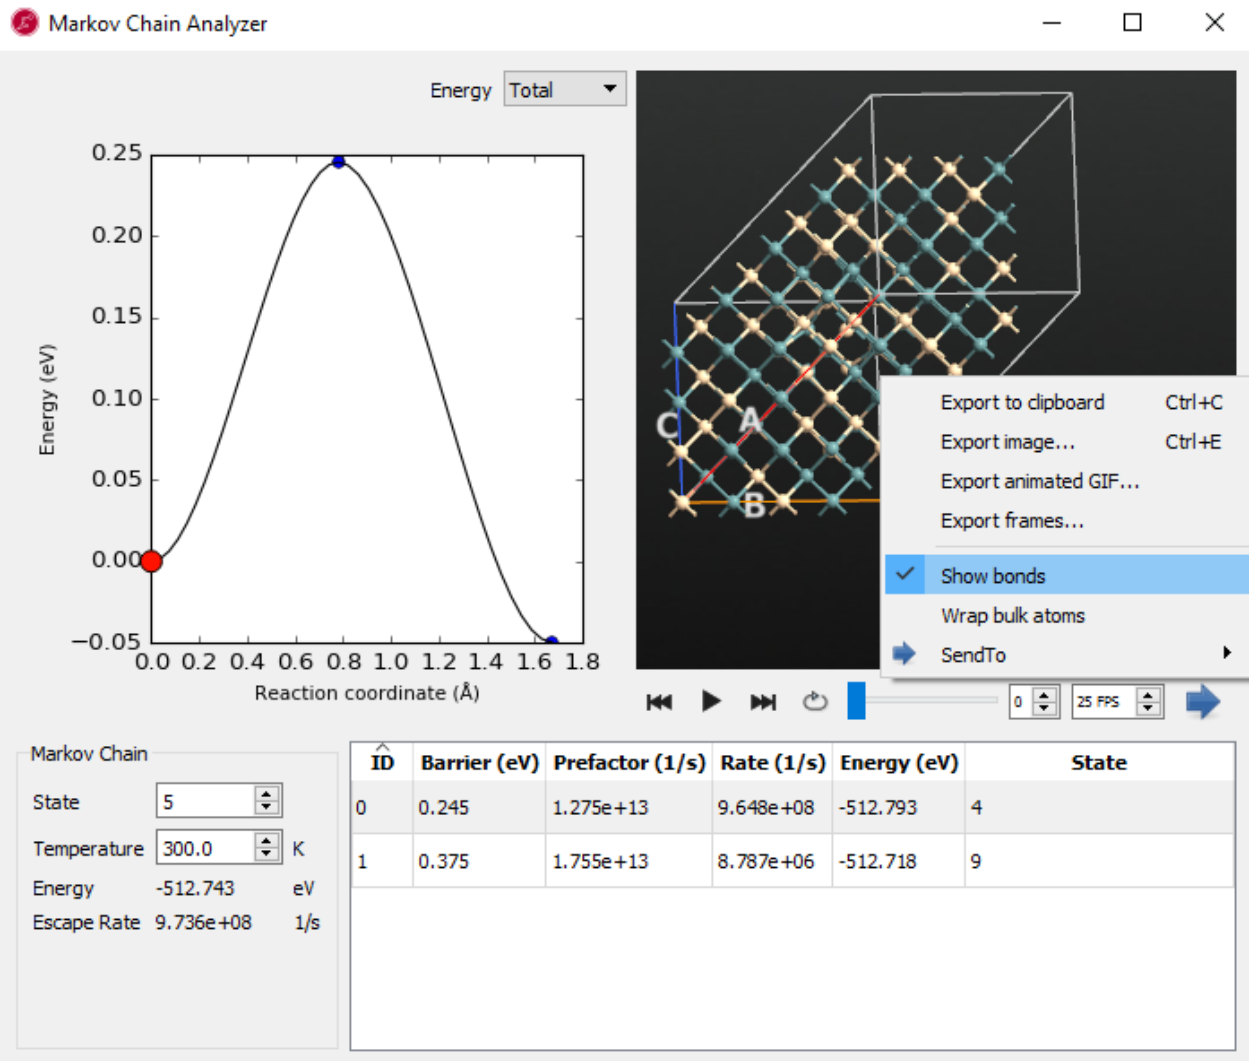
Examine the each state (here, state 0 and state 5 are shown in the below images) and use the play button ▶ in the movie tool to see the diffusion and movement of atoms. From state 0, the system has a very low energy barrier of 0.065 eV towards state 1. When you look at the movie, it seems to be a kind of relaxation and not real diffusion.

•**State 0**



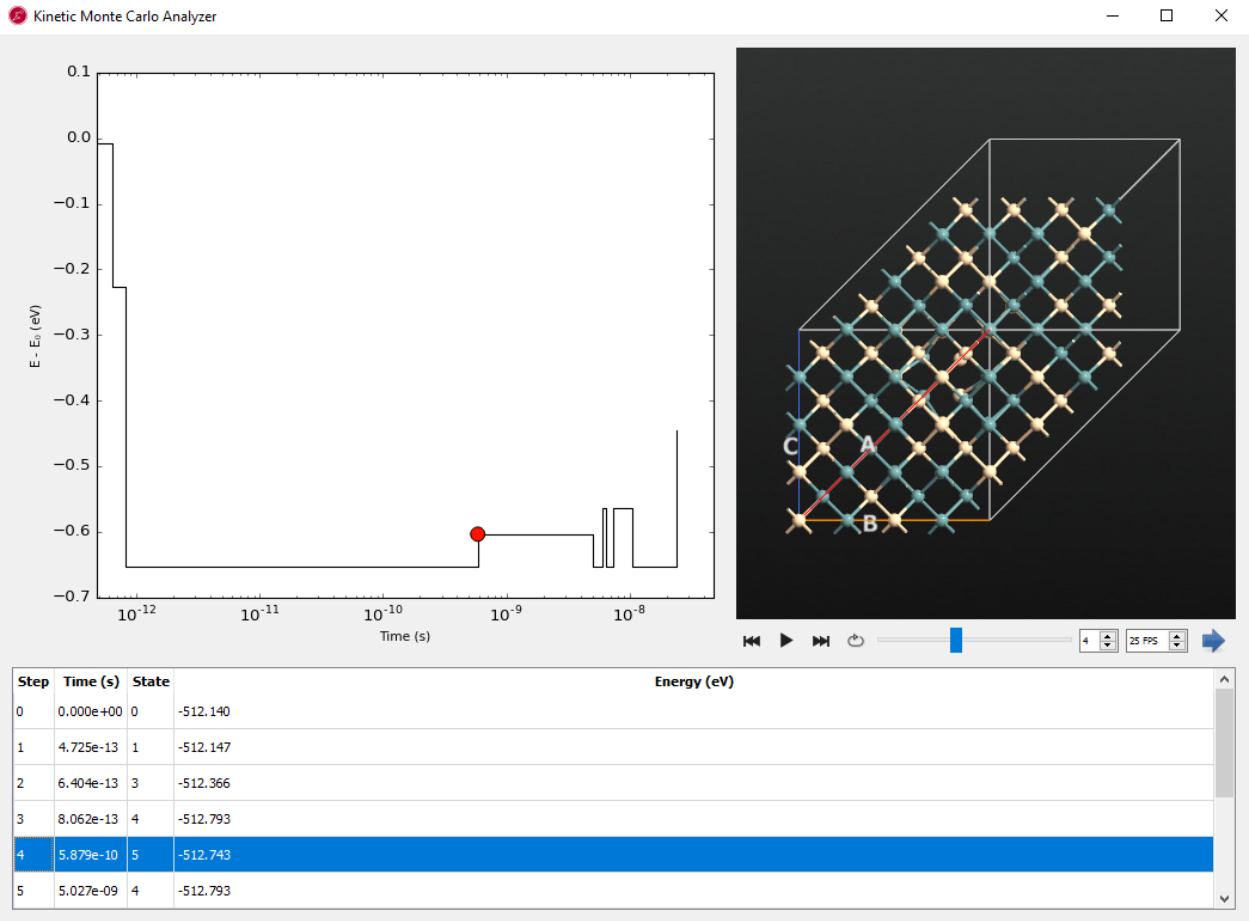
From state 5 we have found saddle points that are connected to state 4 and state 9. They have relatively higher barriers than the one leading from state 0. When you see the movie, silicon and germanium are diffusing and exchanged in the vacancy. If you click the right mouse button on the structure window, you can show the bonds. It can be helpful to show the movement of the atoms when going along the energy diagram.

•**State 5**



Note: Remember that you will probably have other results from a randomly generated alloy.

The *Kinetic Monte Carlo* object stores the time and state-to-state trajectory and is also able to take steps along the Markov chain (i.e. KMC steps). Select both objects, $\sum_i k_i$ in the `akmc_kmc.hdf5` and  in the `akmc_markov_chain.hdf5`, pressing the `ctrl` key, then see the activated **Kinetic Monte Carlo Analyzer** in the right panel. The output should look like, but probably not be identical to, the one seen below:



Step	Time (s)	State	Energy (eV)
0	0.000e+00	0	-512.140
1	4.725e-13	1	-512.147
2	6.404e-13	3	-512.366
3	8.062e-13	4	-512.793
4	5.879e-10	5	-512.743
5	5.027e-09	4	-512.793

This analyzer shows the state-to-state trajectory along time from the *Kinetic Monte Carlo* simulation. The KMC step, elapsed time, visited state id and energy are shown in the table. Click the ▶ movie button. You see the state to state dynamics with the energy vs. time plot. Since the plot is logarithmic on the time axis, the 0 and 1 steps near zero seconds cannot be seen clearly. You can find the different saddle states and staying time or escape time from each state. Starting from the initial state (0 eV), this plot shows the energy difference for other searched saddle points along the time.

In the **LabFloor**, click on the $\sum_i k_i$ object in the `akmc_kmc.hdf5` and select **Text Representation** from the panel on the right.

It includes the same information which we have seen in the **Kinetic Monte Carlo Analyzer** table. Here we show the results from a much longer simulation, with 500 saddle searches. The first column is the step number for the KMC algorithm, the second column represents the total elapsed time in the KMC simulation and the third column shows the current state number, which corresponds to a particular minimum energy configuration in the *MarkovChain* object. Note the break and how the time crosses 1 microsecond in the bottom text part (*step # 1501~1505*), which is actually from the middle of the file: `akmc_kmc_500.hdf5`

Note: Do not confuse the KMC step and saddle point number. The saddle points are discovered as they represent the most likely events to be chosen in the KMC simulation. To ensure the accuracy of the simulation, each state in the Markov chain has an associated confidence. This confidence is an estimate of the probability that for each KMC step taken from that state, the correct event was chosen. Saddle searches are executed in each state until a user defined confidence level is reached. Once the confidence level is reached, the KMC simulation will proceed until a state is reached where the confidence is less than the target level.

The output above includes more KMC steps than the 500 saddle searches that was specified in the script. This shows that the KMC algorithm, to some degree, has been jumping back and forth between the same states. However, as AKMC is a stochastic method it is also entirely possible to see the opposite, with the total number of KMC steps being much smaller than the specified number of saddle searches. This behavior is also very system-dependent.

Note: Note how the final time is greater than a microsecond. This is a much longer timescale than we could probe using MD alone.

On the **LabFloor** you will also find an *akmc_log* object. Open it by clicking on **Text Representation**. You

should see a message equivalent to what is shown below. This shows the results of the 100 saddle searches you specified in the script.

```

The first column is the *id* of the initial state used for the saddle search, the second column is the *search number* (out of the 100 saddle searches), the third column is the calculated *confidence* that the processes starting in the current basin are adequately sampled and the last column is the result of the search. In this case, the algorithm finds 1 new state and meets the confidence of 99% after 5 saddle searches starting from state 0, then go to state 1 (*id* 1). It finds a total number of 2 new states (states 2 and 3), 17 searches find a duplicate state and 6 searches find no new states for various reasons. The initial state from *id* 0 to *id* 1 has changed, showing that the KMC algorithm has taken a step to a new state, and the saddle searches then continue from there.

Conclusion

In this tutorial we examined how to perform an AKMC simulation for the diffusion in an alloy with a vacancy at 300K. The AKMC method is useful to search for saddle points near the initial state which are relevant on a microseconds time scale. When you run a longer simulation or search more saddle points, you can model timescales which are comparable to experiments aiming to understand the state-to-state dynamics.

In a real study it is always important to verify the results of a classical potential and re-optimizing the NEBs describing the barriers using DFT, would be a good idea to determine pathways in the system more exactly.

3.11.15 Computing the piezoelectric tensor for AlN

Version: 2016.0

In this tutorial you will learn how to obtain the piezoelectric tensor and its coefficients with QuantumATK. Specifically, you will:

1. compute the piezoelectric tensor;
2. calculate the e_{33} coefficient by following these steps:

- calculate the changes in the relevant structural parameters due to strain;

•compute the piezoelectric tensor in the clamped-ion approximation and extract the coefficient $e_{33}(0)$;

•compute the Born effective charge.

Introduction

Piezoelectric materials exhibit an induced electric polarization upon the application of external macroscopic strain. The polarization can be reversed by applying an external electric field. These materials find application in a variety of Microelectromechanical Systems (MEMS).

In this tutorial we are going to study the piezoelectric constant of AlN. This synthetic ceramic material is used in a variety of MEMS such as Surface Acoustic Wave sensors (SAWs), and Film Bulk Acoustic Resonators (FBAR).

The piezoelectric tensor

In the absence of external fields, the total macroscopic polarization P of a solid is the sum of the spontaneous polarization P_{eq} (strain independent) of the equilibrium structure, and of the piezoelectric polarization induced by strain P_p (strain dependent).

$$P = P_{eq} + P_p$$

The piezoelectric tensor can be expressed as:

$$\gamma_{\delta\alpha} = \frac{\Delta P_\delta}{\Delta \epsilon_\alpha}$$

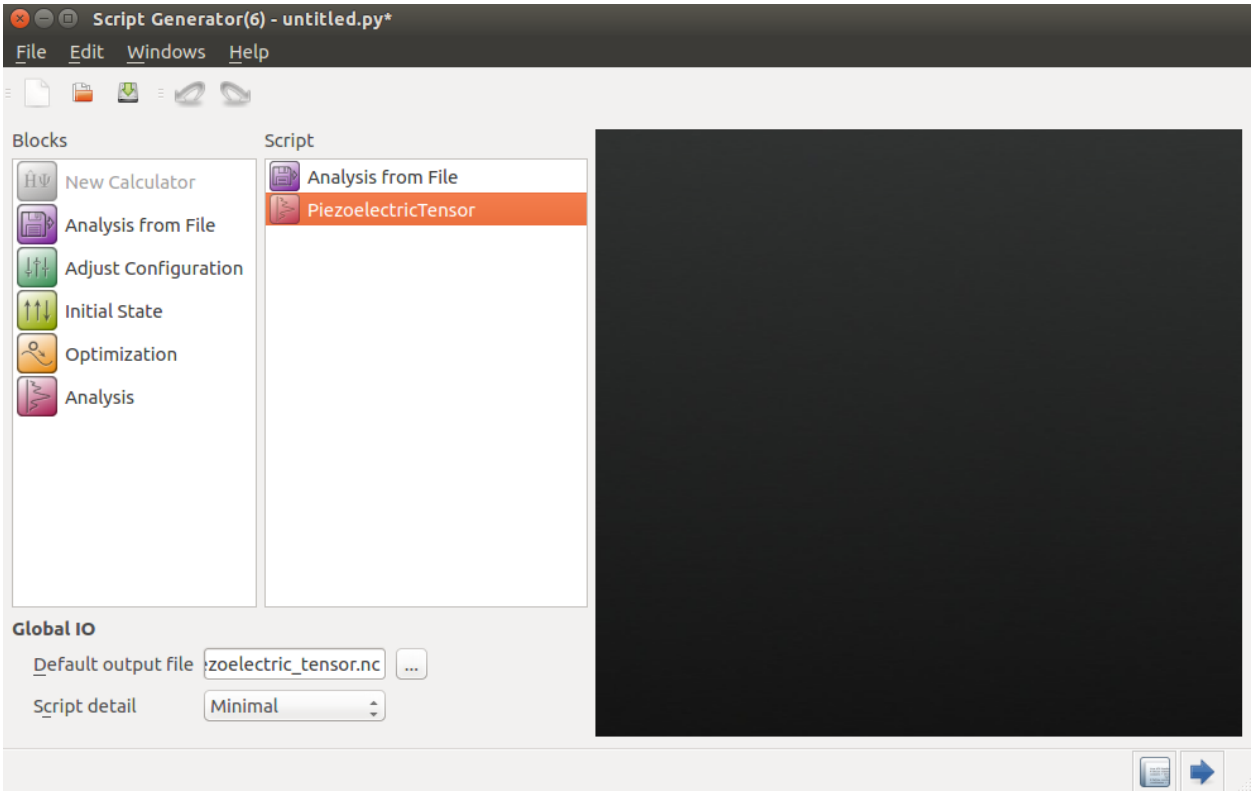
In QuantumATK $\gamma_{\delta\alpha}$ is calculated using a finite-difference approach and P is calculated using a Berry-phase approach. You can refer to the *Polarization* tutorial for more information on how P is evaluated using modern theory of polarization.

Computing the piezoelectric tensor

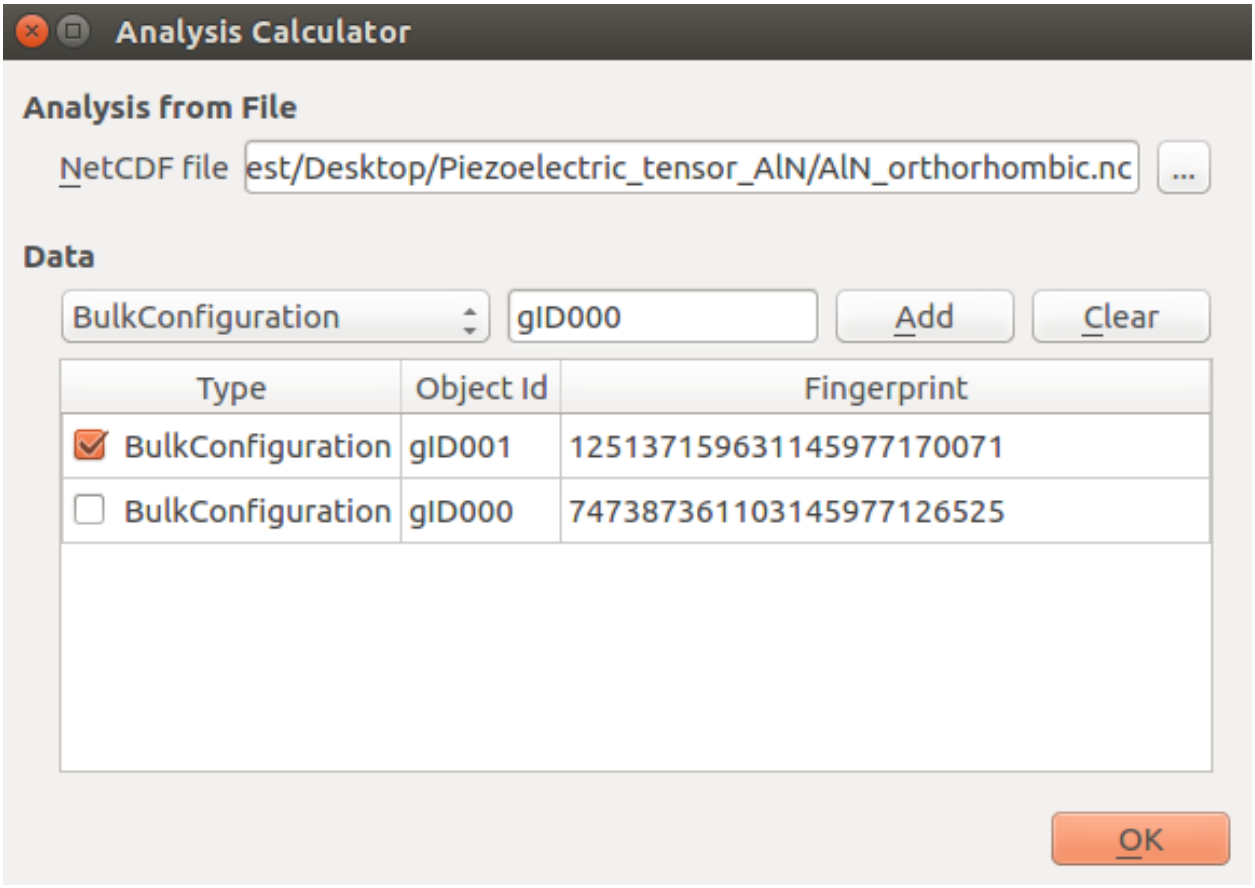
The first thing you should do is to import the AlN (Hexagonal) structure in the **Stash**, optimize its bulk structure and change the cell geometry to Orthorhombic. In this tutorial, you will use a AlN (Orthorhombic) bulk optimized at PBE using FHI pseudopotentials and DZP basis set.

Create a new **QuantumATK project**, and download the HDF5 file containing the optimized structure: (`AlN_orthorhombic.hdf5`). Save it in the **Project Folder** and its content will become visible in the **LabFloor**.

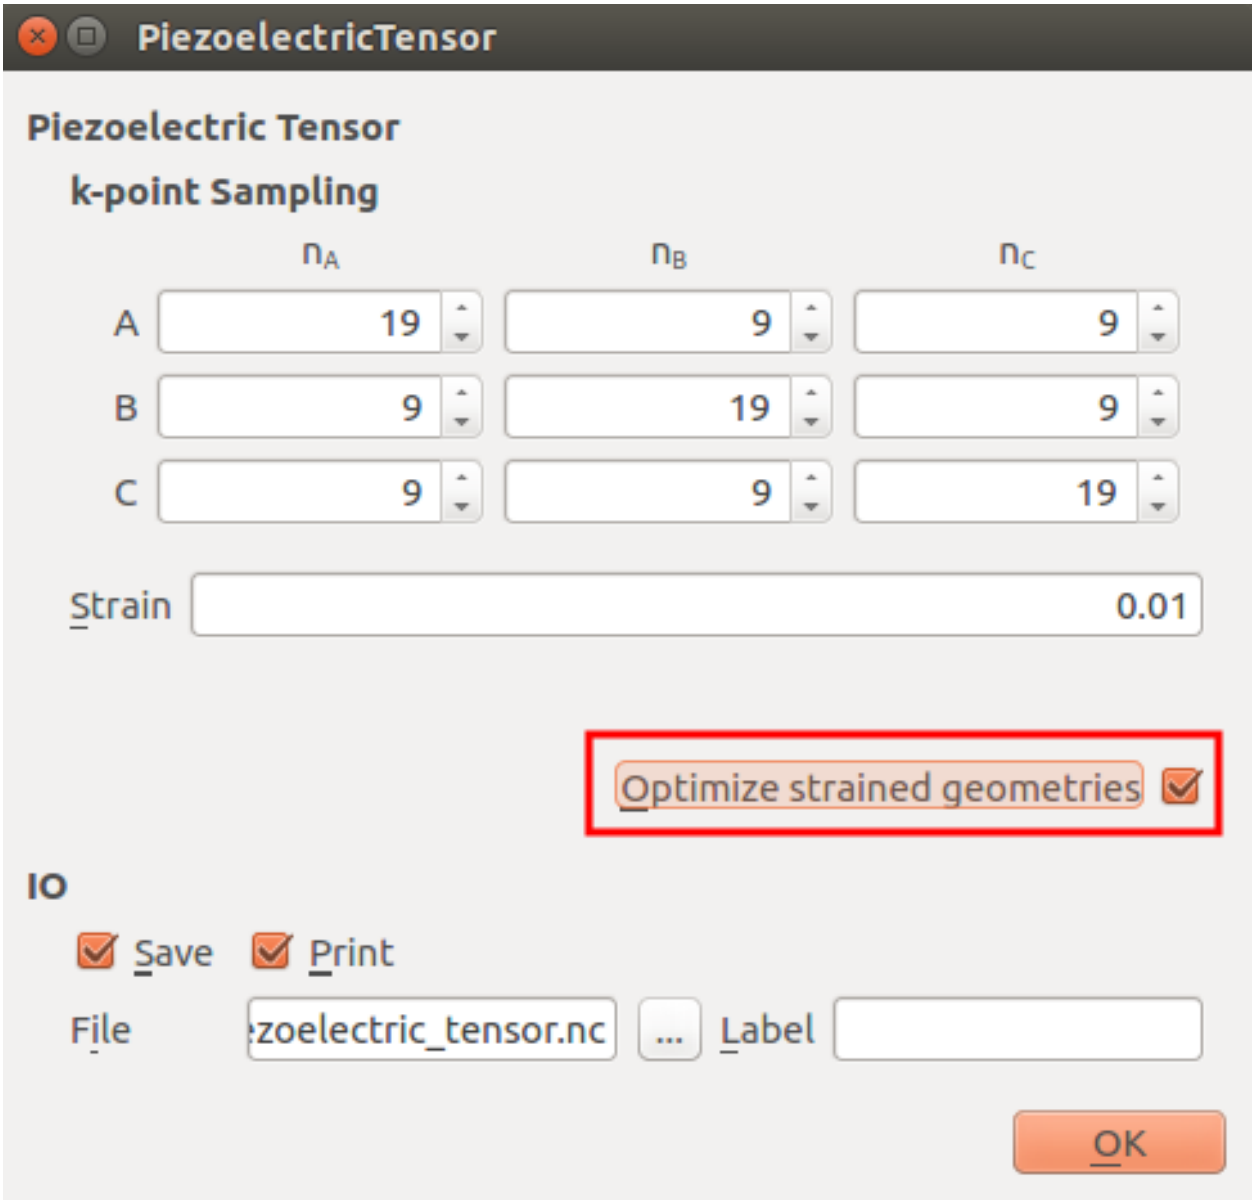
1. Go to **Scripter** and double click the *Analysis from File* and *PiezoelectricTensor* (click *Analysis* → *PiezoelectricTensor*) blocks to add them to the script.



2.Double-click the *Analysis from file* block and select the object containing the optimized bulk structure (object id: *gID001*), as shown below.



3.In the *PiezoelectricTensor* block, set the k-point sampling as in the next figure and tick Optimize strained geometries.



4.Save the HDF5 file and send the script to the **Job Manager** to run it.

Analysis of the e_{33} coefficient

In the **LabFloor**, select the **PiezoelectricTensor** object and click the Text Representation plugin in the left hand panel to inspect the piezoelectric tensor.

```

The predicted value for e_{33} is 1.4849 C/m^2. This value is in good agreement with the value found in the literature (1.46 C/m^2).[1]

In the next section we are going to see how you can calculate e_{33} in an alternative way.

[1] Fabio Bernardini, Vincenzo Fiorentini, and David Vanderbilt. Spontaneous polarization and piezoelectric constants of III-V nitrides. *Phys. Rev. B*, 56:R10024–R10027, Oct 1997. doi:10.1103/PhysRevB.56.R10024.

Alternative way of calculating the piezoelectric coefficient e_{33}

The piezoelectric coefficient e_{33} can be also calculated as the sum of two terms[Page 1569, 12]:

1. the clamped-ion term $e_{33}(0)$, that expresses the electronic response to strain.
2. a second term describing the effect of the internal strain on the piezoelectric polarization.

The complete expression for e_{33} thus reads:

$$e_{33} = e_{33}(0) + \frac{4eZ^*}{\sqrt{3}a^2}\frac{du}{d\epsilon_3}$$

where e is the electronic charge, ϵ_3 is the macroscopic applied strain and Z^* is the Born effective charge, which depends on the change in polarization upon the dispacement of an ion (or rather, a periodic sublattice of equivalent ions):

$$Z^*_{\nu,i,j} = \frac{\Omega}{|e|}\frac{\partial P^i_t}{\partial r^\nu_j}$$

where Ω is the unit cell volume, P^i_t is the total polarization along the Cartesian direction i, and r^ν_j is the coordinate of ion ν in direction j. The Born effective charge is also referred to as effective charge or dynamical charge.

Note: The Born effective charge is a tensor. În fact, when an ion is displaced in direction j, this will clearly affect the polarization in same direction j. However, it may also lead to a change in polarization in another direction i perpendicular to j.

In the calculations below the derivative will be approximated using finite differences:

$$\frac{\partial P^z_t}{\partial r^\nu_z} \approx \frac{P^z_t(+\delta\hat{z},\nu) - P^z_t(-\delta\hat{z},\nu)}{2\delta},$$

where $P^z_t(\pm\delta\hat{z},\nu)$ is the polarization along the z-direction when atom ν has been displaced by the amount δ in the positive/negative z-direction.

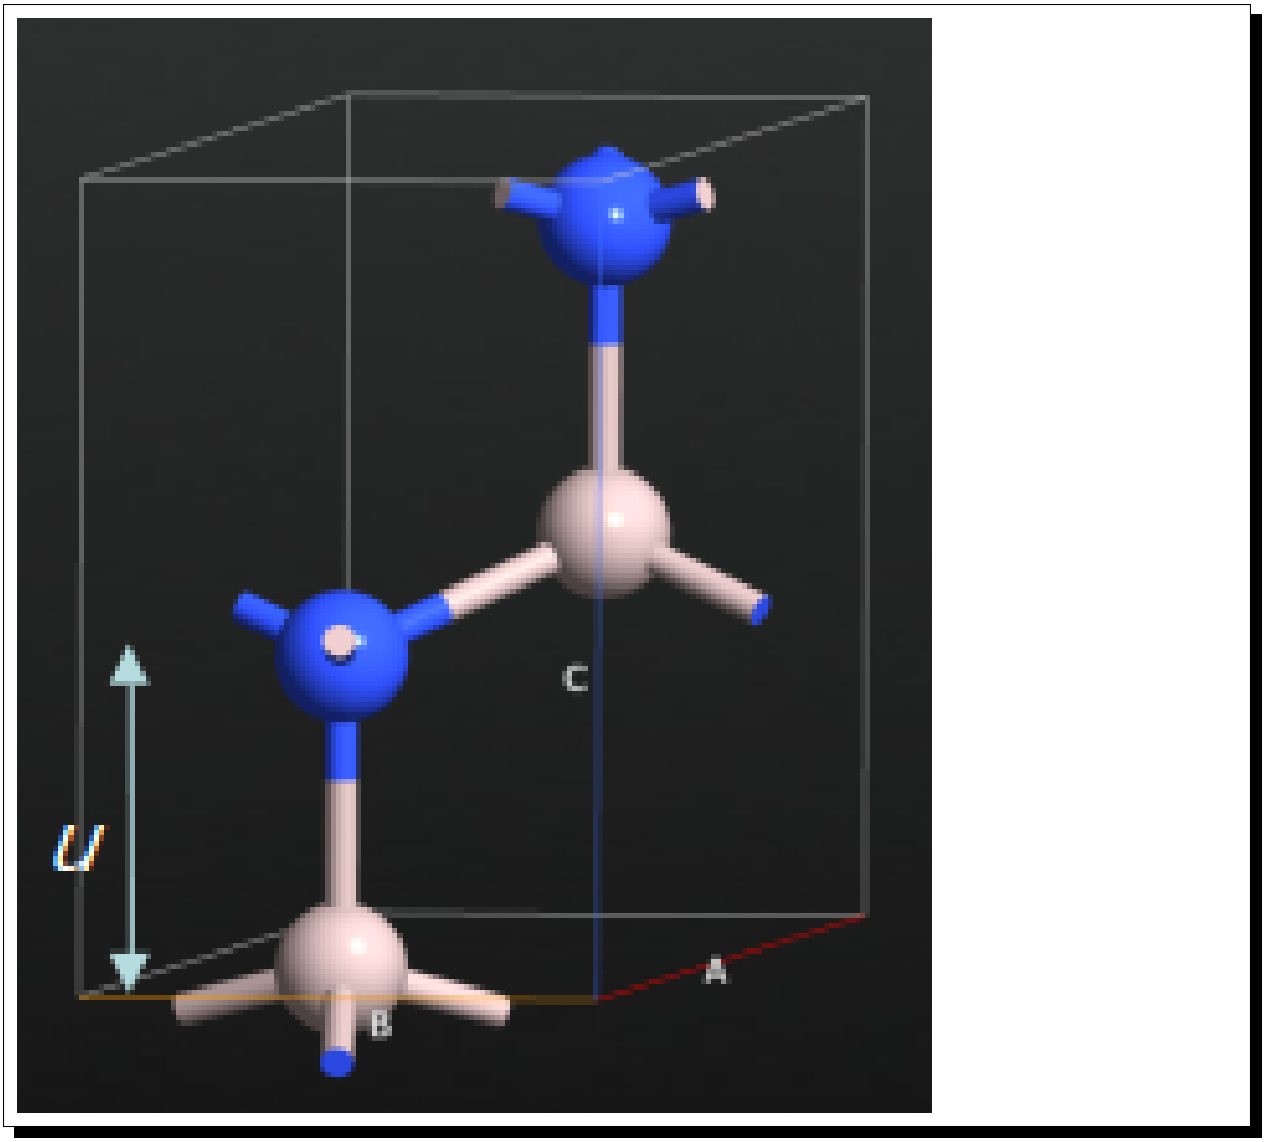
In the following, we will obtain e_{33} by calculating each term explicitly. Specifically, we will:

1. calculate the variation of the interatomic distance due to strain ($\frac{du}{d\epsilon_\alpha}$);
2. compute the piezoelectric constant in the clamped-ion approximation $e_{33}(0)$;
3. compute the Born effective charge Z^*.

The variation of the interatomic distance due to strain

The AlN hexagonal cell

[2] T.ăYokoyama, Y.ăIwazaki, T.ăNishihara, and M.ăUeda. Analysis on electromechanical coupling coefficients in AlN-based bulk acoustic wave resonators based on first-principle calculations. In *Ultrasonics Symposium (IUS), 2012 IEEE International*, 551–554. Oct 2012. doi:10.1109/ULTSYM.2012.0137.



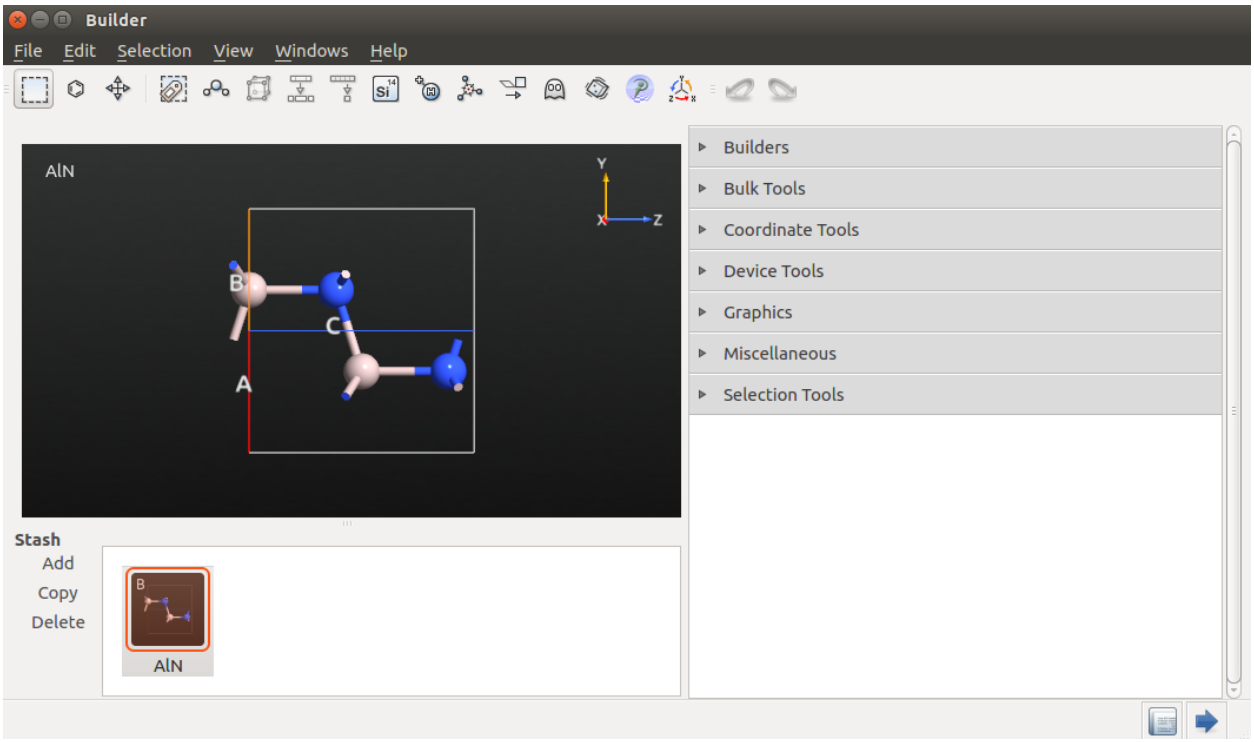
This variation is expressed as $\frac{du}{d\epsilon_\alpha}$ where du represents the difference in the interatomic distance u ($du = u' - u$) and $d\epsilon_3$ represents the applied strain ($d\epsilon_3 = c' - c$) in the direction parallel to the bond.

In order to calculate du we will:

1. relax the bulk structure and calculate u;
2. apply a 1% strain to the unit cell in c direction, relax the internal parameters and get the interatomic distance under strain, u'.

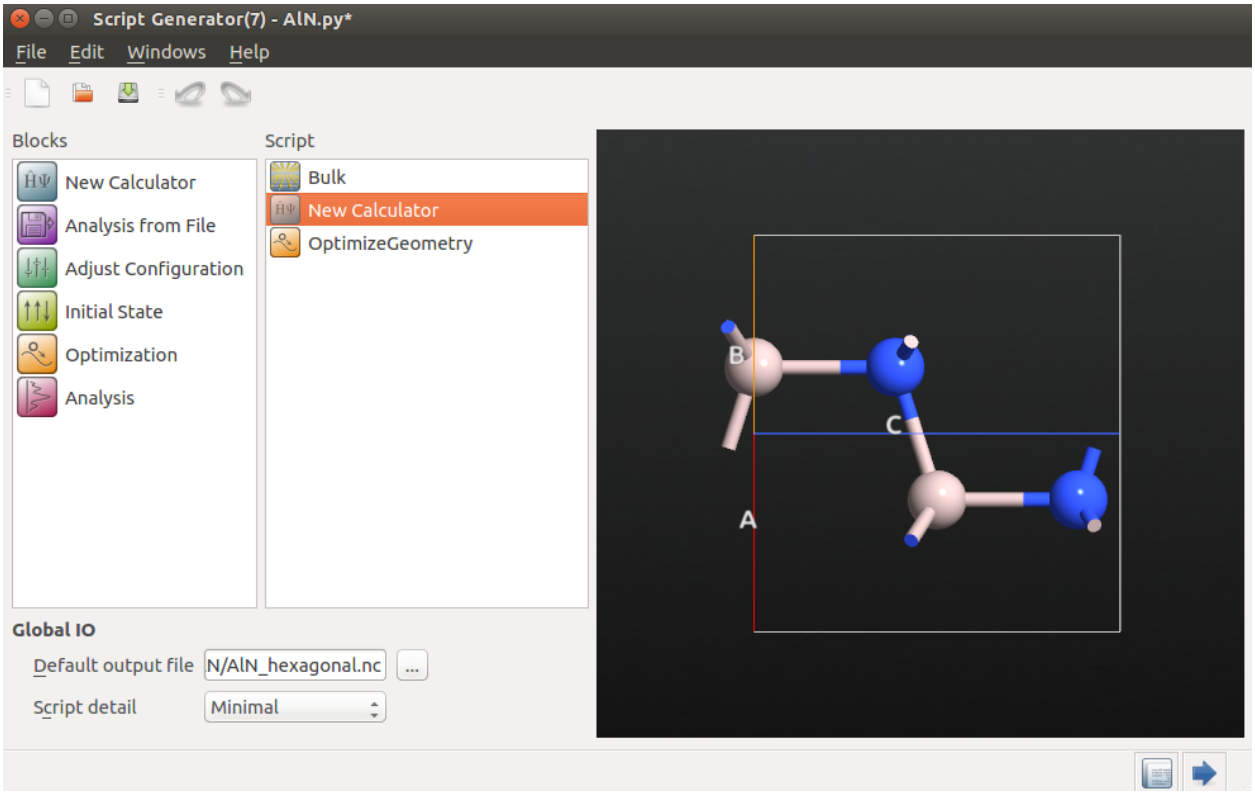
Calculating the interatomic distance u for the relaxed system

1.Go to **Builder** and click *Add* → *Form Database*, locate AlN (Hexagonal) in the database, and add it to the **Stash**.



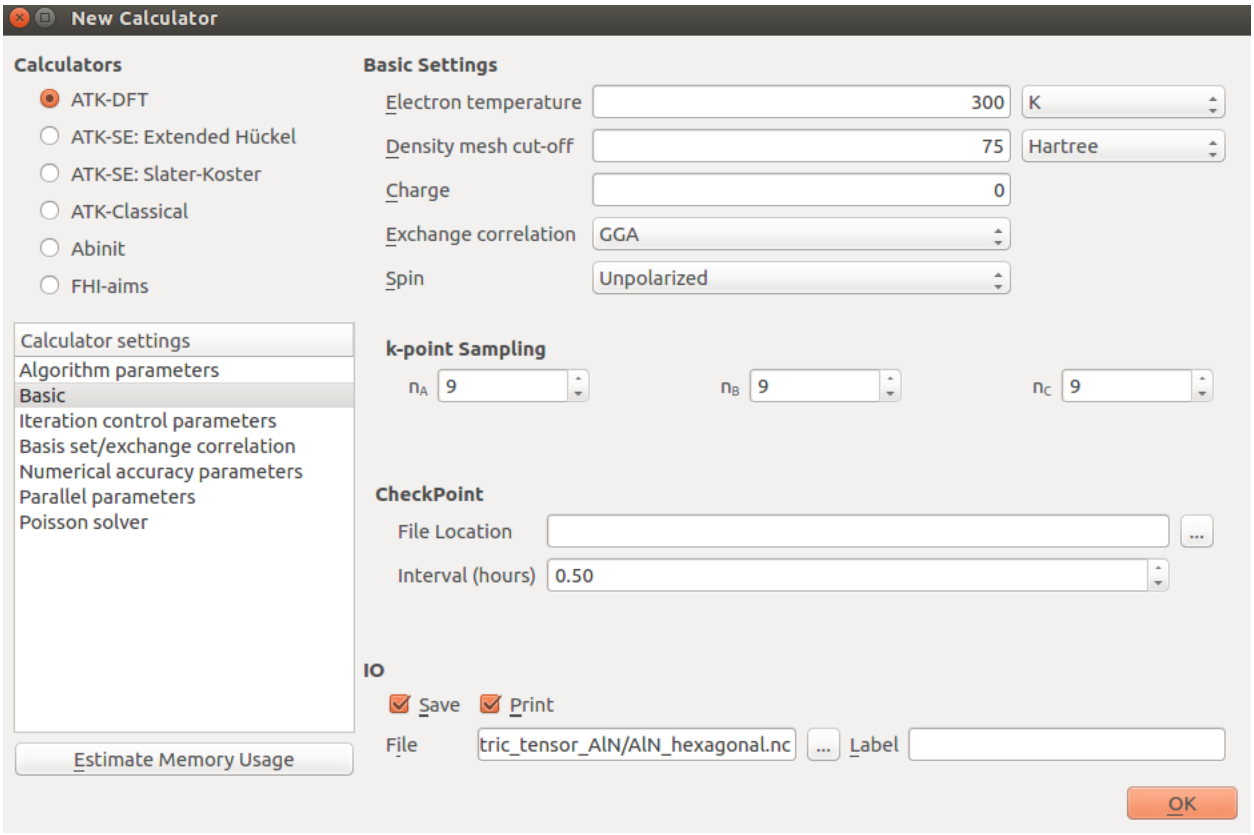
2.Send the bulk configuration to the **Script Generator**.

3.In the Script Generator, double-click the *New Calculator* and *OptimizeGeometry* (click *Optimization* → *Optimize Geometry*) blocks to add them to the script.



4.In the *New Calculator* block set the following parameters:

- *exchange and correlation*: GGA.PBE
- *Basis set*: DZP
- *k-point sampling*: (9,9,9)



5.In the *OptimizeGeometry* block untick Constrain Lattice Vectors.

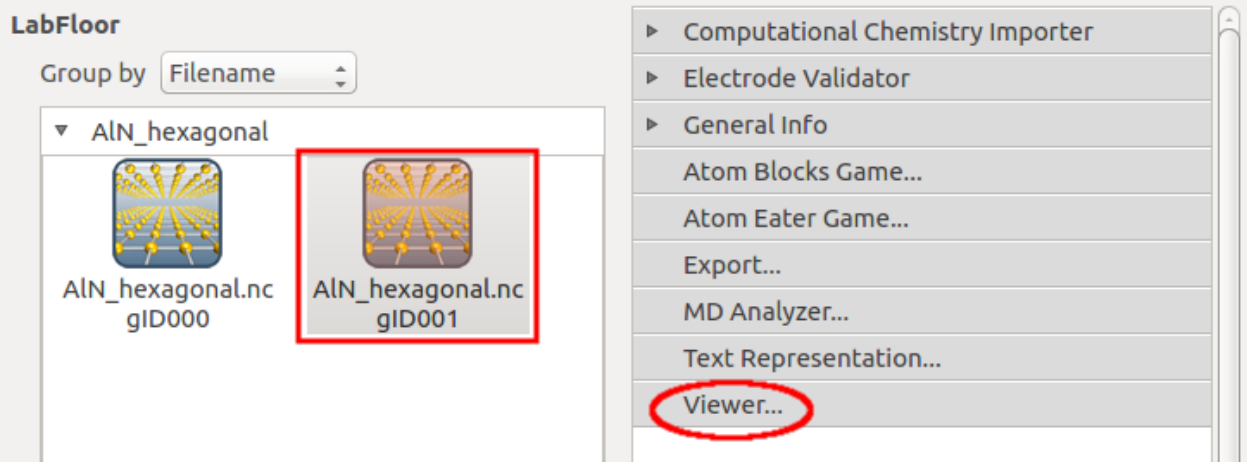
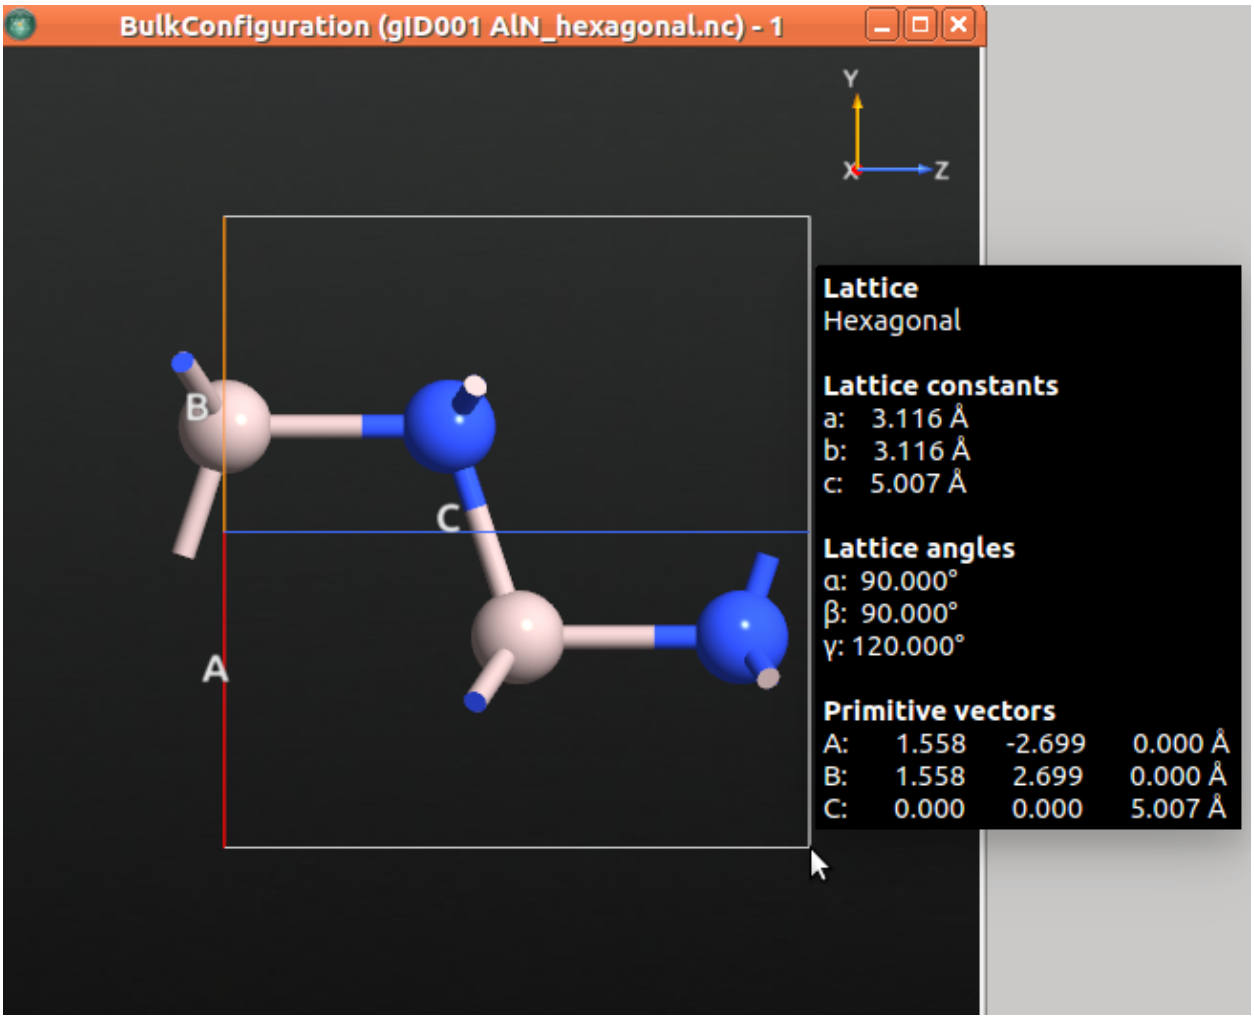
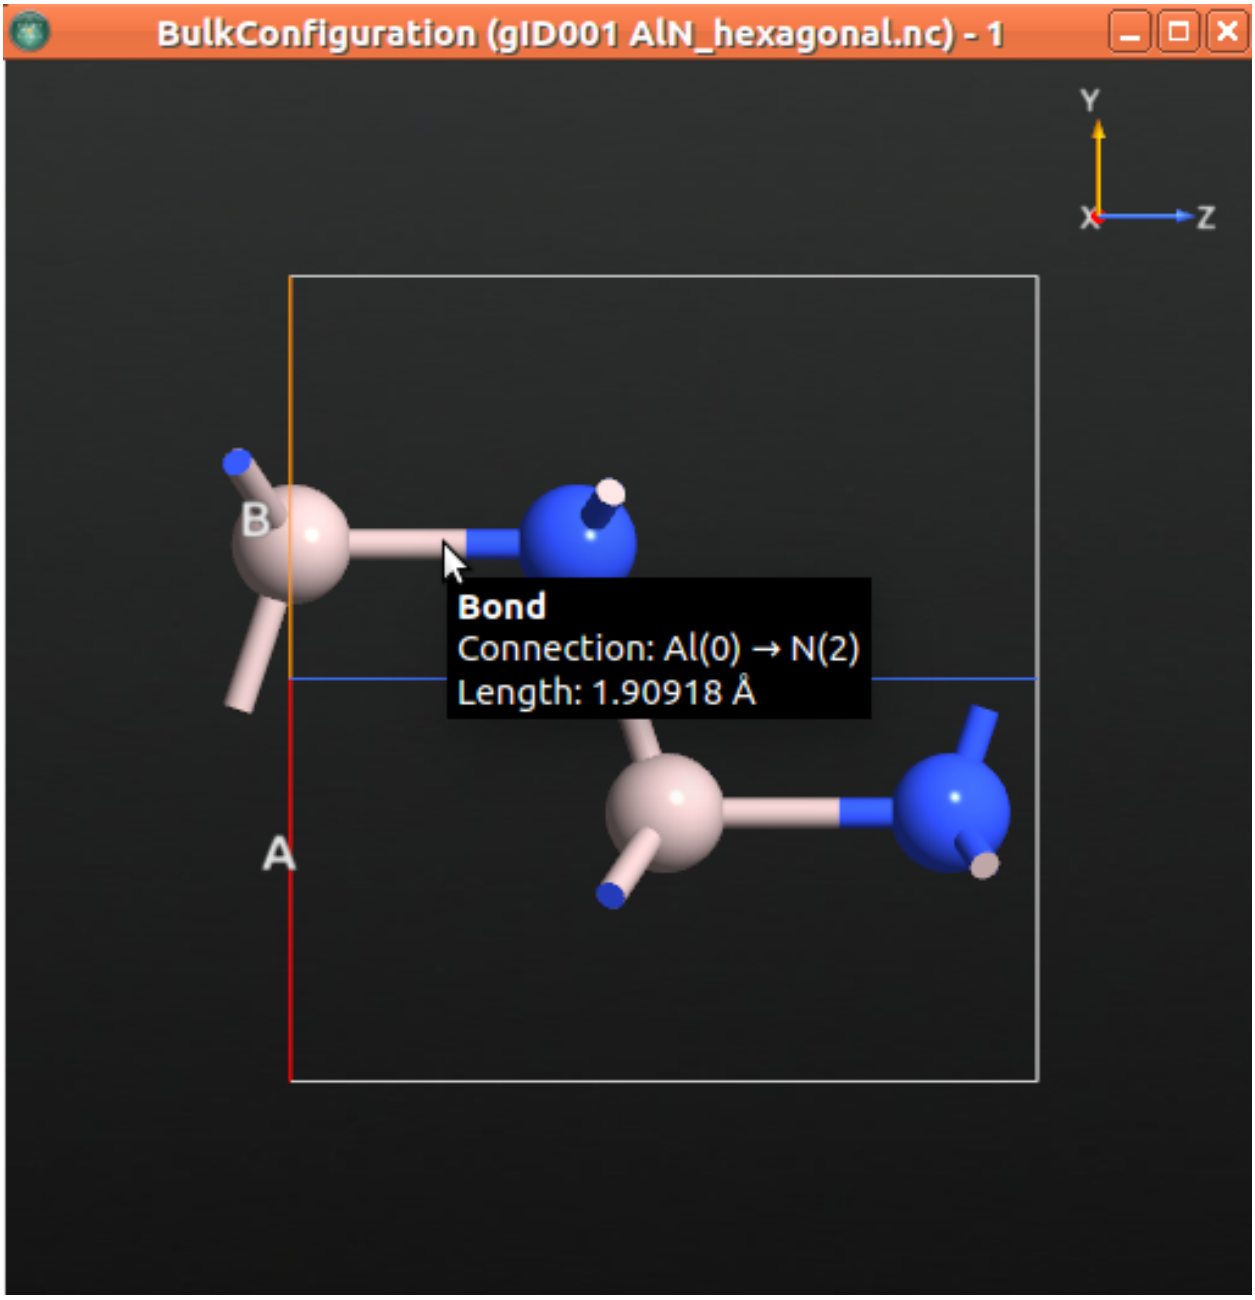
6. Save the HDF5 file as `AlN_hexagonal.hdf5` and send the script to the **Job Manager** to run it.

   Once the job is finshed, the optimized bulk structure should appear in the **LabFloor**. Select it and click the **Viewer** plugin to visualize it.







The table below shows the relaxed structural parameters.

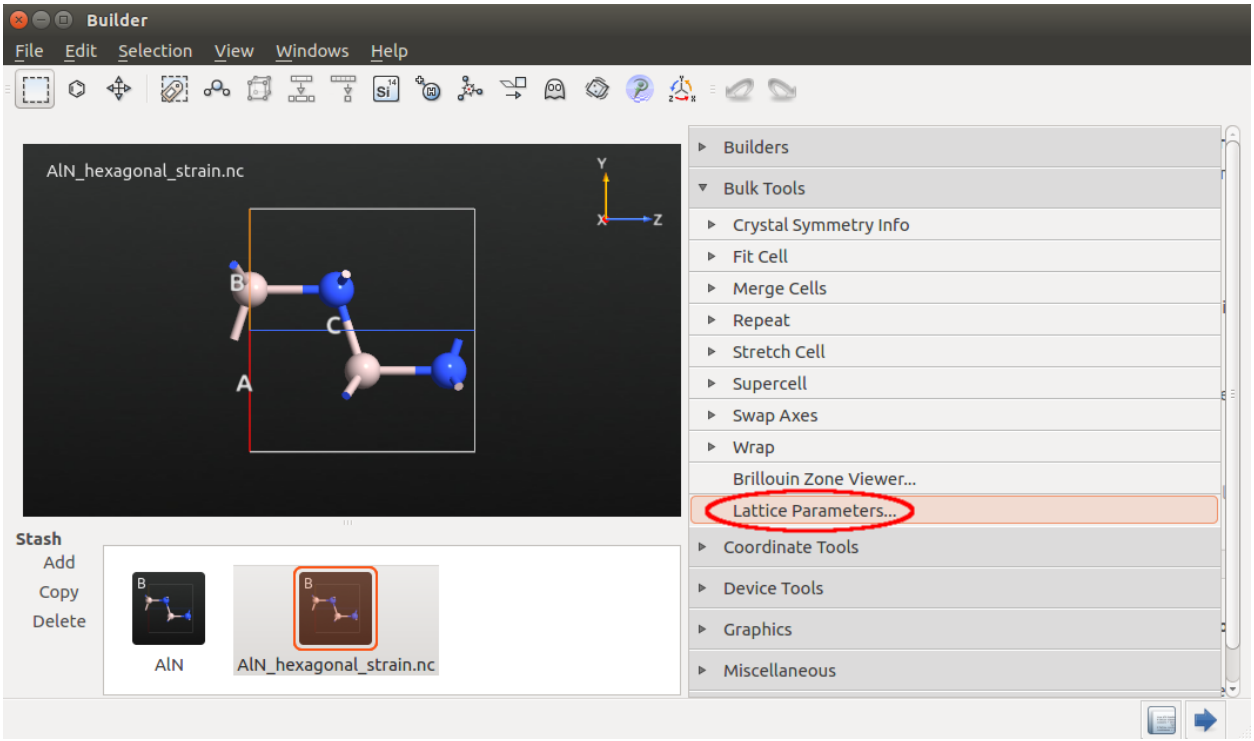
Table 3.6: Table: Relaxed cell parameters in

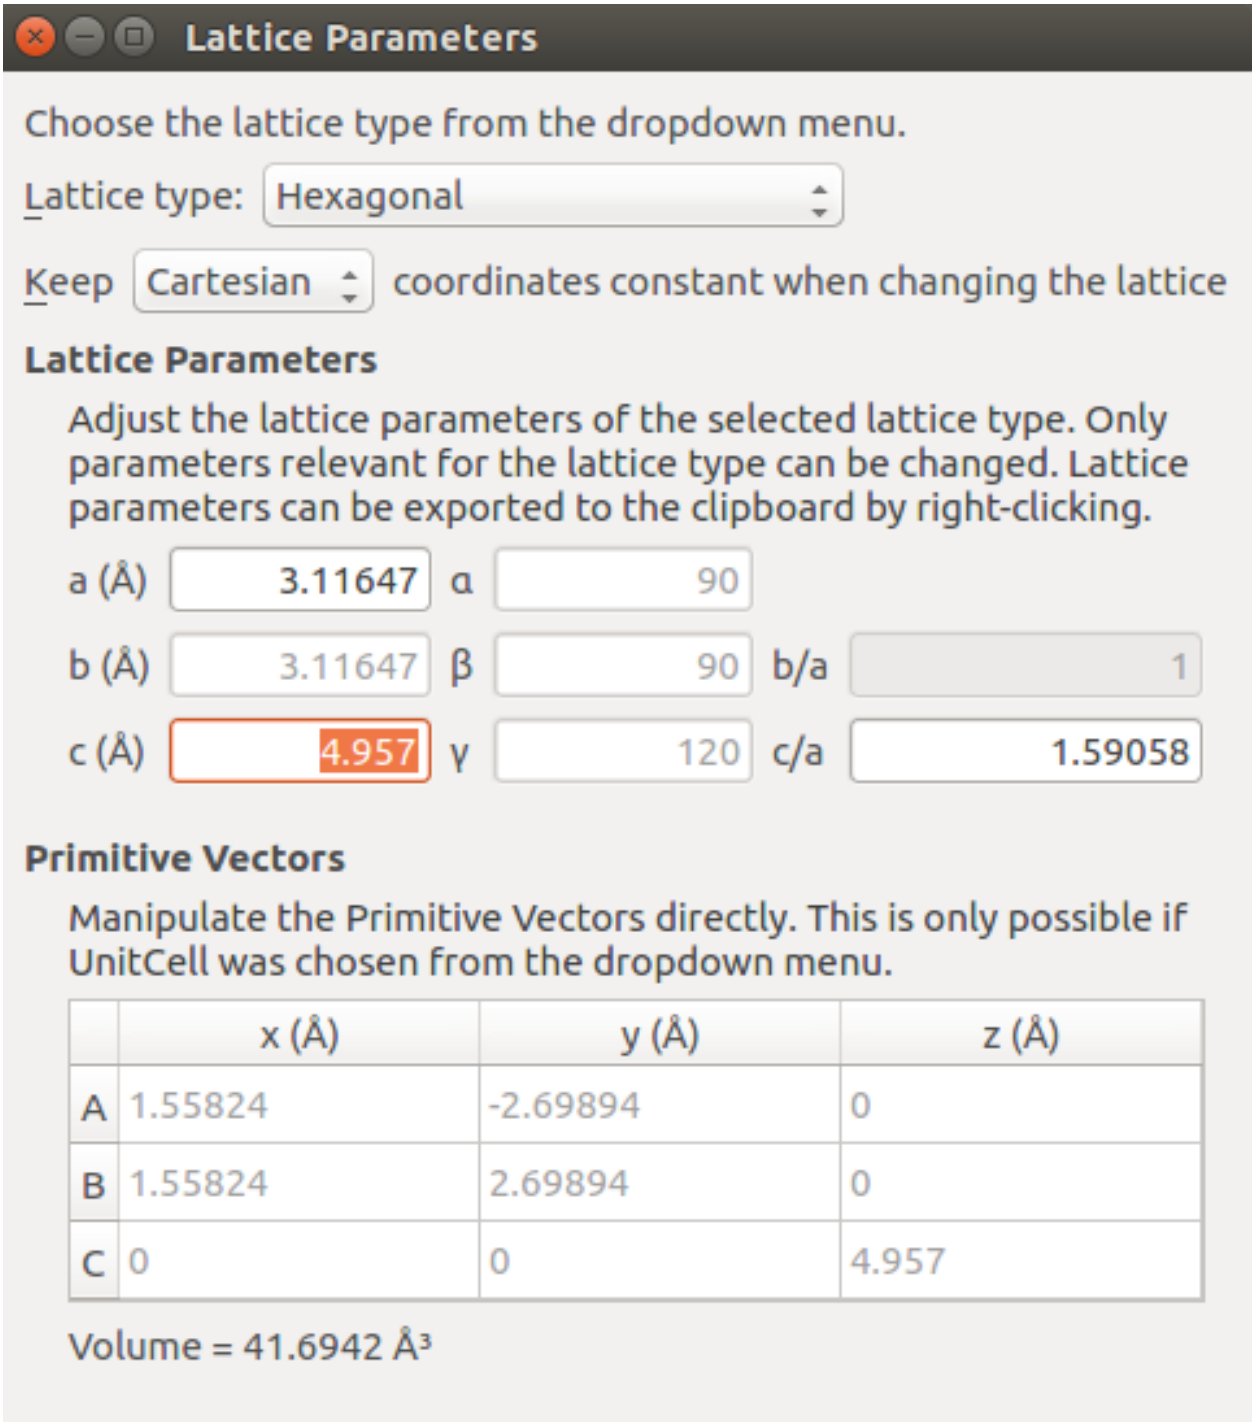
	QuantumATK	Bernardini *et al.*[Page 1569, 1]
a	3.116	3.0766
c	5.007	4.9810
c/a	1.607	1.6190
u/c	0.381	0.380

The value of the relaxed c lattice constant is 5.007 Å. In the next step, we will apply a 1% compressive strain in the c direction by diminishing the lattice constant in c direction in 0.05 Å.

Internal relaxation under strain in z direction

1. Send the relaxed structure to the **Builder** and rename it as `AlN_hexagonal_strain.hdf5`.
2. Go to *Bulk Tools* → *Lattice Parameters* to decrease the lattice parameter in 1% in c direction.





3.Send the structure to the **Script Generator** to create a script.

4.In the **Script Generator**, double-click the *New Calculator* and *OptimizeGeometry* blocks.

5.In the *New Calculator*, set the following parameters:

- *exchange and correlation*: GGA.PBE
- *k-point sampling*: (9,9,9)

6.In the *OptimizeGeometry* block, constrain the lattice vectors as shown in the next figure.

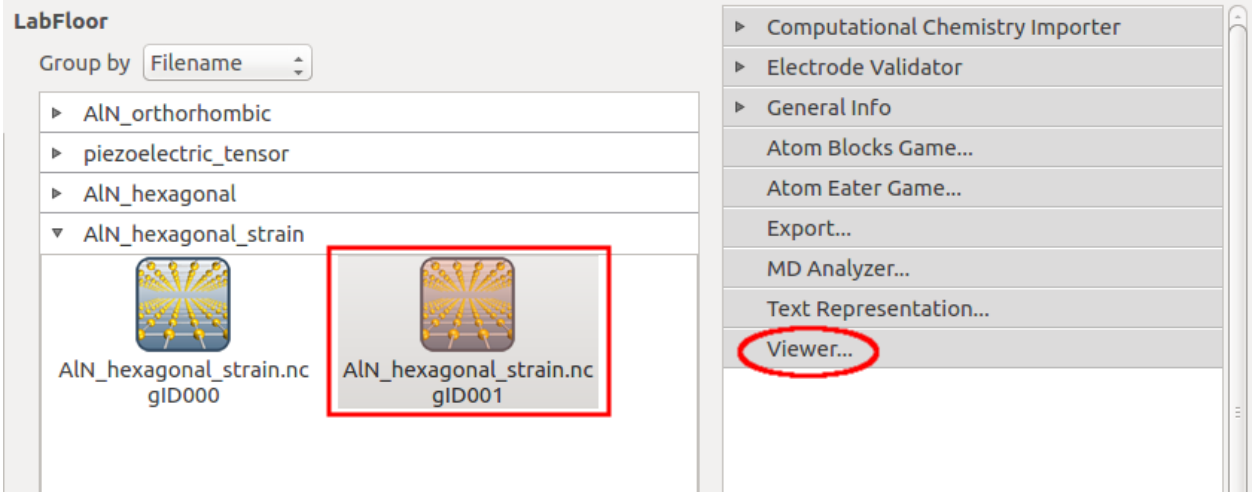
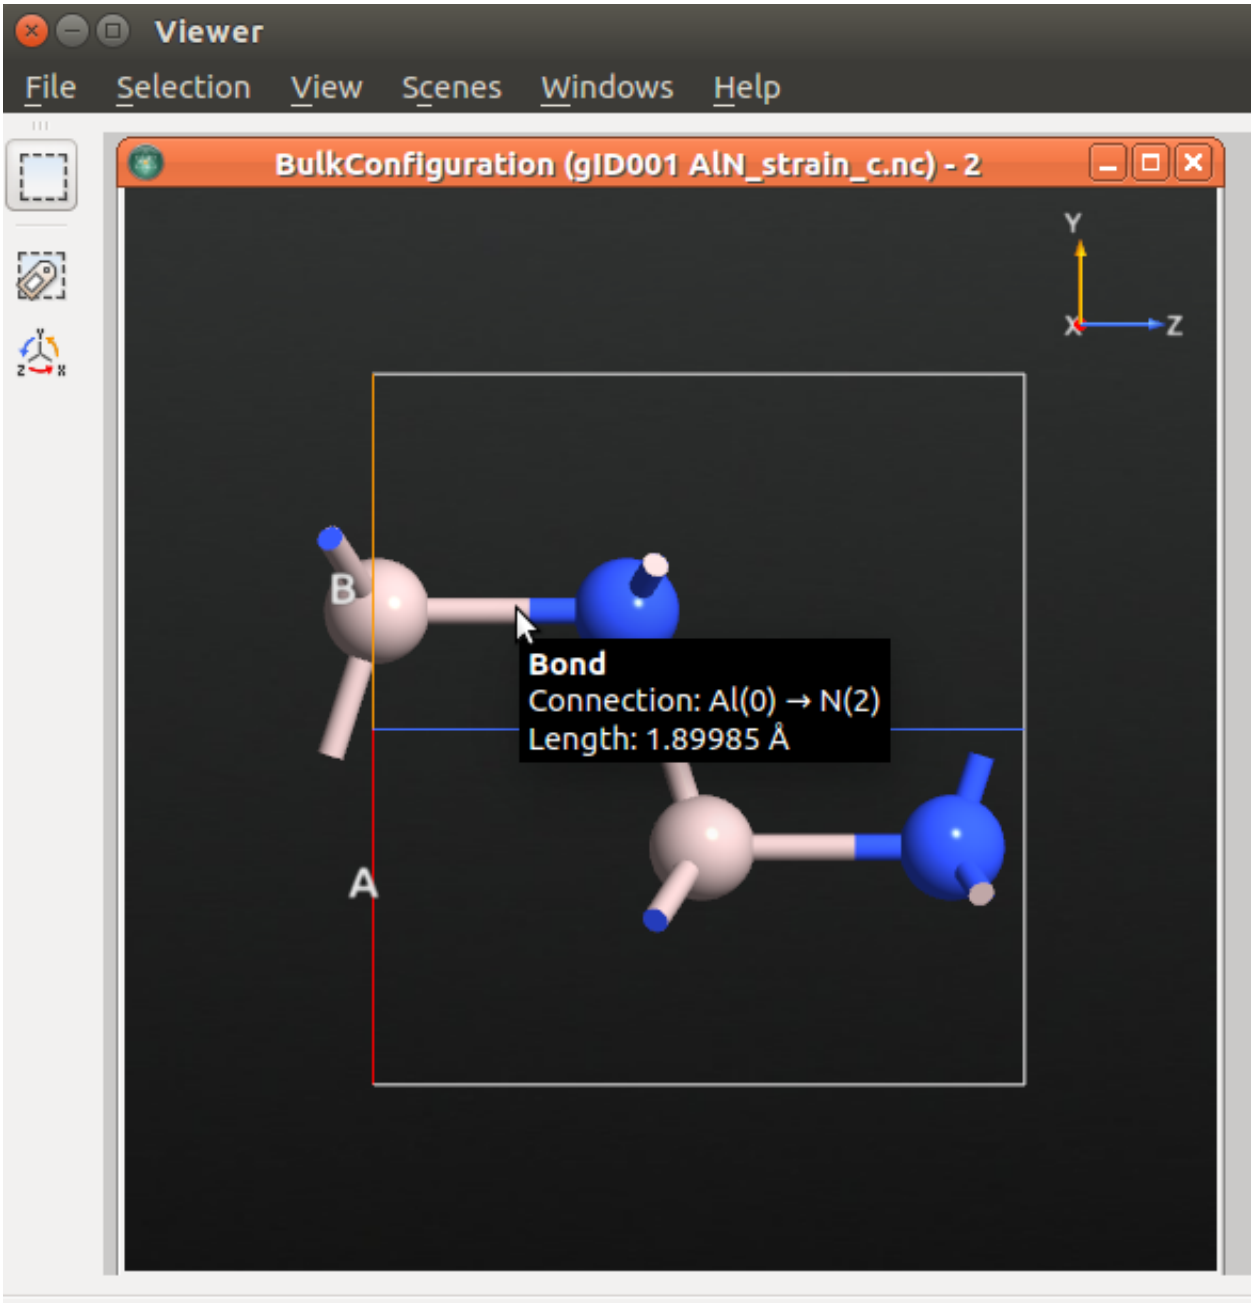
7. Send the script to the **Job Manager** and run the script.

   Once the calculation is finished, select the optimized bulk structure in the **LabFloor** and click the **Viewer** plugin to visualize the parameters.



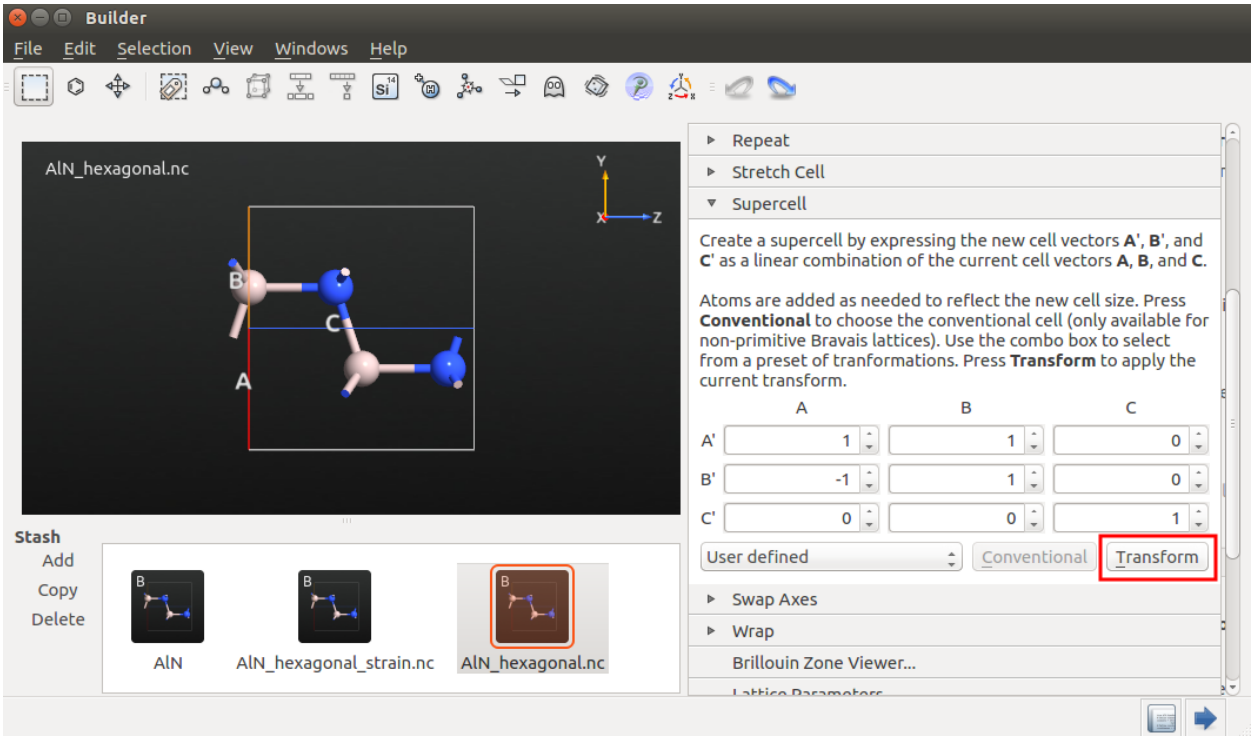


The predicted u' value is 1.89985 Å, and therefore the predicted $\frac{du}{d\epsilon_3}$ value is -0.1866. This value is in agreement with the value found in the literature (-0.18)[Page 1569, 1].

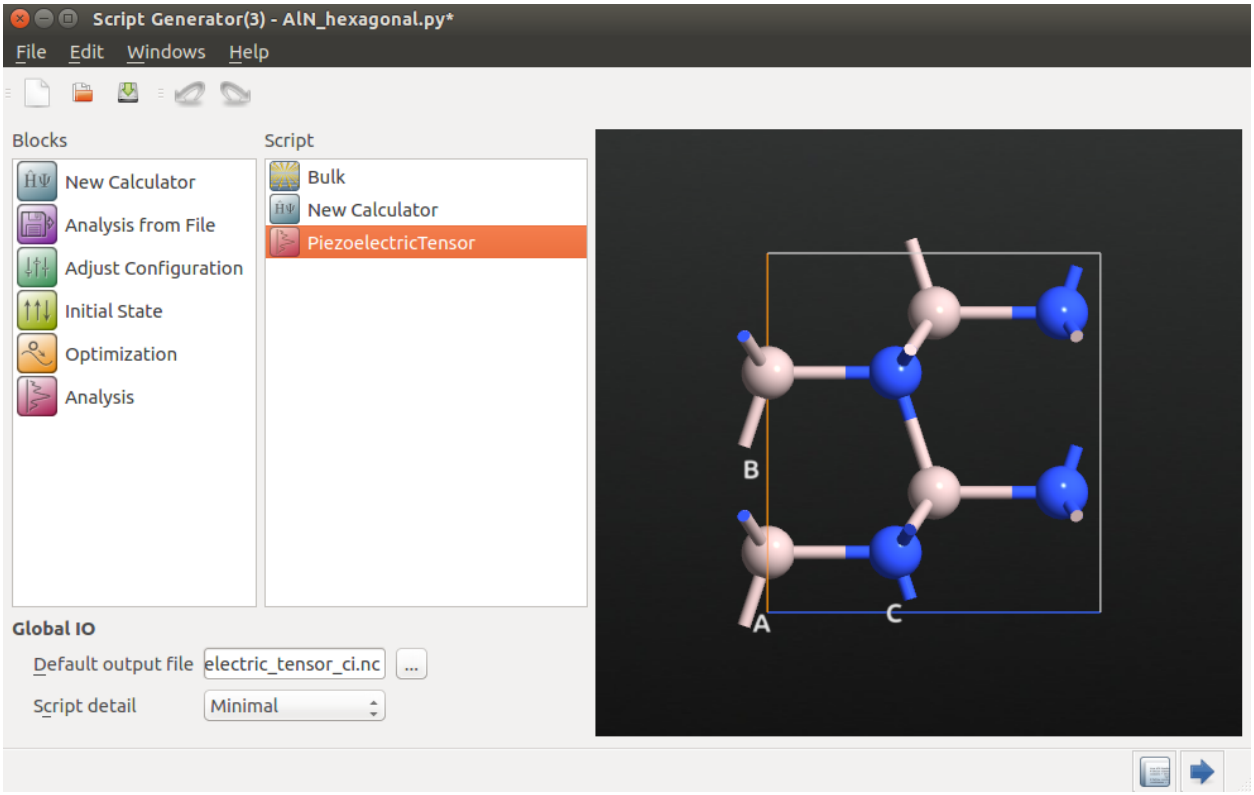
Computing the piezoelectric tensor in the clamped-ion approximation

1.Send the relaxed structure to the **Builder**.

2.In the **Builder**, go to *Bulk Tools* → *Supercell* to transform the cell according to the figure below.



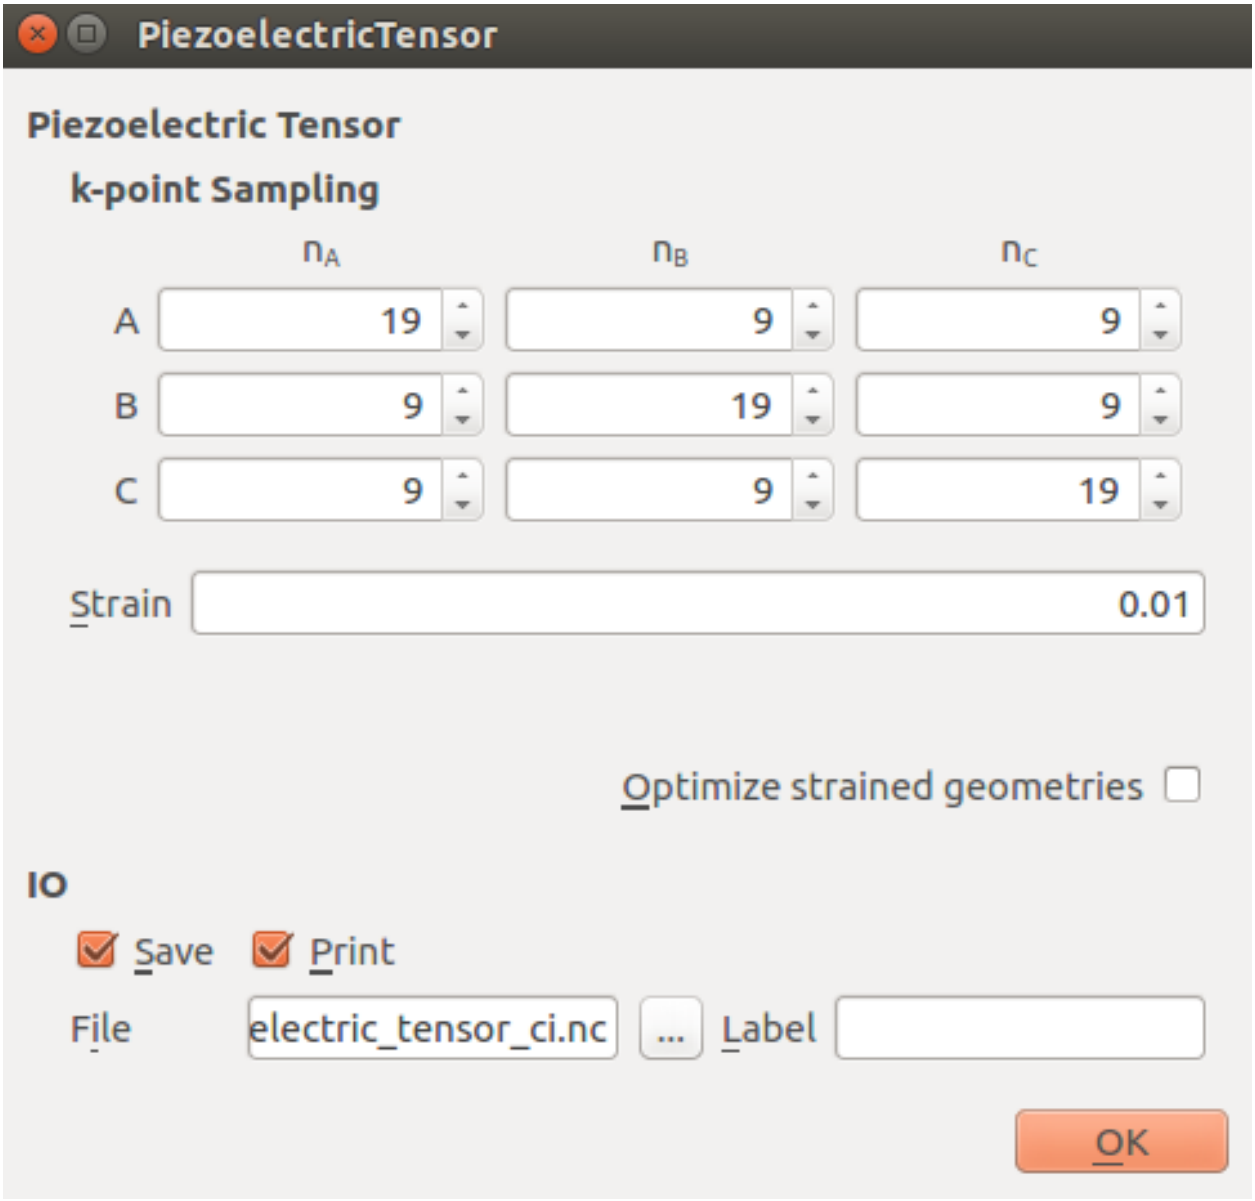
3.Send the bulk configuration to the **Script Generator** and add the *New Calculator* and the *Analysis* → *PiezoelectricTensor* blocks to the script.



4.In the *New Calculator* block set the following parameters:

- *exchange and correlation*: GGA.PBE
- *k-point sampling*: (9,9,9)

5.In the *PiezoelectricTensor* block set a [(19,9,9), (9,19,9), (9,9,19)] k-point sampling as shown below.



6. Save the HDF5 file as `piezelectric_tensor_ci.hdf5` and send the script to the **Job Manager** to run it.

   Once the calculation is finished, the *PiezoelectricTensor* object will appear in the **LabFloor**. Use the mouse to select the object and click the Text Representation plugin to visualize the tensor.

|                                                                               |
+-------------------------------------------------------------------------------+
```

The predicted $e_{33}(0)$ value is -0.4424 C/m^2 , which is in good agreement with the value found in the literature[Page 1569, 1].

Computing the Born effective charge

In order to compute the Born effective charge in QuantumATK, you need to use the script provided here (`born_charges.py`).

```
#read saved configuration
configuration0 = nlread('piezoelectric_tensor_ci.hdf5', object_id='gID000')[0]

# Get the fractional coordinates of read configuration
R0 = configuration0.fractionalCoordinates()

# Get the elements
elements = configuration0.elements()

# Get the lattice
lattice = configuration0.bravaisLattice()
```

(continues on next page)

(continued from previous page)

```

# From the lattice extract unit cell volume and length of lattice vector in z-direction
volume = lattice.unitCellVolume()

vectors = lattice.primitiveVectors()
c = vectors[2][2]

# Get the calculator
calculator = configuration0.calculator()

# Number of atoms
numberOfAtoms = len(R0)

# Fractional displacement in the +/- z direction
delta_z = 0.01

# Array for storing the calculated Born Charges
bornCharges = numpy.zeros(numberOfAtoms)

# Loop over atoms in unit cell
for nAtom in range(numberOfAtoms):
    # Loop over displacement in positive/negative z-direction

    # List with polarization values
    Pz = []
    for s in [1,-1]:
        # Make a copy of the initial coordinates
        R = R0.copy()

        # Displace z-coordinate if atom 'nAtom'
        R[nAtom,2] += s*delta_z

        # Make a new configuration with the displaced atom
        configuration = BulkConfiguration(bravais_lattice=lattice,
                                          elements=elements,
                                          fractional_coordinates=R)

        # Set the calculator using the saved configuration as initial state
        configuration.setCalculator(calculator,initial_state=configuration0)

        # Update the configuration (DFT calculation)
        configuration.update()

        # Calculate polarization. Only use fine k-sampling in the z-direction
        polarization = Polarization(configuration=configuration,
                                    kpoints_a=MonkhorstPackGrid(2,2,2),
                                    kpoints_b=MonkhorstPackGrid(2,2,2),
                                    kpoints_c=MonkhorstPackGrid(5,5,20),
                                    )

        # Print polarization
```

(continues on next page)

(continued from previous page)

```
        nlprint(polarization)

        # Get the total cartesian polarization
        Pt = polarization.totalCartesianPolarization()

        # Append the z-component to the Pz list
        Pz.append(Pt[2])

    # Make a finite difference approximation for the derivative
    dP = (Pz[0]-Pz[1])/(2*delta_z*c)

    # Calculate Born charge
    born_charge = volume*dP

    # Add the value (in units of electron charge) to the list 'bornCharges'
    bornCharges[nAtom] = born_charge.inUnitsOf(elementary_charge)

# Finally print out the results
print('')
print('+-------------------------------+')
print('| Born effective charges (e)    |')
print('+-------------------------------+')

for nAtom in range(numberOfAtoms):
    print('  %2s' %elements[nAtom].symbol() + '  :      %4.4f       '
↪%bornCharges[nAtom]    )

print('+-------------------------------+')
print('  Sum :      %4.4f       ' %numpy.sum(bornCharges))
print('+-------------------------------+')
```

- The script starts reading the results from the previous calculation. This will serve as a good starting guess for the DFT calculations to be performed later in the script (where the atoms are displaced).
- Extract the fractional coordinates, the list of elements, the lattice, and the calculator from the configuration, and define a few convenient variables such as the unit cell volume and the length of the C lattice vector.
- The parameter **delta_z** is the fractional displacement when calculating the derivatives.
- There are two for loops in the script. The outer loop runs over the atoms in the unit cell, and the inner one (over the variable s) performs the displacements in the positive and negative z-direction.
- At the end of the script, the results are printed out.

Running the script

- Download the above `born_charges.py` script and save it in the **Project Folder**.
- Drag the script to the **Job Manager** to run it.
- When the job is finished, the calculated Born effective charges are written in the `born_charges.log` file.
- As indicated by the calculated sum of the Born effective charges, the calculated values fulfill the acoustic sum rule $\sum_s Z^*_{s,ij} = 0$ with only a small error.

You have already got all the components you needed to compute to calculate e_{33}. By substituting the computed values in the formula for e_{33}, you will obtain $e_{33} = 1.464$ C/m^2, which is in good agreement with the value 1.4849 C/m^2 calculated above and with the value found in the literature (1.464 C/m^2)[Page 1569, 1].

3.11.16 Formation energies of charged defects - manual workflow

Version: 2016.4

Downloads & Links

`bulk-As.py` `bulk-GaAs.py` `big-bulk-GaAs.py` `vacancy-calc.py` `formation-energies.py`

In this tutorial you will learn how to calculate formation energies of neutral and charged defects. Specifically, we will work with GaAs, which supports various charge states in both As and Ga vacancies.

You might also want to consult the introductory tutorial on formation energies, which focuses on bulk systems and neutral defects: *Calculation of Formation Energies*.

Note: In the O-2018.6 release, we introduced a so-called *Study Object* to automate the workflows described in this tutorial. That is now the recommended way of studying charged point defects in QuantumATK, and if you have access to O-2018.06 or newer, you should go to the corresponding tutorial *Formation energies and transition levels of charged defects*. Users of previous versions can still do the calculations and analysis using the more complex workflow, that is described here.

Procedure for calculating the formation energy

The formation energy E^f of a defect X is defined as the energy difference between the investigated system and the components in their reference states. This is analogous to the formation energy of a bulk material, but for charged defects it is less clear how to choose the reference states. Here we follow the procedure outlined in the review by C. Freysoldt *et al.*[1]:

$$E^f[X^q] = E_{tot}[X^q] - E_{tot}[bulk] - \sum_i n_i\mu_i + q\left(E_{VBM} + \mu_e\right) + E_{corr}.$$

[1] Christoph Freysoldt, Blazej Grabowski, Tilmann Hickel, Jörg Neugebauer, Georg Kresse, Anderson Janotti, and ChrisăG. Van De Walle. First-principles calculations for point defects in solids. *Rev. Mod. Phys.*, 86(1):253–305, 2014. doi:10.1103/RevModPhys.86.253.

$E_{tot}[X^q]$ is the total energy of the defect state with charge q, which is given in units of the elementary charge ($e > 0$), $E_{tot}[bulk]$ is the total energy of a bulk unit cell of the same size as the defected one, and $n_i\mu_i$ is the reference energy of n_i added atoms of element i at chemical potential μ_i. The term in parenthesis accounts for the chemical potential of the electron(s) involved in charging the defect. E_{VBM} is the valence band maximum as given by the ATK band structure calculation for the bulk material of study (which is bulk undefected GaAs in this tutorial), and μ_e is the electron chemical potential defined here with respect to the top of the corresponding valence band. The μ_e parameter can then be treated as a free parameter, allowing to account for a shift of the Fermi level, e.g., due to doping. Note that $\mu_e = E_{gap}/2$ corresponds to the undoped semiconductor case, where E_{gap} is the intrinsic semiconductor band gap. Finally, E_{corr} is a sum of relevant correctional terms. In our case, it corrects for electrostatic interactions between periodic images of the charged defects. Due to the long-ranged nature of the Coulomb interaction, it is very difficult to work with systems that are large enough not to need this correction. More details of the correction scheme can be found in the *Appendix*.

In order to calculate the formation energy, we need to compute each of the terms outlined above. The workflow is listed below:

•Select the compound and defect to be investigated, and the computational model to be used (exchange-correlation, pseudopotentials, etc.).

•Relax the pristine bulk system using the chosen computational model.

•Determine the chemical potential of the elements in the defect. In this case we use the total energy of the bulk for the element removed to create the vacancy.

•Setup the undefected supercell to calculate $E_{tot}[bulk]$ and E_{VBM}.

•Introduce the (charged) defect and relax the system to obtain $E_{tot}[X^q]$.

•Calculate the correction terms in E_{corr} and finally the formation energy.

Neutral As vacancy in GaAs

As an example of a defect, we will calculate the formation energy of the As vacancy in GaAs, a vacancy which is capable of supporting many different charge states. However, we will first focus on the neutral vacancy defect, V^0, before adding charge. In this case, the formation energy equation reduces to

$$E^f[V^0] = E_{tot}[V^0] - E_{tot}[As] - (-1)\mu_{As}.$$

The first two terms are straightforward to calculate, though possibly time-consuming. Conversely, the third term is the reference chemical potential for As, and our choice here has a direct impact on the absolute value of the computed formation energy for the defect. The most obvious choice here is bulk As, which is what we will use, but other choices may be sensible representations of specific situations. We will not go into details of the matter.

Total energies will be calculated using DFT with the PBESol exchange-correlation functional, a GGA-level approximation designed to work well for solids[2].

[2] J.ăP. Perdew, A.ăRuzsinszky, G.ăI. Csonka, O.ăA. Vydrov, G.ăE. Scuseria, L.ăA. Constantin, X.ăZhou, and K.ăBurke. Restoring the Density-Gradient Expansion for Exchange in Solids and Surfaces. *Phys. Rev. Lett.*, 100(13):136406, 2008. doi:10.1103/PhysRevLett.100.136406.

Optimized bulk geometry

We first need to relax the minimal unit cell and internal coordinates of the GaAs and As bulks. For the latter, we also need the total energy per As atom. Use a DFT calculator with PBESol and the **OptimizeGeometry** object to relax the stress and forces on both bulks. This is described in detail elsewhere, e.g. in the tutorial *Calculation of Formation Energies*. For your convenience, we have also provided the scripts here:

`bulk-GaAs.py`

`bulk-As.py`

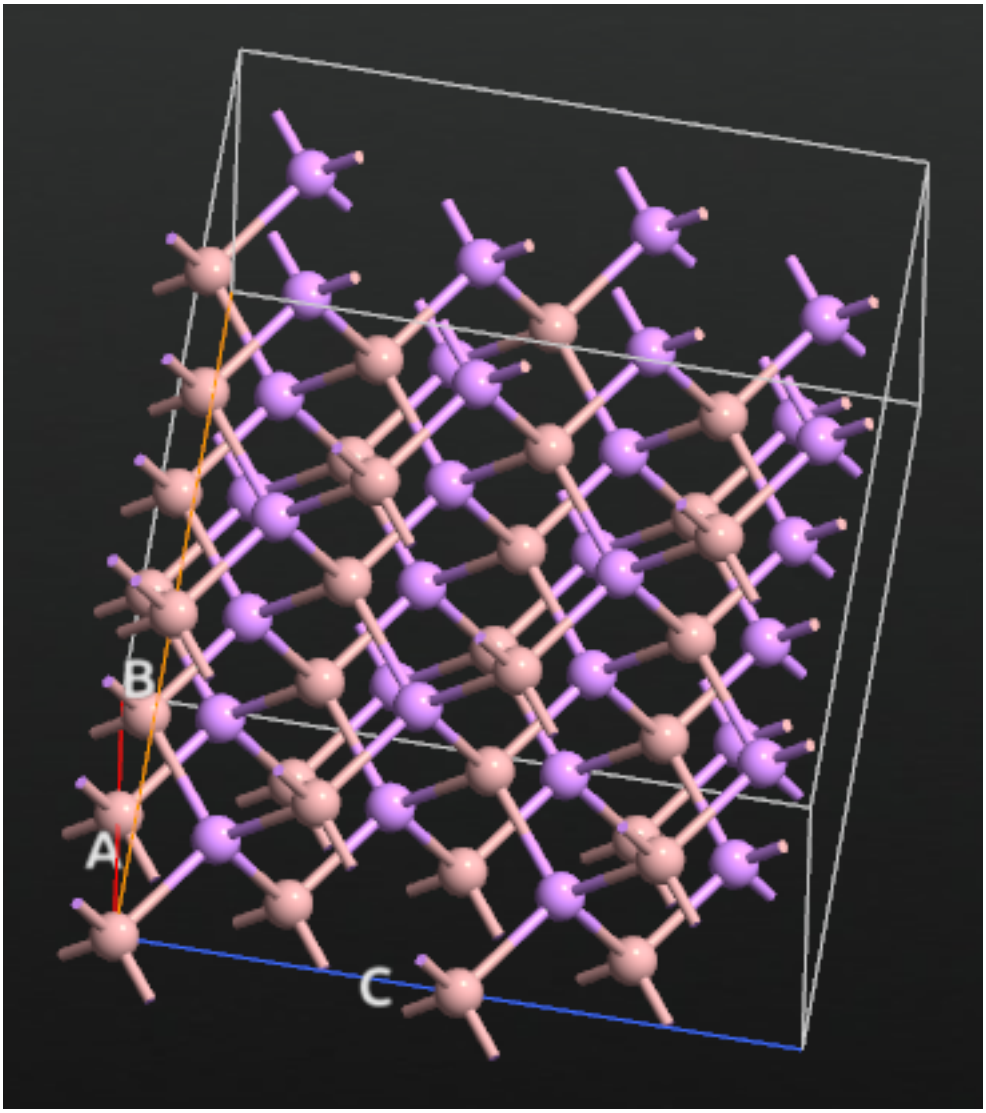
Larger supercell for bulk and defect calculations

Now find the optimized *BulkConfiguration* on the *LabFloor*, it should have an ID of gID001, and drop it on the **Builder** to set up a new *BulkConfiguration* with the optimized lattice constant. You may also find the optimized lattice parameter in the text output. However, we still need to make a bigger cell, and we would also like to have an orthogonal cell, as it will make the electrostatic corrections simpler.

- To do this, select the GaAs system in the *Stash* and go to *Bulk Tools* → *Supercell* on the right, choose *Conventional* and click *Transform*. The GaAs is now represented by a, much larger, cubic cell.
- We still need to make it bigger in order to get somewhat reasonable results for the defect, so go to *Bulk Tools* → *Repeat* and increase all three numbers to 2 and click *Apply*.
- Now send this configuration to the **Script Generator** and add a **New calculator**, a **Density of States** object and a **TotalEnergy** analysis object.
- Change exchange-correlation functional to PBES (for PBESol) and the k-point sampling to 4x4x4, which is adequate due to the large computational cell. Change k-points sampling in **Density of States** object to 8x8x8 k-points.
- Now do the calculation - It should take about 10 minutes.

`big-bulk-GaAs.py`

> **Warning:** Please note that the 2x2x2 supercell used here is too small to get reliable (publication quality) results: The defect concentration is very high, and there will be (artificial) elastic interaction between the defects. At the end of this tutorial we will investigate how results change for a 3x3x3 cell.

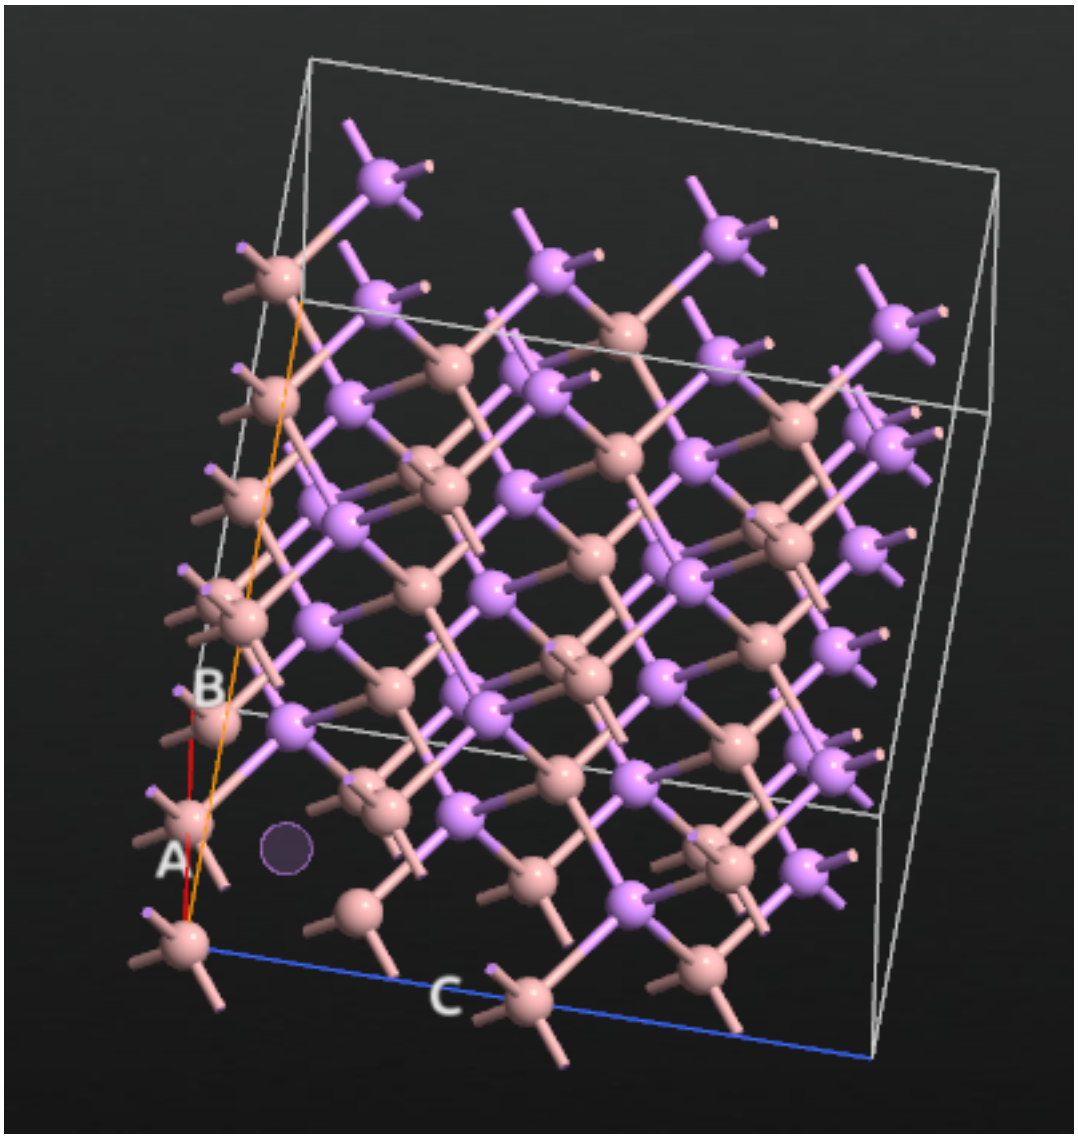


Introducing a vacancy

To set up the neutral defect calculation you can either use the script `vacancy-calc.py` or construct a script on your own. In the latter case, return to the Builder and select the 2x2x2 orthogonal unit cell in the Stash. Then do the following:

- Select an As atom, preferably the one closest to the origin, and convert it to a ghost atom by clicking the icon in the top bar.
- Send this configuration to the **Script generator** and add a **New Calculator**, an **OptimizeGeometry** object and a **TotalEnergy** object.
- Change the calculator settings to match those used for the pristine 2x2x2 GaAs. Default settings are fine for the other two objects. Run the calculation – it may take a couple of hours due to the geometry optimization.

Attention: Be aware that, in general, we need to account for the basis set superposition error, by leaving the basis functions associated with an atom when removing it to create the vacancy. In practice, this is achieved by making the atom into a ghost atom instead of removing it. This improves the result, perhaps only slightly, for most local basis sets, and carries an insignificant increase in computational cost.



Formation energy

We get total energies $E_{tot}[GaAs]$ = -7460.13 eV for the defect-free bulk configuration and $E_{tot}[V^0]$ = -7285.59 eV for the configuration with the neutral As vacancy, and combined with the result for the As bulk above, we find a formation energy for the neutral As vacancy of 3.22 eV. You can also use the script `formation-energies.py` to compute $E^f[V^0]$.

Charged As vacancies in GaAs

Now that we have calculated the formation energy of the neutral defect, we turn our attention to incorporation of charges in our modeling. If we again focus on the As vacancy, the formation energy is computed according to:

$$E^f[V^q] = E_{tot}[V^q] - E_{tot}[GaAs] + \mu_{As} + q\,(E_{VBM} + \mu_e) + E_{corr}.$$

The first term is similar to what we have just calculated for the neutral defect, while the second and third terms are exactly the same as previously and do not need to be re-calculated. The valence band maximum is determined through a density of states (DOS) calculation for the undefected bulk, while μ_e will be treated as a free parameter. The last term, E_{corr} is calculated according to the scheme of Freysoldt et al.[3] , which also includes a small correction to the VBM, to account for the shift introduced by the defect, as discussed in the *Appendix*. Note that the correction term depends on the screening properties of the bulk material surrounding the charged defect. That requires knowing the dielectric constant value for the undefected bulk GaAs that can be either taken from experiment or computed as further explained in the *Appendix*.

Charged defects

The As vacancy can sustain a total of 5 charge states, including the neutral one considered above. We will now calculate the formation energies of these defects. For very large systems it may be worthwhile to use the relaxed state of the neutral defect as the initial guess for the charged ones, but this is not important for the system size used here.

The charges can either be added in the calculator when following the procedure described above, or by directly making copies of the script and adding `charge=q,` in the calculator object. You can also use the script `vacancy-calc.py`, which will take the `.nc` file of a large bulk supercell as input and add a defect before optimizing the geometry and computing the total energy.

Note: Remember to modified the entries `defect_charge` and `saved_filename` in the input section of script `vacancy-calc.py` to select the correct charge state and the name for the corresponding output file.

Formation energies

Now that we have all the pieces we need, we can calculate the full formation energies by extracting the total energies from the saved data files and calculating the correctional terms. For this, you can use the script `formation-energies.py`. It takes as input the `.nc` files with the relaxed defect states, as well as an undefected supercell of the same size including a valid DOS calculation. You will also need the dielectric constant, calculated using your chosen computational model, as detailed in this tutorial: *Optical Properties of Silicon*. We also show how to do it for GaAs in the *Appendix*.

[3] Christoph Freysoldt, Jörg Neugebauer, and ChrisăG. Van De Walle. Fully Ab Initio finite-size corrections for charged-defect supercell calculations. *Phys. Rev. Lett.*, 102:016402, 2009. doi:10.1103/PhysRevLett.102.016402.

Table 3.7: Formation energies (with periodic and band offset corrections included) for an As vacancy in a 2x2x2 GaAs supercell.

Charge state	Formation energy (with E_{corr} included)	Periodic correction	Band offset correction
+1	3.04 eV	0.13 eV	-0.03 eV
0	3.22 eV	0.00 eV	0.00 eV
-1	3.56 eV	0.13 eV	0.00 eV
-2	4.23 eV	0.54 eV	-0.03 eV
-3	5.18 eV	1.20 eV	-0.10 eV

The formation energies given above were calculated for an electron chemical potential at the VBM, that is, for $\mu_e = 0$ eV. Considering μ_e as a free parameter that shifts the Fermi level, we can also plot the formation energy for each defect as a function of the electron chemical potential. This would correspond to varying the doping level of the material. The effect is illustrated in the figure below, where the most stable charge state at a given μ_e is identified with the lowest line. This shows that in p-type doped GaAs, corresponding to $\mu_e = 0$ eV, the As vacancy is most stable with a positive charge. By increasing the electron chemical potential, the most stable charge state changes to neutral and from about $\mu_e > 0.35$ eV, the most stable state is negatively charged. In particular, the As vacancy with the charge $q = -2$ is the most stable defect in the intrinsic (undoped) GaAs for which $\mu_e = E_{gap}/2 \sim 0.75$ eV.

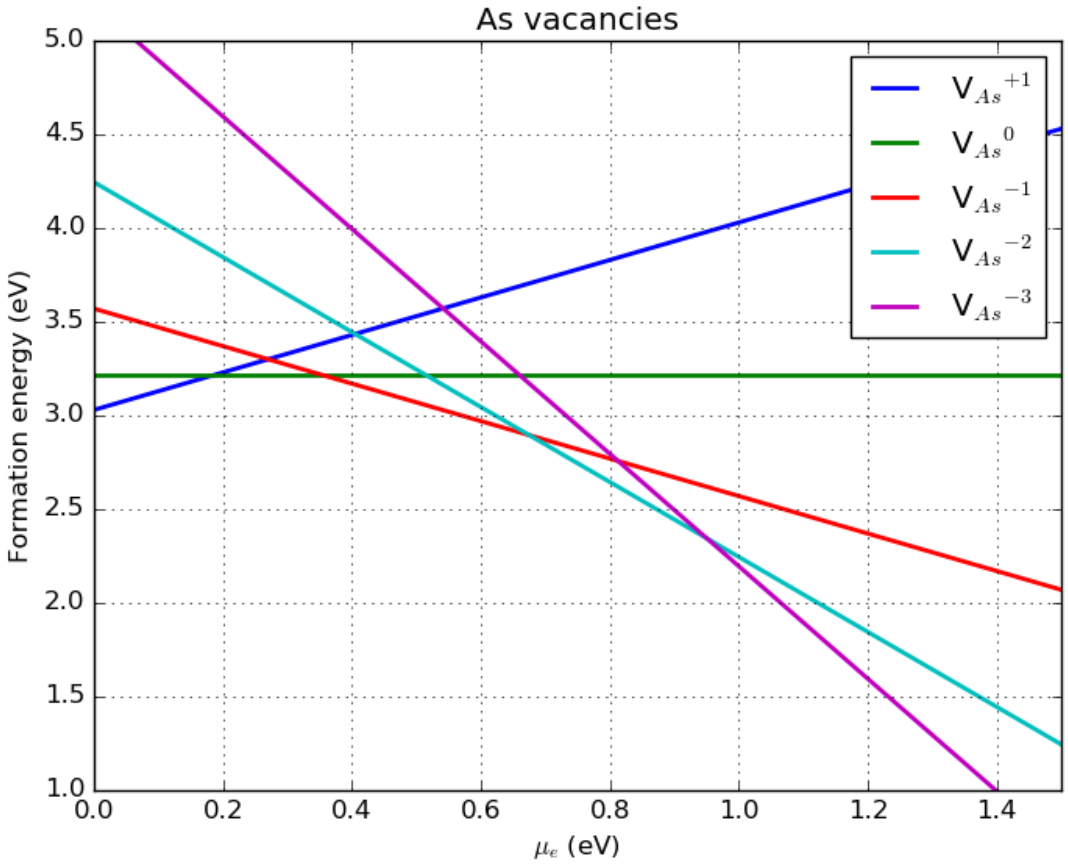


Fig. 3.112: Formation energy for various charge states of the As vacancy in GaAs as a function of μ_e (defined with respect to the VBM), with the VBM at zero, computed with a 2x2x2 orthogonal supercell.

Influence of system size

If we increase the supercell size to 3x3x3, and change the k-point grid to 2x2x2, we find the formation energies listed in the table below, together with literature values from[4], which uses the same size of supercell.

Table 3.8: Formation energies (with periodic and band offset corrections included) compared to literature.

Charge state	2x2x2	3x3x3	Reference (3x3x3)
+1	3.04 eV	2.95 eV	2.79 eV
0	3.22 eV	3.26 eV	3.25 eV
-1	3.56 eV	3.67 eV	3.33 eV
-2	4.23 eV	4.35 eV	4.52 eV
-3	5.18 eV	5.25 eV	5.86 eV

We see how the formation energies are slightly different, with the shift being about 0.04 eV for the neutral defect. The difference is slightly larger for the charged defects, which is due to a slight shift of the VBM, caused by a slightly different k-point density. In this case there is not perfect agreement with the literature reference, but it should be noted that the reference does not use a ghost atom, and uses an older electrostatic correction scheme and LDA for exchange-correlation.

The changes also influence the plot of formation energy versus μ_e; although the slope of the lines are the same, their intercepts are slightly different, leading to a significant change in the overall picture of defect stability. Specifically, the neutral state is now only stable in a very narrow window, and the negatively charged states are most stable from $\mu_e = 0.4$ eV.

Appendix

The periodic correction scheme

As already mentioned, we use the correction scheme proposed by Freysoldt *et al.*[Page 1595, 3] to correct for the electrostatic interaction between the periodic images of the charges and the band shift caused by introduction of the defect. This correction contains two terms:

$$E_{corr} = E_{lat} - q\Delta V_{q/b},$$

where E_{lat} corrects for the interaction between the periodic images of the charge and $q\Delta V_{q/b}$ corrects for the band shift. E_{lat} is calculated by considering the electrostatics of a model charge distribution and comparing the potential in the periodic cell with the potential where the boundary conditions are not periodic:

$$E_{lat} = \int_{\Omega} \left[\frac{1}{2} q(\tilde{V}_q^{lr} - V_q^{lr}) \right] d^3r.$$

V_q^{lr} is the long-range potential of the model charge distribution and $\tilde{V}_q^{lr}$ is the corresponding quantity in the periodic cell. $\Delta V_{q/b}$ is calculated from the shift in the electrostatic potential due to introduction of the defect:

$$\Delta V_{q/b} = \tilde{V}_{q/b} - \tilde{V}_q^{lr},$$

where $\tilde{V}_{q/b}$ is the difference between the electrostatic potential in the pristine bulk configuration and with the defect added. $\Delta V_{q/b}$ should be evaluated far from the defect, where it is constant, in order to get the correct offset in the zero-point reference energy . In our implementation, it is averaged over the five grid points furthest from the defect. We plot these quantities in the figure below, where $\Delta V_{q/b}$ is the black line:

[4] Fedwa El-Mellouhi and Normand Mousseau. Self-vacancies in gallium arsenide: An ab initio calculation. *Phys. Rev. B*, 71(12):125207, 2005. doi:10.1103/PhysRevB.71.125207.

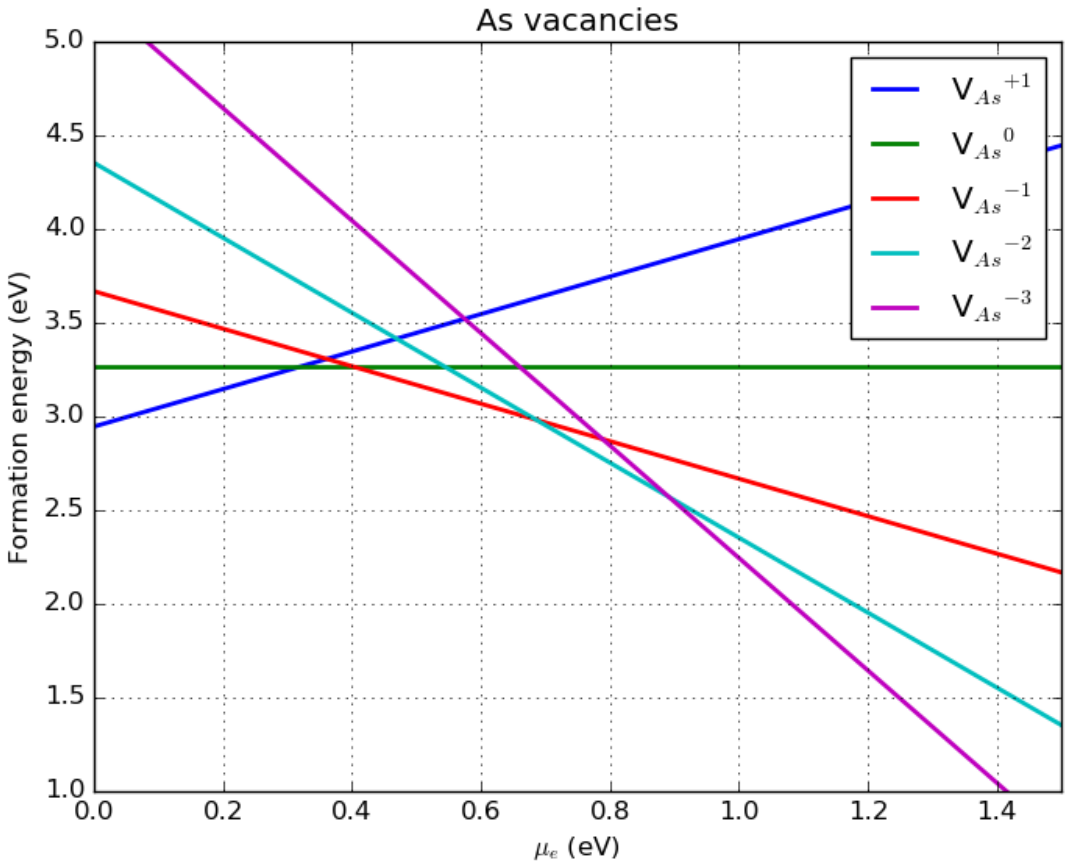

Fig. 3.113: Formation energy for various charge states of the As vacancy in GaAs as a function of μ_e (defined with respect to the VBM), with the VBM at zero, for a 3x3x3 orthogonal supercell.

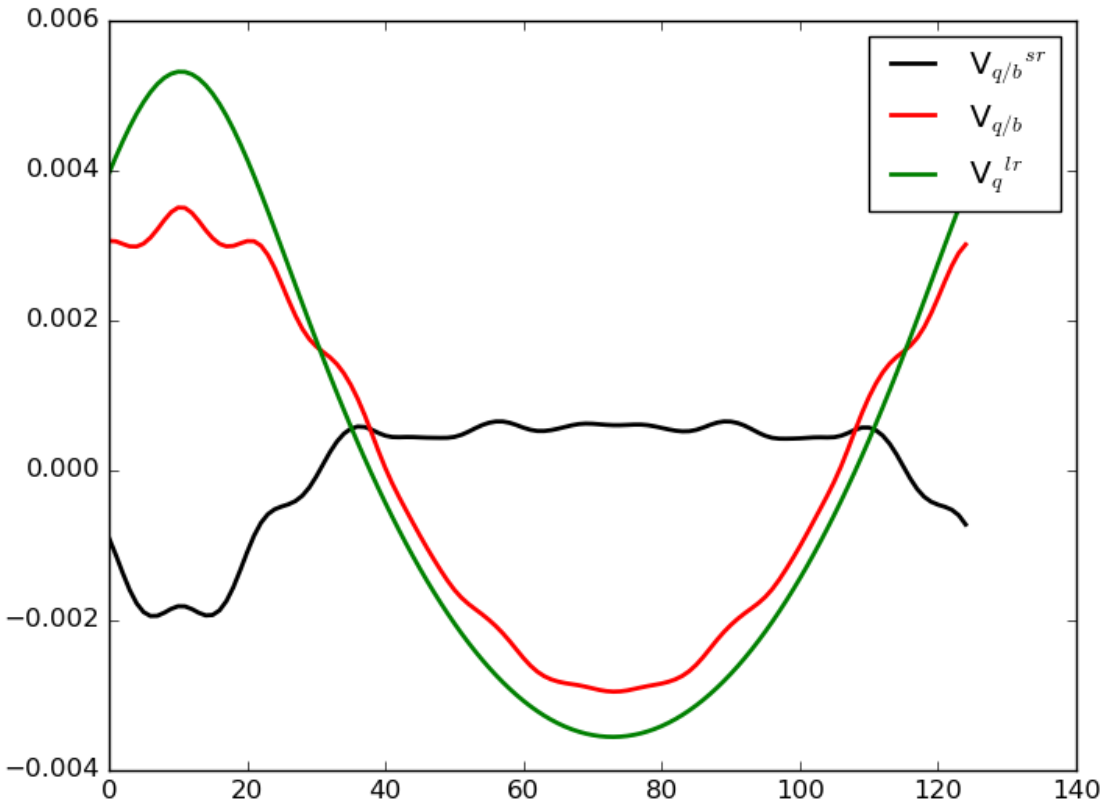

Fig. 3.114: Plot of the terms in the band offset correction. Green is the model potential from the defect, red is the change due to the introduction of the defect, and black is then the offset in the zero-point of the absolute energy.

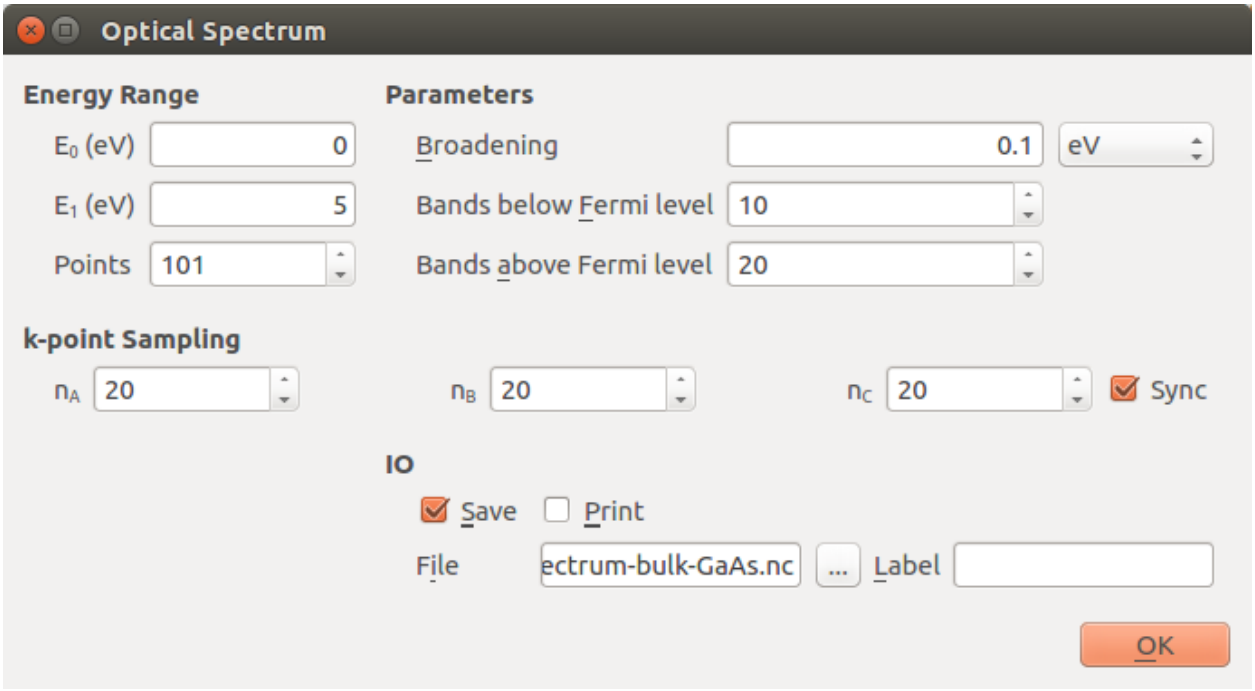
Note that the obtained difference is defined between two *screened* potentials, see the reference[Page 1595, 3] and the script `formation-energies.py`, where the screening is due to the semiconductor material surrounding the charged defect. The dielectric screening is described by the static dielectric constant computed in the following section for bulk GaAs.

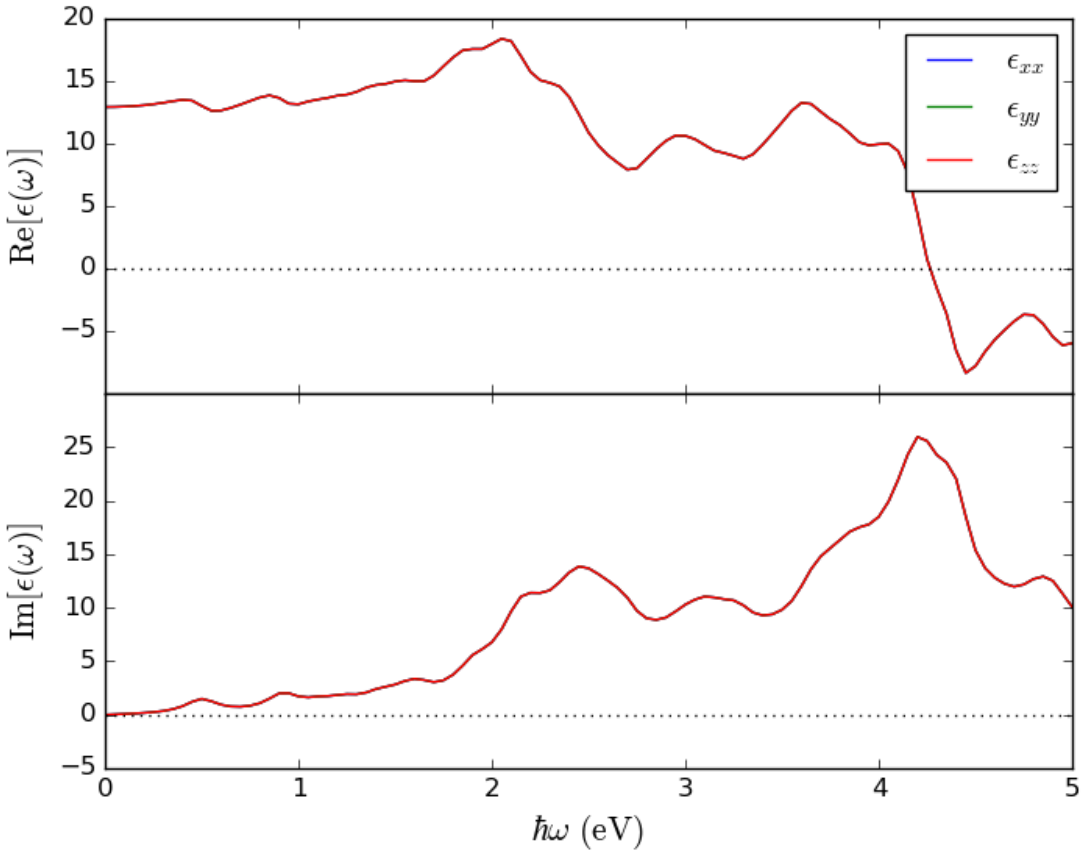
Dielectric constant of GaAs

To account for the screening effect of the semiconductor material (surrounding the charged defect) on the band offset correction, one should compute the dielectric constant to be used in the script `formation-energies.py`. The dielectric constant can be calculated through an *OpticalSpectrum* analysis on a primitive GaAs bulk cell. It is important that the calculation is well-converged with respect to k-points, and also that the number of bands in the OpticalSpectrum is adequate for sampling all relevant transitions. In this case, a 20x20x20 k-point grid, 10 bands below the Fermi level and 20 bands above is sufficient to ensure this.

Drag and drop your optimized GaAs bulk structure to the **Builder** and send it to the **Script Generator**. Add a *New Calculator* and set it to the same parameters as the previous calculation, except for the k-points, which must be 20x20x20. Add an *OpticalSpectrum* analysis object, and set it to 20x20x20 k-points, 10 bands below the Fermi level and 20 above. The box should now look as the one in the figure below.



Run the calculation, which should take no more than a few minutes. You should now see the *OpticalSpectrum* on the **LabFloor**, which you can open with the *Optical Spectrum Analyzer* on the right. This will open a window with a plot which should look like this:



In this case, we are only interested in the intercept of the upper plot, which looks to be about 13. To get the exact calculated value, open the *OpticalSpectrum* with the *Text Representation* and find the part where it says Real part of the dielectric tensor. Here you can find the calculated value for the dielectric constant at zero frequency to be 12.9, as seen in the figure below:

3.11.17 Boron diffusion in bulk silicon

Version: 2016.0

In this tutorial we will use an Adaptive Kinetic Monte Carlo (AKMC) algorithm with ATK-DFT to investigate the diffusion of a single B atom in a bulk Si lattice. You can read more about the AKMC method in the tutorial *Adaptive Kinetic Monte Carlo Simulation of Pt on Pt(100)*.

Boron is known to diffuse though silicon during ion beam implantation due to the presence of a large number of defects. Furthermore, boron is most stable at substitutional lattice sites. In this tutorial we will investigate if the B atom is mobile in a defect-free Si lattice at 300 K, with B in a substitutional lattice site as the initial state.

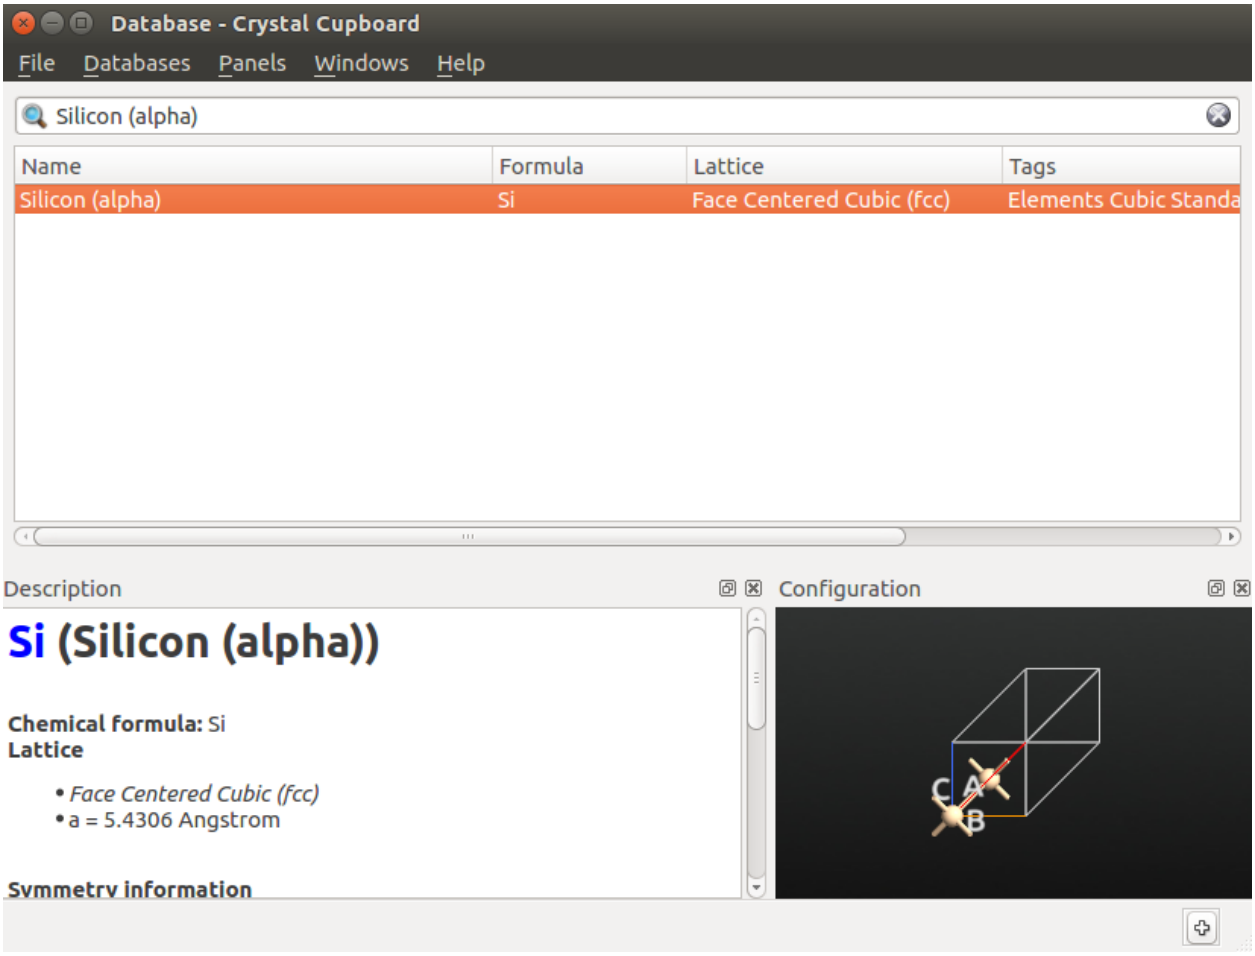
Attention: Note that this tutorial requires access to a computing cluster, as the calculation time exceeds several CPU-weeks. AKMC requires a minimum of 10^4–10^5 force and energy calculations to give meaningful results, making the length of the individual calculation very important for the overall duration.

Creating the B-doped Si crystal

We will need to create a bulk Si crystal with a cubic supercell with 64 atoms and then substitute one of them with B. However, first we need to find the correct lattice constant for Si with the computational model we will be using in this tutorial.

Optimize the Si bulk lattice

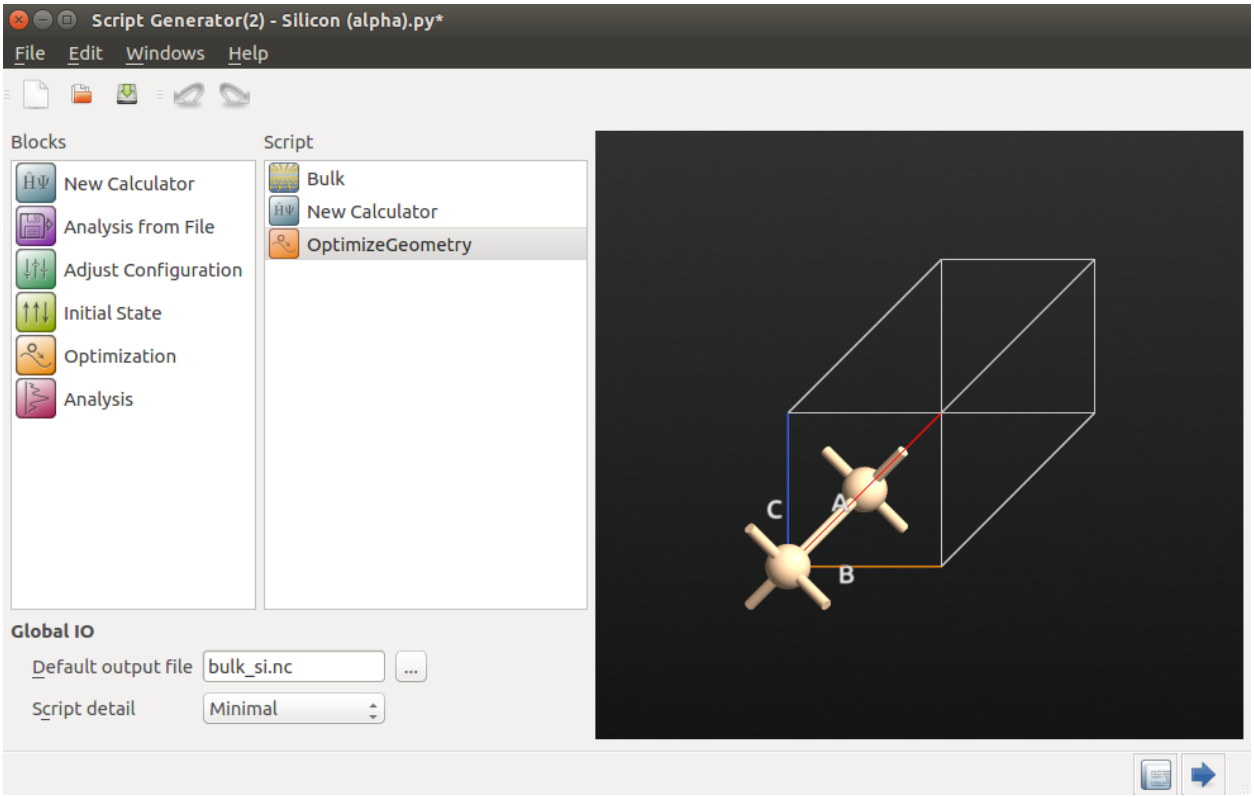
- Open the **Builder** and select *Add* → *From Database* to access QuantumATKs database of compounds.
- Search for Silicon (alpha) and add it to the stash by clicking the icon in the lower right corner.



•Send the configuration to the **Script Generator** (use the icon for this), and add the following blocks to the script:

- New Calculator
- OptimizeGeometry

Then change the default output file to `bulk_si.hdf5`.



Next, we will choose calculator settings that are optimized for speed rather than accuracy, in order to show the functionality of the AKMC algorithm with DFT. Always check the accuracy of your settings when you want publication-quality data.

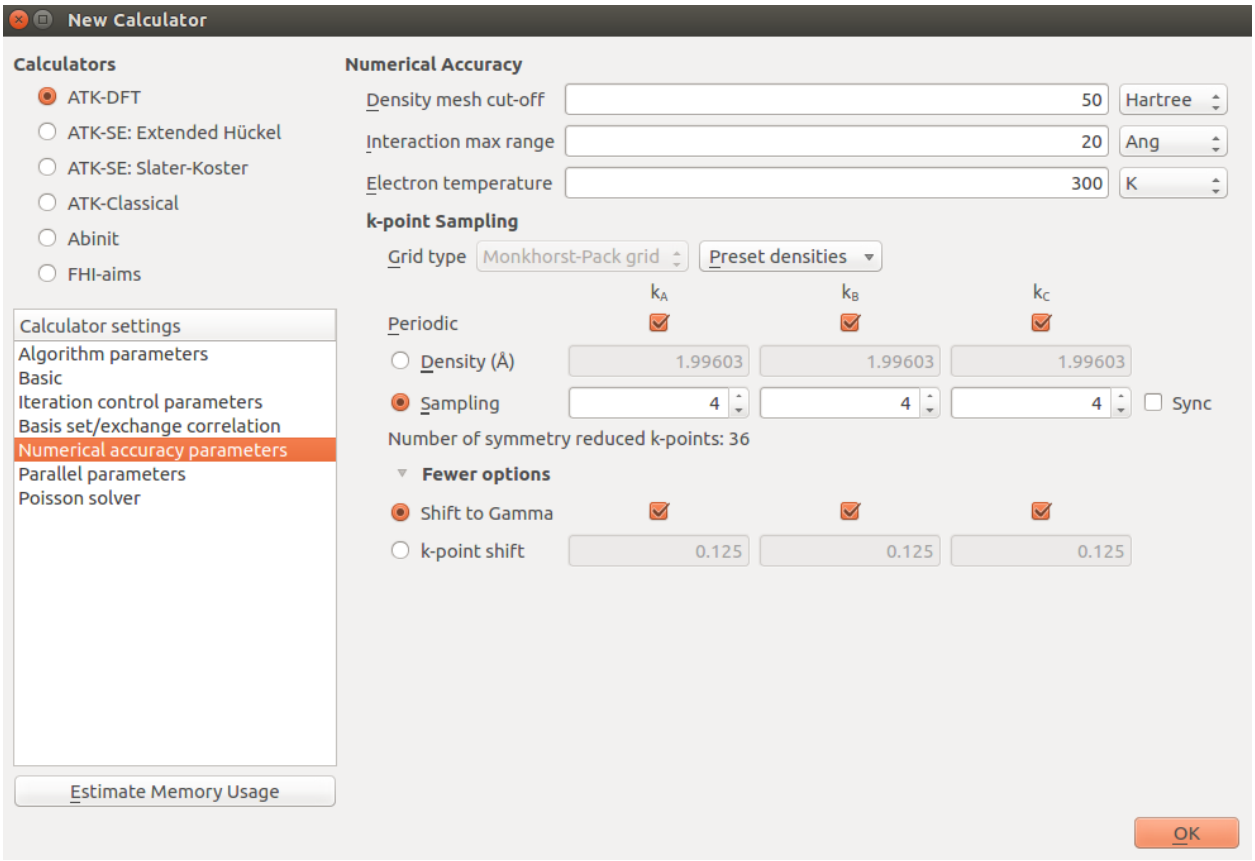
- **New Calculator**

  - Basis set: *SingleZetaPolarized*

  - Exchange-Correlation: *GGA.PBES* to use the PBEsol functional.

  - k-point sampling: *4x4x4* and make sure it is shifted to gamma by ticking the three boxes found by ticking **More options**. This is a very low k-point density, but equivalent to the sampling we will use during the AKMC, where we will use only the gamma point to speed things up.

  - Set the mesh cutoff to 50 Hartree.



•OptimizeGeometry

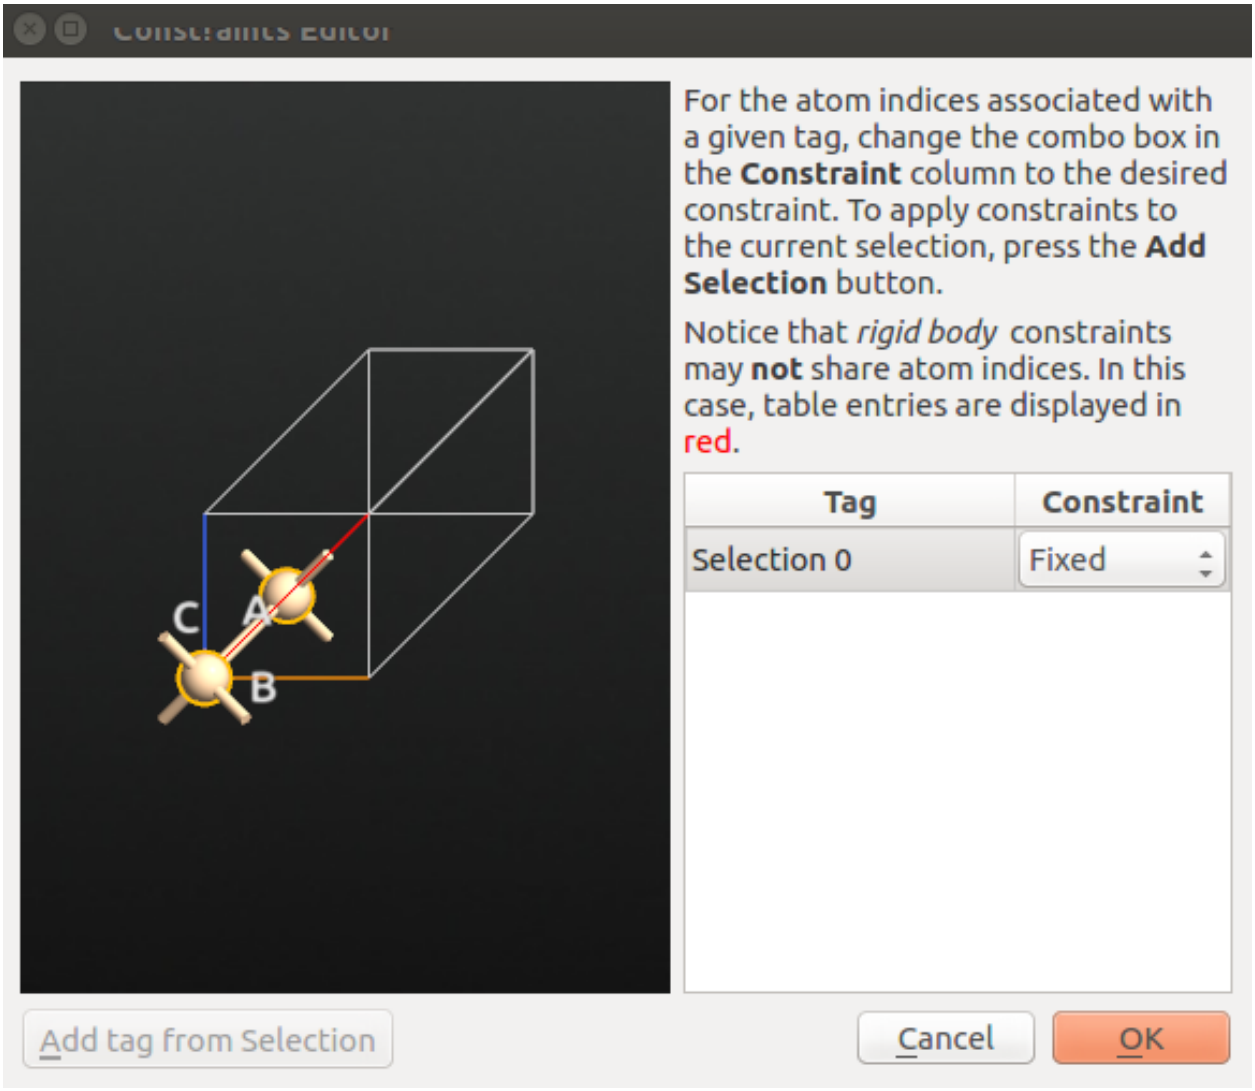
–Untick *Constrain Lattice Vectors*.

–Keep the fractional coordinates of Si atoms fixed:

∗open **Atomic Constraint Editor** and select one Si atom;

∗hold down `Ctrl` while selecting the other atom and click **Add tag from Selection**.

∗choose *Fixed* under **Constraint** and click OK.



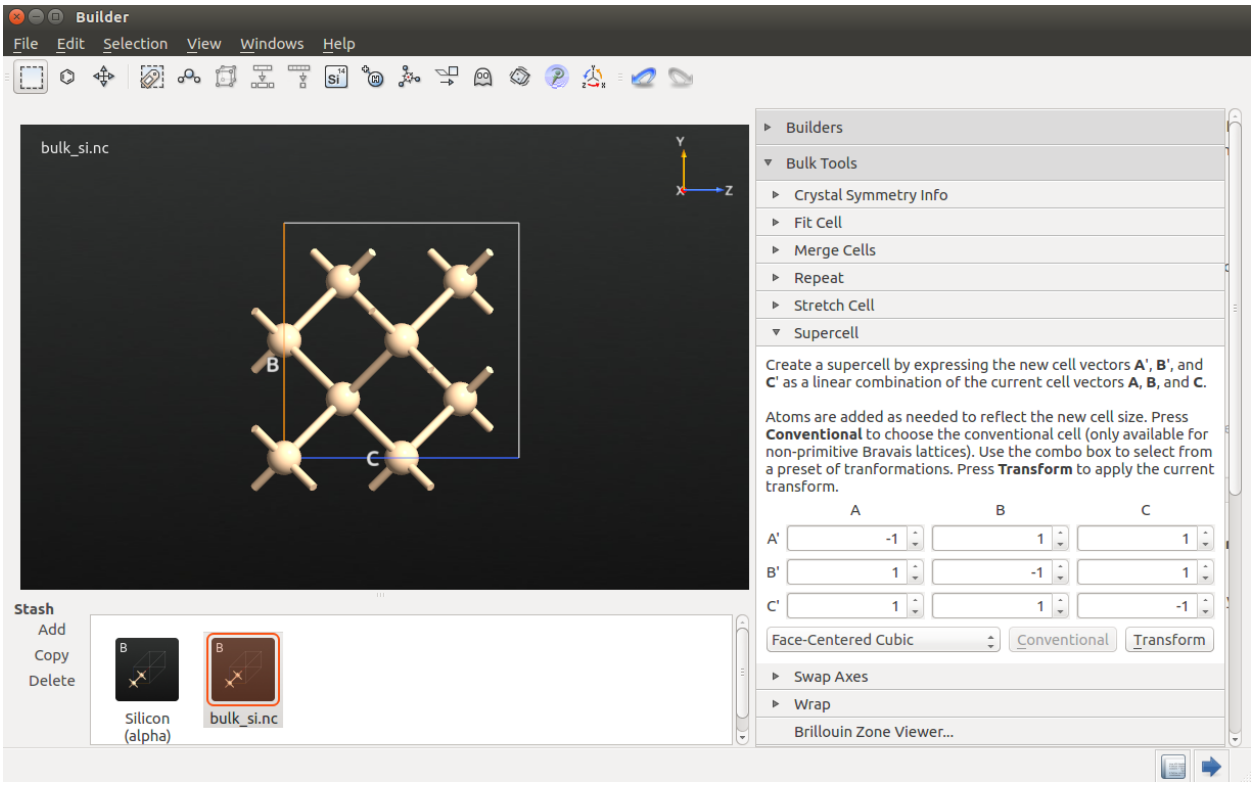
Leave everything else at default in the OptimizeGeometry block and send the script to the **Job Manager** to run the script. The calculation will take a few minutes.

Build the B-doped Si crystal structure

Once the calculation is finished, you can find the optimized Si bulk structure on the **LabFloor**.

•Select the optimized geometry and drop it on the **Builder**.

•Make the cell cubic by clicking on *Bulk Tools* → *Supercell*, then click on *Conventional* and then *Transform*. Note how the number of atoms has increased to 8.



•To make the 64 atom cell, click *Bulk Tools* → *Repeat* and increase A, B and C to 2 before clicking *Apply*.

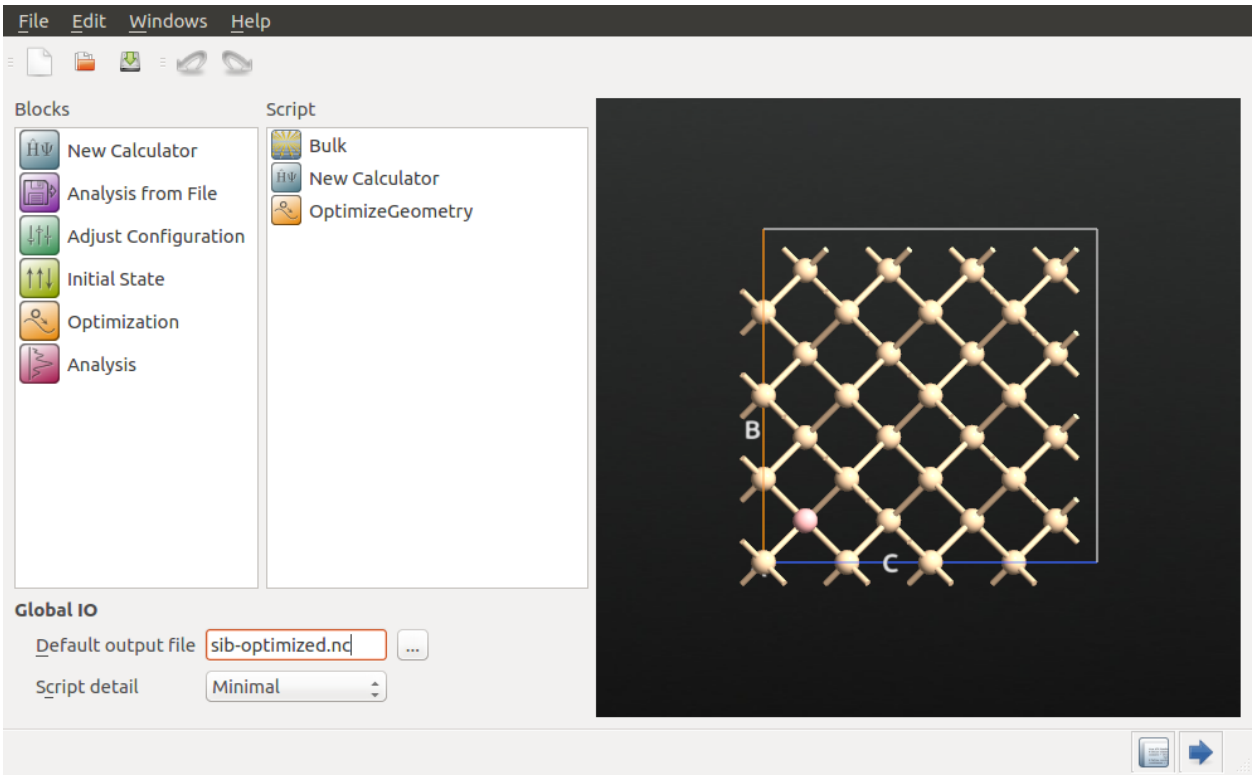
•Select the Si atom you would like to replace with B, e.g. atom number 8, close to the origin at [0.125, 0.125, 0.125] in fractional coordinates.

•Click the Periodic Table plugin and select B in the periodic table.

Setup the script

Send the structure to the **Script Generator**, change the default output file to `sib-optimized.hdf5`, and add the following blocks to the script:

- New Calculator
- OptimizeGeometry



Next, choose the following settings for the respective blocks.

•**New Calculator**:

•k-points sampling: *1x1x1*, sampling only the gamma point;

•basis set: *SingleZetaPolarized* for Silicon and *DoubleZetaPolarized* for Boron;

•apply the same settings as before for everything else.

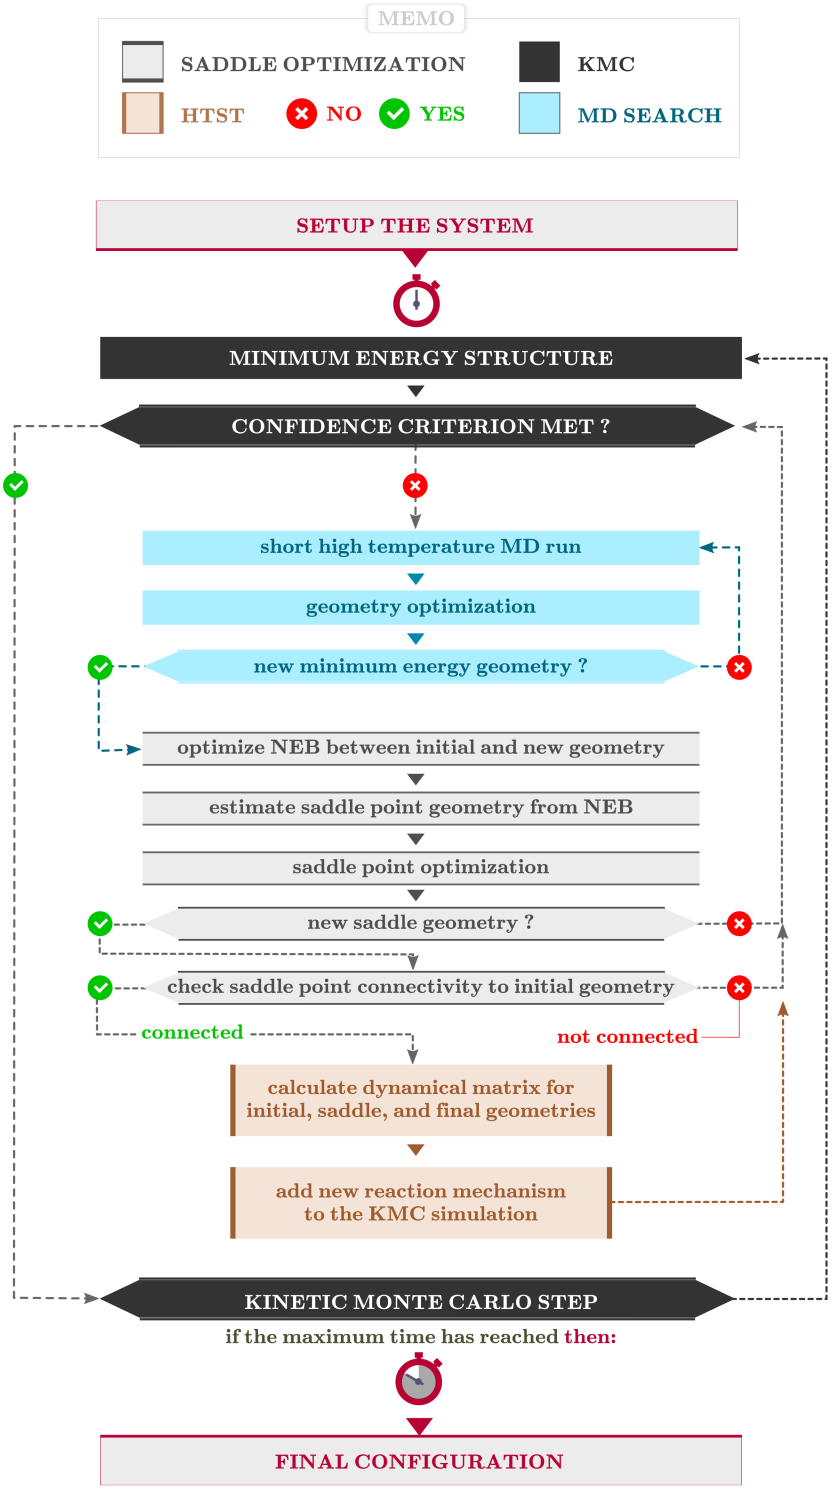
•**OptimizeGeometry**: change the convergence criterion to 0.01 eV/Å, and keep the default values for everything else.

Send the script to the **Job Manager** and run the script.

When the job has finished after about 10 minutes, depending on hardware, we are ready to do the actual AKMC simulation.

Running the AKMC simulation

Setting up the AKMC calculation requires using only a few lines of Python scripting, and has been prepared in the script `sib-with-akmc.py`. The different parts of the script will be explained below. Download the script, and make sure the file name in the beginning points at the file with your optimized *BulkConfiguration*.



Note: Support for setting up an AKMC calculation using the Script Generator is planned for QuantumATK 2017.

Details of the script

First, we change the logging behavior of QuantumATK to the verbosity mode *MinimalLog*, which will greatly reduce the information in the log file for each SCF cycle. This will improve readability of the log files from the AKMC simulation, while leaving essential SCF information available. The optimized configuration is then loaded from the saved `.hdf5`-file.

```
setVerbosity(MinimalLog)

# ------------------------------------------------------------
# Bulk Configuration
# ------------------------------------------------------------

# Read in configuration
bulk_configuration = nlread('../sib-optimized.nc', BulkConfiguration)[-1]
```

See also:

For more information on how to tune the verbosity of QuantumATK logging output, see the Reference Manual entry on *setVerbosity()*. In particular, the options CALCULATOR_UPDATE=False and PROGRESS_BARS=False could be relevant here; they remove all the SCF information and progress bars from the output, respectively.

We then proceed to set up a calculator that is identical to the one used for structural relaxation, except for the addition of the *ParallelParameters* functionality, which is used to ensure that just one process will be used for each AKMC saddle search. For a bigger system, it might make sense to use more than one process per saddle search, but the optimal distribution depends on the setup and queuing rules of your supercomputer.

```
# ------------------------------------------------------------
# Calculator
# ------------------------------------------------------------
#----------------------------------------
# Basis Set
#----------------------------------------
basis_set = [
    GGABasis.Boron_DoubleZetaPolarized,
    GGABasis.Silicon_SingleZetaPolarized,
    ]

#----------------------------------------
# Exchange-Correlation
#----------------------------------------
exchange_correlation = GGA.PBES

k_point_sampling = MonkhorstPackGrid(
    na=1,
    nb=1,
    nc=1,
    shift_to_gamma=[True, True, True],
    )
numerical_accuracy_parameters = NumericalAccuracyParameters(
    k_point_sampling=k_point_sampling,
    density_mesh_cutoff=50.0*Hartree
    )
```

(continues on next page)

(continued from previous page)

```
parallel_parameters = ParallelParameters(
    processes_per_saddle_search=1,
    )

calculator = LCAOCalculator(
    basis_set=basis_set,
    exchange_correlation=exchange_correlation,
    numerical_accuracy_parameters=numerical_accuracy_parameters,
    parallel_parameters=parallel_parameters,
    )

bulk_configuration.setCalculator(calculator)
nlprint(bulk_configuration)
bulk_configuration.update()
```

The final part of the script is the actual AKMC simulation. First, there are two blocks which check if a previous AKMC simulation has already been run, and reuse that information if possible, or initialize new objects if no previous results are present.

```
# ------------------------------------------------------------------
# AKMC
# ------------------------------------------------------------------

# Reusing existing MarkovChain object if it already exists, otherwise a new one is␣
↪created
if os.path.isfile('akmc_markov_chain.nc'):
    markov_chain = nlread('akmc_markov_chain.nc')[0]
else:
    markov_chain = MarkovChain(bulk_configuration, TotalEnergy(bulk_configuration).
↪evaluate())

# Reusing existing KMC object if it already exists, otherwise a new one is created
if os.path.isfile('akmc_kmc.nc'):
    kmc = nlread('akmc_kmc.nc')[0]
else:
    kmc = None
```

Next comes *SaddleSearchParameters*, where we restrict NEB calculations to no more than 5 images. For this system, we expect fairly simple reactions, which will be well-described with 5 images or less. For more complicated systems, more than 5 images per NEB might be needed. This is not a very expensive part of the overall calculation, but we need to optimize for speed when using DFT.

```
# Modify the default maximum number of NEB images to 5.
saddle_search_parameters = SaddleSearchParameters(max_neb_images=5)
```

Finally the AKMC calculation is set up, including the *SaddleSearchParameters* object, and then started in the final line. For solid state systems it is often a good approximation to assume the prefactor, which is very expensive to calculate. In this case we use a value of 10^{13} s^{-1}, which should be appropriate for this system. As AKMC is a stochastic method, it is important to do enough saddle searches to ensure the reaction space is adequately sampled. This is also why this script is designed to make additional runs straightforward to do.

```
# Setup the AKMC simulation.
akmc = AdaptiveKineticMonteCarlo(markov_chain,
```

(continues on next page)

(continued from previous page)

```
                                    calculator=calculator,
                                    kmc_temperature=300*Kelvin,
                                    md_temperature=3000*Kelvin,
                                    saddle_search_parameters=saddle_search_parameters,
                                    constraints=[15],
                                    kmc=kmc,
                                    confidence=0.99,
                                    assumed_prefactor=1e13/Second,
                                    write_searches=False,
                                    write_kmc=True,
                                    write_markov_chain=True,
                                    write_log=True)

# Run 200 saddle searches.
akmc.run(200)
```

Warning: In AKMC calculations, you must constrain at least one atom to avoid drift of the system during the high-temperature MD. However, this will introduce a slight error in the potential energy surface (PES) close to the constrained atom(s), so the constraint(s) should in general be applied as far as possible from where you expect transitions to happen. In this case the constraint is chosen to be an atom exactly half a supercell away from the B atom in all directions, to minimize the impact on any reactions involving B.

Note: For further information on the parameters in the AKMC calculation, see for example the tutorial: *Modeling Vacancy Diffusion in Si0.5 Ge0.5 with AKMC* . In the present tutorial we focus on those features which need special attention when a DFT calculator is used.

Running the AKMC job

The script needs to run on a supercomputer, as it takes up to two full days per saddle search. In this case we run 2x50 hours on 3 nodes, for a total of 48 cores.

Attention: If you modify the parallelization options to better fit your system and the architecture of your favorite supercomputer, remember to leave one process for the AKMC algorithm itself. If you have N available CPU cores, only N-1 cores are available for saddle searches.

Analyzing the results

The script generates the following output files:

•One log-file for each saddle search:

–`saddle_search_*_*.log`

•The central log-file for the AKMC algorithm:

–`akmc_log.hdf5`

•A file containing the Markov Chain object:

–akmc_markov_chain.hdf5

•If any KMC steps have been taken by the algorithm: A file containing the Kinetic Monte Carlo object:

–akmc_kmc.hdf5

•A file containing everything sent to std out:

–sib-with-akmc.log

```
4.7M Sep  4 12:54 saddle_search_0_141.log
4.8M Sep  4 13:06 saddle_search_0_136.log
5.3M Sep  4 14:17 saddle_search_0_144.log
3.9M Sep  4 14:23 saddle_search_0_150.log
620K Sep  4 14:23 akmc_markov_chain.nc
136K Sep  4 14:23 akmc_log.nc
 14M Sep  4 14:44 saddle_search_0_118.log
2.8M Sep  4 14:48 saddle_search_0_142.log
6.1M Sep  4 14:48 saddle_search_0_149.log
4.9M Sep  4 14:48 saddle_search_0_153.log
3.6M Sep  4 14:49 saddle_search_0_148.log
3.2M Sep  4 14:49 saddle_search_0_140.log
4.3M Sep  4 14:50 saddle_search_0_147.log
3.1M Sep  4 14:50 saddle_search_0_139.log
7.5M Sep  4 14:51 saddle_search_0_151.log
3.2M Sep  4 14:51 saddle_search_0_146.log
3.2M Sep  4 14:53 saddle_search_0_145.log
5.2M Sep  4 14:53 saddle_search_0_155.log
124M Sep  4 14:53 sib-with-akmc.log
9.0M Sep  4 14:53 saddle_search_0_98.log
 20M Sep  4 14:53 saddle_search_0_87.log
 19M Sep  4 14:53 saddle_search_0_82.log
 21M Sep  4 14:53 saddle_search_0_66.log
 20M Sep  4 14:53 saddle_search_0_58.log
 20M Sep  4 14:53 saddle_search_0_50.log
128K Sep  4 14:53 saddle_search_0_176.log
146K Sep  4 14:53 saddle_search_0_175.log
424K Sep  4 14:53 saddle_search_0_174.log
494K Sep  4 14:53 saddle_search_0_173.log
```

In this case, no KMC steps have been taken, so there is no file named `akmc_kmc.hdf5`. This is also why all the saddle search files have a 0 as the first number; they have all been started from the original initial state. Many of the saddle

search files have the same time-stamp, as they have been killed by the queuing system on the cluster.

Inspecting the AKMC log-file

The AKMC log file can be most easily inspected using *Text Representation* in the QuantumATK Panel bar. This will bring up the following window:

```
# Title: akmc_log.nc - gID000
# Type:  AKMCLog
state id search number confidence  message
       0             0   0.000000  Found new state
       0             1   0.000000  The saddle point optimization did not converge.
       0             2   0.000000  Found new state
       0             3   0.000000  Found new state
       0             4   0.000000  The saddle point does not connect back to the initial minimum.
       0             5   0.000000  Found new state
       0             6   0.000000  Found new state
       0             7   0.000000  Found new state
       0             8   0.000000  Found new state
       0             9   0.000000  Found new state
       0            10   0.000000  Found new state
       0            11   0.000000  Found new state
       0            12   0.000000  Found new state
       0            13   0.000000  Found new state
       0            14   0.000000  Found new state
       0            15   0.000000  The saddle point does not connect back to the initial minimum.
       0            16   0.000000  Found new state
       0            17   0.000000  The saddle point optimization did not converge.
       0            18   0.000000  Found new state
       0            19   0.000000  The saddle point does not connect back to the initial minimum.
       0            20   0.000000  The saddle point does not connect back to the initial minimum.
       0            21   0.000000  The saddle point does not connect back to the initial minimum.
       0            22   0.000000  The saddle point does not connect back to the initial minimum.
       0            23   0.000000  The saddle point does not connect back to the initial minimum.
       0            24   0.000000  The saddle point does not connect back to the initial minimum.
       0            25   0.000000  The saddle point does not connect back to the initial minimum.
       0            26   0.000000  The saddle point does not connect back to the initial minimum.
       0            27   0.000000  The saddle point does not connect back to the initial minimum.
       0            28   0.000000  The saddle point does not connect back to the initial minimum.
       0            29   0.000000  The saddle point does not connect back to the initial minimum.
       0            30   0.000000  The saddle point does not connect back to the initial minimum.
       0            31   0.000000  Found new state
       0            32   0.000000  Found new state
       0            33   0.000000  The saddle point does not connect back to the initial minimum.
       0            34   0.000000  The saddle point does not connect back to the initial minimum.
       0            35   0.000000  The saddle point does not connect back to the initial minimum.
       0            36   0.000000  The saddle point does not connect back to the initial minimum.
       0            37   0.000000  Found new state
       0            38   0.000000  Found new state
       0            39   0.000000  Found new state
       0            40   0.000000  The saddle point optimization did not converge.
       0            41   0.000000  The saddle point does not connect back to the initial minimum.
       0            42   0.000000  Found new state
       0            43   0.000000  The saddle point does not connect back to the initial minimum.
       0            44   0.000000  The saddle point does not connect back to the initial minimum.
       0            45   0.000000  Found new state
       0            46   0.000000  The saddle point does not connect back to the initial minimum.
       0            47   0.000000  Found new state
       0            48   0.000000  The saddle point optimization did not converge.
       0            49   0.000000  Found new state
       0            50   0.000000  The saddle point optimization did not converge.
       0            51   0.000000  Found new state
       0            52   0.000000  The saddle point optimization did not converge.
       0            53   0.022956  Found saddle connecting to state 3 again
       0            54   0.018549  Found new state
       0            55   0.018491  Found new state
       0            56   0.018470  Found new state
```

This shows information about each completed saddle search.

•state id is the id number of the state, which the saddle searches are originating from – in this case state 0, which is the

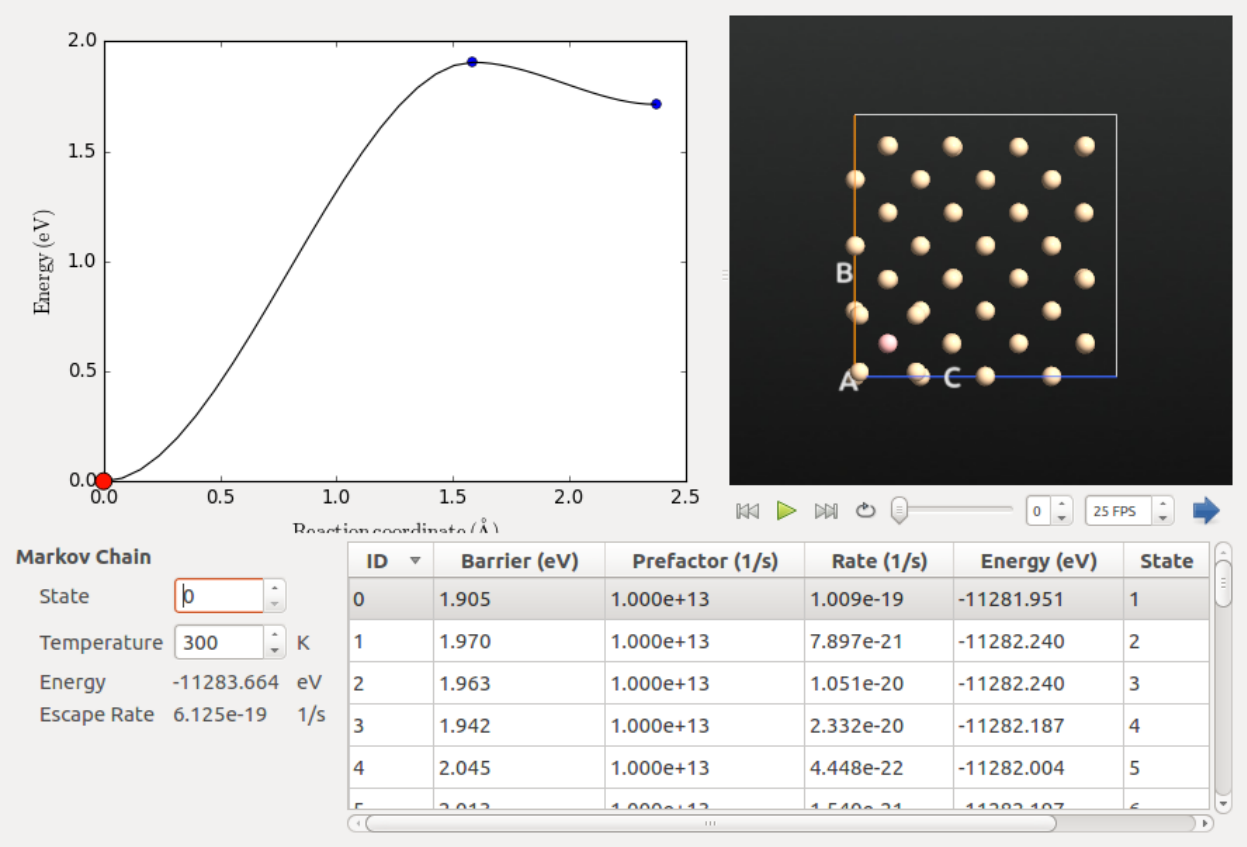
original initial state.

- search number is the id number of the saddle search, corresponding to the second number in the name of the log files.
- confidence is the confidence, on a scale from 0 to 1, that the current initial state has been adequately sampled.
- message is a short message describing the result of the saddle search.

We see that many saddle searches find new states and that about as many find saddle points which are not connected to the initial state. The former indicates that there are many saddle points with similar barriers, while the latter indicates that the potential energy surface (PES) is somewhat complicated. The confidence remains low because many searches discover new states, while only one search finds an already known state. This indicates that there are many relevant states, and the algorithm thus requires much more data before the PES has been adequately sampled around our original initial state and the first KMC step can be performed.

Inspecting the Markov Chain

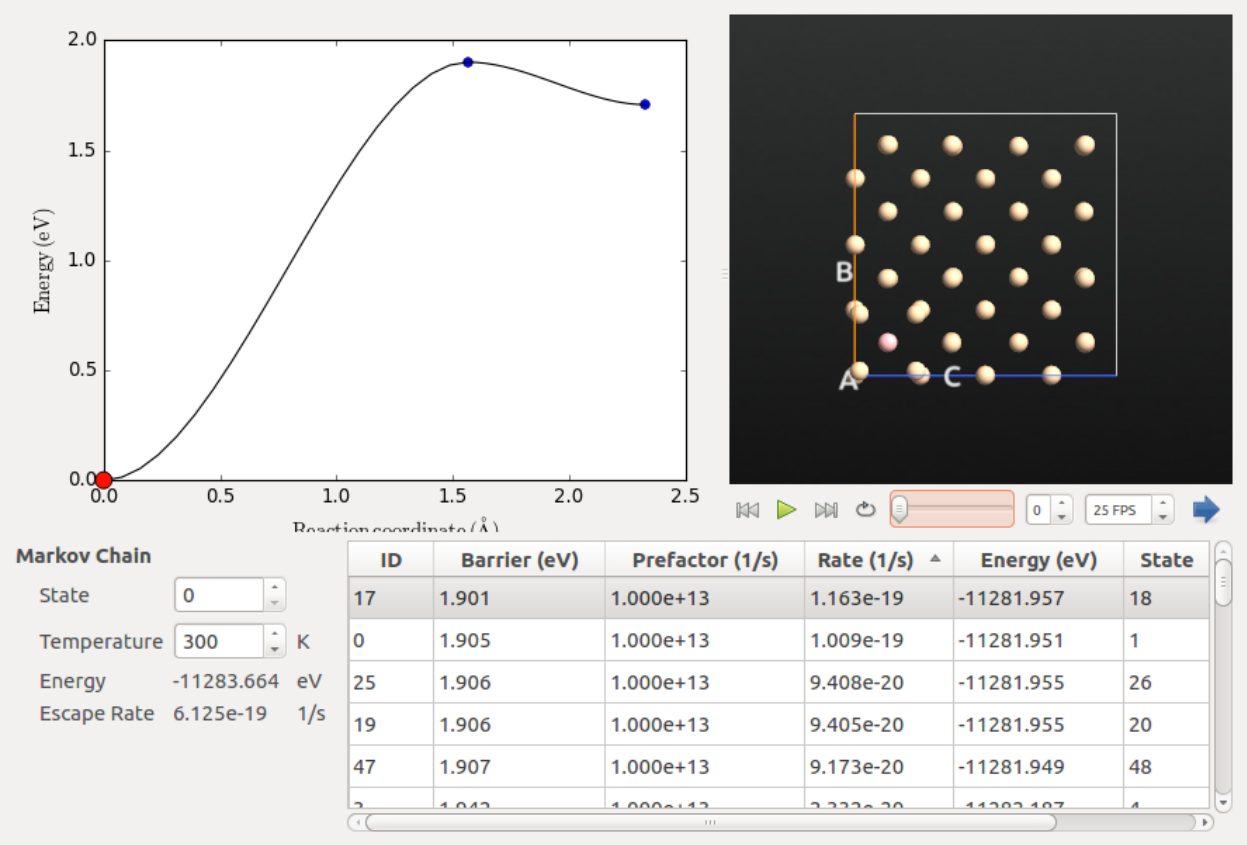
The Markov Chain is a list of all the discovered states and the connections between them. It can be visualized using the **Markov Chain analyzer** plugin in the QuantumATK panel bar. In this case, all the connections originate in the original initial state (state 0). You can view all the connections for a different state by changing *State* to a value other than 0. You can also change the *Temperature* to see how the rates change. In this case the rates are all extremely small at 300 K, as the barriers are quite high. However, due to the exponential dependence of the rate on 1/T, doubling the temperature to 600 K increases the rates by about 16 orders of magnitude.



ID	Barrier (eV)	Prefactor (1/s)	Rate (1/s)	Energy (eV)	State
0	1.905	1.000e+13	1.009e-19	-11281.951	1
1	1.970	1.000e+13	7.897e-21	-11282.240	2
2	1.963	1.000e+13	1.051e-20	-11282.240	3
3	1.942	1.000e+13	2.332e-20	-11282.187	4
4	2.045	1.000e+13	4.448e-22	-11282.004	5

Validating the assumed prefactor

We will now verify that the assumed prefactor used in the AKMC calculations is reasonable. We select the transition between states 0 and 17, as it has the lowest barrier and involves atoms close to the B atom.



ID	Barrier (eV)	Prefactor (1/s)	Rate (1/s)	Energy (eV)	State
17	1.901	1.000e+13	1.163e-19	-11281.957	18
0	1.905	1.000e+13	1.009e-19	-11281.951	1
25	1.906	1.000e+13	9.408e-20	-11281.955	26
19	1.906	1.000e+13	9.405e-20	-11281.955	20
47	1.907	1.000e+13	9.173e-20	-11281.949	48

Tip: You can sort the states by each of the columns. In this case, we sorted by barrier to identify the states with the lowest barrier. They also have the highest rates as the prefactor is identical for all transitions.

The procedure for this calculation is as follows:

- Extract the initial, saddle and final states from the Markov Chain, and optimize their geometry.
- Create a NEB configuration with more images and optimize it, first without and then with climbing image.
- Do the actual prefactor calculation using *HTSTEvent*.

The first point is covered in the script: `extract-neb-from-markov-chain.py`. The Markov Chain object stores the final states and saddle point states for all the discovered transitions between the known states. These configurations can then be extracted as shown in the first lines of code below, for the initial and final states. Afterwards, we define a calculator identical to the one used in the AKMC simulation and optimize the geometry with a tolerance of 0.01 eV/Å. This is a stricter criterion than the default in **OptimizeGeometry**, but identical to the default in the AKMC simulation, which is selected to ensure convergence of the prefactor calculation. For some systems it might be needed to converge even more tightly.

```
markov_chain = nlread('akmc_markov_chain.nc')[0]

initial_state_id = 0
```

(continues on next page)

(continued from previous page)

```
final_state_id = 17

initial_conf = markov_chain.getStateConfiguration(initial_state_id)
final_conf = markov_chain.getStateConfiguration(final_state_id)
```

extract-neb-from-markov-chain.py

In the next script, `optimize-neb-from-markov-chain.py`, we create a NEB configuration based on the minimized initial and final configurations, plus the saddle configuration as extracted from the Markov Chain.

```

markov_chain = nlread('akmc_markov_chain.nc')[0]

initial_conf = nlread('initial_conf.nc',BulkConfiguration)[-1]
final_conf = nlread('final_conf.nc',BulkConfiguration)[-1]

initial_state_id = 0
final_state_id = 17

# Make the NEB configuration

saddle_conf = markov_chain.getSaddleConfiguration(initial_state_id, final_state_id)

configuration_list = [initial_conf, saddle_conf, final_conf]

neb_configuration = NudgedElasticBand(configuration_list, image_distance=1.0*Angstrom,␣
↪generate_images=True, wrap_pbc=True)

nlsave('neb-configuration.nc',neb_configuration)
```

Then we define a calculator identical to the one used in the AKMC simulation (not shown here), and proceed to optimize the NEB; this is done with a regular optimization first, and then an additional one with climbing image turned on. This optimization can take several hours, even on a multi-core machine.

```

neb_configuration.setCalculator(calculator)

optimized_neb_configuration = OptimizeNudgedElasticBand(
        neb_configuration,
        max_forces=0.01*eV/Ang)

nlsave('optimized-neb-configuration.nc',optimized_neb_configuration)

ci_optimized_neb_configuration = OptimizeNudgedElasticBand(
        optimized_neb_configuration,
        climbing_image=True,
        max_forces=0.01*eV/Ang)

nlsave('ci-optimized-neb-configuration.nc',ci_optimized_neb_configuration)
```

optimize-neb-from-markov-chain.py

Note: You can also do the NEB optimization with climbing image turned on from the beginning, but this is a less

stable approach and can lead to convergence problems. Doing it in two steps, as we do here, is slightly slower, but will be much more likely to converge without issues.

Finally, we calculate the prefactor with a simple script using HTSTEvent, reading in the fully optimized NEB configuration.

```
neb_configuration = nlread('ci-optimized-neb-configuration.nc',NudgedElasticBand)[-1]

# ------------------------------------------------------------
# HTST Event
# ------------------------------------------------------------
htst_event = HTSTEvent(
    neb_configuration,
    finite_difference_method=Central,
    minimum_displacement=0.05*Angstrom,
    )
nlsave('htst-event.nc', htst_event)
nlprint(htst_event)
```

calculate-prefactor.py

This script requires approximately 600 energy and force calculations and ran for about 2.5 hours on an 8-core node. When it has finished, the results are found at the end of the log-file containing the std output:

```
+-------------------------------------------------------------------------------+
|                                                                               |
| HTST Event Information                                                        |
|                                                                               |
+-------------------------------------------------------------------------------+
|    Reactant Energy: -11283.6643027 eV                                         |
|    Saddle   Energy: -11281.7203394 eV                                         |
|    Product  Energy: -11282.1925809 eV                                         |
|   Forward  Barrier:      1.9439633 eV                                         |
|   Backward Barrier:      0.4722415 eV                                         |
| Forward  Prefactor:      1.792e+14 1/s                                        |
| Backward Prefactor:      6.939e+13 1/s                                        |
+-------------------------------------------------------------------------------+
```

We see that the forward prefactor is a little more than an order of magnitude larger than the estimated value of 10^{13} s^{-1}, while the backward prefactor is a little less than an order of magnitude off. This validates our assumed prefactor, as this deviation from the assumption is much smaller than the many orders of magnitude the rate can vary due to the exponential dependence on the barrier.

Conclusions

The AKMC simulations indicate that atomic boron in bulk silicon is very stable in a substitutional lattice site, and effectively immobile at temperatures close to room temperature. A reaction rate prefactor of 10^{13} s^{-1} per second was assumed and later verified.

3.11.18 Adaptive Kinetic Monte Carlo Simulation of Pt Island Ripening

Version: 2017

Downloads & Links

`initial.py` `morse_potential.py` `adding_akmc.py` `akmc.py`

This tutorial is on the use of the Adaptive Kinetic Monte Carlo (AKMC) method. It will cover setting up a simulation to model Pt island ripening on a Pt(111) surface, how to implement the Morse potential, and how to analyze the results. For more information on the AKMC method, you may look at the following tutorials: *AKMC Simulation of Pt on Pt(100)* and *Modeling Vacancy Diffusion in SiGe alloy*.

Introduction

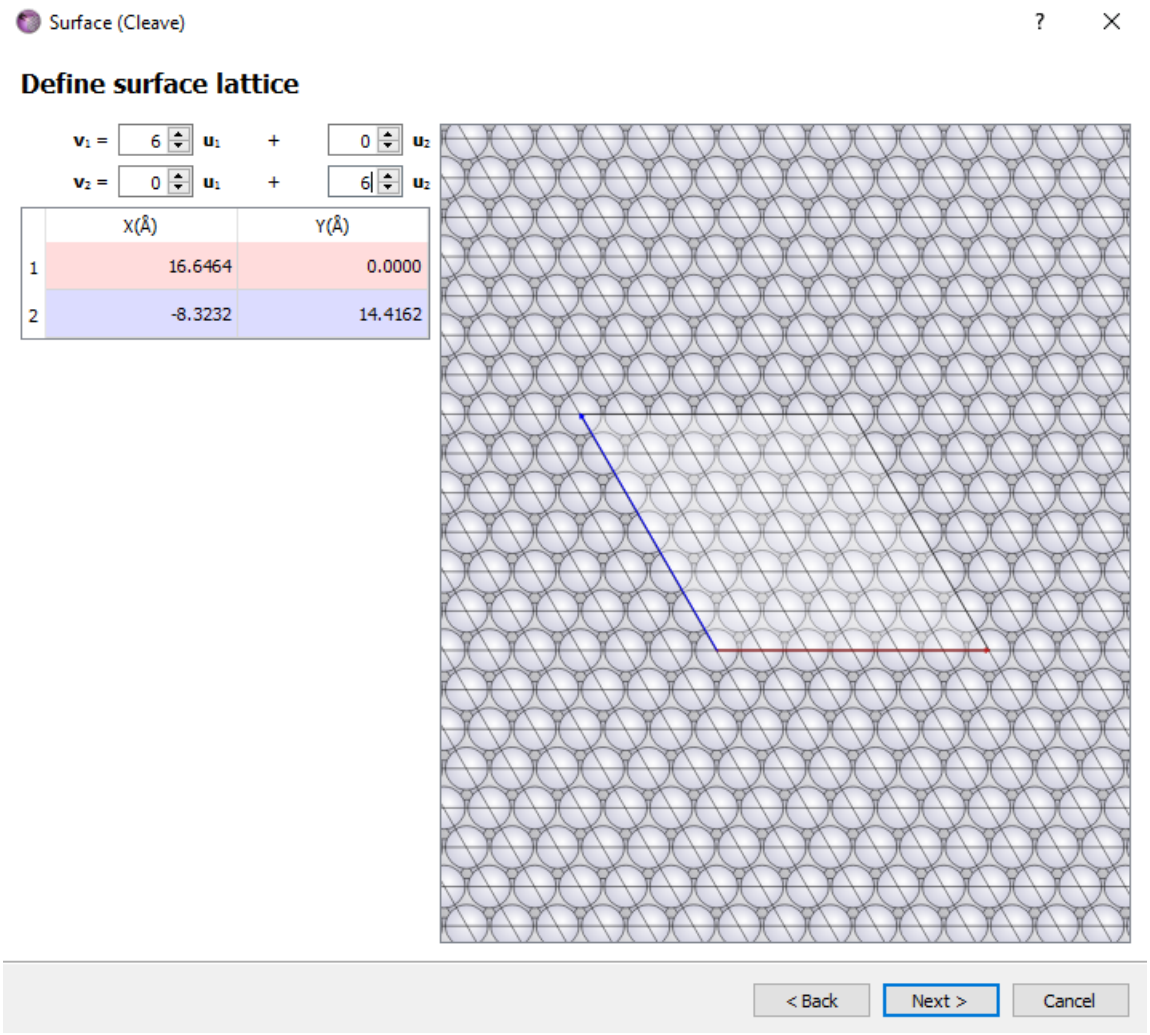
In this tutorial we will model island ripening of Pt adatoms on a Pt(111) surface at 300 K using the Adaptive Kinetic Monte Carlo (AKMC) method. The initial surface will have seven adatoms and the most stable structure is a compact heptamer island. The atomic interactions will be modeled using a simple Morse potential to allow us to compare our results to a published benchmark study[1]. The use of the Morse potential also allow us to showcase the use of AKMC without resorting to computationally expensive DFT calculations, but it is not expected to directly reproduce a particular experimental result.

Creating the initial configuration

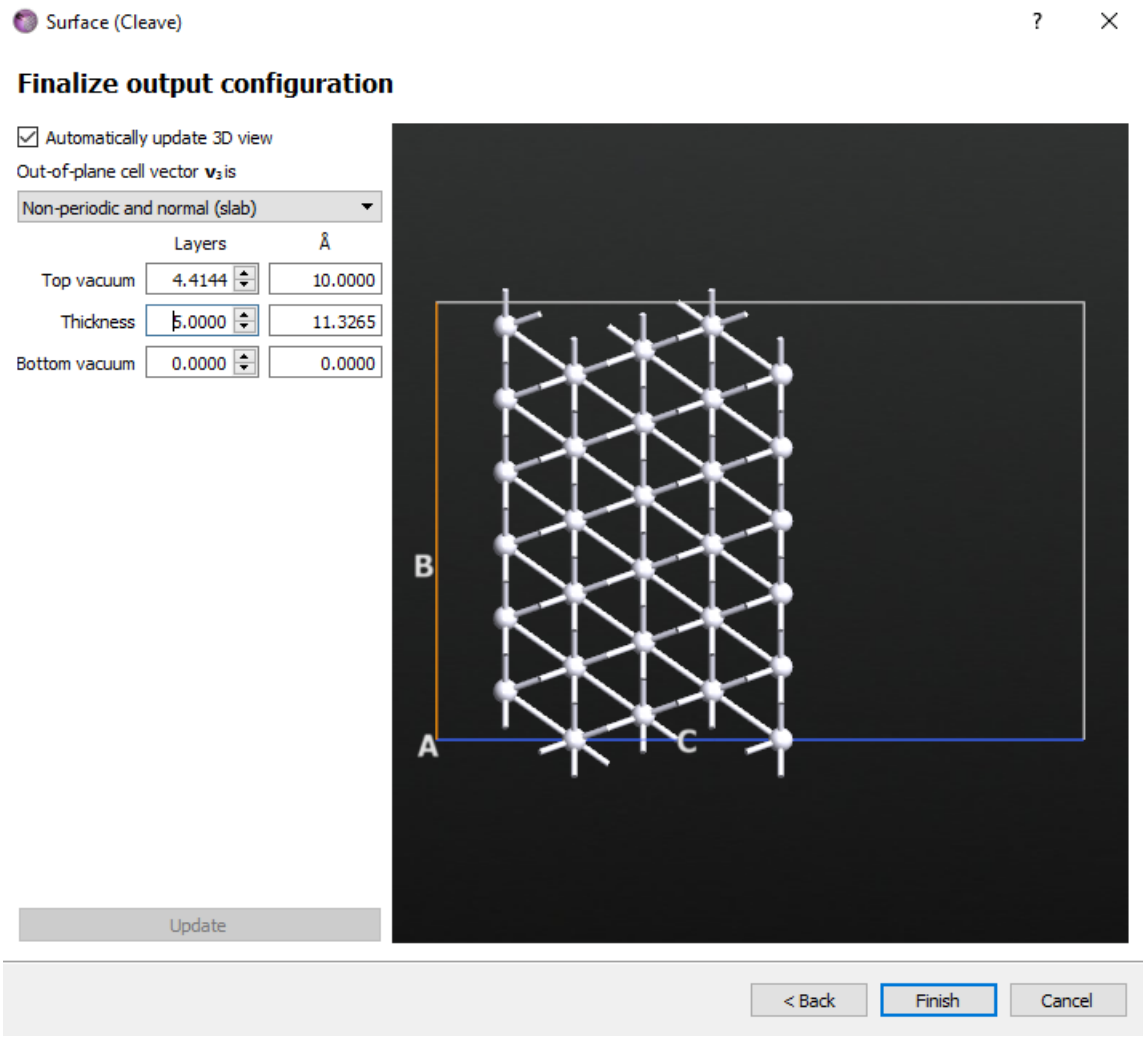
The initial configuration will be a 4 layer *p* (6x6)-Pt(111) slab with seven adatoms occupying three-fold hollow sites.

1. Open the **Builder**.
2. Import the Pt *fcc* bulk configuration by clicking on *Add* → *From Database* and search for Platinum.
3. The Pt primitive cell will appear in the **Stash**.
4. Click on *Builders* → *Surface (Cleave)*.
5. In the new window, choose the (111) Miller indices.
6. Define the *p* (6x6) surface unit cell.

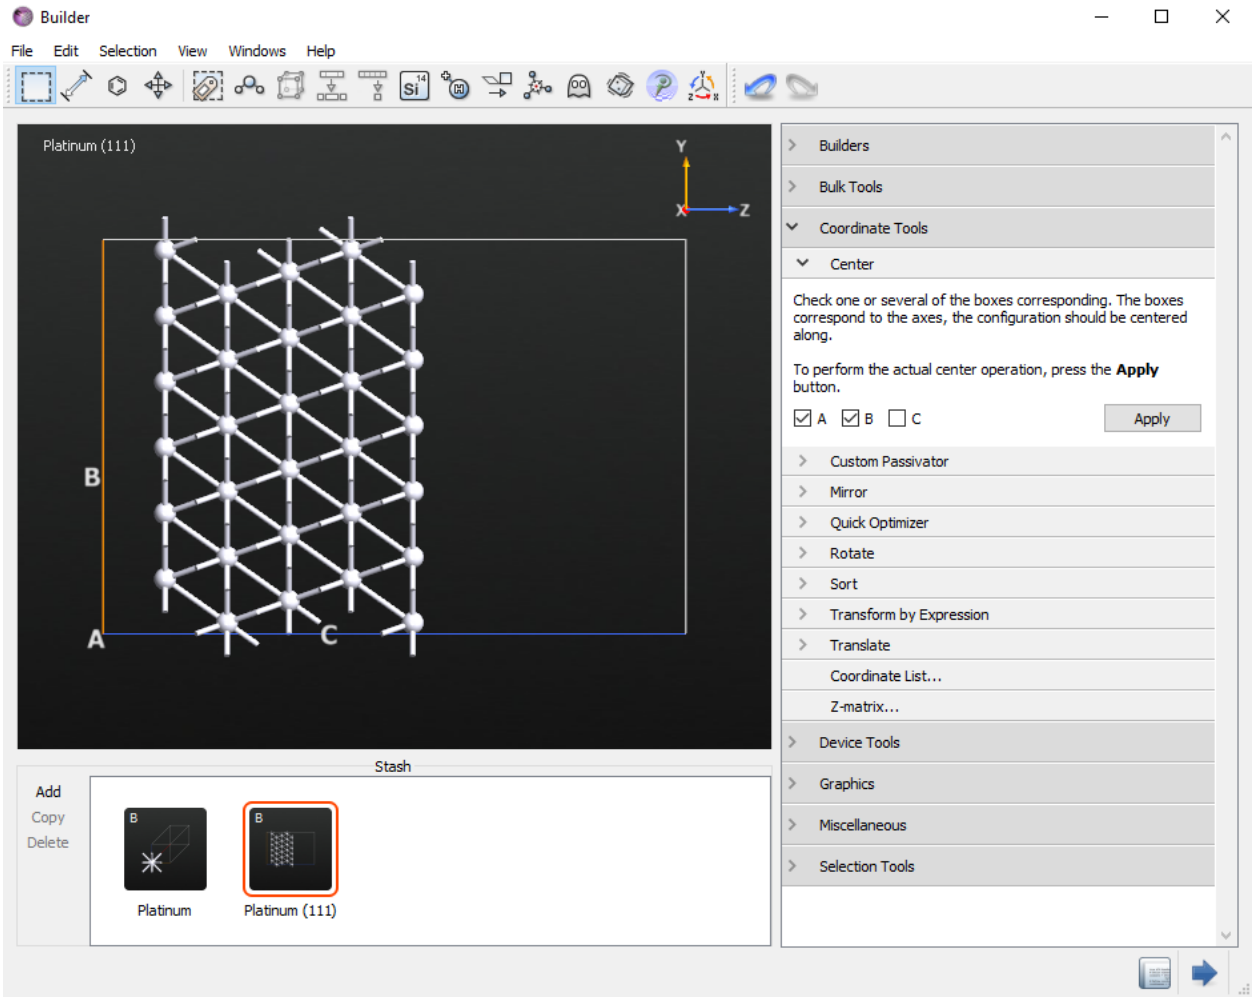
[1] Rye Terrell, Matthew Welborn, SamuelăT. Chill, and Graeme Henkelman. Database of atomistic reaction mechanisms with application to kinetic Monte Carlo. *J. Chem. Phys.*, 137:014105, 2012. doi:10.1063/1.4730746.



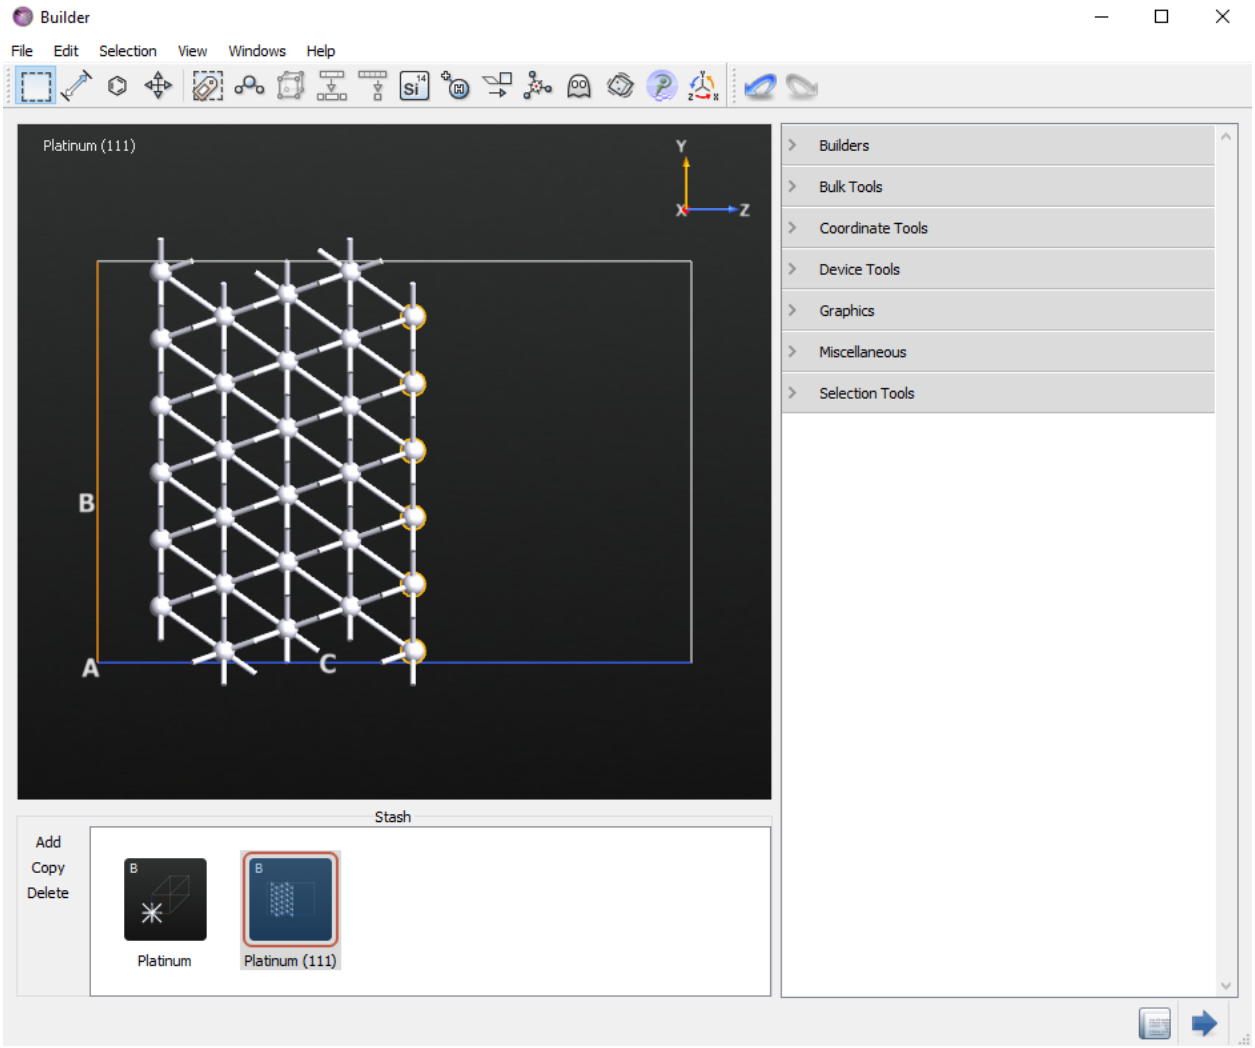
7.Choose the *Non-periodic and normal (slab)* option and a thickness of 5 layers. Click *Finish* button.



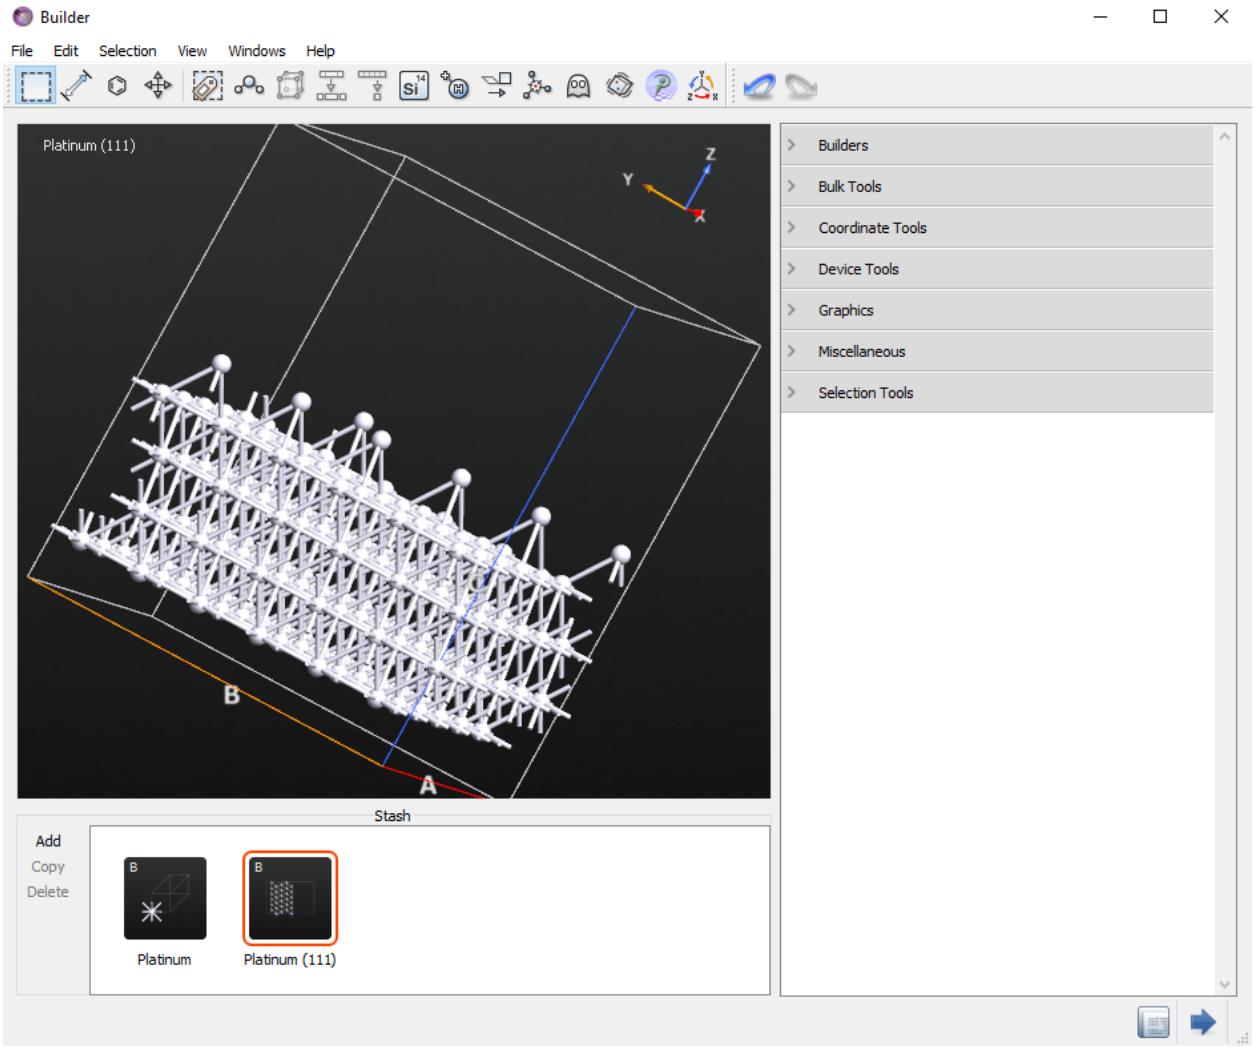
8.Click on *Coordinate Tools* → *Center* and select the *A* and *B* axes and click the *Apply* button.



9.Select the whole top layer.



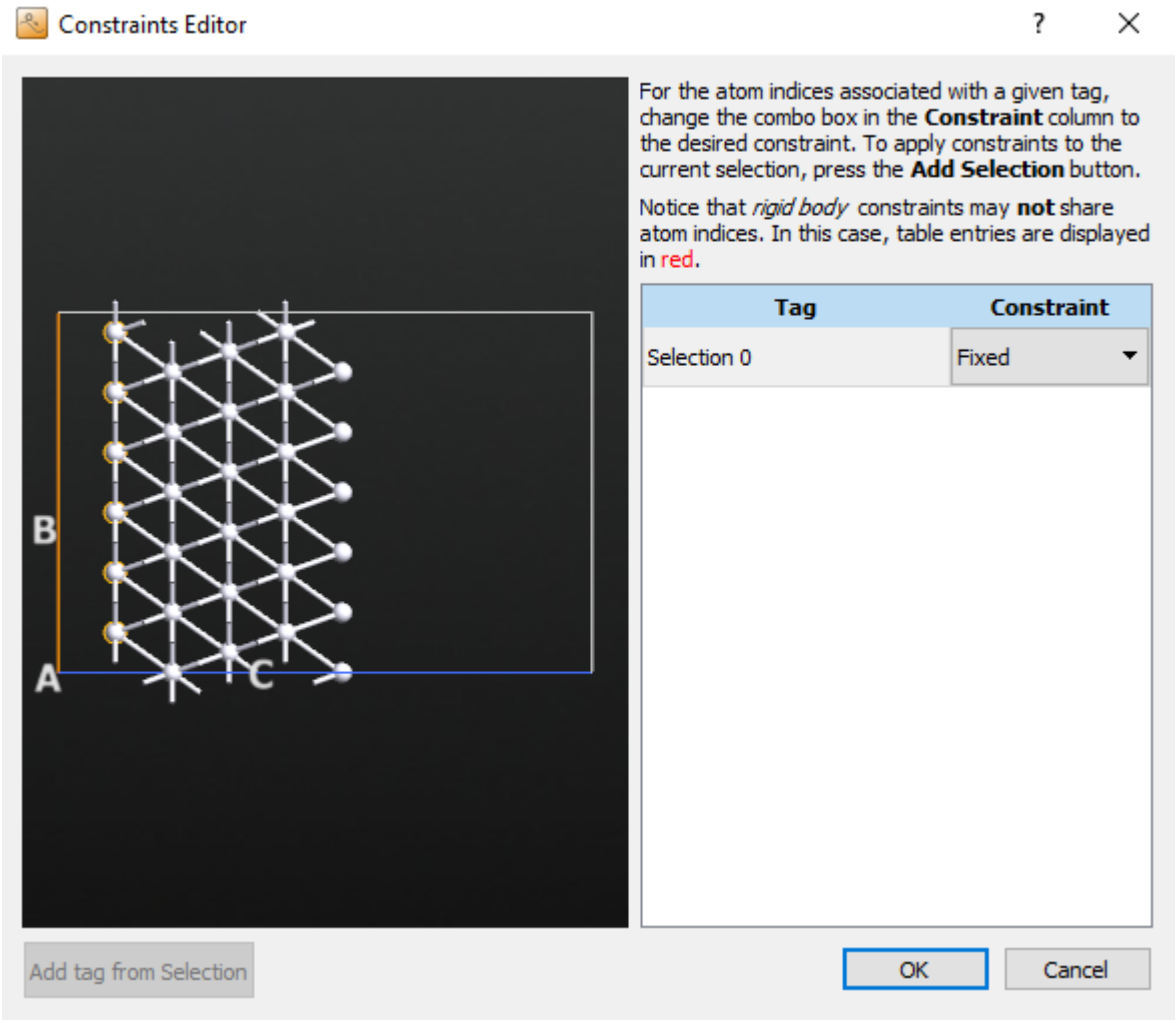
10. Un-select seven non-contiguous atoms holding the `shift` key on your keyboard and then press the `del` key to remove the selected atoms. There should now be seven adatoms. It should look similar to the image below.



11. Send the configuration to the **Script Generator** by clicking the or dragging the structure onto the **Scripter**.

For now, do not add a calculator block. Since we are using a *Morse potential*, we will specify the calculator later. The parameters for the Morse potential were originally fitted to model bulk Pt and are the same as used inPage 1619, 1.

1. Add an *Optimization* → *OptimizeGeometry* block and double-click it. Set the Force tolerance to 0.01 eV/Å. Then click *Add Constraints* and select the bottom row of atoms, click *Add tag from Selection*, and then set the Constraint to *Fixed*.



2.Change the Default output file to `initial.hdf5`.

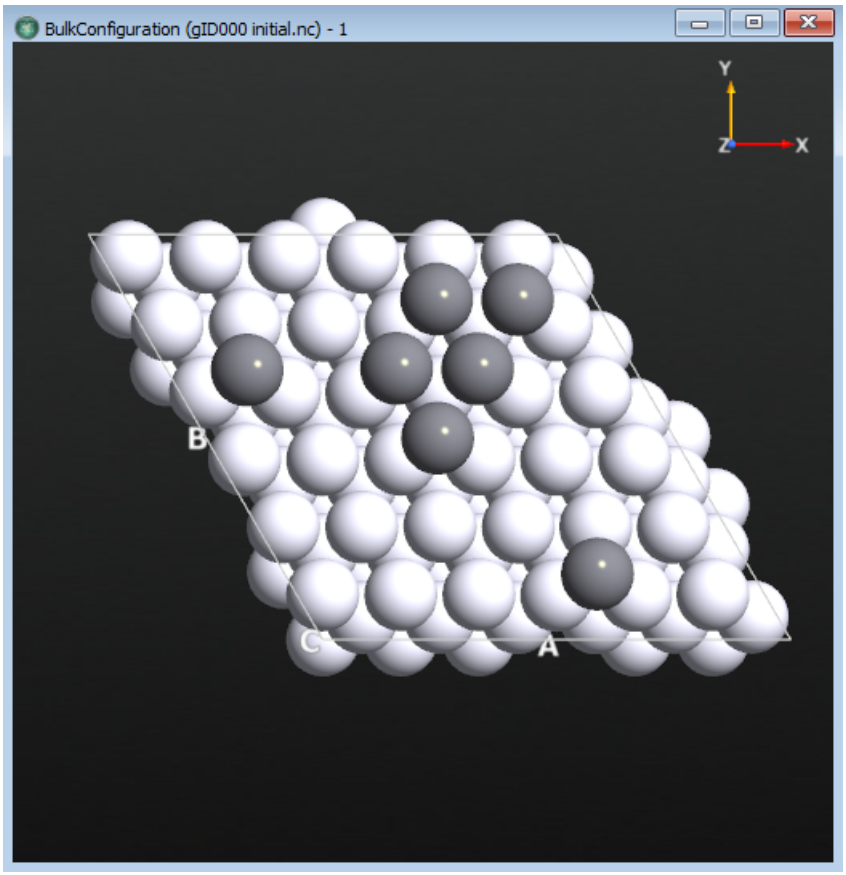
3.Send the script to the **Editor**.

4.We now need to define the Morse calculator. Insert the following code above the call to *OptimizeGeometry*: `morse_potential.py`

```
potentialSet = TremoloXPotentialSet(name='Pt-Morse')
potentialSet.addParticleType(ParticleType.fromElement(Platinum))
potentialSet.addPotential(MorsePotential(
    'Pt',
    'Pt',
    r_0=2.897*Angstrom,
    k=1.6047*Angstrom**-1,
    E_0=0.7102*eV,
    r_i=6.5*Angstrom,
    r_cut=9.5*Angstrom)
)
calculator = TremoloXCalculator(parameters=potentialSet)
bulk_configuration.setCalculator(calculator)
```

5.Now **save** the script as `initial.py` or download the `initial.py` and send it to the **Job Manager** and run it.

The optimized geometry can now be selected on the **LabFloor** and visualized in the **Viewer**. It may be useful to click on **Properties** in the right-hand panel and tweak the way the atoms are rendered to more easily distinguish the adatoms from the bulk atoms. In the image below, the atoms are rendered as covalent radius spheres and the adatoms are in a darker gray than the bulk Pt.



Tip: If you wish to re-create the above figure, you can do the following: Select the file `initial.hdf5` file on the **LabFloor**. Click the **Viewer** on the right-hand panel. Open the **Properties** window. Select the *Covalent* option under **Atoms** and check *Wrap atoms* under **Bulk**. The atoms are now shown as balls with their covalent radius. Choose the top 7 Pt atoms and then change to another color (here we chose gray). Now you can distinguish the 7 adatoms on the Pt surface.

Setting up the AKMC Simulation

We will now set up and run the AKMC simulation. The goal is to determine the time required to form a compact heptamer island at 300 K.

Now that you have an optimized initial structure, you can run the AKMC simulation. Drag `initial.hdf5` from the main QuantumATK window to the **Scripter**. Starting from **ATK 2017**, **AdaptiveKineticMonteCarlo** is implemented in the Scripter.

Note: If you have an older version, you can download the script `adding_akmc.py` and append the contents in the

Editor instead of following the steps below. Instead, go to the next section: *Adding the calculator*

We use the Morse potential which is the same as used in[Page 1619, 1]. After setting up the AKMC simulation, we will add the Morse Potential calculator in the editor in the next section.

In the **Scripter**, add an *Optimization* → *AdaptiveKineticMonteCarlo* block.

1. Double click the **AdaptiveKineticMonteCarlo** block.
2. Go to the **Optimization** tab, and click on the *Atomic Constraint Editor* to add a constraint.
3. Select the bottom layer to be constrained, as in the initial optimization, and press the *Add tag from Selection* button. Change to the *Fixed* constraint. This will remove the red-colored warning.
4. In the **Kinetic Monte Carlo** tab, set the value to 20 in the *Superbasin creation threshold*.
5. For **HTST Prefactor**, we use a fixed Prefactor value of 10^{13} s^{-1} because it does not change much from one reaction to another.

Note: For most solid-state systems, the prefactor is not important to calculate directly (and it is expensive to do so). The primary difference between different reaction mechanisms is the size of the energy barrier. In the referenced simulation we are comparing against, this step was skipped.

6. In the *Saddle Search* settings, set the number of searches to 200.
7. Change the Default output file name to `akmc.hdf5` and go to the **Editor** by clicking the icon.

Adding the calculator

Now we need to add the *Morse potential* calculator above the AKMC calculation in the **Editor** using the script `morse_potential.py`.

```
# Morse-potential
potentialSet = TremoloXPotentialSet(name='Pt-Morse')
potentialSet.addParticleType(ParticleType.fromElement(Platinum))
potentialSet.addPotential(MorsePotential(
    'Pt',
    'Pt',
    r_0=2.897*Angstrom,
    k=1.6047*Angstrom**-1,
    E_0=0.7102*eV,
    r_i=6.5*Angstrom,
    r_cut=9.5*Angstrom)
)
calculator = TremoloXCalculator(parameters=potentialSet)
bulk_configuration.setCalculator(calculator)

# ------------------------------------------------------------
# Adaptive Kinetic Monte Carlo
# ------------------------------------------------------------
htst_parameters = HTSTParameters(
```

(continues on next page)

(continued from previous page)

```
    assumed_prefactor=1e+13*1/Second,
    )

if os.path.isfile('akmc_markov_chain.hdf5'):
    markov_chain = nlread('akmc_markov_chain.hdf5')[-1]
else:
    markov_chain = MarkovChain(
        configuration=bulk_configuration,
        configuration_energy=TotalEnergy(bulk_configuration).evaluate(),
        )

if os.path.isfile('akmc_kmc.hdf5'):
    kmc = nlread('akmc_kmc.hdf5')[-1]
else:
    kmc = None

constraints = [ 0,  1,  2,  3,  4,  5,  6,  7,  8,  9, 10, 11, 12,
                13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25,
                26, 27, 28, 29, 30, 31, 32, 33, 34, 35]

akmc = AdaptiveKineticMonteCarlo(
    markov_chain=markov_chain,
    kmc_temperature=300.0*Kelvin,
    md_temperature=2000.0*Kelvin,
    calculator=bulk_configuration.calculator(),
    kmc=kmc,
    superbasin_threshold=20,
    htst_parameters=htst_parameters,
    constraints=constraints,
    confidence=0.99,
    filename_prefix='akmc',
    )

akmc.run(max_searches=200, max_kmc_steps=10000)
```

You can also download the input file `akmc.py` to start the run for the AKMC simulation.

Running the Simulation

This script will run 200 saddle searches each time it is called. The first time the script is run, it creates a new AKMC simulation, while subsequent runs resume the simulation. Each saddle search takes about 15 seconds. So, in serial, 200 saddle searches will take under 1 hour to complete. The calculation can also be run in parallel using MPI, but note that you need at least 3 processes to get a speed-up. The goal of this simulation is to find the time it takes to form a compact heptamer (7 atom) island. This is the lowest energy configuration of the system. The AKMC script will have to be run several times to reach this point. After each run, you should follow the analysis below to monitor the progress of the simulation.

Note: You will probably need to run more searches to find a heptamer island with the AKMC simulation. If you do not find it within 200 searches, you can restart the simulation to search for more saddle points by using the files: `akmc_markov_chain.hdf5` and `akmc_kmc.hdf5`, which the script is set up to do automatically. Here we ran it again up to 1000 searches.

Analyzing the AKMC Simulation

Since AKMC simulations are stochastic, your results will be slightly different from what is shown here. You can download the current results for the same analysis. `akmc_log.hdf5`, `akmc_markov_chain.hdf5` and `akmc_kmc.hdf5`.

There are three output files to examine: `akmc_log.hdf5`, `akmc_markov_chain.hdf5` and `akmc_kmc.hdf5`. The `akmc_log.hdf5` file contains information about the results of each saddle search. If there are errors they will be reported here. The file `akmc_markov_chain.hdf5` contains the energies and geometries of the different configurations and how the different configurations are connected through saddle points and their energy barriers. It also contains the data needed to compute rate constants using harmonic transition state theory. The file `akmc_kmc.hdf5` stores the Kinetic Monte Carlo simulation data. This includes the current state identifier and the simulation time.

AKMC Log File

The log file should be looked at first to make sure that the simulation ran correctly. Below is an example of what the log file will look like. The log file can be viewed by clicking on the `akmc_log.hdf5` file on the **LabFloor** and clicking the **Text Representation** button in the panel on the right.

The first column shows the state *id* number that is used to identify each configuration in the Markov Chain. The second column shows the search number, which is a unique identifier for each saddle search. The third column shows the confidence estimate, which is a measure of the probability that all relevant saddle points have been found in that state. Saddle searches are run in each until the confidence exceeds the chosen threshold passed to the AKMC simulation. In the log file below, you can see that the initial state 0 is visited until the confidence meets 0.99, then the next state 2 is reached.

The fifth column contains a message about the saddle search. The message *found new state* represents a new reaction mechanism being discovered, while the message *Found saddle connecting to state* i *again* represents state *i* having been found again. In the state *id* 0, there are 7 *Found new state* and several *Found saddle connecting to state* i *again*. There is only one search that ended in an error in this example: search number 17. In this search a new saddle point was found, but it does not connect back to the current state. This means it is a saddle point that describes a reaction between two different states. This is expected to happen sometimes, but if a large number of the saddle searches have this message, then it probably means that the MD temperature is too high.

```

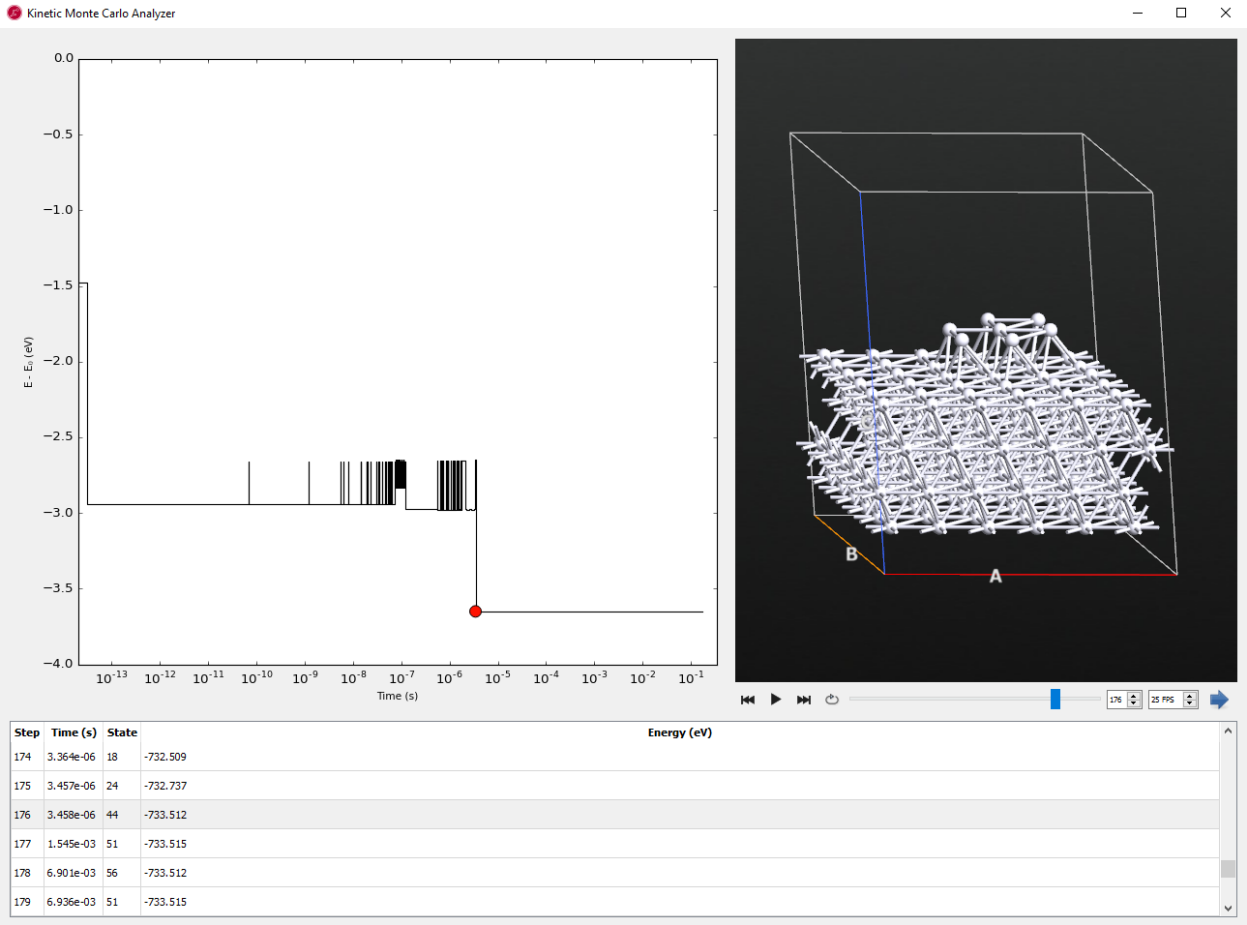
Kinetic Monte Carlo Analyzer

The main way to view the results of the AKMC simulation is with the **Kinetic Monte Carlo Analyzer**. To use this tool, select both the KMC object in the `akmc_kmc.hdf5` and the MarkovChain object  in the `akmc_markov_chain.hdf5` files (if you hold the `ctrl` key, you can select on multiple files in the LabFloor) and then click on **Kinetic Monte Carlo Analyzer** in the panel on the right.

The Kinetic Monte Carlo Analyzer shows a plot of energy vs. time during the AKMC simulation on the left and the geometry of the currently selected configuration/time step on the right.



Tip: You can click on the image to see a version with higher resolution.

The above image shows the results after 1000 saddle searches, which results in the simulation of about 0.17 s of dynamics. The compact island was formed at KMC step 176, which corresponded to a simulation time of 3.4 ms. After the compact island is formed, the entire island diffuses across the surface using a concerted sliding mechanism. When you click the play button, you see the dynamics along time.

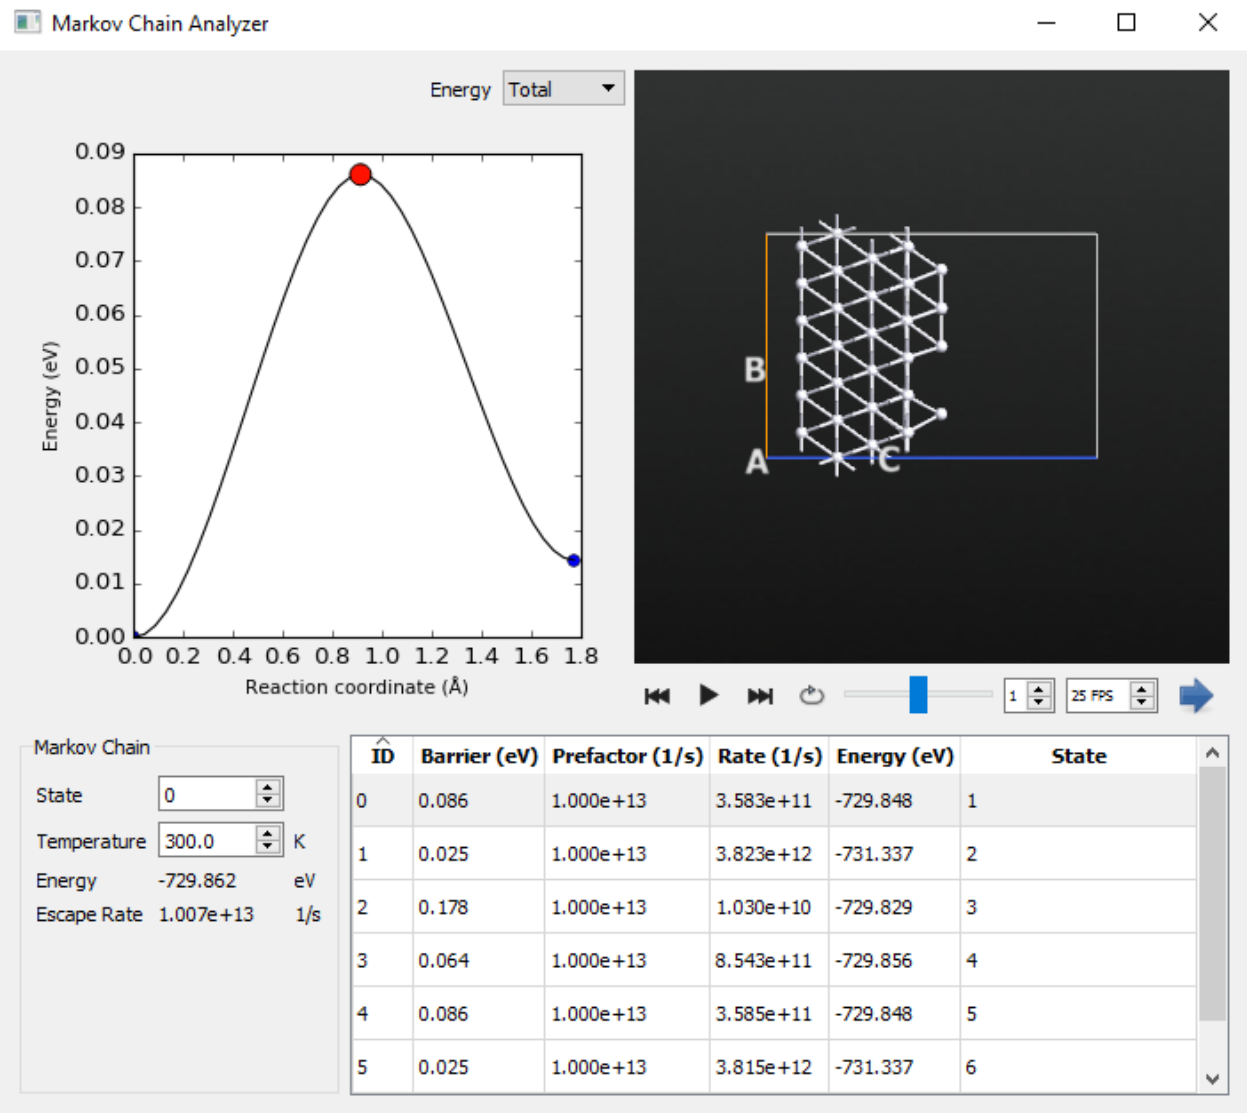
Markov Chain Analyzer

The Markov Chain Analyzer allows you to look at which reactions are present at each step of the KMC simulation. It can be invoked in two ways:

1)From the **Kinetic Monte Carlo Analyzer** by double clicking on a entry in the table.

2)By selecting the object in the `akmc_markov_chain.hdf5` on the **LabFloor** and clicking the **Markov Chain Analyzer** button in the panel.

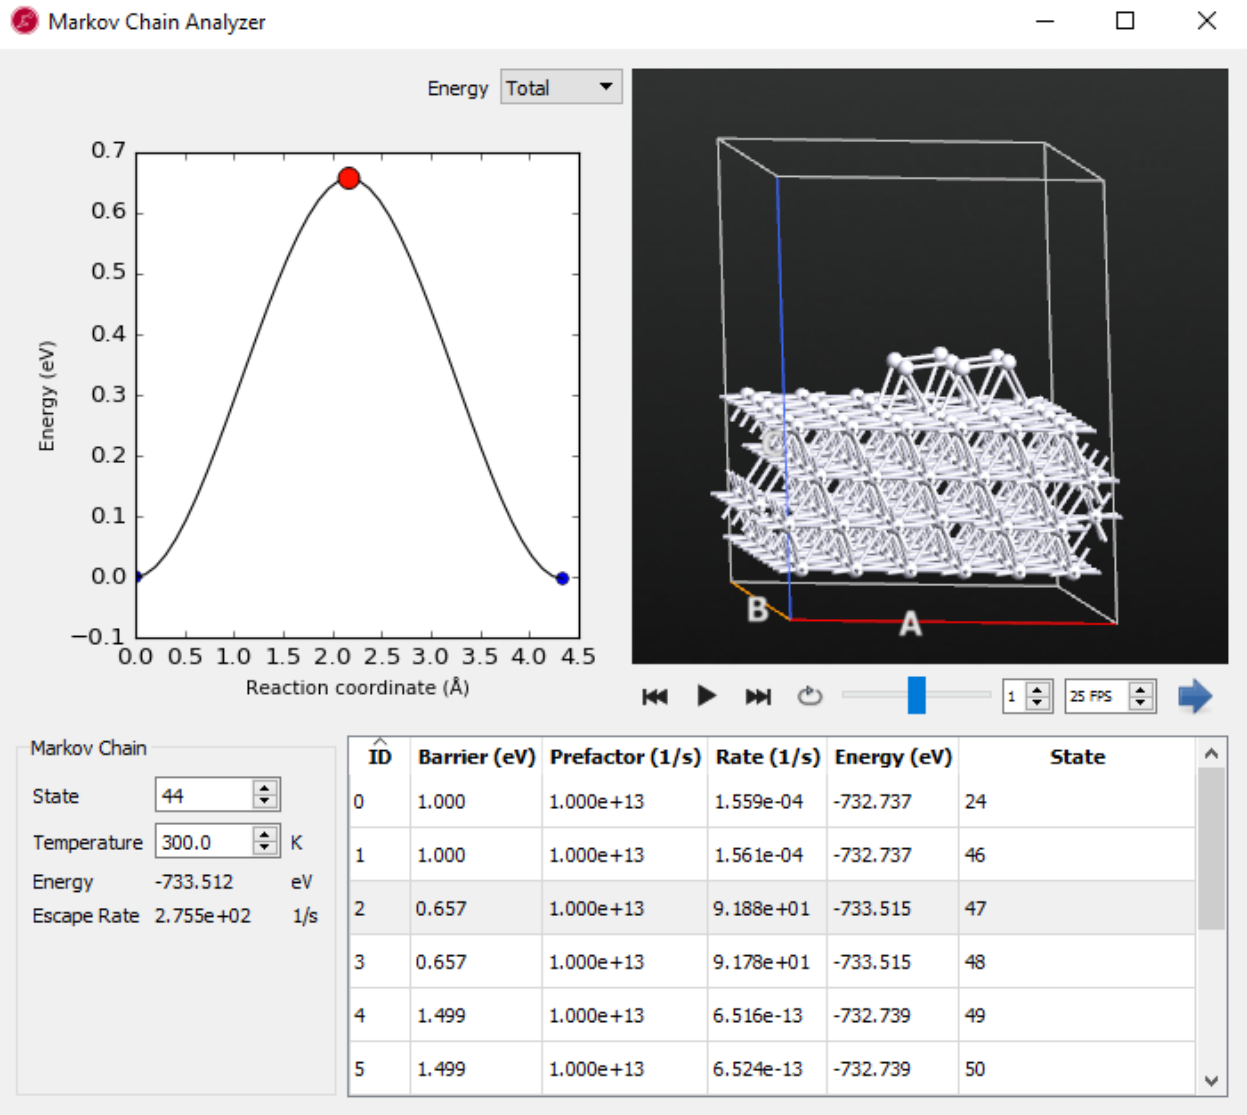
If we go to the first line in the table in the Kinetic Monte Carlo Analyzer and double click the line, it will open the Markov Chain Analyzer for the initial state.



ID	Barrier (eV)	Prefactor (1/s)	Rate (1/s)	Energy (eV)	State
0	0.086	1.000e+13	3.583e+11	-729.848	1
1	0.025	1.000e+13	3.823e+12	-731.337	2
2	0.178	1.000e+13	1.030e+10	-729.829	3
3	0.064	1.000e+13	8.543e+11	-729.856	4
4	0.086	1.000e+13	3.585e+11	-729.848	5
5	0.025	1.000e+13	3.815e+12	-731.337	6

Each of these reaction mechanisms has a very small barrier, indicating that the initial configuration is very unstable. By selecting different mechanisms from the table, each can be visualized. Now we will examine what reaction mechanisms are present for the compact island. Double-click on the line with the 176th step, which is where we found the island formation in the Kinetic Monte Carlo Analyzer. This will take us to state 44, which is the first state containing the compact island.

Note: Remember that the step number is most likely different in your simulation because of its randomly selected initial structure and dynamics.



The compact island shows several reaction mechanisms. Each corresponds to the entire 7 atom island diffusion in concert. The barriers are much larger (> 0.65 eV) than those from the initial state and explain why once the compact island is formed a large amount of time passed during the KMC simulation.

The increase in reaction barriers from the initial state with disconnected adatoms to the final compact island shows that the diffusion coefficient of the adatoms decreases dramatically over the course of the simulation.

Conclusion

In this tutorial, we looked at how to model surface diffusion of Pt adatoms using a simple Morse interaction potential. The initial configuration was 7 lone Pt adatoms and the final configuration was a compact 7 atom island. The AKMC simulation modeled longer than 0.1 s of dynamics and the formation time of the compact island took 3.4 ms at 300 K. If a molecular dynamics simulation with a 1 fs timestep had been performed instead, it would have taken 3.4 billion steps to reach the compact island formation. Thus the use of AKMC allowed us to model reaction dynamics on a timescale that is virtually unaccessible using molecular dynamics.

3.11.19 Adaptive Kinetic Monte Carlo Simulation of Pt on Pt(100)

Version: 2017

Downloads & Links

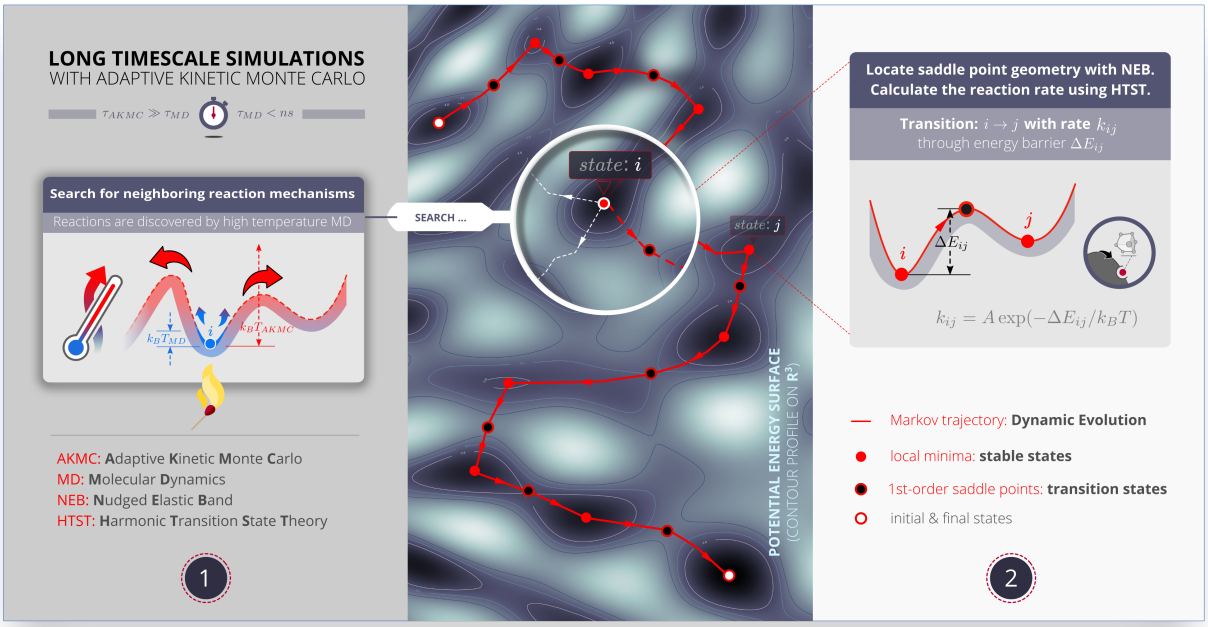
AKMC_ATK2017.py AKMC_ATK2016.py AKMC_ATK2015

In this tutorial you will learn how to run an Adaptive Kinetic Monte Carlo (AKMC) simulation to investigate the diffusion of a Pt adatom on a Pt(100) surface.

Introduction

How an atom diffuses on the surface is important to understand material properties and processes such as adsorption phenomena, thin-film growth, and sintering. Especially defect sites with vacancies or adsorbates on the surface are critical to determining the reaction pathway and rate. In general, an atom has two possible diffusion paths on a surface; by the exchange mechanism or the hopping mechanism. In this tutorial, we examine the diffusion path of a Pt adatom on the Pt(100) surface.

However, there is significant difference between the timescale of these rare events and the timescale of nano- or microseconds which is achievable with direct classical dynamics simulations. There are several approaches to bridging this time scale gap. One of these methods is *Adaptive Kinetic Monte Carlo (AKMC)* which can be used to speed up the saddle point searches along the potential energy surface quite effectively. In the next section, we will introduce the details of the AKMC method.



The AKMC method

In solid state systems, atoms reside near their equilibrium positions and reactions are rare events. Because the reactions occur on a much longer timescale than the typical vibrational period of the system (~100 fs), it is not possible to use molecular dynamics (MD) simulations to model solid-state reactions. MD simulations can only routinely access the nanosecond timescale while room temperature solid-state reactions of interest may occur on the millisecond timescale or longer.

Adaptive Kinetic Monte Carlo (AKMC) is a powerful tool for simulating the dynamics of solid-state systems that works by identifying the bottleneck regions between the stable minima and then modeling the reactions between them using statistical mechanics. More specifically, the bottleneck regions are the saddle points on the potential energy surface. These points lie on the minimum energy pathway between two minima, which is the statistically most likely path for a reaction to occur along. The primary computational expense in an AKMC simulation is in locating these saddle points.

In the AKMC implementation in QuantumATK, the saddle points are located by running high temperature MD trajectories. These trajectories should be hot enough that a few picoseconds of dynamics will be sufficiently long for a reaction to occur. The saddle points are located by periodically minimizing the MD trajectory to detect when the trajectories minimizes to a new geometry. Once the new minimum is located, the saddle point is found by running a nudged elastic band (NEB) calculation.

Once the saddle points are identified, the reaction rates can be estimated using harmonic transition state theory (HTST). In HTST, the reaction rate is given by:

$$k = A \exp\left(- \frac{E}{k_B T} \right)$$

where k is the reaction rate, A is the vibrational prefactor, E is the difference in energy between the saddle point and the minimum (energy barrier), k_B is Boltzmanns constant, and T is the temperature.

The HTST rates can then be used to run a kinetic monte carlo (KMC) simulation. In KMC, the system is represented using a Markov chain. Each state of the Markov chain represents a stable state of the system (a local energy minimum) and the transition probabilities between the states are related to the reaction rates (determined from the saddle points). The state of the system is evolved from minimum to minimum. The next state is chosen with a probability proportional to its rate. The amount of time taken to transition to the next state is drawn from an exponential distribution with a rate parameter equal to the total escape rate from the state. When the dynamics are modeled in this way, the computational cost to model one step of the dynamics is very small. Tens of thousands of steps can be performed per second on a typical computer.

For the AKMC simulation to be accurate, it is crucial that the fastest reaction mechanisms are discovered as they represent the most likely events to be chosen in the KMC simulation. To ensure the accuracy of the simulation, each state in the Markov chain has an associated confidence. This confidence is an estimate of the probability that for each KMC step taken from that state, the correct event was chosen. Saddle searches are executed in each state until a user defined confidence level is reached. Once the confidence level is reached, the KMC simulation will proceed until a state is reached where the confidence is less than the target level.

Below is a basic flowchart for the AKMC algorithm. The *adaptive* part finds saddle points in inner loops. The *KMC* part updates the total time and the current configuration.

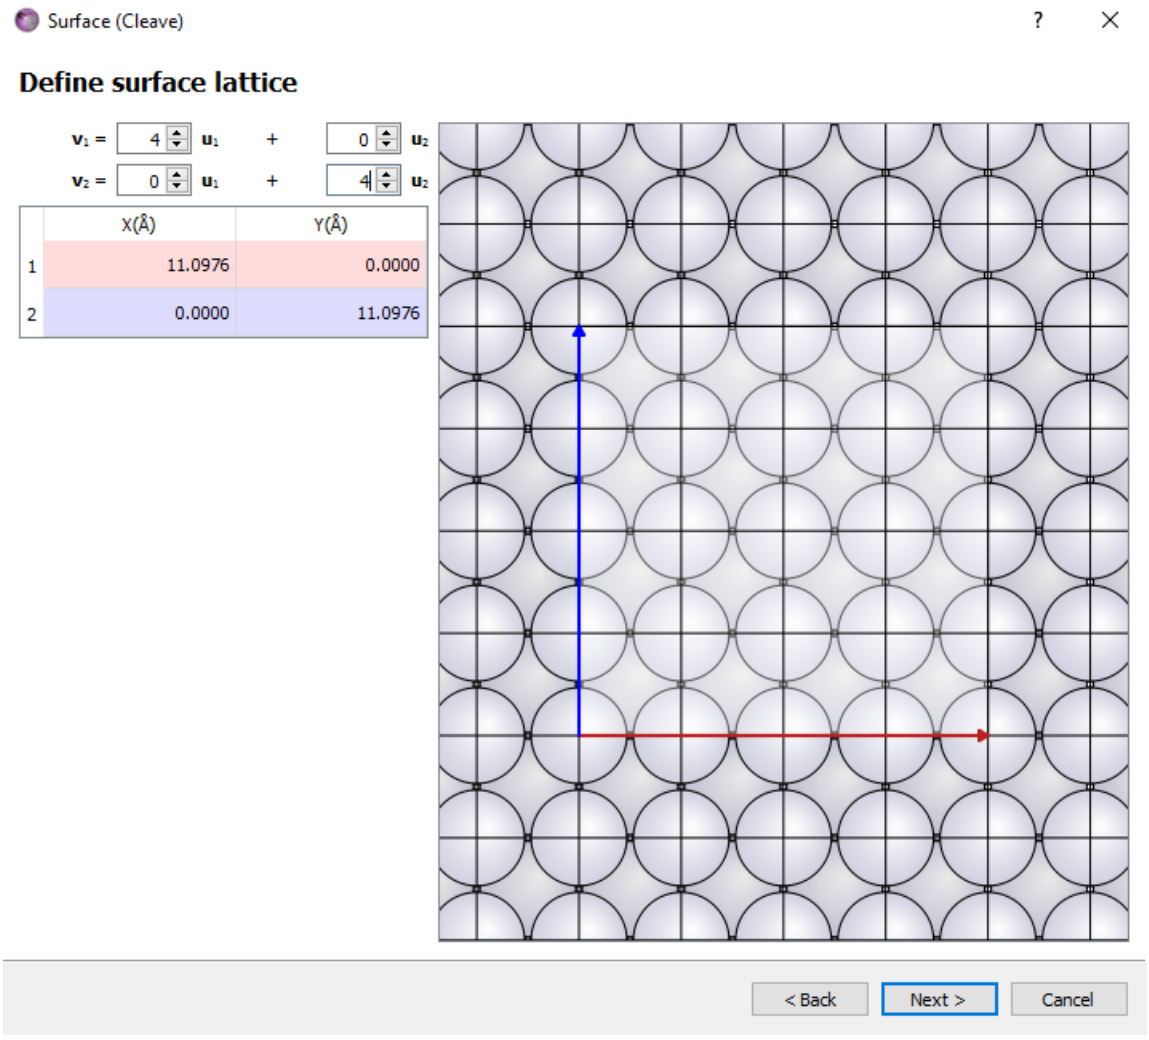
FINAL CONFIGURATION

For more details on AKMC and HTST see f.ex.[1] and[2]. For an introduction to KMC see[3].

Creating the initial configuration

The initial configuration will be a 4 layer *p* (4x4)-Pt(100) slab with a single adatom occupying a four-fold hollow site.

1. As the first step, import the Pt *fcc* bulk configuration by clicking on *Add* → *From Database* and search for *Platinum*. The Pt primitive cell will appear in the Stash.
2. Click on *Builder* → *Surface (Cleave)*
3. In the new window choose the (100) Miller indices.
4. Define the *p* (4x4) surface unit cell.

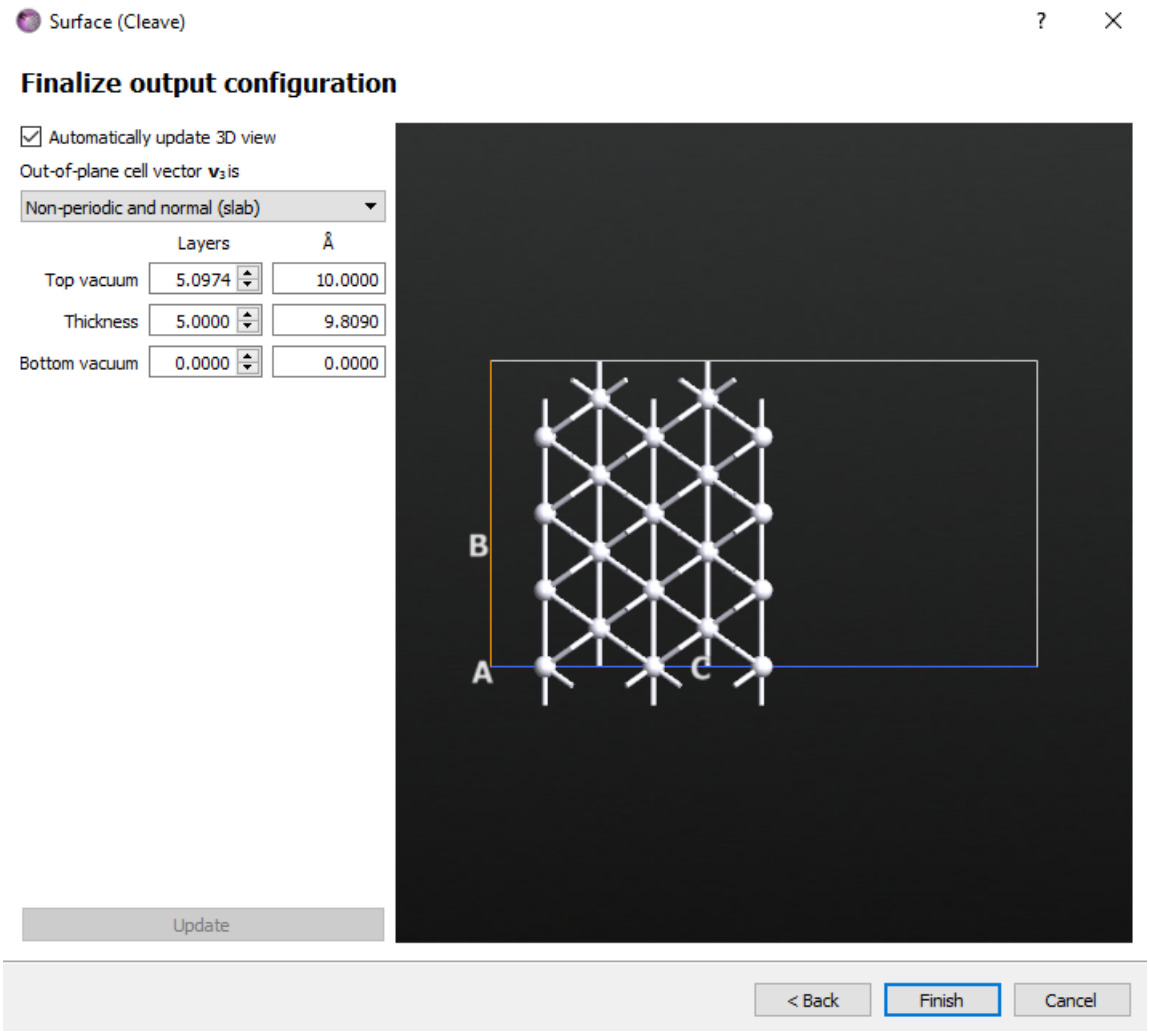


5. Choose the *non-periodic and normal (slab)* configuration with five layers, 10 Å of top vacuum. Click Finish.

[1] SamuelăT. Chill and Graeme Henkelman. Molecular dynamics saddle search adaptive kinetic Monte Carlo. *The Journal of Chemical Physics*, 140:214110, 2014. doi:10.1063/1.4880721.

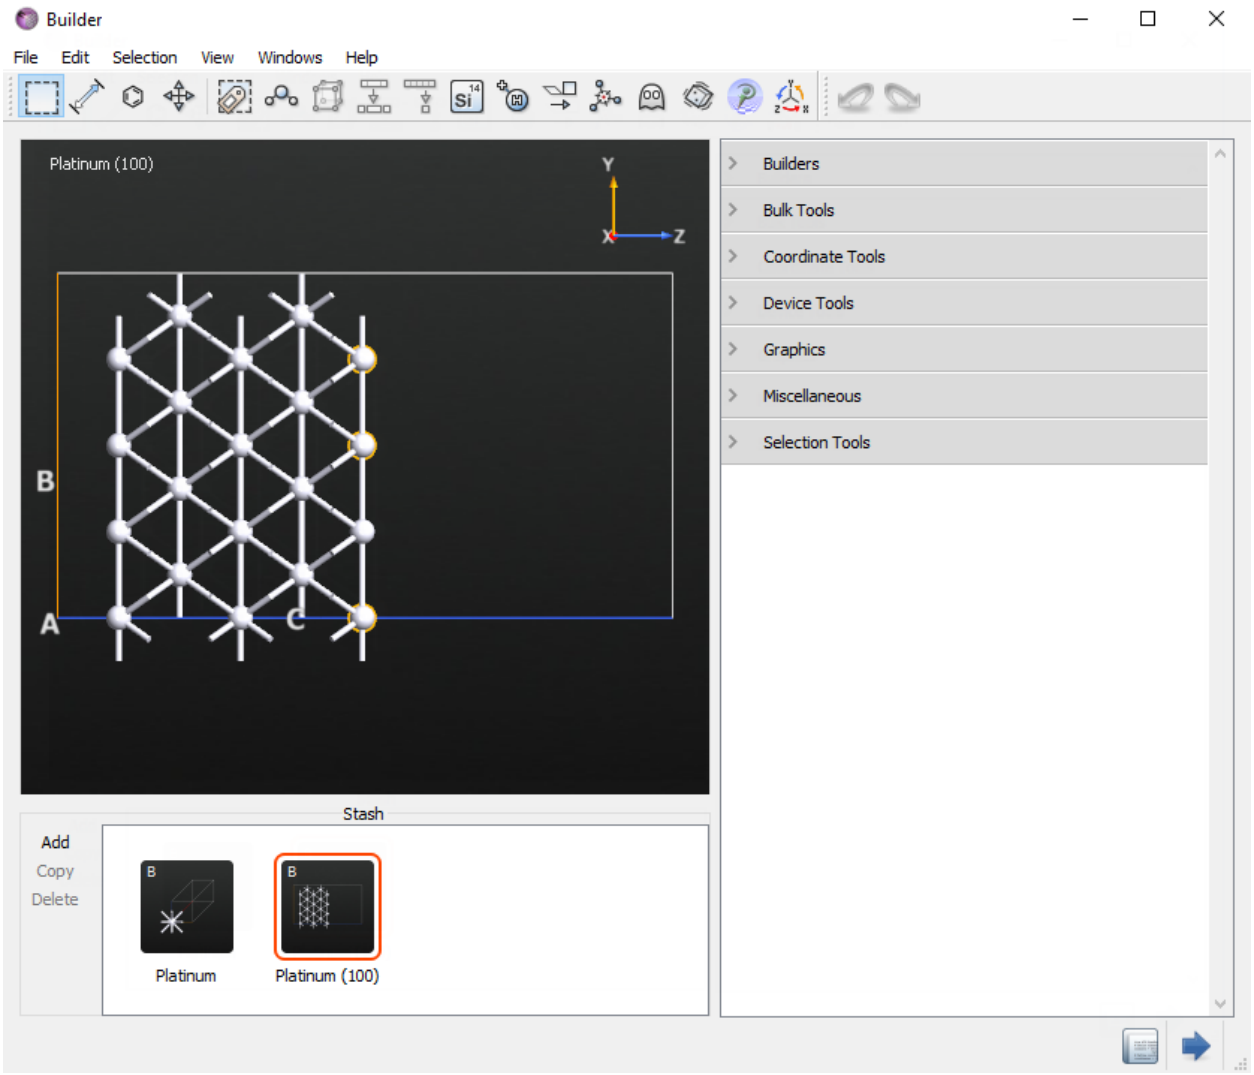
[2] L.ăXu and G.ăHenkelman. Adaptive kinetic Monte Carlo for first-principles accelerated dynamics. *Journal of Chemical Physics*, 129(11):114104, 2008. doi:10.1063/1.2976010.

[3] ArthurăF. Voter. *Introduction to the Kinetic Monte Carlo Method*, pages 1–23. Springer Netherlands, Dordrecht, 2007. URL: http://dx.doi.org/10.1007/978-1-4020-5295-8_1, doi:10.1007/978-1-4020-5295-8_1.

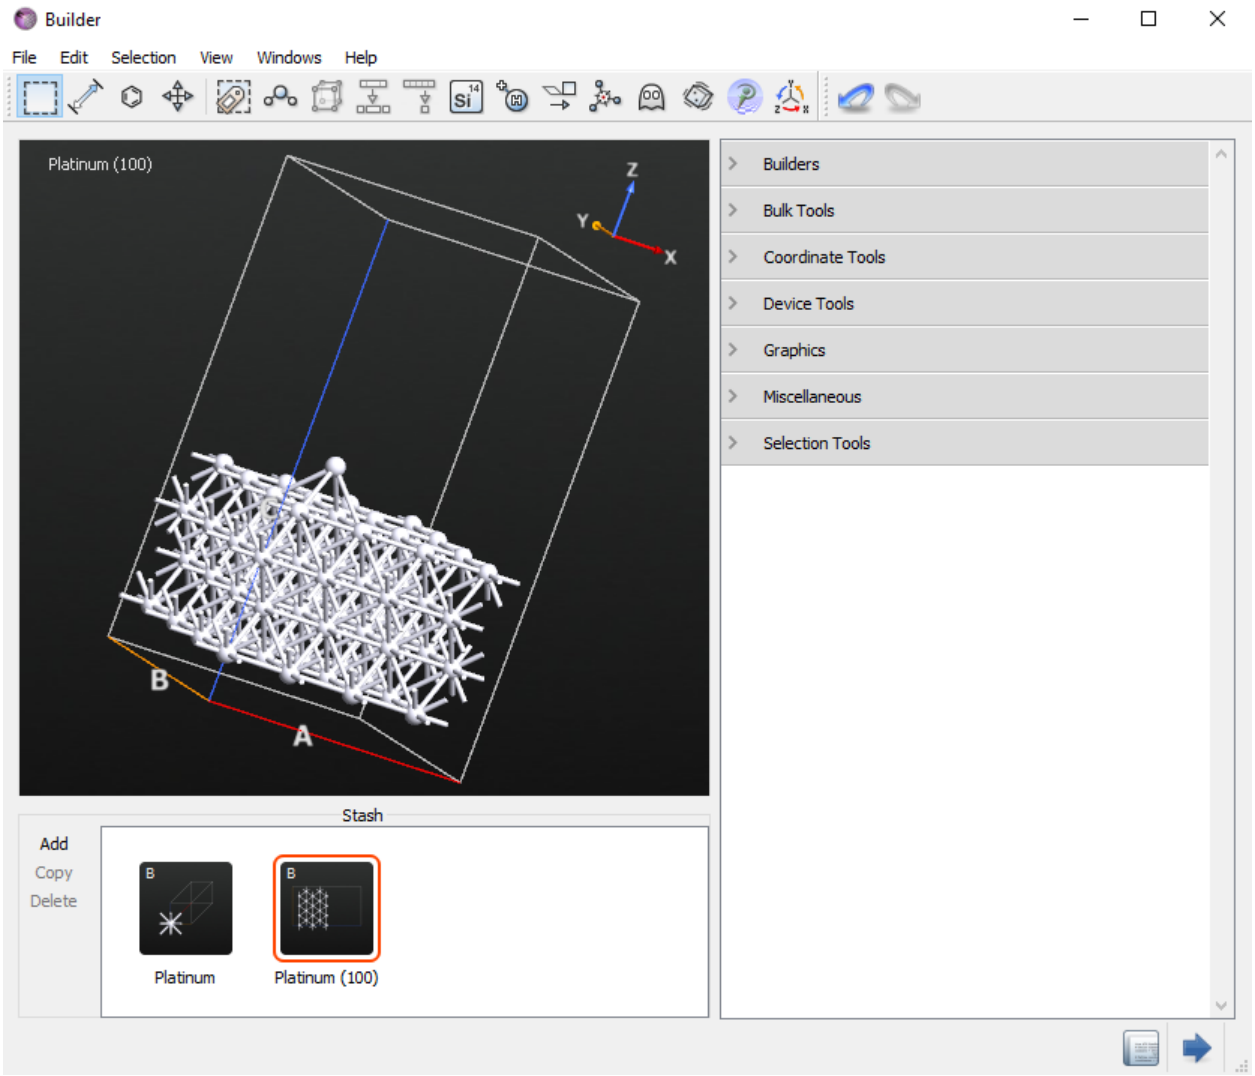


Your Pt(100) slab is now present in the **Stash**. The next step is to add the Pt adatom in a four-fold hollow position. Instead of adding a new atom on top of the slab, we will instead delete all but one atom from the topmost layer.

1. Select three of the four top rows of atoms as shown below and then press the delete key.



2.Now rotate the configuration so that the remaining row of four surface atoms is visible. Select three of the four atoms and then press the delete key. The final surface should have just one adatom in a four-fold hollow site.



Creating the AKMC script

Now that we have the initial configuration, we can start the AKMC simulation.

1. Send the initial configuration to the **Script Generator** by clicking the button.

2. Add **New Calculator** and *Optimization* → *OptimizeGeometry* blocks.

3. Change the output name to `akmc.nc`.

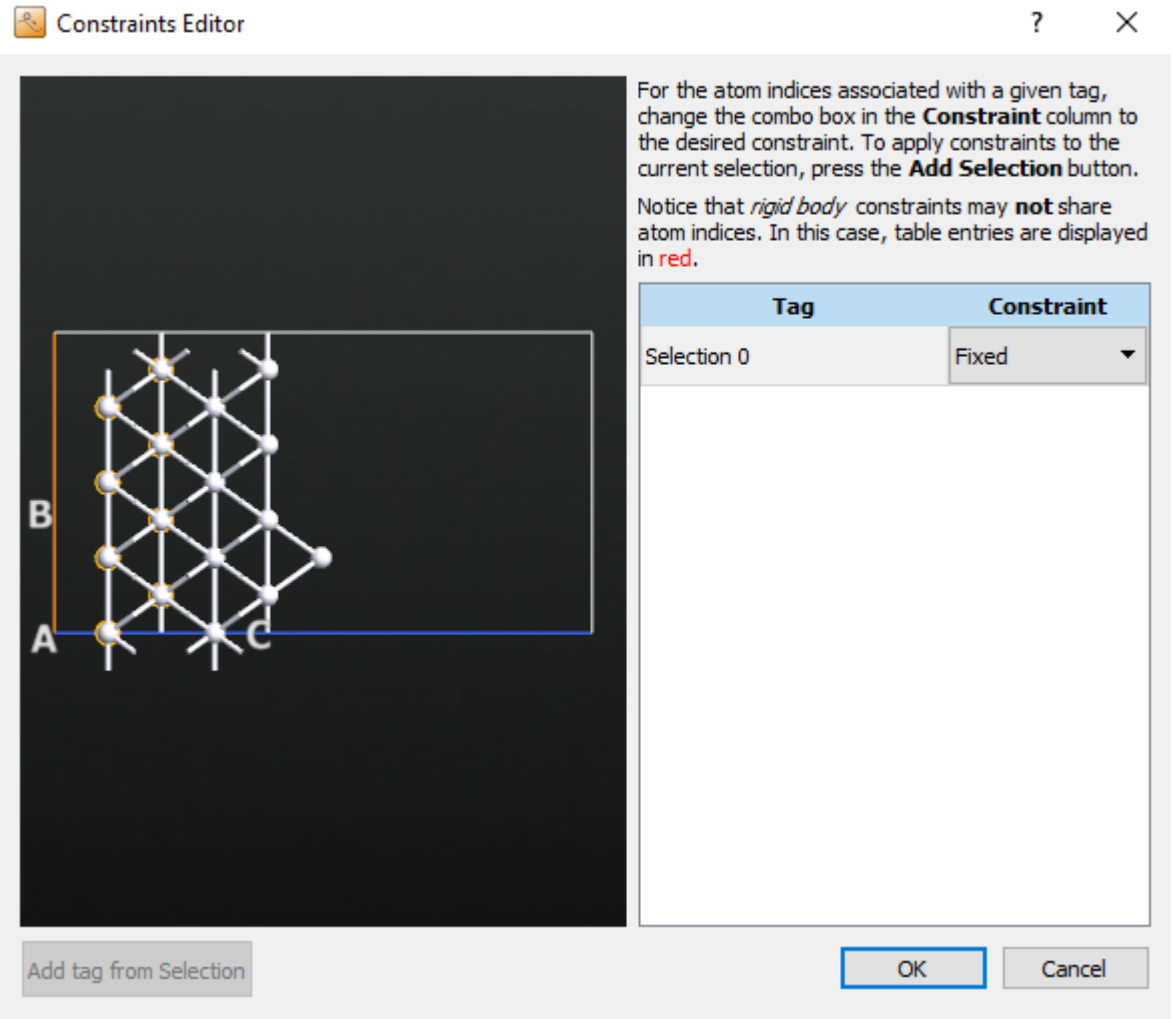
4. Double-click the **New Calculator** block and modify the following parameters:

   - Select the ATK-ForceField calculator
   - Choose the EAM_Pt_2004 Parameter set

5. In the **OptimizeGeometry** block, change the following parameters:

   - Set the maximum force to 0.01 eV/Å

•Click the *Atomic Constraint Editor* button, select the 2 bottom layers, click *Add tag from Selection*, and change the constraint type from None to *Fixed*



Now, you will add the AKMC part of the script.

Note: Starting from the **ATK 2017** version, you can use the **AdaptiveKineticMonteCarlo** block in the Script Generator. While if you have an older version, you need to follow the below instructions on appending the AKMC code in the editor. *Link to 2016 and 2015 versions*.

Note: For QuantumATK-versions older than 2017, the **ATK-ForceField** calculator can be found under the name **ATK-Classical**.

In the **2017** version, add the *OptimizeGeometry* → *AdaptiveKineticMonteCarlo* object, and double click the **AdaptiveKineticMonteCarlo** block. You can see the warning for the Atomic Constraint Editor setting. You need to define the atomic constraint *again*, usually in the same way as in the Optimization, but not necessarily

•In **Kinetic Monte Carlo**, change the *confidence* to 0.95

•In **Saddle Search** Settings, set the *number of searches* to 100

•Click the *Atomic Constraint Editor* in the **Optimization**, select the two bottom layers, change to *Fixed* for the constraint.

•For **Nudged Elastic Band**, *Maximum number of images* is 5 and check *the Climbing image method*

Note: If you need more information to setup the condition, click the **Help** button in the Adaptive Kinetic Monte Carlo widget.

If you now send the script to the editor, you will see the following at the end of the script.

```
# ------------------------------------------------------------
# Adaptive Kinetic Monte Carlo
# ------------------------------------------------------------

saddle_search_parameters = SaddleSearchParameters(
    max_neb_images=5,
    neb_climbing_image=True,
    )

if os.path.isfile('akmc_markov_chain.nc'):
    markov_chain = nlread('akmc_markov_chain.nc')[-1]
else:
    markov_chain = MarkovChain(
        configuration=bulk_configuration,
        configuration_energy=TotalEnergy(bulk_configuration).evaluate(),
        )

if os.path.isfile('akmc_kmc.nc'):
    kmc = nlread('akmc_kmc.nc')[-1]
else:
    kmc = None

constraints = [ 0,  1,  2,  3,  4,  5,  6,  7,  8,  9, 10, 11, 12,
                13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25,
                26, 27, 28, 29, 30, 31]

akmc = AdaptiveKineticMonteCarlo(
    markov_chain=markov_chain,
    kmc_temperature=300.0*Kelvin,
    md_temperature=2000.0*Kelvin,
    calculator=bulk_configuration.calculator(),
    kmc=kmc,
    saddle_search_parameters=saddle_search_parameters,
    constraints=constraints,
    confidence=0.95,
    filename_prefix='akmc',
    )

akmc.run(max_searches=100, max_kmc_steps=10000)
```

Note: If you look at the **2017** version of the script, there are two *if* blocks for repeating runs; it reuses the already

completed saddle searches.

In **ATK 2016** and **ATK 2015**, send the script to the **Editor** using the **Send To** icon. Then append the below code to the bottom of the script.

•ATK 2016

```
# ------------------------------------------------------------
# AKMC
# ------------------------------------------------------------
saddle_search_parameters = SaddleSearchParameters(max_neb_images=5)
markov_chain = MarkovChain(bulk_configuration, TotalEnergy(bulk_configuration).
↪evaluate())
akmc = AdaptiveKineticMonteCarlo(markov_chain,
                                 kmc_temperature=300.0*Kelvin,
                                 md_temperature=2000*Kelvin,
                                 calculator=calculator,
                                 saddle_search_parameters=saddle_search_parameters,
                                 write_searches=True,
                                 constraints=fix_atom_indices_0,
                                 confidence=0.95)
akmc.run(100)
```

•ATK 2015

```
# ------------------------------------------------------------
# AKMC
# ------------------------------------------------------------
saddle_search_parameters = SaddleSearchParameters(max_neb_images=5)
markov_chain = MarkovChain(bulk_configuration, TotalEnergy(bulk_configuration).
↪evaluate())
akmc = AdaptiveKineticMonteCarlo(markov_chain,
                                 kmc_temperature=300.0*Kelvin,
                                 md_temperature=2000*Kelvin,
                                 calculator=calculator,
                                 saddle_search_parameters=saddle_search_parameters,
                                 write_searches=True,
                                 constraints=constraints,
                                 confidence=0.95)
akmc.run(100)
```

Note: The only difference between the **2016** and **2015** versions is how the constraints are defined.

This code defines an AKMC simulation that will model the dynamics of the system at 300 K (kmc_temperature). The MD saddle searches will be performed at 2000 K (md_temperature). The confidence is set to 95% (confidence).

Save the script as `akmc.py` and send it to the **Job Manager** and run it.

In this case, the calculation will take around 2 hours to complete when run in serial. Additionally, the AKMC simulation can be parallelized using MPI. When run in parallel one MPI process is reserved as the *master* process that schedules the work. The remaining *worker* processes are then used to carry out the saddle searches. This means that if two MPI

processes are used no speedup will be observed since there will only be one worker process. There should be a linear speedup as the number of MPI processes is increased.

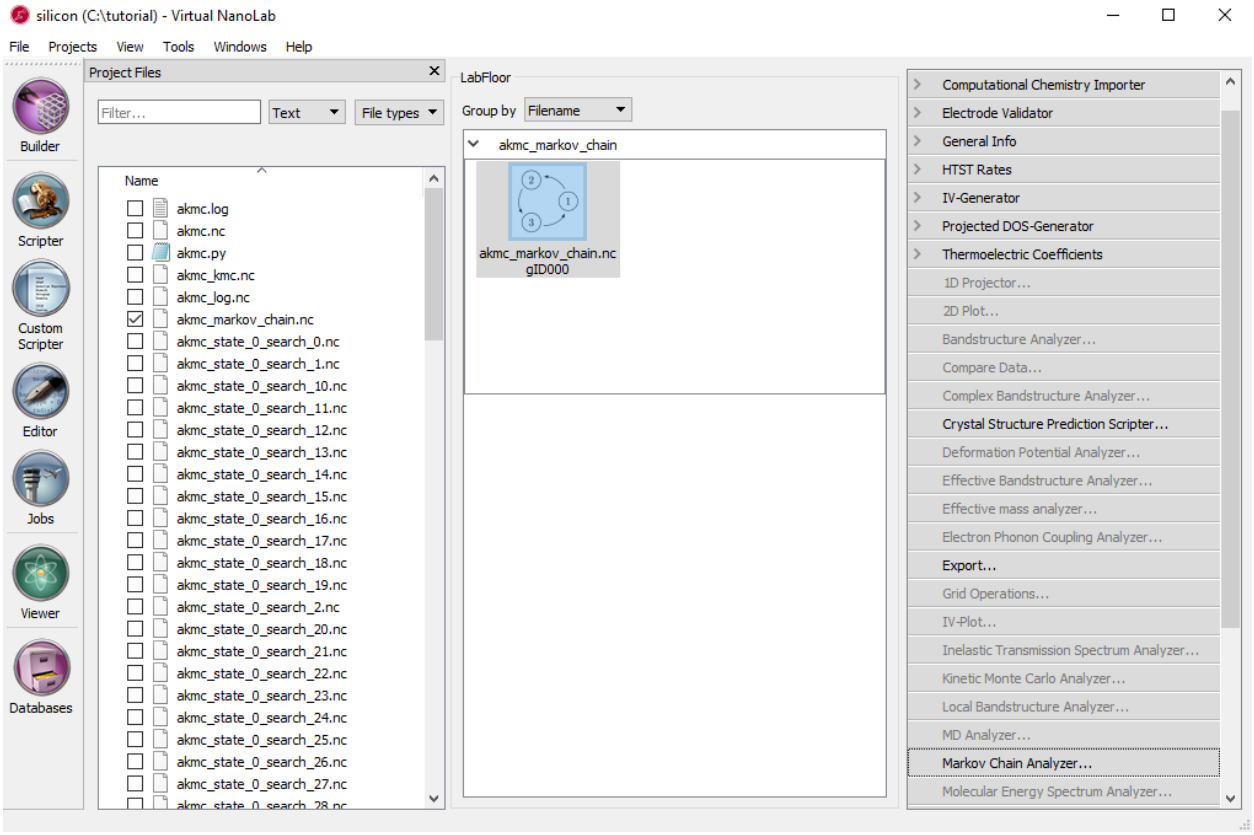
Analyzing the results

Note: Since AKMC is a stochastic method, your results may differ slightly from what is shown here.

Since a large number of files are created during the calculation, it may be useful to click on the list of project files and click *Uncheck*. But if you uncheck the *write searches* box in the *I/O settings* in the AKMC widget or set *write_searches = False* in the script, fewer files will be written.

Markov Chain Analyzer

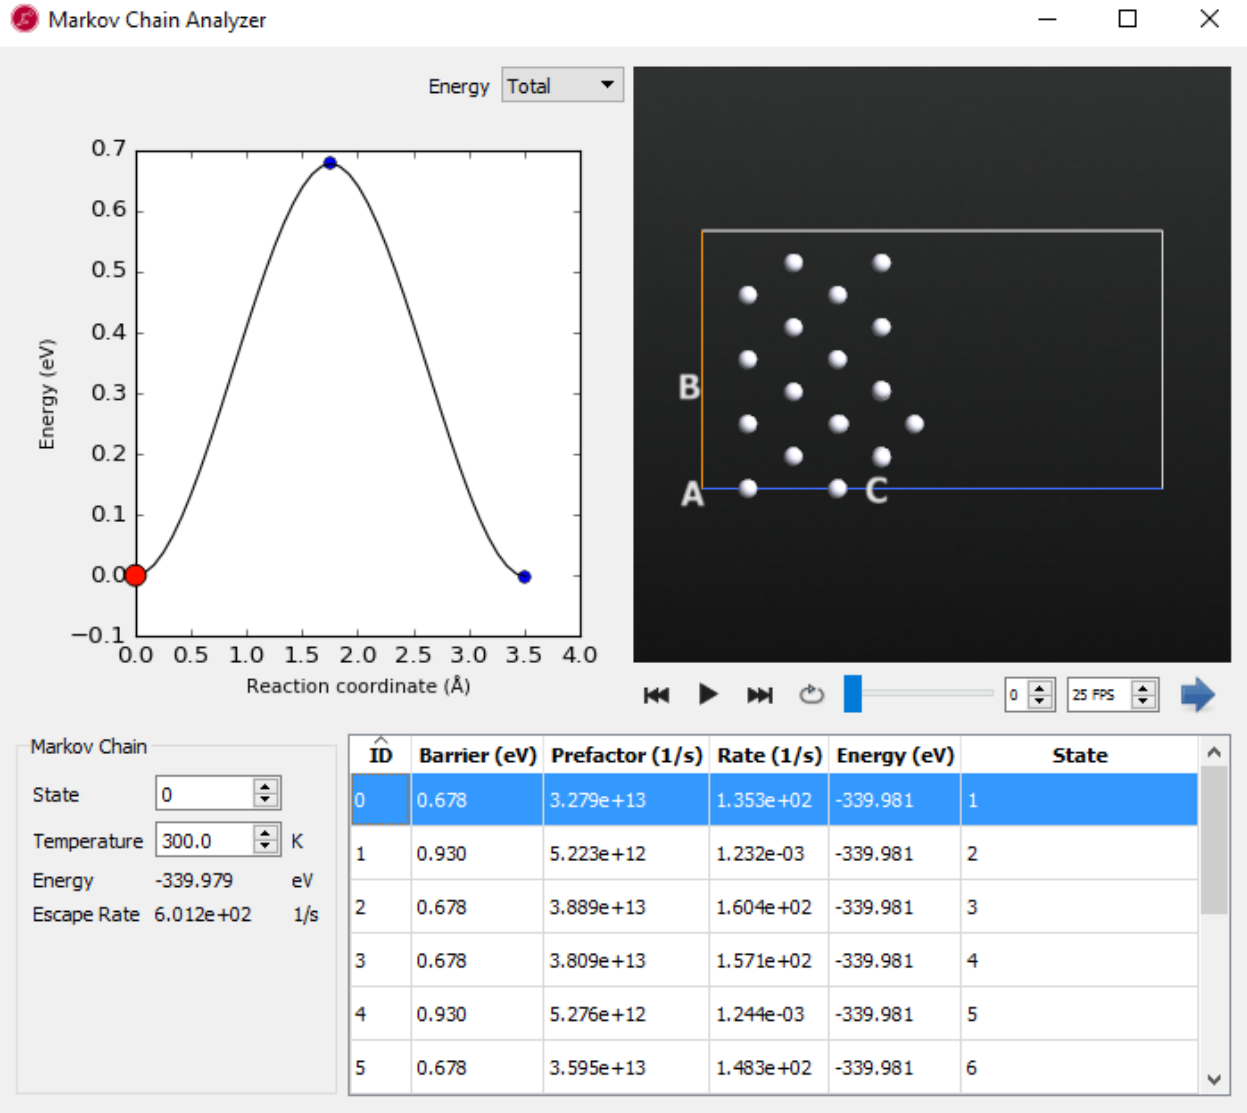
The file `akmc_markov_chain.nc` contains all of the saddle points and minima that were found during the calculation. Check the box next to the filename to load it onto the **LabFloor**. Then select it and click on the **Markov Chain Analyzer** button in the panel.



The new window that popped up can be used to examine all of the minima and saddle points that make up the Markov chain.

State 0 is shown in the below table, this corresponds to the initial configuration made at the beginning of this tutorial. By clicking on item in the table, different events can be visualized. In the top left, an energy coordinate diagram is shown for the event and in the top right is a viewer for the trajectory of the minima and saddle point configurations.

For each event, the energy barrier, harmonic prefactor (the variable A in the HTST equation above), reaction rate at the current temperature, and the energy of the final state as well as the state number for the final state are displayed.



ID	Barrier (eV)	Prefactor (1/s)	Rate (1/s)	Energy (eV)	State
0	0.678	3.279e+13	1.353e+02	-339.981	1
1	0.930	5.223e+12	1.232e-03	-339.981	2
2	0.678	3.889e+13	1.604e+02	-339.981	3
3	0.678	3.809e+13	1.571e+02	-339.981	4
4	0.930	5.276e+12	1.244e-03	-339.981	5
5	0.678	3.595e+13	1.483e+02	-339.981	6

In these results you can see that there are 4 identical reactions with a barrier of 0.678 eV. By using the viewer to look at the saddle point configuration it is apparent that these correspond to the so-called exchange mechanism of adatom diffusion where the adatom pushes a surface atom up onto the surface.

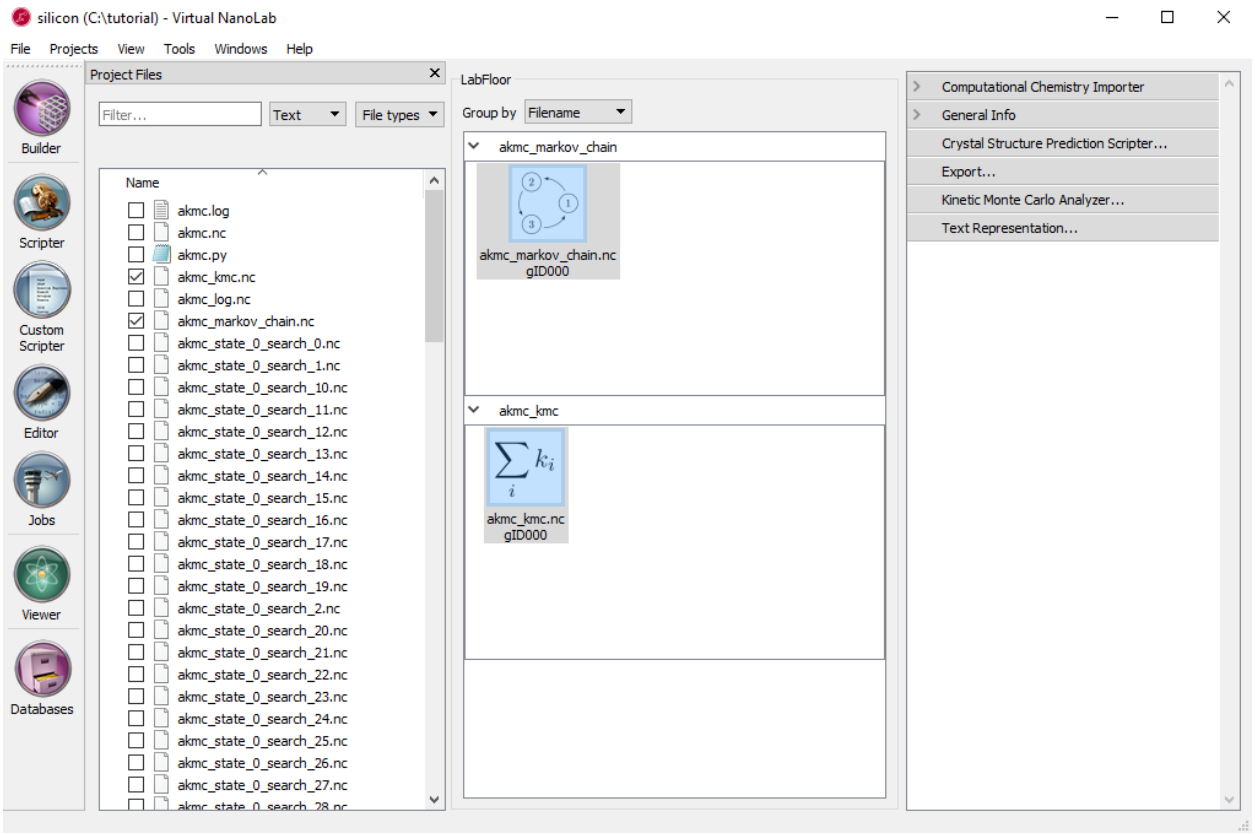
This is in contrast to the most obvious diffusion mechanism - the hop - where the adatom directly moves to an adjacent four-fold hollow site. The relative rates of these two diffusion mechanisms show that at room temperature the exchange mechanism is the primary way that the adatom diffuses. This is because the rate of the exchange mechanism is 5 orders of magnitude larger than the hop mechanism.

Kinetic Monte Carlo Analyzer

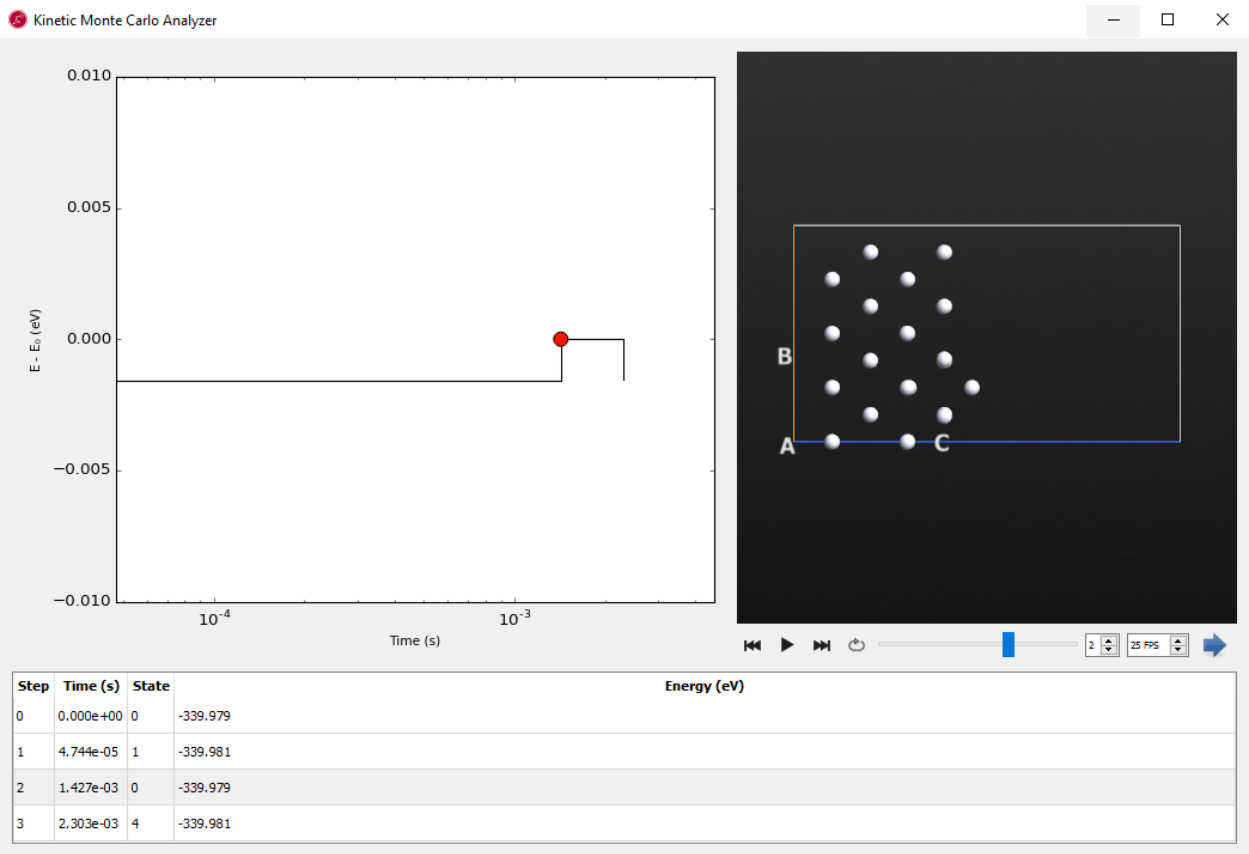
The file named `akmc_kmc.nc` contains the state-to-state KMC trajectory. Click the checkbox next to the filename to load it onto the **LabFloor**. Click on its icon and click **Text Representation** in the panel. The popup window will display the state of the KMC simulation as a function of time. The state number in the right-hand column corresponds to the state numbers in the Markov chain file we just looked at. In this example, the simulation took one step from state 0 to state 1 and 47 microseconds of time elapsed.

```
# Item:  0
# File:  C:\tutorial\akmc_kmc.nc
# Title: akmc_kmc.nc - gID000
# Type:  KineticMonteCarlo
     Step #   Time (seconds)  State
        0   0.00000000e+00      0
        1   4.74388502e-05      1
        2   1.42688935e-03      0
        3   2.30287130e-03      4
```

A graphical representation of the KMC trajectory is also available. In order to use it, both the *KineticMonteCarlo* and *MarkovChain* objects on the **LabFloor** must be selected. Then you may click on **Kinetic Monte Carlo Analyzer** in the panel.



The Kinetic Monte Carlo Analyzer displays the same information shown in the text representation in the table at the bottom of the windows. However, it also makes a plot of the energy versus time and shows the geometry of the currently selected state. Since the energy plot is logarithmic on the time axis the first state at zero seconds cannot be seen, and there are only three data points. The energies are plotted by the difference between the first state 0 and searched state versus time.



Step	Time (s)	State	Energy (eV)
0	0.000e+00	0	-339.979
1	4.744e-05	1	-339.981
2	1.427e-03	0	-339.979
3	2.303e-03	4	-339.981

AKMC Log

The next file to examine is `akmc_log.nc`. This file contains a brief summary of the outcome of each of the saddle searches used to find the states shown above. Click the checkbox next to the filename to load it onto the **LabFloor**. Click on its icon and click **Text Representation** in the panel.

```
# Item:  0

↪frequency, not 2 negative frequencies.
       0            11   0.444580  Found new state
```

(continues on next page)

(continued from previous page)

```
      0            12   0.670587  Found saddle connecting to state 4 again
      0            13   0.670587  First order saddles have exactly one negative␣
↪frequency, not 2 negative frequencies.
      0            14   0.670587  First order saddles have exactly one negative␣
↪frequency, not 2 negative frequencies.
      0            15   0.670587  First order saddles have exactly one negative␣
↪frequency, not 2 negative frequencies.
      0            16   0.692947  Found saddle connecting to state 4 again
      0            17   0.700029  Found saddle connecting to state 1 again
```

The output above shows the first 17 lines of output. Each line corresponds to a single saddle search.

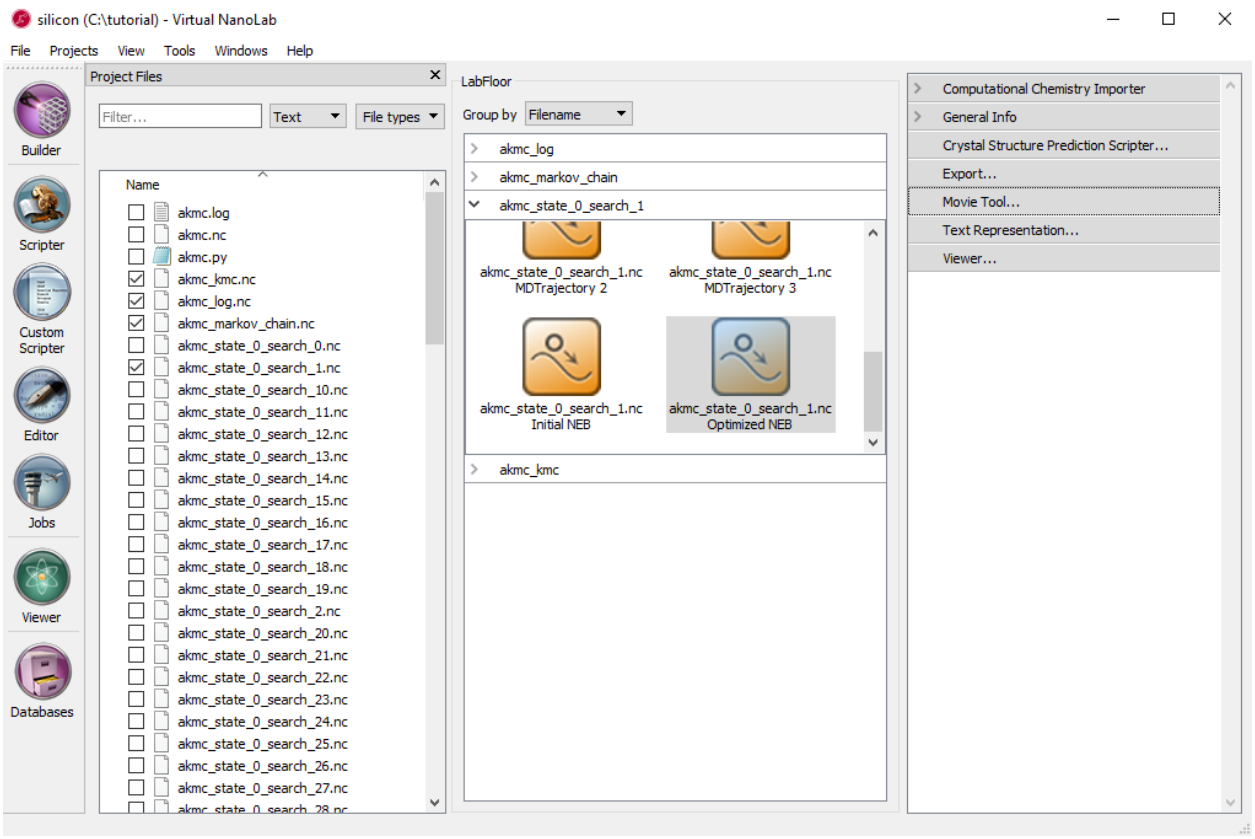
The *state id* column represents the id number for the state that the saddle searches are started from. The *search number* is unique identifier for each search. The *confidence* represents an estimate of the confidence in the KMC simulation for the state. The confidence is used as the stopping criteria for the saddle searches. The *message* column summarizes the result of the saddle search.

The message *Found new state* means that a new reaction mechanism was discovered. The message *Found saddle connecting to state 1 again* means that a previously discovered saddle point was found.

There are a number of possible error messages that can occur. In this case the message *First order saddles have one negative frequency not 2 negative frequencies* means that a saddle point was found, but when the vibrational modes were calculated more than one negative frequency was identified. There could be a number of reasons for this issue. Often times classical potentials are not fit near saddle points and can have unexpected behavior.

Diagnosing Errors

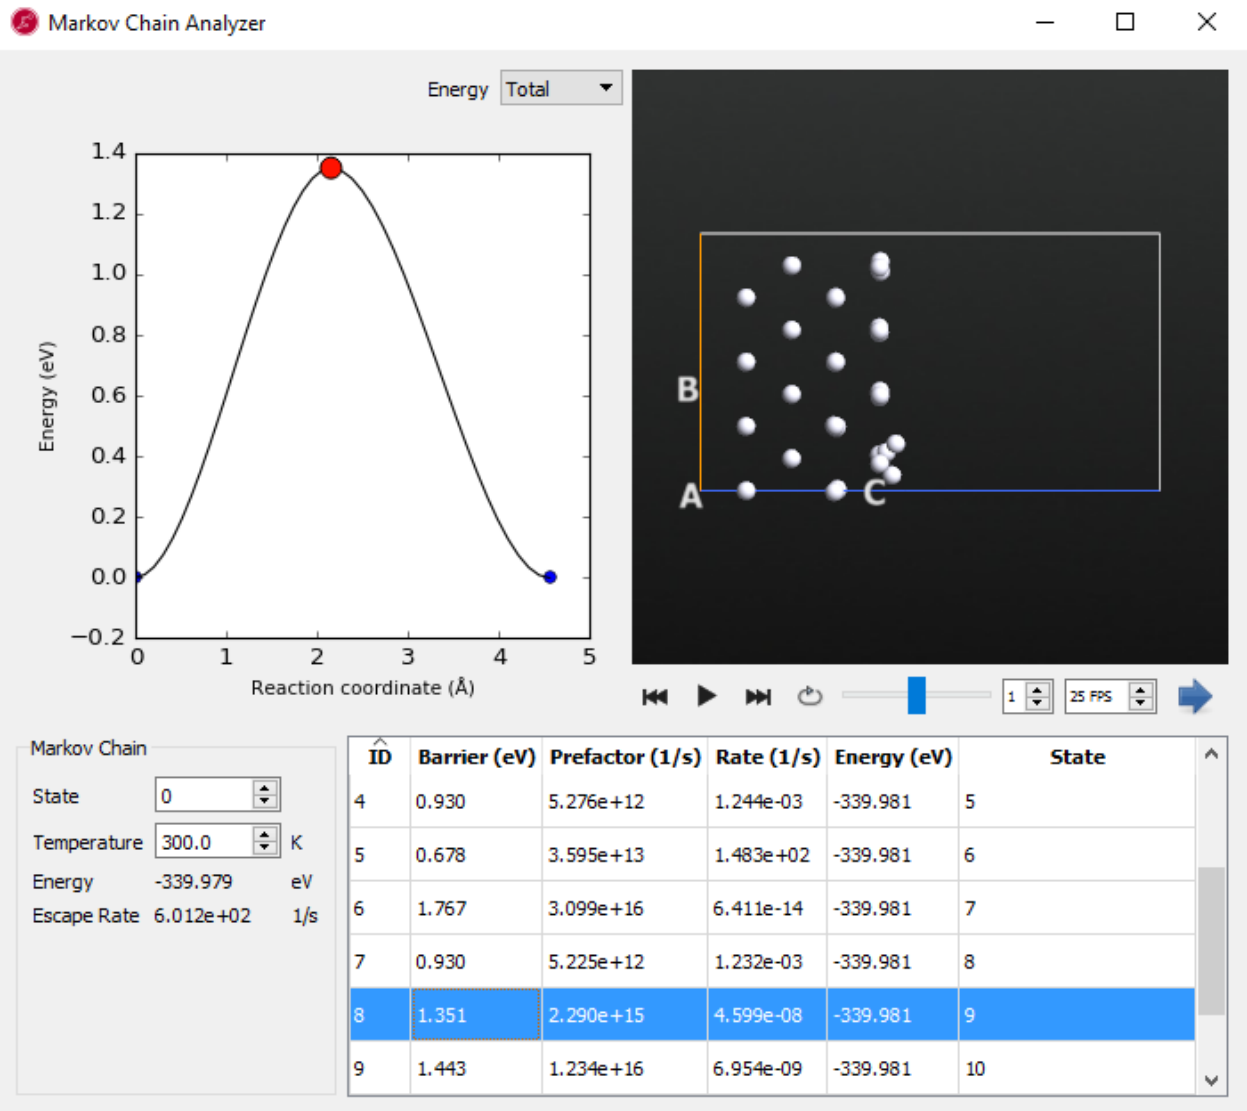
When there is an issue with a saddle search, an error message will be displayed in the log. The *state id* and *search number* columns can then be used to locate a file with more information about the search, if the parameter *write_searches=True* was passed to the *AdaptiveKineticMonteCarlo* class. In this case we look at search number 1. The filename is `akmc_search_0_search_1.nc`. Remember, in your simulation the numbers may be different. Click the checkbox by the filename of akmc search you wish to inspect. Then you can click on the *Optimized NEB* item and then click on **Movie Tool** in the panel to visualize the reaction pathway.



In general, if it was lower energy barrier, it will be an important reaction path. But in this case, we see that this is another type of exchange diffusion mechanism even higher in energy than the hopping mechanisms that we already showed was too slow to contribute to adatom diffusion.

By using the *Movie Tool* in the **Markov Chain Analyzer**, we can examine each state to understand the diffusion mechanism.

In a real study it is always important to verify the results of a classical potential and re-optimizing this NEB using DFT would be a good idea to determine if it was a real pathway in the system.



Conclusion

In this tutorial we examined how to construct a Pt(100) slab model with a single adatom. We then performed an AKMC simulation to model the diffusion of the adatom at 300 K. The results showed two different diffusion mechanisms: the exchange and hop processes. The exchange process was found to be the dominant mechanism for adatom diffusion.

This simulation was a very simple case. No matter how the adatom diffuses the system is the same by symmetry (i.e. the adatom will always have the same set of 4 exchange and 4 hop diffusion mechanisms). So once one state has been explored, there is nothing left to learn. However, in the current implementation, the AKMC code does not take symmetry into account and must do saddle searches for each new state. Most systems of interest do not contain such high levels of symmetry.

References

3.11.20 Crystal Structure Prediction Scripter: Phases of TiO_2

Version: 2016.2

In this tutorial, we will use the Crystal Structure Prediction method to investigate the possible crystal structures of TiO_2. At zero temperature and pressure, the *rutile* phase of TiO_2 is the most stable one, while the *anatase* and *brookite* phases are meta-stable. Both rutile and anatase can be described in a unit cell of 6 atoms, while brookite requires a much larger cell. QuantumATK uses a genetic algorithm for crystal structure prediction.

Note: A **genetic algorithm** is a method for solving both constrained and unconstrained optimization problems based on a natural selection process that mimics biological evolution. The algorithm repeatedly modifies/refines a population of individual solutions.

In practice, the algorithm starts out from an initial population of crystals (a generation), and iteratively refines the generation by producing new generations through application of **genetic operators** to the previous generation, e.g. *promotion* (lowest-energy crystals live on), *heredity* (mixing of good genes from two different low-energy crystals), as well as *mutation* and *permutation* (ensures genetic diversity).

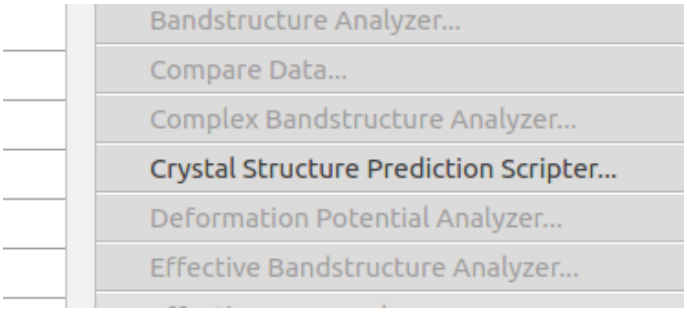
Please refer to[1],[2] and[3] for more information.

Setting up the calculation

We will use the **Crystal Structure Prediction Scripter**, which is available in recent versions of QuantumATK. This custom scripter widget is used to produce a template script for running the crystal structure prediction algorithm. The scripter does not add script lines defining the specific calculator engine to be used – they must be added manually.

Crystal Structure Prediction Scripter

Open the Crystal Structure Prediction Scripter from the right-hand plugins panel in QuantumATK.



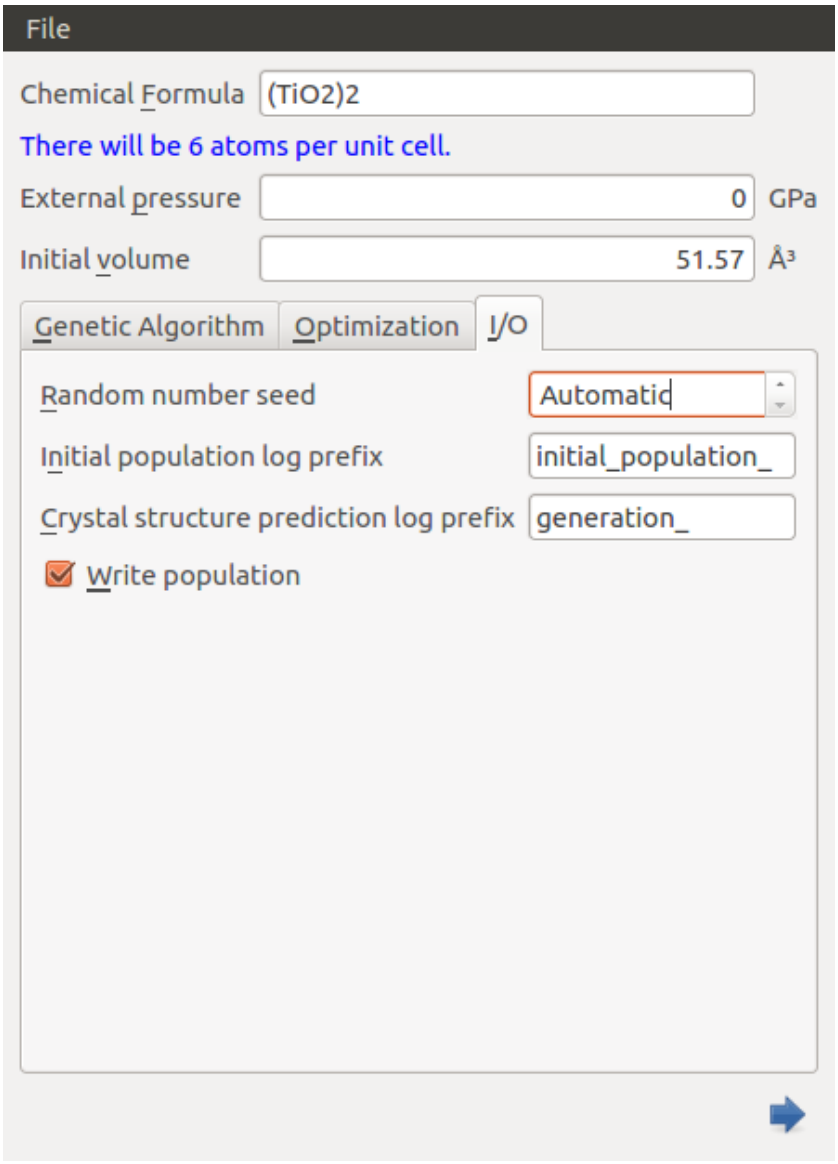
The widget will open, and will initially display the I/O tab.

[1] WilliamăW Tipton and RichardăG Hennig. A grand canonical genetic algorithm for the prediction of multi-component phase diagrams and testing of empirical potentials. *J. Phys. Condens. Matter*, 25(49):495401, 2013. doi:10.1088/0953-8984/25/49/495401.

[2] ArtemăR. Oganov. *Modern Methods of Crystal Structure Prediction*. Wiley, 2011. ISBN 9783527643776.

[3] Eva Zurek. *Discovering New Materials via A Priori Crystal Structure Prediction*, pages 274–326. John Wiley & Sons, Inc, 2016. doi:10.1002/9781119148739.ch5.

First of all, you need to write the **chemical formula** of the crystal to investigate. In this case, you should write (TiO2)2 (or Ti2O4) as we need two TiO_2 formula units to describe the unit cells of both anatase and rutile. Leave the external pressure at 0 GPa. The initial volume will be set automatically, based on the expected volume of the elements. The window should now look as seen below.



Genetic algorithm settings

Next, set up the parameters for the genetic algorithm, which is used to search for viable crystal structures. Click the tab named Genetic Algorithm to start. It has the following parameters:

Population size
The number of crystal structures in each generation. Set this to 10.

Number of generations
The number of steps the algorithm will run. Set this to 20.

Selection pressure
Determines how strongly the fitness score (see note below) will be taken into account when individuals are selected for

application of a genetic operator. A high value will make it much more likely that genetic operators are applied to the individuals with the highest fitness, while a value of 0 will make all (elite, see below) individuals equally likely. Leave this value at 2.00.

Number of elites
The number of individuals which will be considered when creating the next generation. The difference between Population size and Number of elites indicates the number of individuals with lowest fitness that will simply be discarded after each iteration step. Leave this value at 10, so that no individuals will be discarded.

Number to promote
The number of individuals, with the highest fitness scores, which are promoted (copied) to the next step without any alteration. Set this to 4.

Note: The fitness score is defined as minus the enthalpy. This ensures that the algorithm searches for the thermodynamically most stable structures.

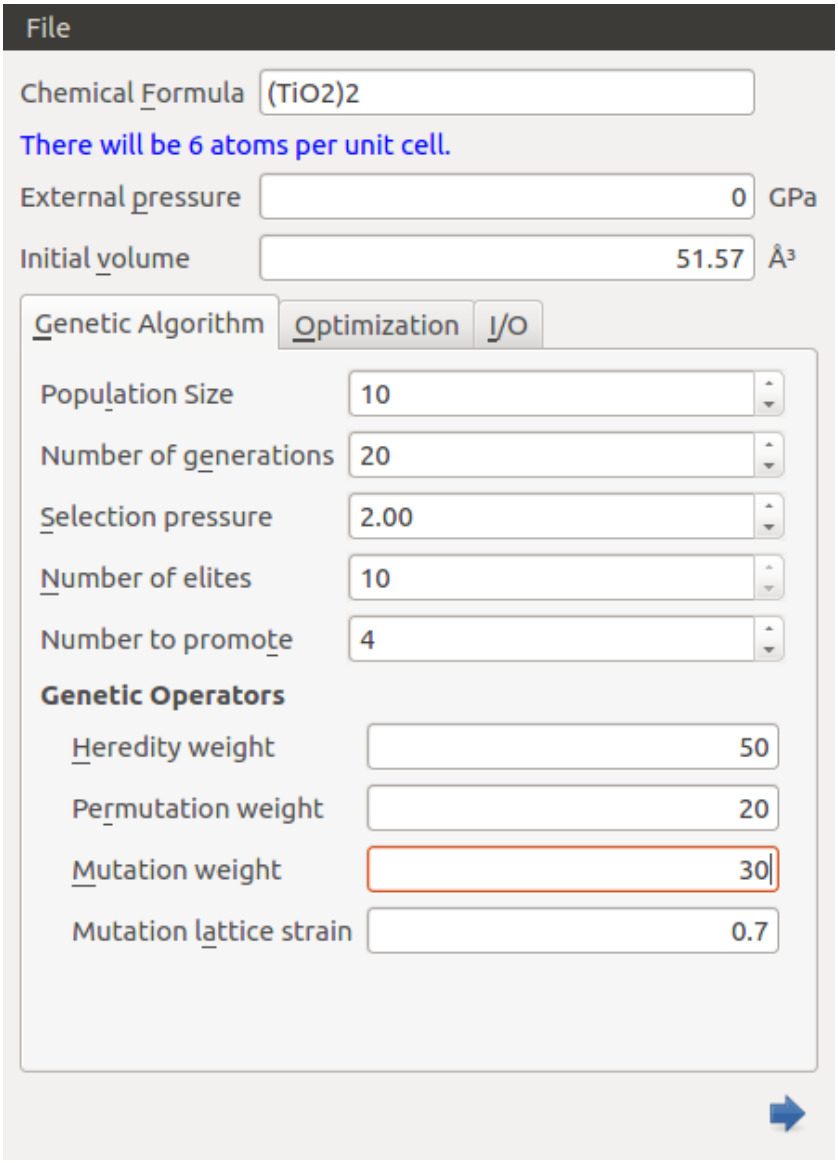
The remaining members of each new generation are created by applying **genetic operators** to the elite individuals from the previous generation. There are three genetic operators, with an additional setting for one of them. The probability of applying each operator is calculated from the following **weights**, which may be considered to be unnormalized probabilities.

Heredity weight
The unnormalized probability that the *Heredity* operation is used to create the next individual in the next generation. This operator uses two structures, and combines one-half of each as determined by a randomly chosen cut-plane. Set this value to 50.

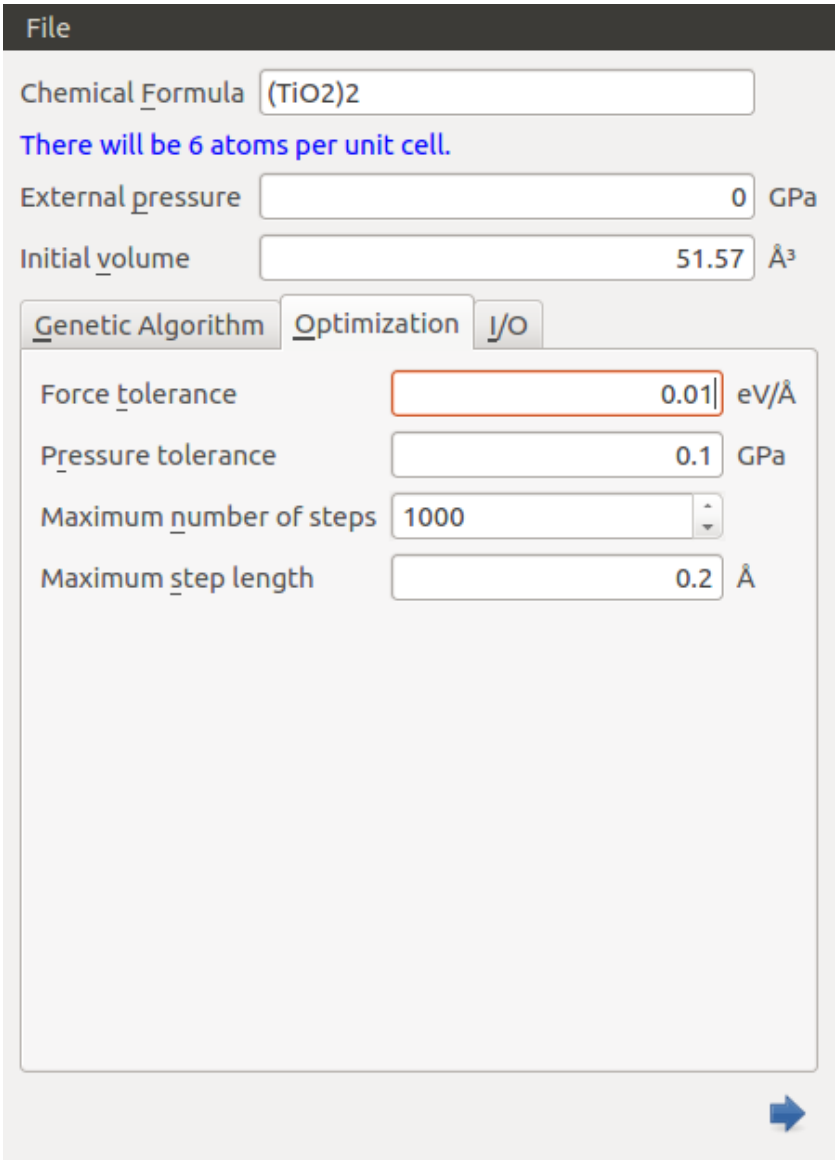
Permutation weight
The unnormalized probability of using the *Permutation* operator. This operator will exchange the positions of two randomly selected atoms of different elements. Set this value to 20.

Mutation weight
The unnormalized probability of using the *Mutation* operator. This operator applies a symmetric strain matrix with elements drawn randomly from a gaussian distribution with a standard deviation of *Mutation lattice strain*. This will change the lattice parameters and angles of the unit cell. Set the *Mutation weight* to 30 and leave the *Mutation lattice strain* at 0.7.

The Crystal Structure Prediction Scripter should now look like this:



Next, go to the **Optimization** tab and verify that it looks like this:

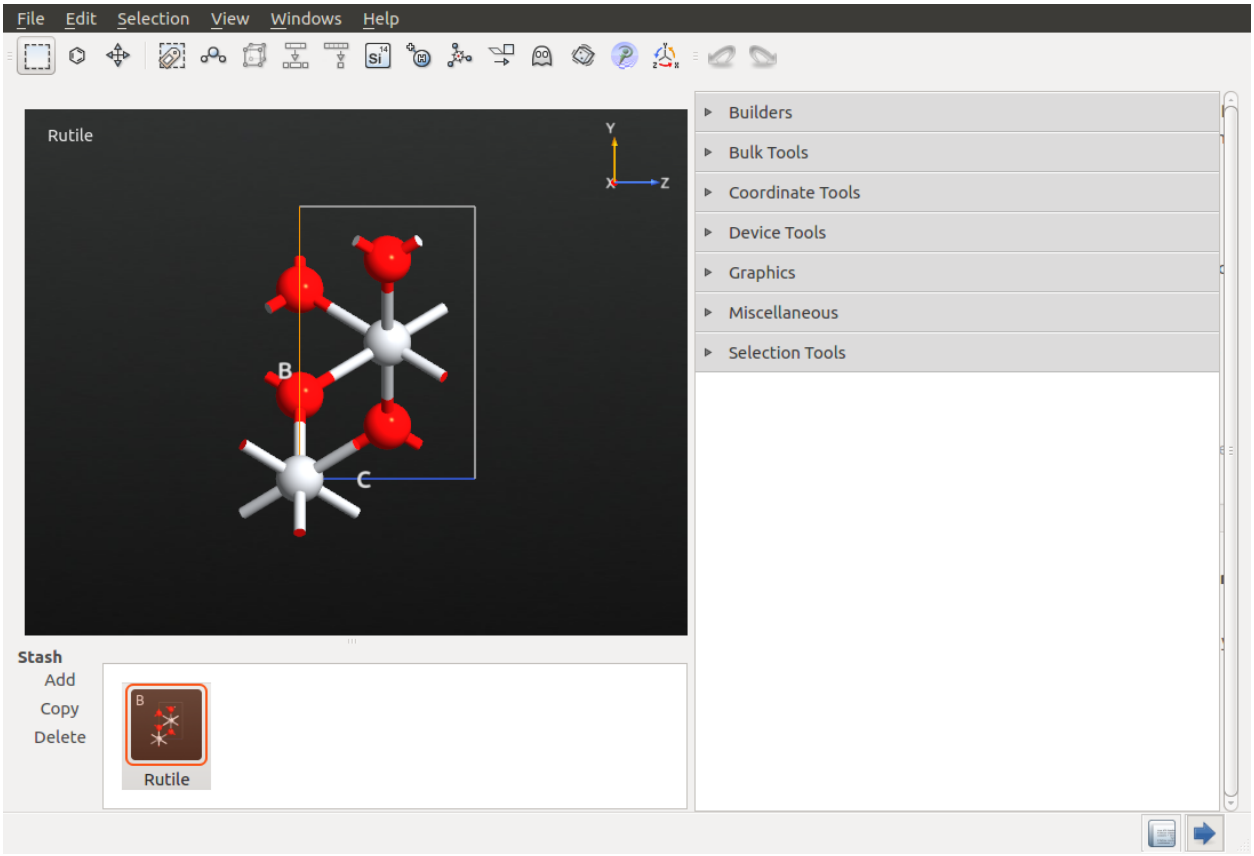


Tip: You can of course change the geometry optimization settings, e.g. to tighten the force tolerance, but the default values should work well for most purposes.

Send the script to the **Editor** using the button. The produced script should be identical to this one: `csp-script.py`. Note that `calculator = None`. You therefore need to manually add the script lines defining the calculator to be used (could be an *ATK-DFT* or *ATK-ForceField* calculator).

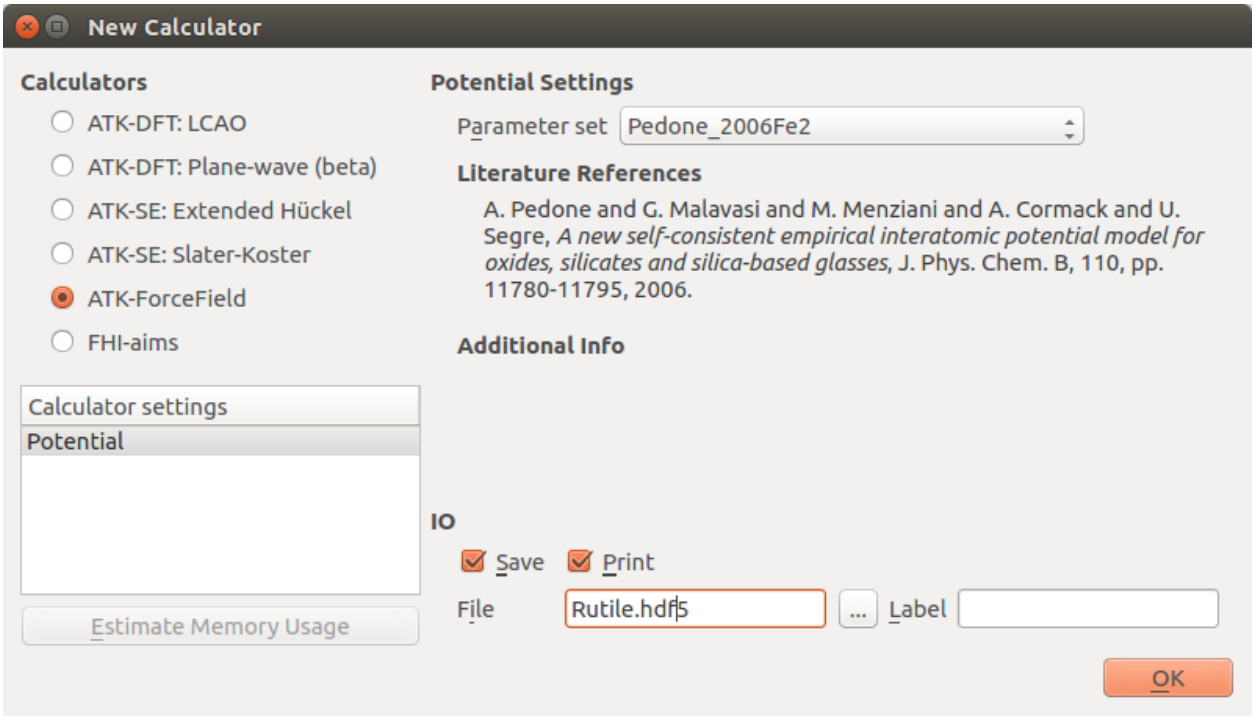
Adding a calculator

In principle, you can just add a calculator to the script, particularly if you already have an appropriate one defined in another script or can write it up manually. However, here we will go through the steps of defining it using QuantumATK. Open the **Builder** and find the rutile structure of TiO_2:



Send this configuration to the **Script Generator** and set up an **ATK-ForceField** calculator. QuantumATK will automatically suggest relevant parameter sets. In this case, choose **Pedone_2006Fe2**.

Note: For QuantumATK-versions older than 2017, the **ATK-ForceField** calculator can be found under the name **ATK-Classical**.



Send the script to the **Editor**, and copy the script lines defining the calculator:

```
potentialSet = Pedone_2006Fe2()
calculator = TremoloXCalculator(parameters=potentialSet)
calculator.setVerletListsDelta(0.25*Angstrom)
```

Insert those lines into the script generated using the Crystal Structure Prediction Scripter, and save it. You can also download the complete script here: `csp-script-with-calculator.py`

Running the calculations and analyzing results

Run the script using the **Job manager** or from the command line. It will take no more than a few minutes to run.

The script will generate a significant number of files, since it saves an `.nc` file and 6 log-files for each generation. The `.nc` files contain the *BulkConfigurations* for each individual in the given generation, and the log-files contain information from the 6 geometry optimizations carried out in each generation. This is the total population minus the number of promoted individuals, as they do not need to be re-optimized. However, we will focus on the overall log-file, in this case called `csp-script-with-calculator.log`. We are particularly interested in the information about the final generation:

```

First, the genetic algorithm performs **Niching**, which is removal of any duplicate structures from the generation. Below that, we see the final generation, sorted by decreasing fitness, which is simply the negative of the enthalpy. We see that the first two structures (those with lowest energy) have *P4_2/mnm* and *I4_1/amd* symmetries, consistent with the rutile and anatase phases of TiO_2.

The **History** shows how the algorithm arrived at this particular generation, and it turns out that, in this case, both the rutile and anatase structures have simply been promoted all the way from the initial population. Note also how the volume varies quite a bit between the different crystal structures, showing how the genetic algorithm is able to find highly different local minima on the potential energy surface of this system.

3.11.21 DFT-D and basis-set superposition error

In this tutorial you will calculate the distance between two graphene layers. To calculate this distance you will need to account properly for van der Waals interactions (also termed dispersion interactions). The latter are underestimated by local (LDA) and semi-local (GGA) exchange-correlation functionals. As a result, using these functionals the layers do not bind (or bind too weakly) and the minimal total energy configuration becomes one where the layers are infinitely separated. The long-range van der Waals interaction will be included through the semi-empirical corrections

by Grimme D2[1] and D3[2]. These corrections do not attempt to describe the actual source of the interaction (fluctuating dipoles) but rather its effect on the DFT mean-field effective potential.

You will also learn that incompleteness of the LCAO basis set can give rise to a so-called basis set superposition error (BSSE). The BSSE will contribute with an artificial attraction between the graphene layers, which actually partly compensates for the lack of van der Waals attraction, so with some exchange-correlation potentials the graphene layers will bind, but for the wrong reason. Thus, if you introduce the Grimme correction but do not account for BSSE, the layers will instead bind too strongly and a too small layer separation will be obtained. To remove the BSSE you will use the counterpoise correction[3].

The BSSE is mostly noticeable when computing cohesive energies or binding energies where two subsystems can be clearly defined, like in the case of a molecule on a surface[4] or, as in this tutorial, in layered systems. It is however also an issue for vacancy formation energies, where the material surrounding the vacancy has a lower number of basis orbitals than available in the vacancy case[5].

The DFT-D dispersion corrections

The corrections by developed by Grimme an co-workers[Page 1659, 1 2] add an additional term E_{disp} to the DFT total energy E_{DFT} in order to account for van der Waals interactions:

$$E_{\mathrm{DFT+D}} = E_{\mathrm{DFT}} + E_{\mathrm{disp}}$$

The D2 and D3 corrections differ in the way the term E_{disp} is evaluated.

D2 correction

In the D2 correction[1] the E_{disp} term include only two-body energies and is given by an attractive semi-empirical pair potential V^{PP} which accounts only for the lowest-order dispersion term:

$$E_{\mathrm{disp}} = -S_6 \sum_{A<B} V^{\mathrm{PP}}(Z_A, Z_B, R_{AB}),$$

where R_A (R_B) and R_{AB} are the atomic number of atom A (atom B) and the interatomic distance, respectively. The global scaling parameter S_6 has been fitted to reproduce the thermochemical properties of a large training set of molecules and depends on the exchange-correlation functional employed.

The pair potential between two atoms with atomic numbers A and B separated by a distance R_{AB} is:

$$V^{\mathrm{PP}} = \frac{\sqrt{C_6^A C_6^B}}{R_{AB}^6} f(R_{AB})$$

where

$$f(R_{AB}) = \frac{1}{1 + e^{-d_6\left[\frac{R_{AB}}{R_0^A + R_0^B} - 1\right]}}$$

is a damping function and C_6 and R_0 are element-specific parameters. Typically, the damping factor d_6 is set to 20.

D3 correction

In the D3 correction[2], the E_{disp} term includes both two- and three-body energies:

$$E_{\mathrm{disp}} = E^{(2)} + E^{(3)}.$$

Two-body energy term

The two-body energy include dispersion terms up to the 8th order:

$$E^{(2)} = -S_6 \sum_{A<B} V_6^{\mathrm{PP}}(Z_A, Z_B, R_{AB}) - S_8 \sum_{A<B} V_8^{\mathrm{PP}}(Z_A, Z_B, R_{AB}).$$

In the equation above, $S_6 = 1$ for all elements, whereas S_8 depends on the exchange-correlation functional employed. The 6th order pair potential is

$$V_6^{\mathrm{PP}} = \frac{C_6^{AB}}{R_{AB}^6} f_6(R_{AB}),$$

where

$$C_6^{AB} = \frac{\sum_i^{N_A} \sum_j^{N_B} C_{6,\mathrm{ref}}^{AB}\, e^{-4[(n^A - n_i^A)^2 + (n^B - n_j^B)^2]}}{\sum_i^{N_A} \sum_j^{N_B} e^{-4[(n^A - n_i^A)^2 + (n^B - n_j^B)^2]}},$$

and the 8th order pair potential is constructed using the 6th order data as:

$$V_8^{\mathrm{PP}} = \frac{3 C_{6,\mathrm{ref}}^{AB} \left(\sqrt{Z_A} \frac{\langle r^4 \rangle_A}{\langle r^2 \rangle_A} \sqrt{Z_B} \frac{\langle r^4 \rangle_B}{\langle r^2 \rangle_B} \right)^{\frac{1}{2}}}{R_{AB}^8} f_8(R_{AB}).$$

$C_{6,\mathrm{ref}}^{AB}$ are reference dispersion coefficients derived from time-dependent DFT (TDDFT) calculations using a training set of N_A (N_B) molecules for atom A (B). $\langle r^2 \rangle$ and $\langle r^4 \rangle$ are geometrically averaged multipole-type expectation values derived from atomic densities. n^A and n_i^A (n^B and n_j^B) are the atomic fractional coordination number for atom A in the system and in the i-th (j-th) molecule of training set N_A (N_B),

$$n_A = \sum_{B \neq A} \frac{1}{1 + e^{-16[\frac{4}{3}(R_{A,\mathrm{cov}} + R_{B,\mathrm{cov}})/R_{AB} - 1]}},$$

where $R_{A,\mathrm{cov}}$ and $R_{B,\mathrm{cov}}$ have been taken from[6]. Finally, the damping functions for 6th ($f_6(R_{AB})$) and 8th ($f_6(R_{AB})$) orders terms are, respectively:

$$f_6(R_{AB}) = \frac{1}{1 + 6[R_{AB}/(d_6\, R_0^{AB})]^{-14}},$$

and

$$f_8(R_{AB}) = \frac{1}{1 + 6[R_{AB}/(d_8\, R_0^{AB})]^{-16}},$$

with R_0^{AB} being the cutoff radius for the AB element pair, and d_6 and d_8 are damping factors depending on the exchange-correlation functional.

Note: As it is evident from the equations above, in the D3 method V_6^{PP} and V_8^{PP} depend not only on the interatomic distance but also on the chemical enviroment of each atom via the fractional coordination number. This is one of the major differences compared to the D2 method.

---

[6] P.ăPyykkö and A.ăMichiko. Molecular Single-Bond Covalent Radii for Elements 1-118. *Chemistry: a European Journal*, 15:186–197, 2009. doi:10.1002/chem.200800987.

Three-body energy term

The additional three-body energy contribution is evaluated as:

$$E^{(3)} = \sum_{A<B<C} V^{\mathrm{TBP}}(Z_A, Z_B, Z_C, R_{AB}, R_{AC}, R_{BC}, \cos\theta_a, \cos\theta_b, \cos\theta_c),$$

where the three-body potential V^{TBP} is constructed starting from the two-body terms,

$$V^{\mathrm{TBP}} = f(\bar{R}_{ABC}) \frac{\sqrt{C_6^{AB} C_6^{AC} C_6^{BC}}(3\cos\theta_a \cos\theta_b \cos\theta_c + 1)}{(R_{AB} R_{BC} R_{CA})^3},$$

using the following damping function,

$$f(\bar{R}_{ABC}) = \frac{1}{1 + 6\left[\bar{R}_{ABC}/(\frac{4}{3}\bar{R}_0^{ABC})\right]^{-16}}$$

where the geometrically averaged radii are

$$\bar{R}_{ABC} = (R_{AB} R_{BC} R_{CA})^{\frac{1}{3}} \qquad \text{and} \qquad \bar{R}_0^{ABC} = \left(R_0^{AB} R_0^{BC} R_0^{CA}\right)^{\frac{1}{3}}.$$

Note: The evaluation of $E^{(3)}$ changes the scaling behavior of the D3 algorithm from $O(N^2)$ to $O(N^3)$, where N is the number of atoms. Computing the three-body energy term can therefore be extremely expensive for large systems. Since the magnitude of the $E^{(3)}$ energy correction is much smaller than the two-body energy correction $E^{(2)}$, the former is switched-off by default in QuantumATK.

BSSE and the counterpoise correction

In polyatomic systems, the so-called basis set superposition error (BSSE) arises due to the localised nature of the LCAO basis set. To understand the origin of the BSSE, consider a system formed by two subunits A and B. For simplicity, consider each subunit to be a single atom. When A and B are far apart, they are described only by the basis orbitals centered at their respective atomic nuclei. However, when A couples to B the basis functions centered at A overlap with those centered at B. As a result, part of the basis orbitals centered at B are available to describe A. This gives rise to an artificial attraction between A and B.

The BSSE can be minimized by using the counterpoise (CP) correction[Page 1659, 3]:

$$E = E_{AB} + E^{\mathrm{cp}},$$

where E_{AB} is the total energy of system AB and E is the counterpoise energy correction.

The counterpoise correction is obtained through:

$$E^{\mathrm{cp}} = (E_A - E_{A\tilde{B}}) + (E_B - E_{\tilde{A}B}),$$

where $E_{A\tilde{B}}$ is the energy of system A in the AB basis, which is obtained by taking the full system at its equilibrium geometry and defining the atoms of B as ghost atoms.

Note: Ghost atoms have no charge and no mass, but they have basis orbitals, defined by whichever element (and basis set) that defines the atom if it was not a ghost.

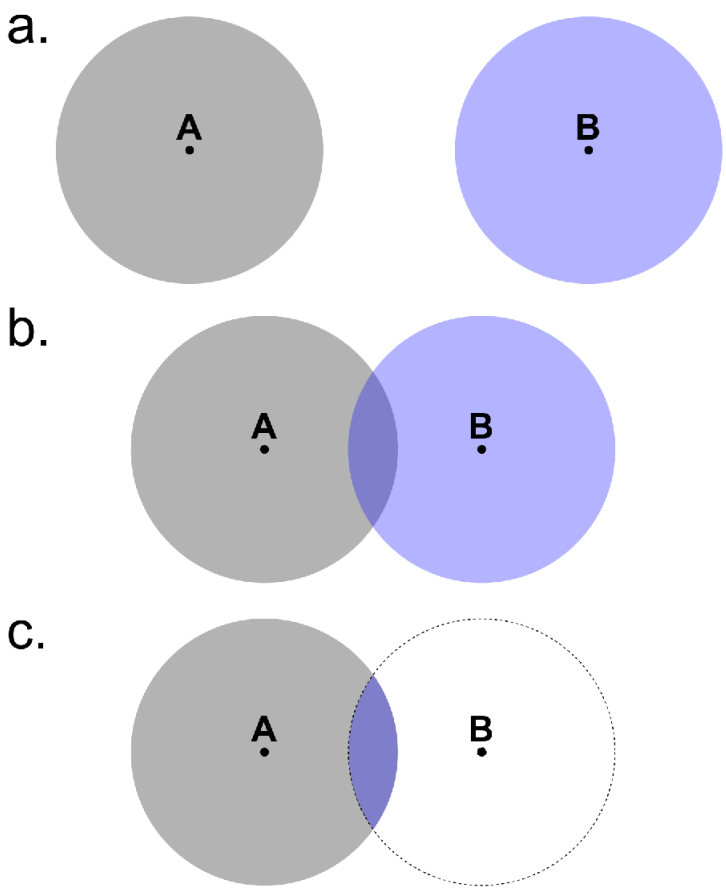

Fig. 3.115: Origin of the basis set superposition error. (a) A and B far apart from each other; (b) basis orbitals overlap when A couples to B; (c) the region in blue indicated the part of the basis orbitals centered at B that are available to describe A.

The counterpoise correction is readily extended to several subunits, A_i , through:

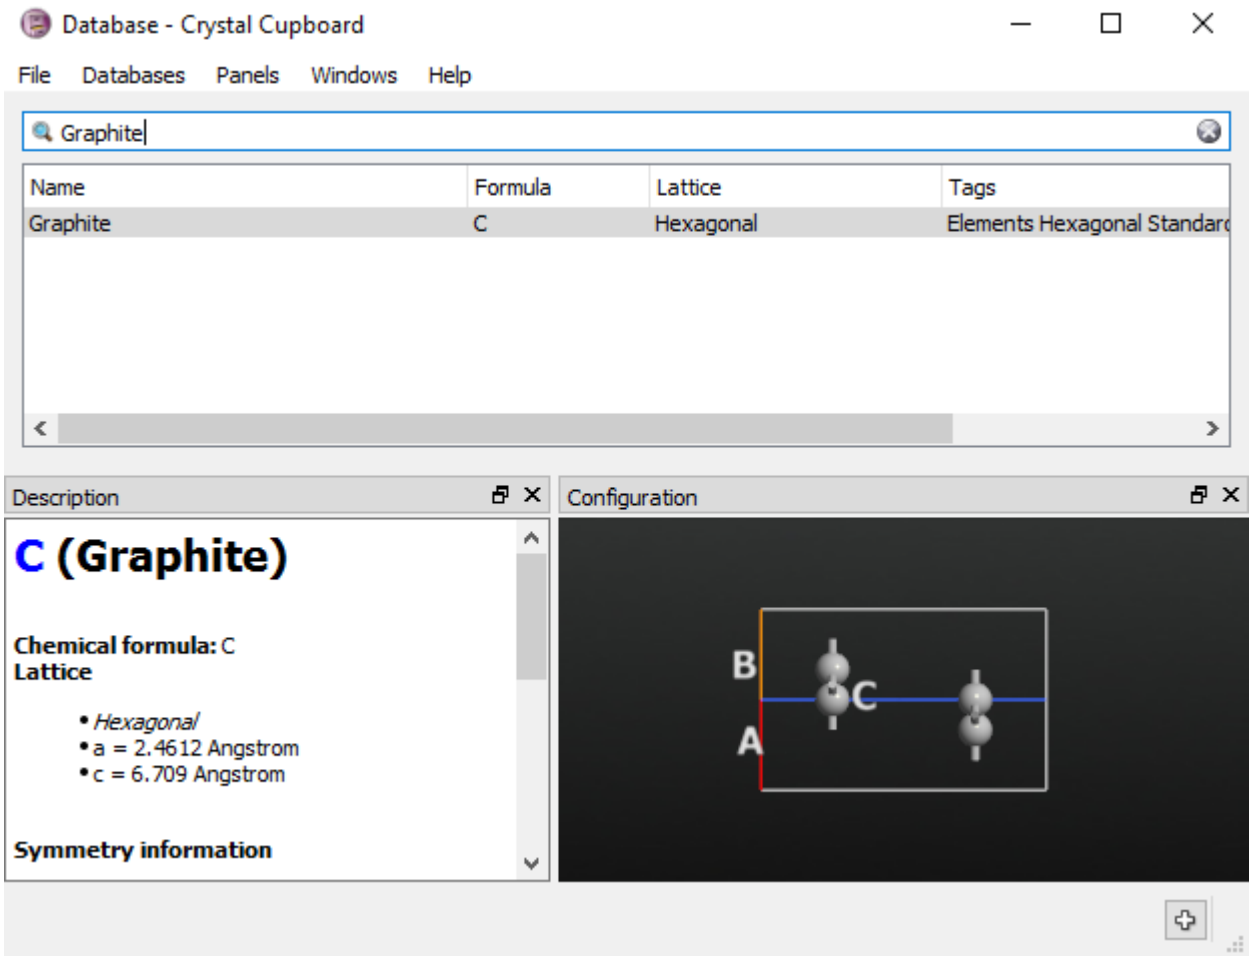
$$E^{\mathrm{cp}} = \sum_i (E_{A_i} - E_{A_i \tilde{C}_i}),$$

where C_i is the A_i complement, i.e. the atoms not in region A_i.

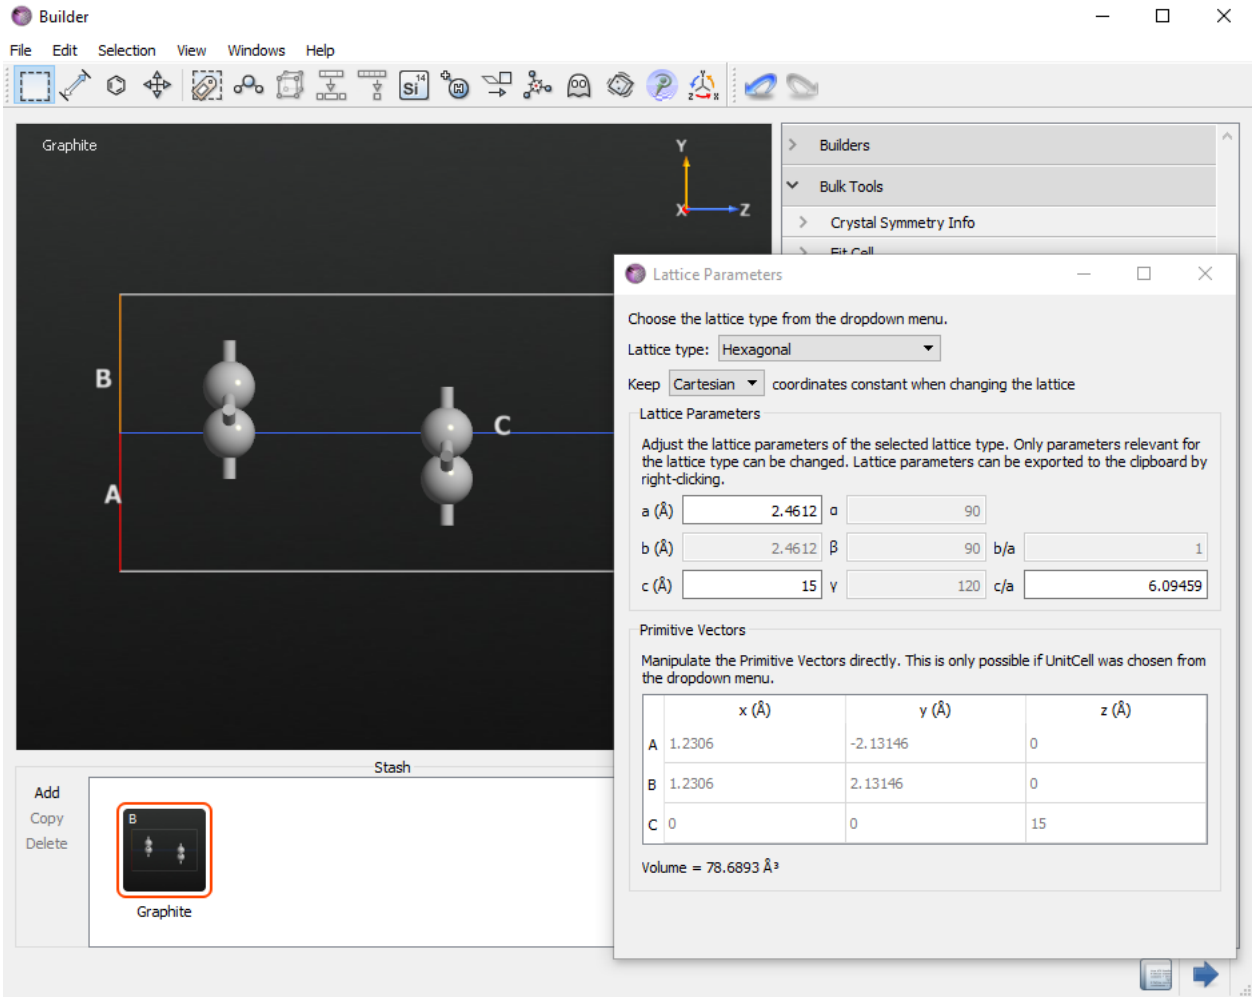
In the following section you will explicitly see the effects of these two corrections on the calculated equilibrium distance between two graphene layers.

Set-up the graphene bilayer system

In the **Builder**, click on *Add* → *From Database*, search for *Graphite* and add the structure to the stash.

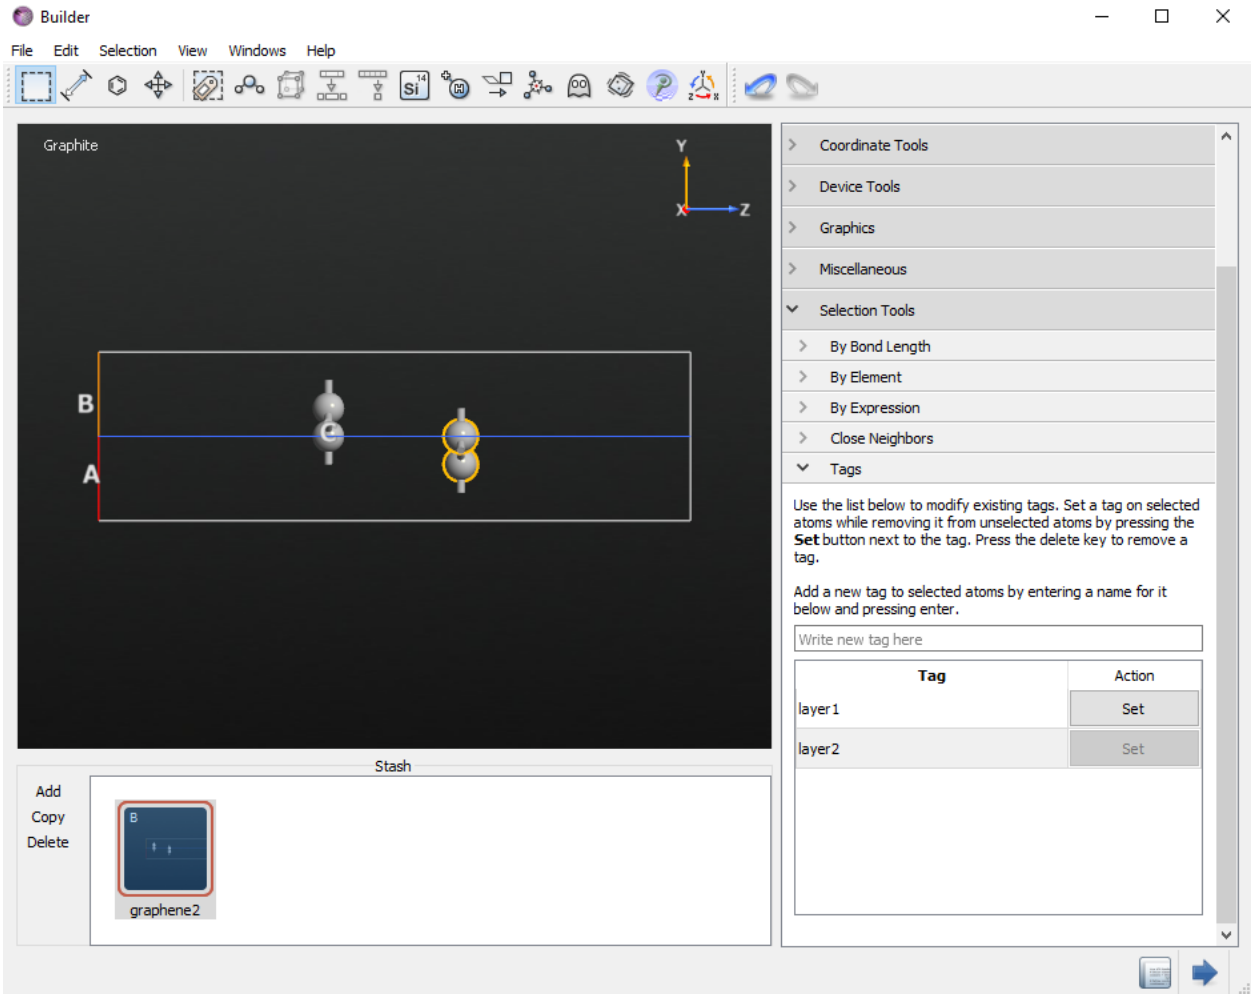


Rename the structure as *graphene2*, then open *Bulk Tools* → *Lattice parameters* and set the length of the C-vector to 15 Å. This transforms the graphite crystal into a bilayer graphene model.



Finally, center the geometry by using *Coordinate Tools* → *Center*.

To finish the setup of the structure you must add a tag to each graphene layer. Tags are used to distinguish the two layers, in order to define the counterpoise correction. In order to add the tags, select the two atoms in the first graphene layer, open *Selection Tools* → *Tags*, write *layer1* in the bottommost field and press `enter`. Then, repeat the same steps for the second layer and tag it as *layer2*.



Tip: You can check that the tags are correctly set using the Selection by Tag tool on the toolbar on the top of the **Builder**.

Geometry optimization without counterpoise correction

In the **Builder**, use the button to send the graphene bilayer structure to the **Script Generator**. Change the default output name to *graphene2.nc* and add the following blocks:

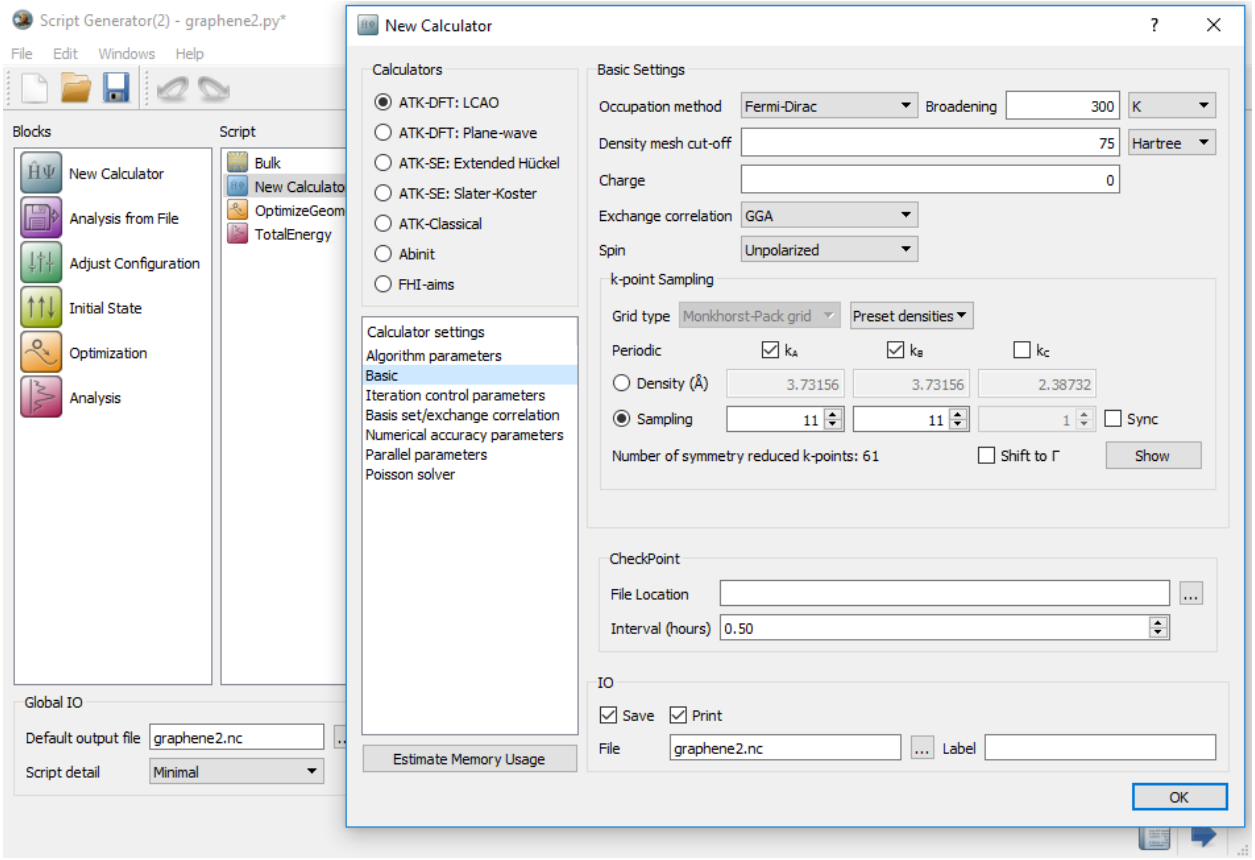
- *New Calculator*
- *Optimization → Optimize Geometry*
- *Analysis → Total Energy*

Click on the *New Calculator* block and modify the following parameters:

•Select the PBE functinal

•Set the k-point sampling to a grid of $11 \times 11 \times 1$ k-points.

Then, click on the *Optimize Geometry* block and set the force tolerance to 0.01 eV/Å.



To start the calculation, click the **Send To** icon located in the lower-right of the scripter and select **Job Manager** from the pop-up menu. **Save** the script as `graphene2.py` in the project directory.

The Job Manager will now pop up. Select the dropped script and press icon to start the job.

Analysis of the optimized structure

To inspect the relaxed configuration, expand graphene on the **LabFloor**. The file contains two configurations *gID000* and *gID001*. These are the input and relaxed structures, respectively.

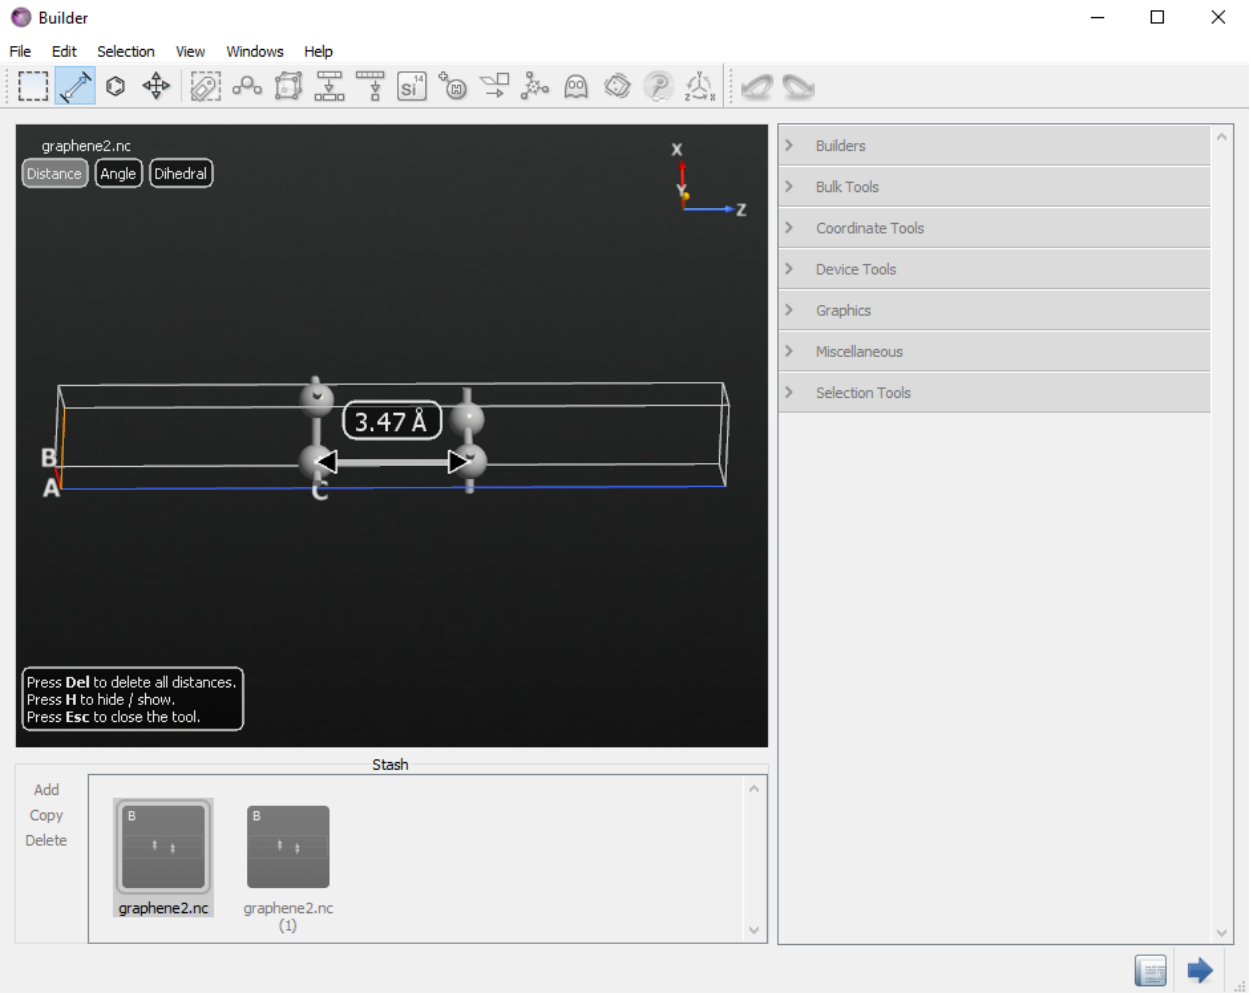
Drag and drop the relaxed structure (*gID001*) to the **Builder**.

In the **Builder**, click the measurements option for distance, and measure the distance between the two carbon atoms that sit on top of each other in the Z direction. The interatomic distance is 3.47 Å, which is fairly close to the experimental value 3.32 Å[7]. As you will soon see, this is however a result of a cancellation of two errors!

Note: Most literature experimental values for the graphene interlayer distance are valid for graphite but not for the bilayer graphene system discussed in this tutorial. Hence there can be small differences between the calculated results

[7] N.N. Greenwood and A.ăEarnshaw. Chemistry of the elements. *Pergamon*, 1984.

and experimental data.

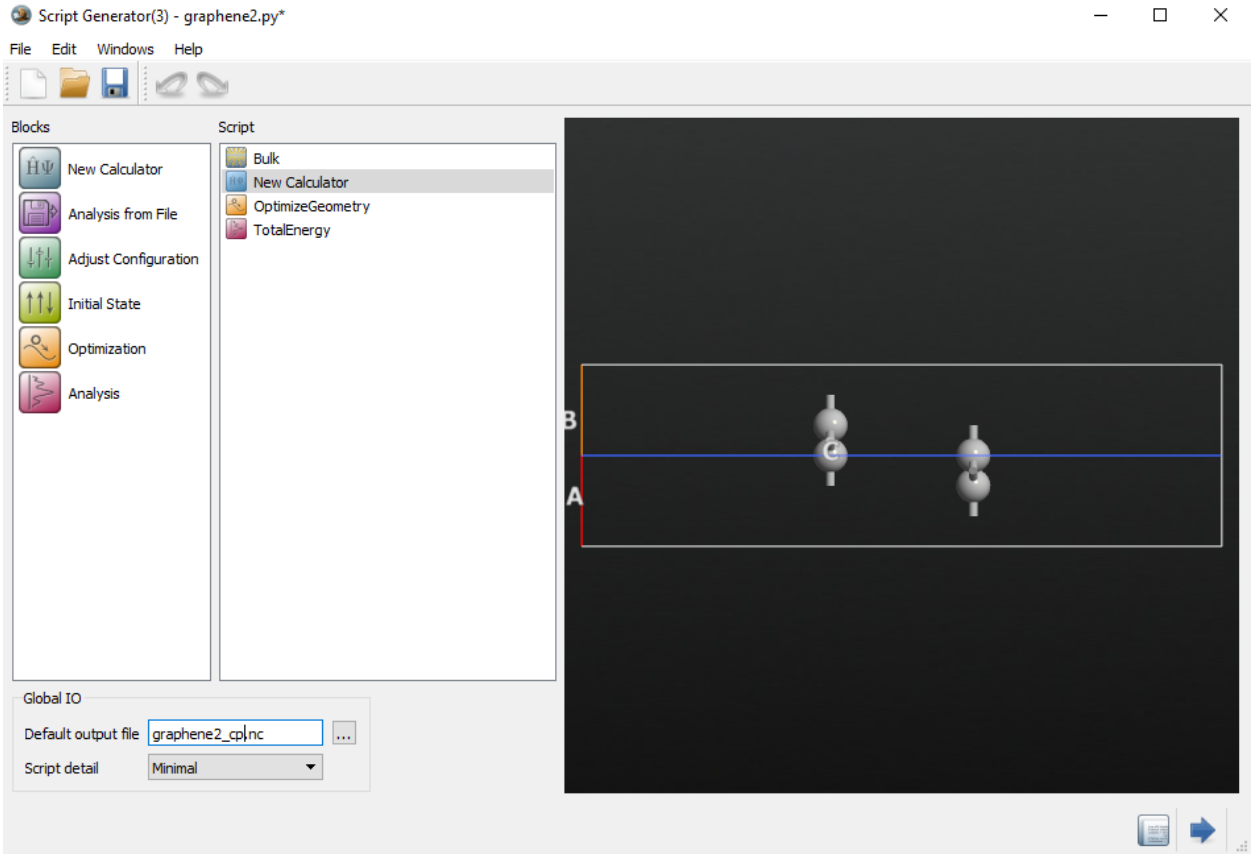


Including the counterpoise correction

You will now relax the geometry using the CP correction to correct for the basis set superposition error. To this end, open again the **Scripter** window where you set up the previous calculation.

Tip: All active tools are available through the Windows menu at the top of each tool.

Change the name of the output file to `graphene2_cp.nc`.



It is currently not possible to set up the CP correction in the Scripter. The CP correction must therefore be manually added by editing the QuantumATK script. Therefore, transfer the script to the **Editor** using the **Send To** icon.

In the **Editor**, change the definition of the Calculator as follows:

```
#calculator = LCAOCalculator(
#    basis_set=basis_set,
#    exchange_correlation=exchange_correlation,
#    numerical_accuracy_parameters=numerical_accuracy_parameters,
#    correction_extension=correction_extension,
#    )

#BSSE CP correction
bsse_calculator = counterpoiseCorrected(LCAOCalculator, ["layer1", "layer2"])
calculator = bsse_calculator(
    basis_set=basis_set,
    exchange_correlation=exchange_correlation,
    numerical_accuracy_parameters=numerical_accuracy_parameters,
    correction_extension=correction_extension,
    )
```

Note how the system is separated into two parts (*layer1* and *layer2*) using the tags. The system can be divided into an arbitrary number of parts, and the counterpoise correction is applied to each couple of parts. The only requirement is that the parts are adjoint and sum up to the entire system.

Save the script as `graphene2_cp.py`, send it to the **Job Manager** and start the calculation. The run time will be

2–5 times longer than before, since now at each geometry optimization step, 5 different systems need to be calculated, *viz.* $AB, A, A\tilde{B}, B, \tilde{A}B$.

When the calculation is done, inspect the interlayer distance and you will find it to be 4.23 Å. This is considerably larger than the previous result, and far from the experimental value (3.32 Å). As mentioned in the introduction, the BSSE creates an artificial attraction between the graphene layers, which reduces the interlayer distance. The counterpoise correction eliminates this error, but you are now left with the problem that the layers are essentially unbound, due to the omission of van der Waals forces.

Including the D2 dispersion correction

Since the interlayer distance calculated with the CP correction is too large, there must be a missing attractive contribution to the total force. This is the van der Waals (dispersion) force which is not correctly described with the PBE functional. The vdW contribution to the total forces can be approximately added using the semi-empirical DFT-D2 approach.

To add the D2 correction, drag and drop the `graphene2_cp.nc` file to the **Scripter** :

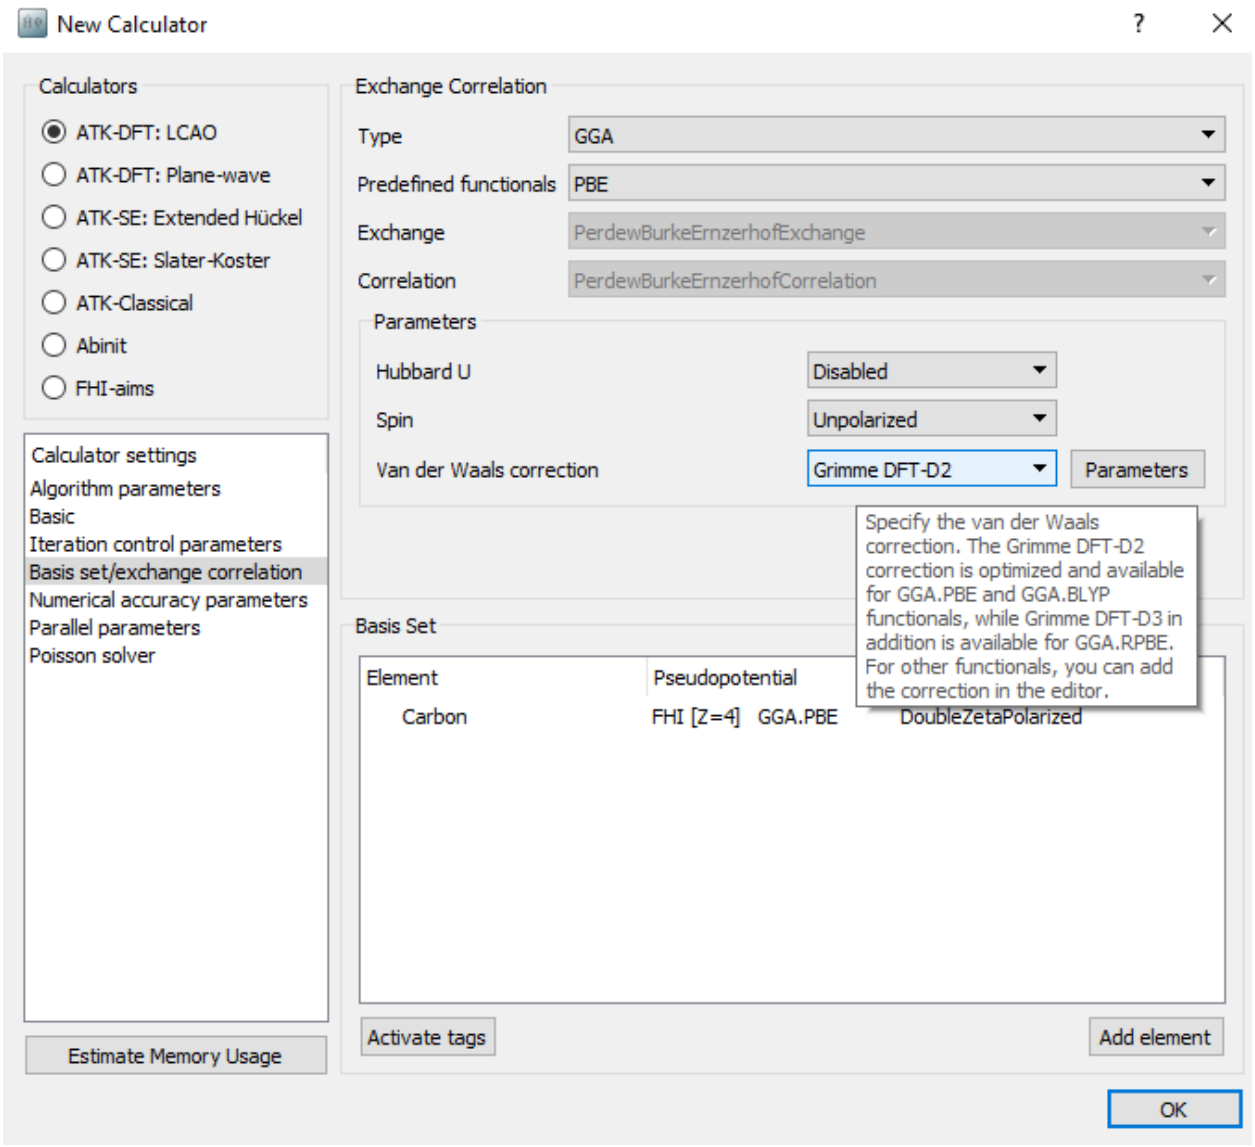
•Change the output file to `graphene2_cp_d2.nc`.

•Double-click **Optimization** and select **OptimizeGeometry**.

•Double-click **Analysis** and select **TotalEnergy**.

Now double-click the **New Calculator** block in the Script panel to open the calculator widget.

Under Calculator setting and Basis set/Exchange correlation select the Grimme DFT-D2 van der Waals correction. Note that you can modify all the specific parameters by clicking the *Parameters* button.



Double-click on the **OptimizeGeometry** block and set the force tolerance to 0.01 eV/Å.

Send the script to the **Editor** and edit the python script in order to add the counterpoise correction as you did before.

```
#-----------------------------------------
# Grimme DFTD2
#-----------------------------------------
correction_extension = GrimmeDFTD2(
    global_scale_factor=0.75,
    damping_factor=20.0,
    maximum_neighbour_distance=30.0*Ang,
    element_parameters={
        Carbon: [1.452*Ang, 1.75*J*nm**6/mol],
        },
```

```
    )

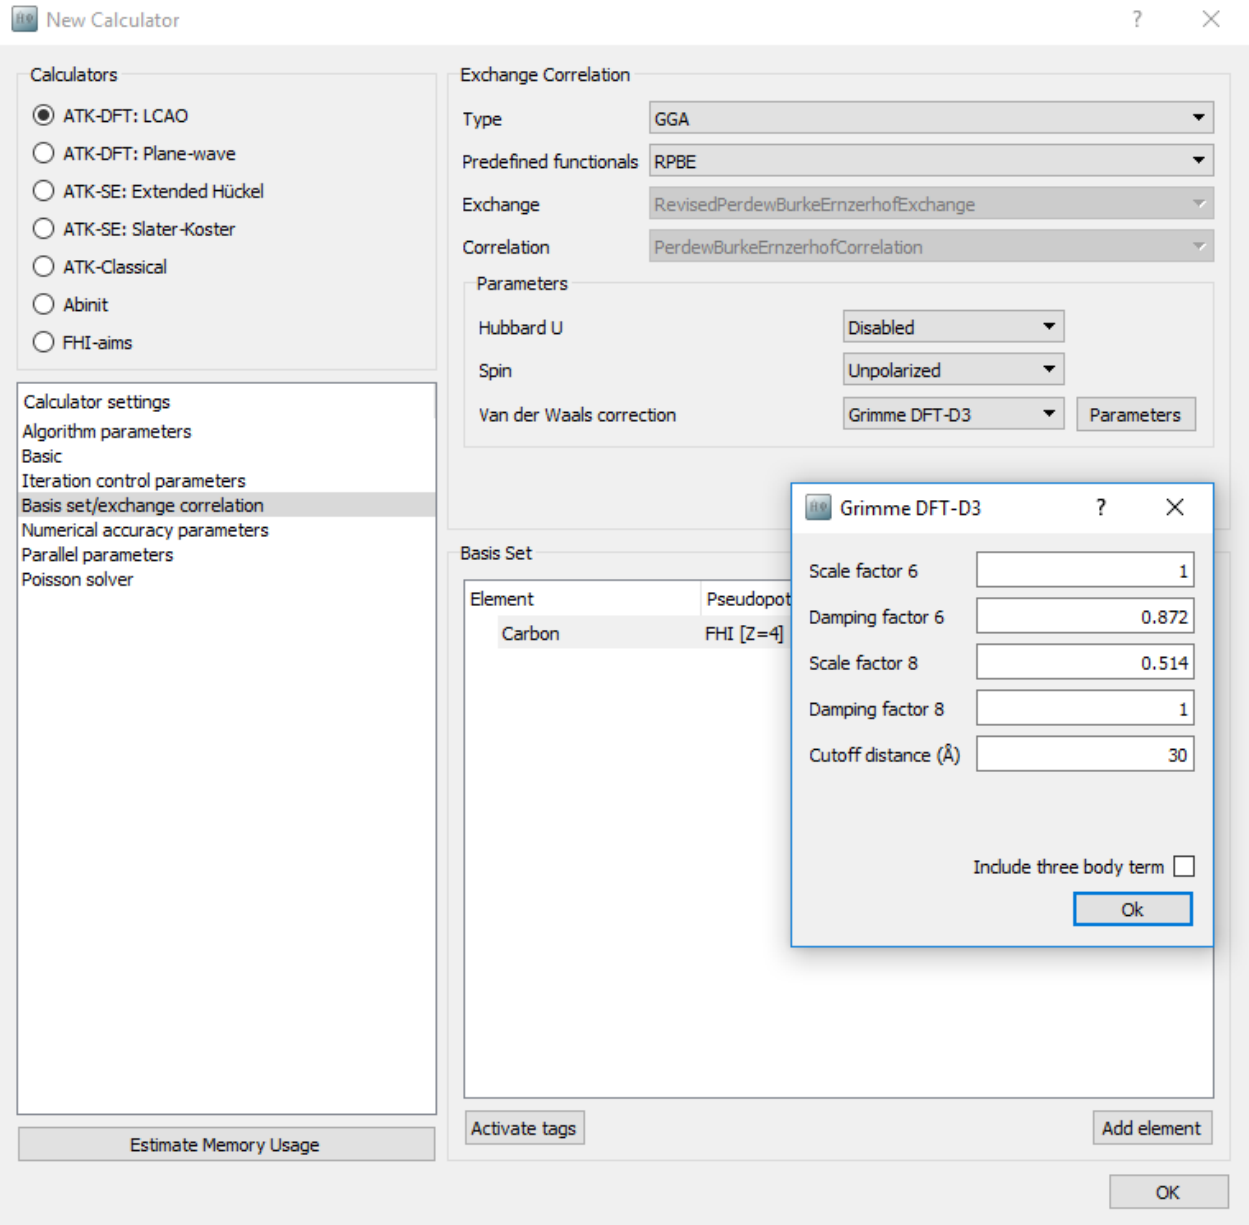
#BSSE CP correction
bsse_calculator = counterpoiseCorrected(LCAOCalculator, ["layer1", "layer2"])
calculator = bsse_calculator(
    basis_set=basis_set,
    exchange_correlation=exchange_correlation,
    numerical_accuracy_parameters=numerical_accuracy_parameters,
    correction_extension=correction_extension,
    )
```

Press the **save** button and save the script as `graphene2_cp_d2.py` in the project directory.

Run the script and when the calculation is done, inspect the interlayer distance. You will now find it to be 3.31 Å. Thus, including the dispersion correction and accounting for BSSE, an interlayer distance close to the experimental result can be obtained.

Including the D3 dispersion correction

The D3 correction can be applied in a similar way as shown for the D2 correction. However, as discussed in[Page 1659, 2] in this case the best results for the interlayer distance and binding energy are obtained using a revised PBE-type functional (revPBE) instead of the original PBE. Therefore, when adding the D3 correction, one also need to change the exchange-correlation functional from PBE to revPBE as shown below (RPBE in the list of predefined functionals).



As discussed in the method section the D3 correction can be supplemented with a three-body energy term $E^{(3)}$ for an even more accurate evaluation of the vdW forces. However, evaluation of this term is computationally demanding, and the $E^{(3)}$ term is therefore not computed by default. If one wants to used DFT-D3 including three-body interactions, we suggest to first optimize the structure using DFT-D3 without the $E^{(3)}$ term, and then perfom a single-point calculation on the optimized geometry including the $E^{(3)}$ term.

Summary of the results

The result of the calculations are summarized in the following table.

Table 3.9: Results for the distance, d, and binding energy per atom, E_B, of bilayer graphene.

	E_B (meV/atom)	d (Å)
PBE	-15	3.47
PBE+CP	-0.6	4.23
PBE-D2+CP	-22.9	3.31
revPBE-D3+CP	-22.6	3.35
revPBE-D3+CP+3body	-18.6	3.36

The binding energy ΔE of the bilayer system was calculated as:

$$\Delta E = E_{\mathrm{tot}}^{\mathrm{bilayer}} - 2E_{\mathrm{tot}}^{\mathrm{monolayer}}$$

where $E_{\mathrm{tot}}^{\mathrm{bilayer}}$ and $E_{\mathrm{tot}}^{\mathrm{monolayer}}$ are the total energies of bilayer and monolayer graphene respectively.

Note: The calculation of the binding energies must be consistent in terms of exchange-correlation functional and dispersion correction. For example, to obtain the PBE-D2+CP result, the single layer graphene reference calculation must be performed using DFT-D2.

3.12 Miscellaneous

3.12.1 The DFTB model in ATK-SE

The purpose of this tutorial is to show you how to install new parameter sets into the Density Functional based Tight Binding (DFTB) model[1],[2] implemented in **ATK-SE**.

ATK is shipped with Slater-Koster parameter files from the CP2K and Hotbit consortia, for use in the semi-empirical DFTB model. This tutorial will show how to download additional parameters from the DFTB website and install them such that they work as a native part of **ATK**.

Once the parameters are installed, they can be used for modeling molecules, bulk and device systems. In this tutorial, you will first download and install a DFTB parameter set, and then learn how to calculate properties of spin polarized bulk systems using a Slater-Koster calculator.

Note: You will primarily use the graphical user interface **QuantumATK** for setting up and analyzing the results. If you are not familiar with **QuantumATK**, we recommend you first go through a few of the **QuantumATK Tutorials**.

---

[1] M.Elstner, D. Porezag, G. Jungnickel, J. Elsner, M. Haug, T. Frauenheim, S. Suhai, and G. Seifert, Phys. Rev. B **58**, 07260 (1998)

[2] C.Kohler, T. Frauenheim, B. Hourahine, G. Seifert, and M. Sternberg, J. Phys. Chem. A **111**, 5622 (2007)

The underlying calculation engine for this tutorial is **ATK-SE**, the semi-empirical part of **QuantumATK**. A complete description of all the parameters, and in many cases a longer discussion of their physical relevance, can be found in the ATK Reference Manual.

In order to run this tutorial, and in general use the semi-empirical models in **ATK**, you must have a **license for ATK-SE**. If you do not have one, you may obtain a time-limited demo license by contacting us via our website: Contact QuantumATK.

Installing DFTB parameters

Getting a DFTB license

The dftb.org website has a number of parameters for the DFTB method, which can be used with **ATK-SE**. In order to download the parameters, you will need to fill out their registration form. When your registration has been processed, you will receive a username and password to their website.

Downloading the parameters

On the DFTB download page, you can get an overview of the different DFTB parameter sets. The primary ones are named mio, pbc, and matsci; the mio set can further be extended by a number of specialized sets listed further below. The page also lists the papers that must be referenced when using the parameter sets.

Log into dftb.org and download the parameter sets of your interest. The downloaded files will be in a compressed tar ball (`.tar.gz`).

Installing the parameters

ATK has a special folder for each of the three DFTB parameters sets. For instance, to install the mio parameter set, unpack the downloaded tar ball and copy the `.skf` files to the directory `share/tightbinding/dftb/mio/` in the directory where **ATK** is installed. In Linux you can use the following commands:

```
tar zxvf mio-1-1.tar.gz
cp mio-1-1/* [ATKPATH]/share/tightbinding/dftb/mio
```

where `[ATKPATH]` is the path to your installation of QuantumATK. Similarly, the pbc and matsci parameter files should be copied to the `dftb/pbc` and `dftb/matsci` directories. Note that these directories already exist, but are empty.

> **Warning:** If you use **QuantumATK** on a laptop or workstation to set up the calculations, and then a separate installation of **ATK** on a cluster for running the calculations, then the parameter files must be installed on both systems separately.

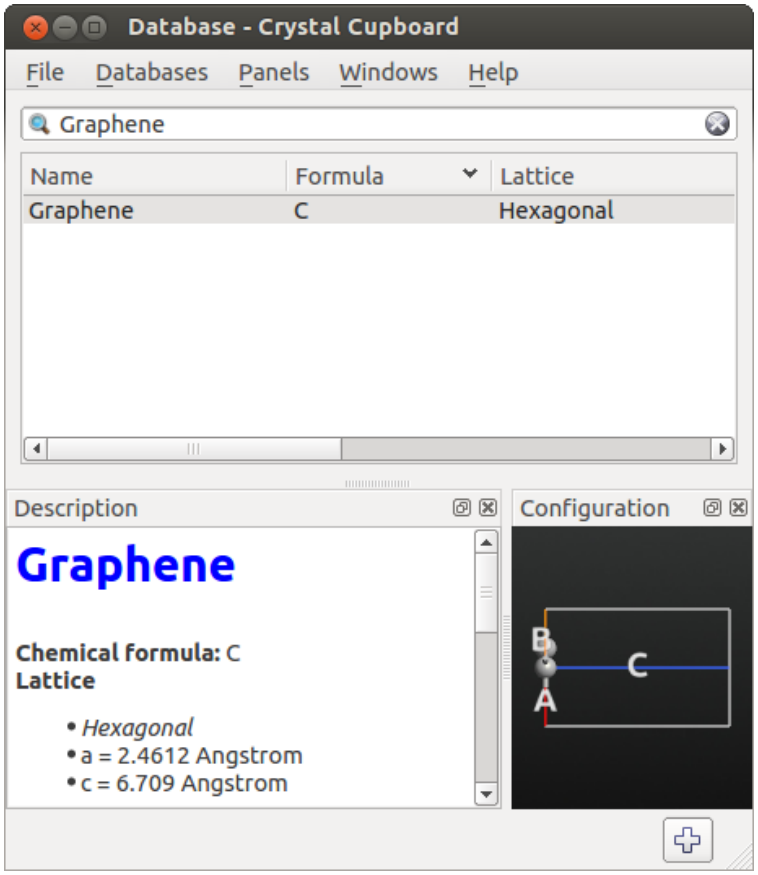
Testing the installation

Bandstructure calculation

To test that the parameters are correctly installed you, can perform the following bandstructure calculation for graphene.

•Start **QuantumATK** and create a new project, then click **Open**.

•Launch the **Builder** and click *Add* → *From Database*. Find Graphene.



•Add the structure to the **Stash** (double-click or use the icon).

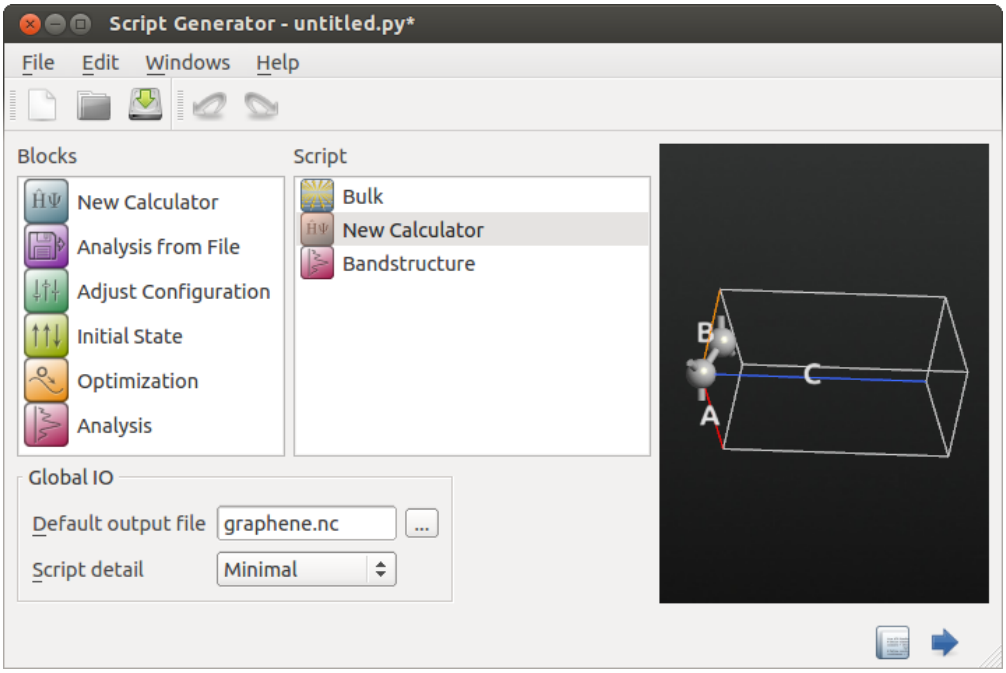
•Send the structure to the **Script Generator** using the button.

•In the **Script Generator**, add the following blocks:

1. **New Calculator**
2. **Bandstructure**

•Change the output filename to `graphene.nc`.

The **Script Generator** should now have the following settings:

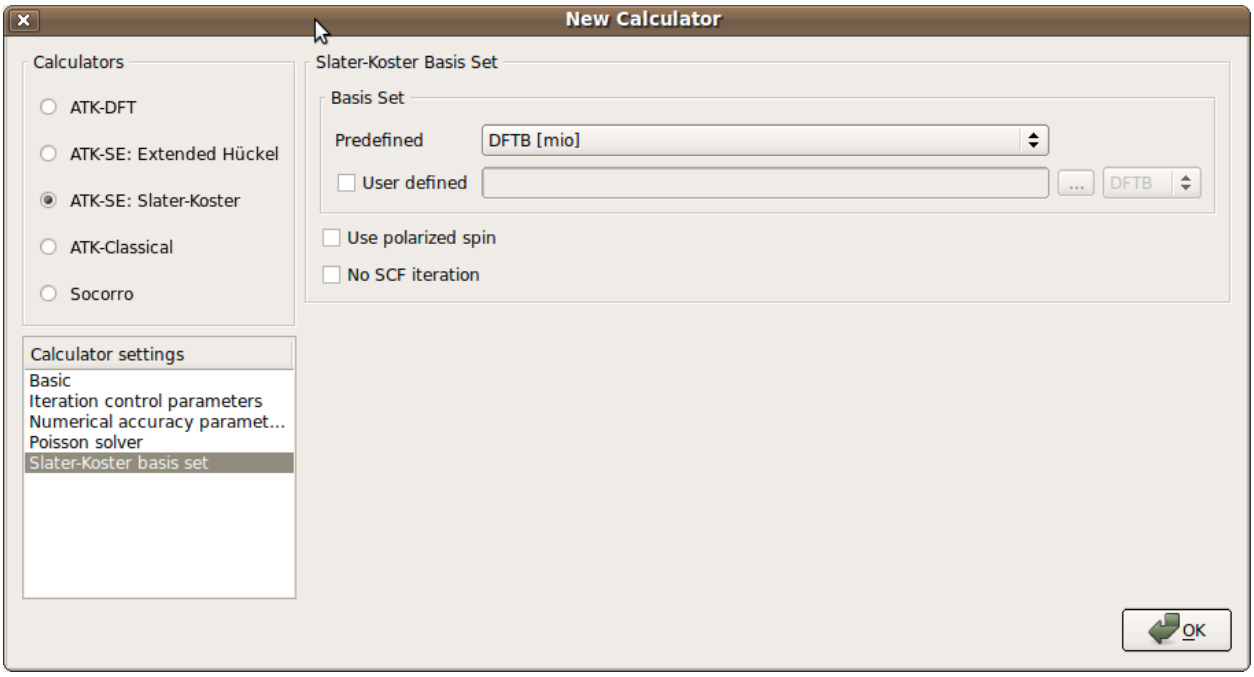


Now open the **New Calculator** block and make the following changes:

- Select the **ATK-SE: Slater-Koster** calculator.
- Change the **k-point sampling** to (5, 5, 1).
- Go to the **Slater-Koster basis set**, and check that the installed basis sets are in the basis set list. Select the DFTB [mio] basis set.

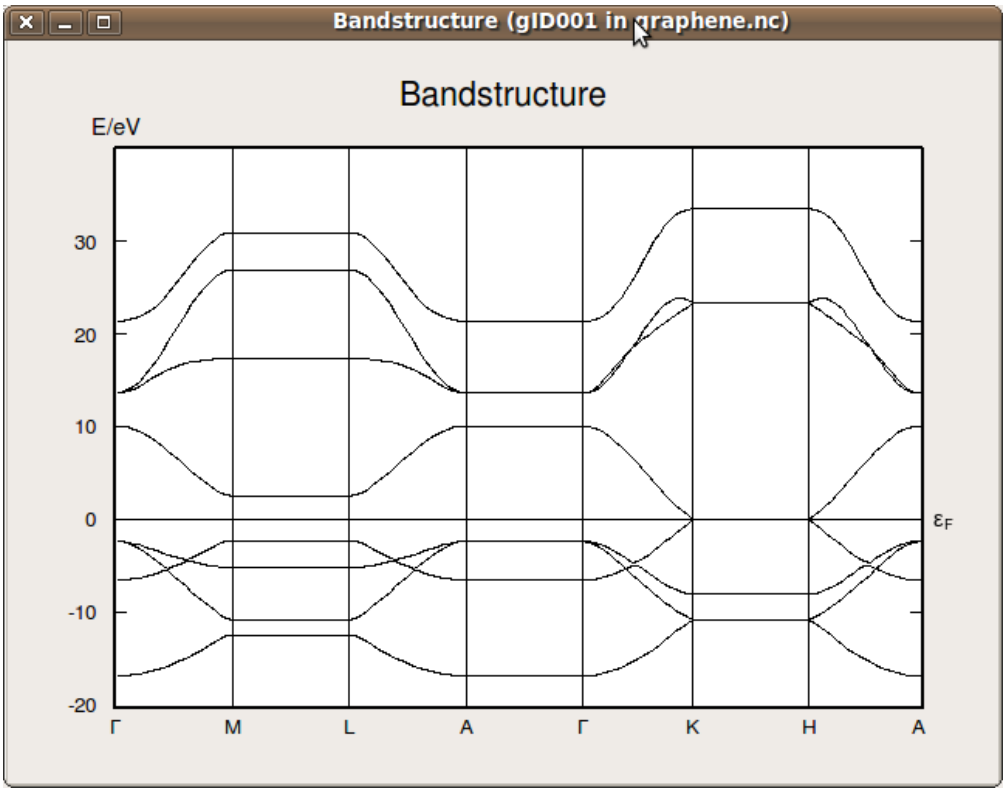
Note: If you do not see the DFTB [mio] basis set in the list, something went wrong in the installation process. Check that the file `atkpython/share/tightbinding/dftb/mio/C-C.skf` exists in your **ATK** installation directory.

- Uncheck the **No SCF iteration** box, in order to invoke a self-consistent DFTB calculation.



Attention: The default assumption is that a tight-binding model is non-self-consistent. It is the responsibility of the user to uncheck the **No SCF iteration** box for models which are to be self-consistent. Most DFTB models are self-consistent.

- Transfer the script to the **Job Manager** using the **Send To** button ( ), and start the calculation.
- When the job has finished, locate the file `graphene.nc` under project files in the main **QuantumATK** window, and plot the bandstructure using the *Bandstructure Analyzer* from the right-hand tool bar. You should get the result shown below:



Note: If the test went well, the DFTB parameters are properly installed. You are then able to use DFTB parameters instead of DFT for some of the other **ATK** tutorials available on the QuantumATK website (including quantum transport calculations), in order to save computational time.

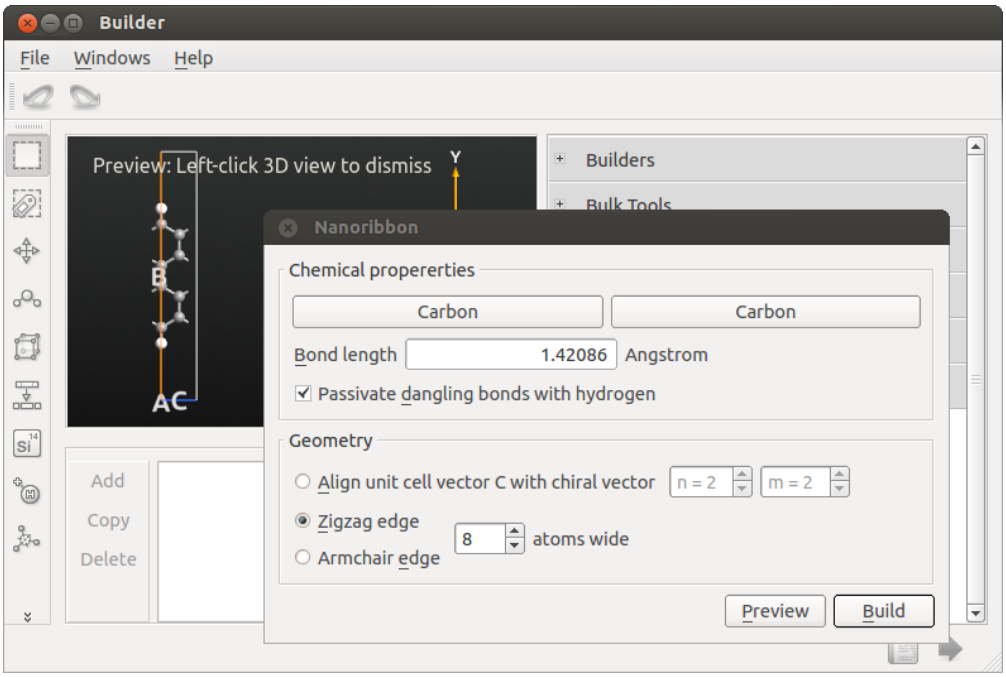
Obviously, this only works if the elements used are covered by the DFTB basis sets.

Spin polarized calculations with DFTB

Calculating the spin polarization of a graphene ribbon

In the following you will set up a graphene nanoribbon, and perform a spin-polarized calculation using the DFTB [mio] model.

- Open the Builder and click *Add* → *From Plugin* → *Nanoribbon*.
- Build a zigzag ribbon that is 8 atoms wide.



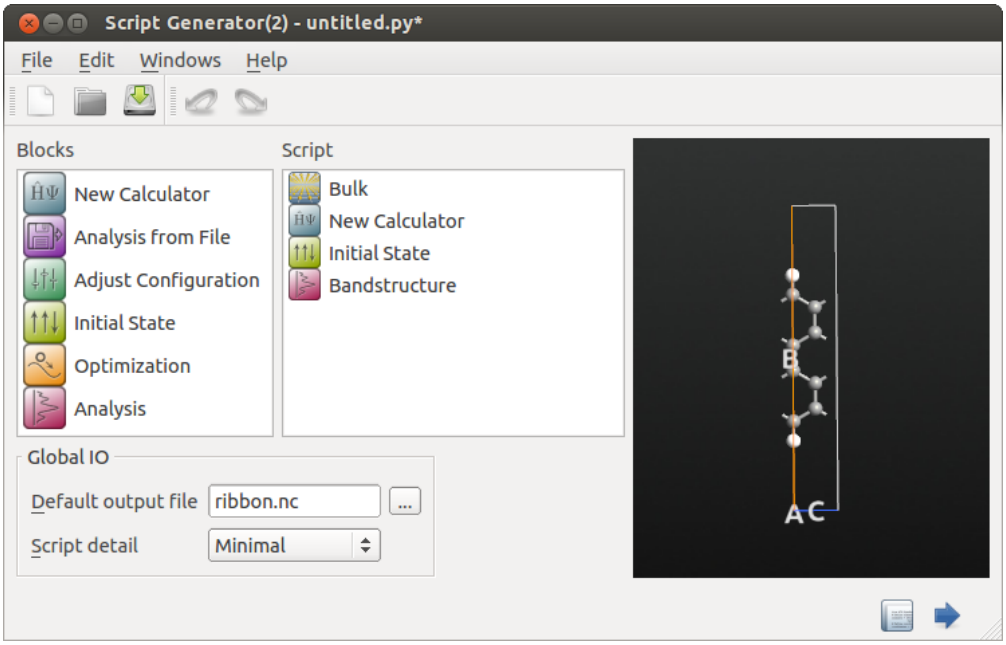
To set up a calculation of the band structure, send the structure to the **Script Generator** using the button in the lower right-hand corner of the builder window.

In the **Script Generator**, add the following blocks:

- **New Calculator**
- **Initial State**
- **Bandstructure**

and change the output filename to `ribbon.nc`.

The **Script Generator** should now have the following settings:



Open the **New Calculator** block.

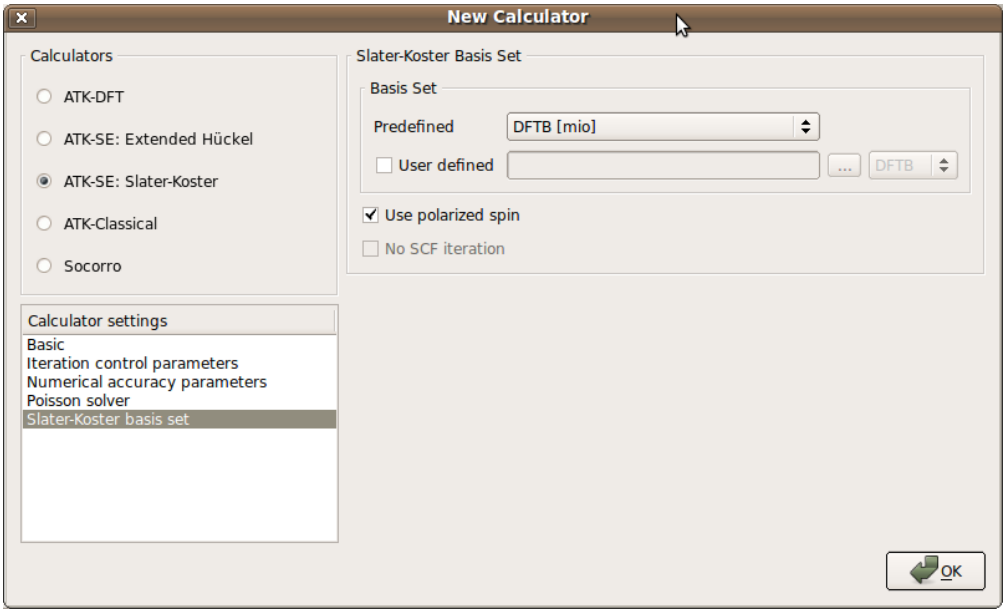
•Select the **ATK-SE: Slater-Koster** calculator.

•Change the **k-point sampling** to (1,1,11).

•Go to the **Slater-Koster basis set** and select the DFTB [mio] basis set.

•Check the **Use polarized spin** box, in order to perform a spin-polarized DFTB calculation.

Note: The DFTB parameter set does not include spin polarization parameters. Instead, spin polarization parameters are obtained from the ATK_W database.



Finish by clicking **OK**.

Next, set up the initial spin state of the system:

•Open the **Initial State** block by double-clicking it.

•Set the **Initial state type** to *User spin*.

•Under Spin, set the default spin of both Carbon and Hydrogen to 0.

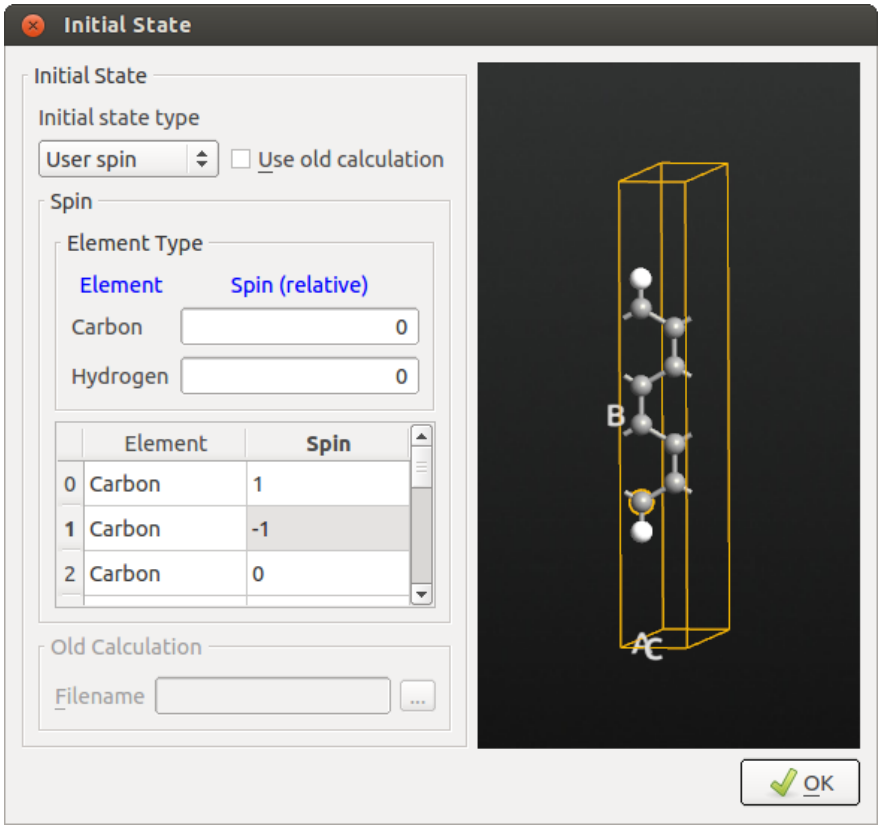
•In the 3D view:

–Click the upper carbon atom (index 0 in the list of atoms) and set its **initial relative spin** to 1.0.

–Repeat this procedure for the lower carbon atom (number 1 in the list), setting its **initial relative spins** to -1.0. (Dont be confused by the fact that the carbon atoms are not ordered by Y coordinate).

–Leave the hydrogen atoms and the other carbon atoms with **initial relative spin** values of 0.0.

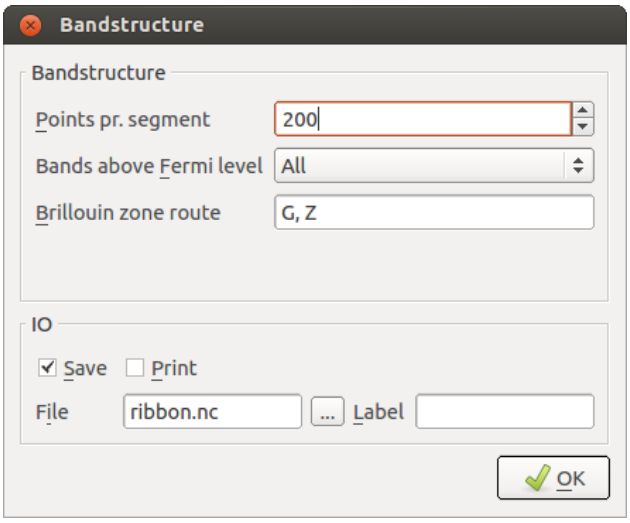
The dialogue should now look as shown below.



Finally, open the **Bandstructure** block:

•Change **Points pr. segment** to 200. This implies that each band will be calculated with a resolution of 200 points.

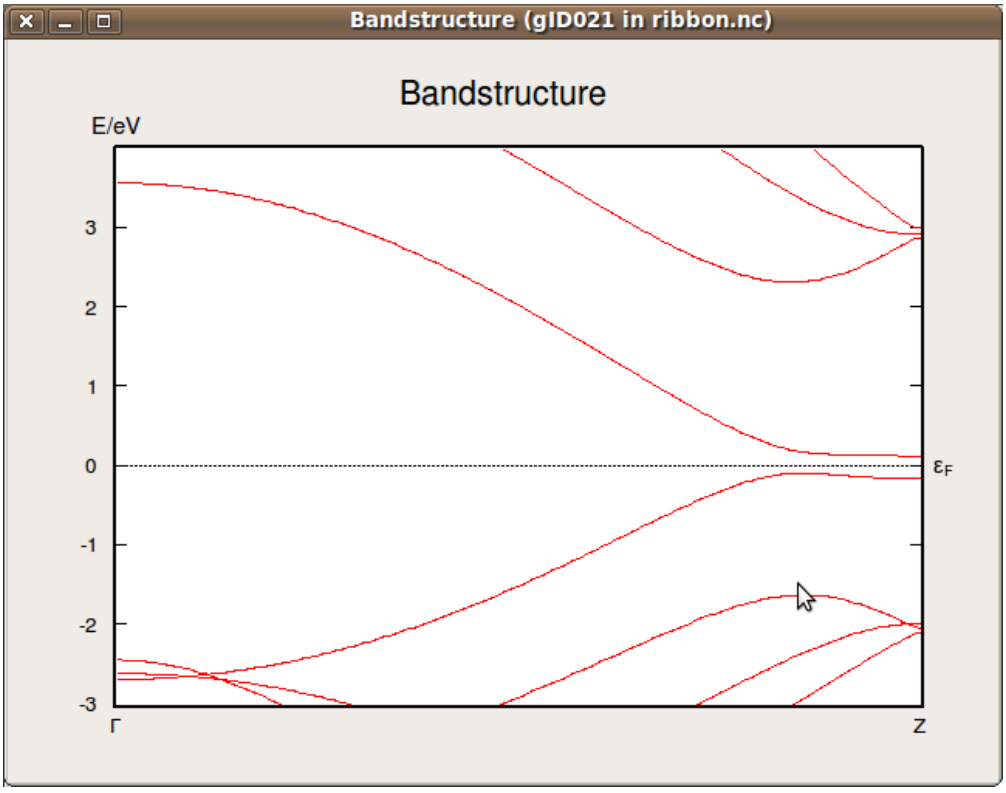
•Also notice that the default suggested route in the Brillouin zone (from the Γ-point G=(0,0,0) to Z=(0,0,1/2) in units of the reciprocal lattice vectors) is the appropriate one.



•Send the script to the **Job Manager** and run it.

•Return to the main **QuantumATK** window and select the file `ribbon.nc` and plot the bandstructure.

•By using the zoom functionality, you should be able to obtain the following figure:



Calculate the properties of a series of configurations using scripting

If you want to calculate the bandstructure of a number of nanoribbons, it is very convenient to use Python scripting. The script below performs a calculation of the bandstructure of nanoribbons with chiral index (n,n), where n runs from 1 to 10.

Attention: The *chiral index* notation for nanoribbons in **ATK** is based on the linear combination of the planar graphene unit vectors that are used to form the unit cell. Thus, (n,n) have zigzag edges, and actually correspond to an unrolled armchair nanotube with the same chiral indices.

For armchair edge nanoribbons, the chiral indices are (n,0).

```
# Setup the DFTB Calculator
basis_set = DFTBDirectory("dftb/mio/")
pair_potentials = DFTBDirectory("dftb/mio/")

numerical_accuracy_parameters = NumericalAccuracyParameters(
    k_point_sampling=(1, 1, 51),
    )

iteration_control_parameters = IterationControlParameters()

calculator = SlaterKosterCalculator(
    basis_set=basis_set,
    pair_potentials=pair_potentials,
    numerical_accuracy_parameters=numerical_accuracy_parameters,
    iteration_control_parameters=iteration_control_parameters,
    spin_polarization=True,
    )

#loop over different NanoRibbons
for n in range(1,10):
    #generate the nanoribbon
    bulk_configuration = NanoRibbon(n,n)

    #Determine the initial spin of the configuration
    elements = bulk_configuration.elements()
    coords = bulk_configuration.fractionalCoordinates()
    scaled_spins = numpy.zeros(len(elements))

    #find the index of the two edge Carbon atoms,
    ymin = 0.5
    ymax = 0.5
    imin=0
    imax=0
    for i in range(len(elements)):
        if coords[i][1] < ymin and elements[i] == Carbon:
            ymin = coords[i][1]
            imin = i
        if coords[i][1] > ymax and elements[i] == Carbon:
            ymax = coords[i][1]
            imax = i
```

(continues on next page)

(continued from previous page)

```
    # set opposite spins on the edge Carbon atoms
    scaled_spins[imin] = 1
    scaled_spins[imax] = -1

    #attach calculator, and set the initial spin
    bulk_configuration.setCalculator(
        calculator(),
        initial_spin=InitialSpin(scaled_spins=scaled_spins),
        )
    bulk_configuration.update()

    # Calculate Bandstructure
    bandstructure = Bandstructure(
        configuration=bulk_configuration,
        route=['G', 'Z'],
        points_per_segment=200,
        bands_above_fermi_level=All
    )
    nlsave('bandgap.nc',bandstructure)
```

•Download the script to the project folder (`bandgap.py`) and send it to the **Job Manager** by drag-and-drop in the **QuantumATK** window.

•This will generate the file `bandgap.nc`.

•To analyze the data, download (`analyze_bandgap.py`) and drop the following script on the **Job Manager**.

```
w_list = []
gap0_list = []
gap1_list = []
# read a list with the bandstructure data
bandstructure = nlread('bandgap.hdf5', Bandstructure)

for i in range(len(bandstructure)):
    # get all the bandlines
    energies = bandstructure[i].evaluate().inUnitsOf(eV)
    #calculate the number of occupied bands
    occupied_bands = numpy.sum(numpy.array(energies[0]) < 0)
    #calculate the minimum direct band gap
    gap0 = numpy.min(energies[:,occupied_bands]- energies[:,occupied_bands-1])
    #calculate the band gap at the zone boundary
    gap1 = energies[-1,occupied_bands]- energies[-1,occupied_bands-1]
    #determine the coordinates in the y direction
    y_values = NanoRibbon(i+1,i+1).cartesianCoordinates().inUnitsOf(Ang)[:,1]
    # calculate the width, as distance between furthest carbon atoms
    # i.e. calculate the  H-H distance and subtracting the C-H distance
    w = numpy.max(y_values)-numpy.min(y_values)-2.2
    #append calculated values to the list
    w_list.append(w)
    gap0_list.append(gap0)
```

(continues on next page)

(continued from previous page)

```
    gap1_list.append(gap1)

#print the data
import pylab
pylab.figure()
pylab.plot(w_list,gap0_list, 'k-o')
pylab.plot(w_list,gap1_list, 'k-o', markerfacecolor='white')
pylab.xlabel(r"$w_z$ ($\AA$)", size=16)
pylab.ylabel("$\Delta_z$ (eV)", size=16)
pylab.show()
```

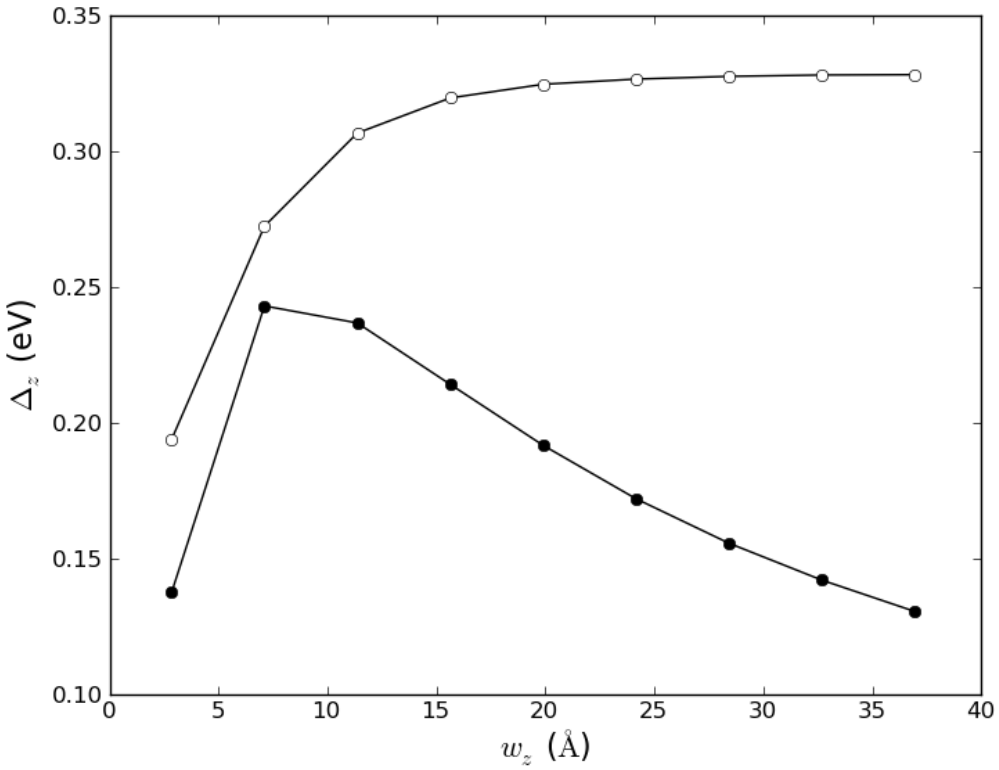


Fig. 3.116: Direct band gap (solid circles) and the band gap at the zone boundary as function of the width of the nanoribbon.

Attention: Except for the smallest ribbon, the plot shows the same qualitative behavior as Fig. 4c in Ref.[3]. The discrepancy in the results are related to the accuracy of the DFTB method compared with a DFT-LDA calculation. To test this, you can modify the script and change the definition of the calculator:

```
calculator = LCAOCalculator(
    numerical_accuracy_parameters=numerical_accuracy_parameters,
    exchange_correlation = LSDA.PZ
    )
```

Remember to also modify the name of the output file in order to separate the new data from the old data. Then execute the script.

3.12.2 Accessing QuantumATK internal variables

Version: 2016.0

The purpose of this tutorial is to illustrate how to extract internal quantities from QuantumATK. In the following, the quantities are briefly described and several sections then illustrate with examples how the information can be used to compute different sorts of transport coefficients.

Internal matrices accessible in QuantumATK

The table below lists some of the internal matrices in QuantumATK, e.g. the Hamiltonian H and the overlap matrix S. The commands listed in the left-hand column in the table allow users to extract these matrices through the so-called low level entities module in QuantumATK.

Table 3.10: Internal matrices accessible in QuantumATK. Further description of the variables can be found in the ATK Reference Manual.

Command	Symbol
`orbitalInfo()`	$[(i,l,m),\cdots]$
`calculateHamiltonianAndOverlap()`	$H(\mathbf{k}), S(\mathbf{k})$
`calculateDensityMatrix()`	$D(\mathbf{k})$
`calculateSelfEnergy()`	$\Sigma^{L/R}(E,\mathbf{k})$
`calculateRetardedGreenFunction()`	$G^{r}(E,\mathbf{k})$
`calculateGreenFunctionComponent()`	$G^{L/R}(E,\mathbf{k})$
`calculateDynamicalMatrixAndOverlap()`	$C(\mathbf{k}), M(\mathbf{k})$
`calculatePhononSelfEnergy()`	$\Pi^{L/R}(E,\mathbf{k})$
`calculatePhononRetardedGreenFunction()`	$D^{r}(E,\mathbf{k})$
`calculatePhononGreenFunctionComponent()`	$D^{L/R}(E,\mathbf{k})$

You will in this tutorial see examples of how to extract these matrices and use them to compute transport coefficients. The underlying calculation engine to be used here is ATK-SemiEmpirical (ATK-SE), but could also have been ATK-DFT.

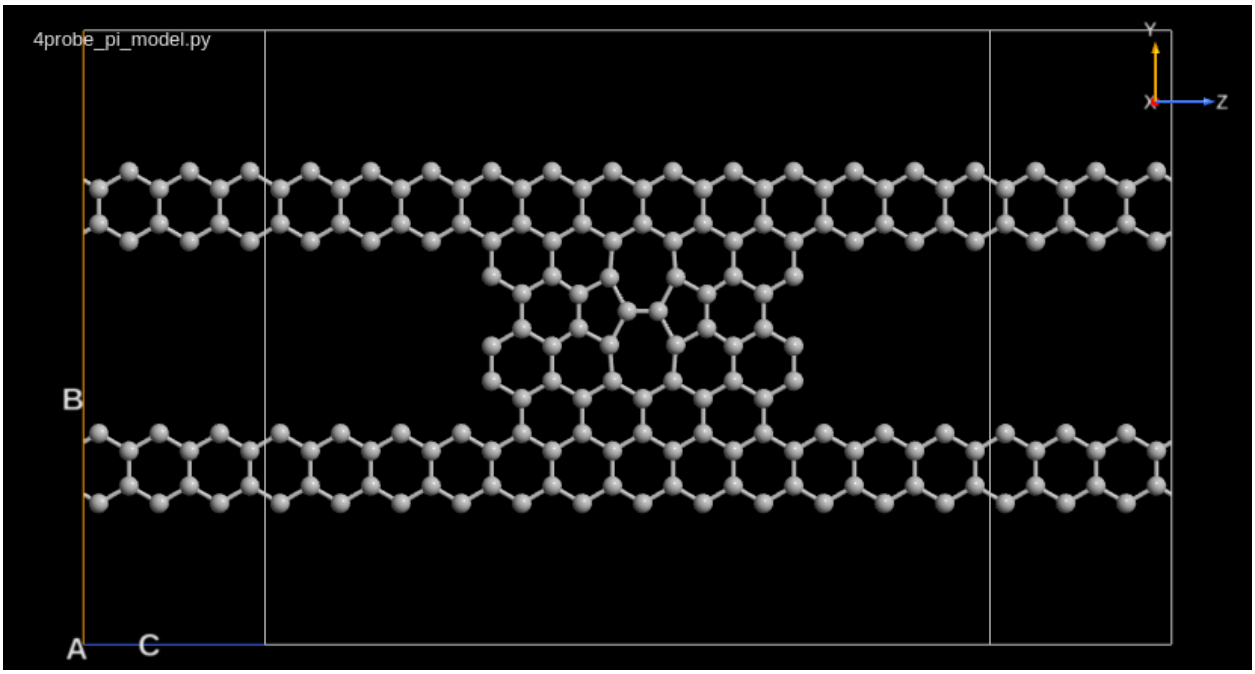
[3] Y.W. Son, M.L. Cohen, and S.G. Louie, Phys. Rev. Lett. **97**, 216803 (2006)

Multi-terminal conduction

You will in this section consider a 4-probe graphene device, and calculate the transmission between each of the four probes. For the calculation, you will extract the self energies of each of the four probes and implement the Fisher–Lee transmission function in a small QuantumATK Python script. The example is inspired by the 4-probe setup in[1].

Device calculations

You should first use the Slater–Koster tight-binding method to compute the ground state and zero-bias transmission at the Fermi level for the 4-terminal graphene device illustrated below.



Start up QuantumATK with a new project, for instance named 4probe graphene. Then download this pre-made QuantumATK Python script and save it in the project folder: `4probe_pi_model.py`. It sets up the device configuration with a Slater–Koster calculator, and then performs the calculation and computes the transmission at the Fermi level. All output is saved in `4probe_pi_model.hdf5`.

Run the script, either using the **Job Manager** or from command line:

```
$ atkpython 4probe_pi_model.py > 4probe_pi_model.log
```

The script will finish very quickly, and reports the Fermi level transmission in the log file:

```
+-----------------------------------------------------------+
| Transmission Spectrum Report                              |
| --------------------------------------------------------- |
| Left electrode Fermi level  =  3.851459e-01 eV            |
| Right electrode Fermi level =  3.851459e-01 eV            |
| Energy zero                 =  3.851459e-01 eV            |
+-----------------------------------------------------------+
```

(continues on next page)

(continued from previous page)

```
  energy       T(up)
    eV
0.000000e+00   7.553672e-01
```

Calculating the transmission between the 4 leads

The calculated transmission in the previous section is from the two leads on the left-hand side of the device, which are tagged lead1 and lead2, to the two leads on the right-hand side of the device, tagged lead3 and lead4.

Tip: You can check the tags if you send the device configuration to the Builder.

ATK has no analysis functions for calculating transmission between individual leads. For such a calculation, you need to calculate the broadening function of each lead, Γ_i, and then evaluate the Fisher–Lee relation,

$$T_{ij} = \mathrm{Tr}[\Gamma_i G^r \Gamma_j (G^r)^\dagger],$$

where G^r is the retarded Green function of the device.

The downloadable script `4probe_trans.py` performs this calculation. The script extracts internal QuantumATK quantities for the calculation, and the following section discusses details of the script.

Details of the script

The first part of the script is a utility function, which can zero out all entries in the Γ matrix, except for the orbitals belonging to the indices of the specified atoms. To obtain a list of the orbitals on the atoms, the function uses a `ProjectionList` object.

```
# Utility function to project out Gamma of the lead1, lead2, lead3, lead4
def projectGamma(configuration, gamma, indices):
    """Zero all components in Gamma which are not in the indices list
    @param configuration : The configuration giving the full Gamma
    @param gamma         : The full gamma
    @param indices       : Indices of the atoms to project onto

    @return              : The projected gamma
    """

    projection_list = ProjectionList(indices)
    orbital_index = projection_list.orbitalIndex(configuration)
    # Make a filter matrix consisting of 1's at the orbital_index
    filter = 0*gamma
    for i in orbital_index:
        for j in orbital_index:
            filter[i,j] = 1
    return gamma*filter
```

Another important part is the lines shown below, which use the tags on the device configuration to determine the indices of the atoms in each electrode.

```
# Project onto Lead 1, 2, 3, 4
lead1_index = device_configuration.indicesFromTags('lead1')
Gamma1 = projectGamma(device_configuration, Gamma_L, lead1_index)
lead2_index = device_configuration.indicesFromTags('lead2')
Gamma2 = projectGamma(device_configuration, Gamma_L, lead2_index)
lead3_index = device_configuration.indicesFromTags('lead3')
Gamma3 = projectGamma(device_configuration, Gamma_R, lead3_index)
lead4_index = device_configuration.indicesFromTags('lead4')
Gamma4 = projectGamma(device_configuration, Gamma_R, lead4_index)
```

The rest of the script should be self explanatory to experienced QuantumATK users.

Running the script

Save the script and execute it. It should produce the following output:

```
T: L (1,2) -> R    (3,4)   : 0.756157362529
T: Up(1,3) -> Down (2,4)   : 0.232988936132

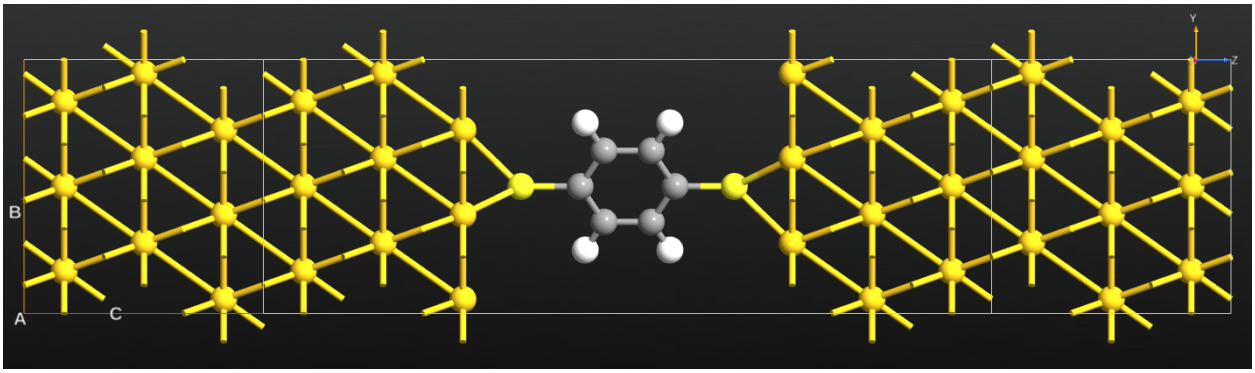
Transmission Matrix
[[ 3.99103191  0.05825146  0.04799848  0.05832079]
 [ 0.05825146  4.60578343  0.05853133  0.59130676]
 [ 0.04799848  0.05853133  3.74982393  0.05788536]
 [ 0.05832079  0.59130676  0.05788536  1.96636417]]
```

The script reports the transmission matrix, T_{ij}. By summing up $i \in L$, $i \in R$ it is possible to get the transmission from left to right, which is identical (within numerical noise), to the value from the bare QuantumATK transmission calculation.

By summing up the transmission coefficients between the upper leads and the lower leads, it is possible to calculate the up-down transmission, as in[Page 1687, 1].

Transmission projection

You will here learn how to resolve a transmission calculation into molecular projected self-consistent Hamiltonian (MPSH) eigenstates. In this way, you can analyze how large a fraction of a transmission function is propagating through a particular eigenstate or part of the system. As an example, you will investigate a dithiol-benzene (DTB) ring between two gold surfaces, see[2].



[2] K.ăStokbro, J.ăTaylor, M.ăBrandbyge, J.-L. Mozos, and P.ăOrdejón. Theoretical study of the nonlinear conductance of Di-thiol benzene coupled to Au(111) surfaces via thiol and thiolate bonds. *Computational Materials Science*, 27(1-2):151–160, 2003. doi:10.1016/S0927-0256(02)00439-1.

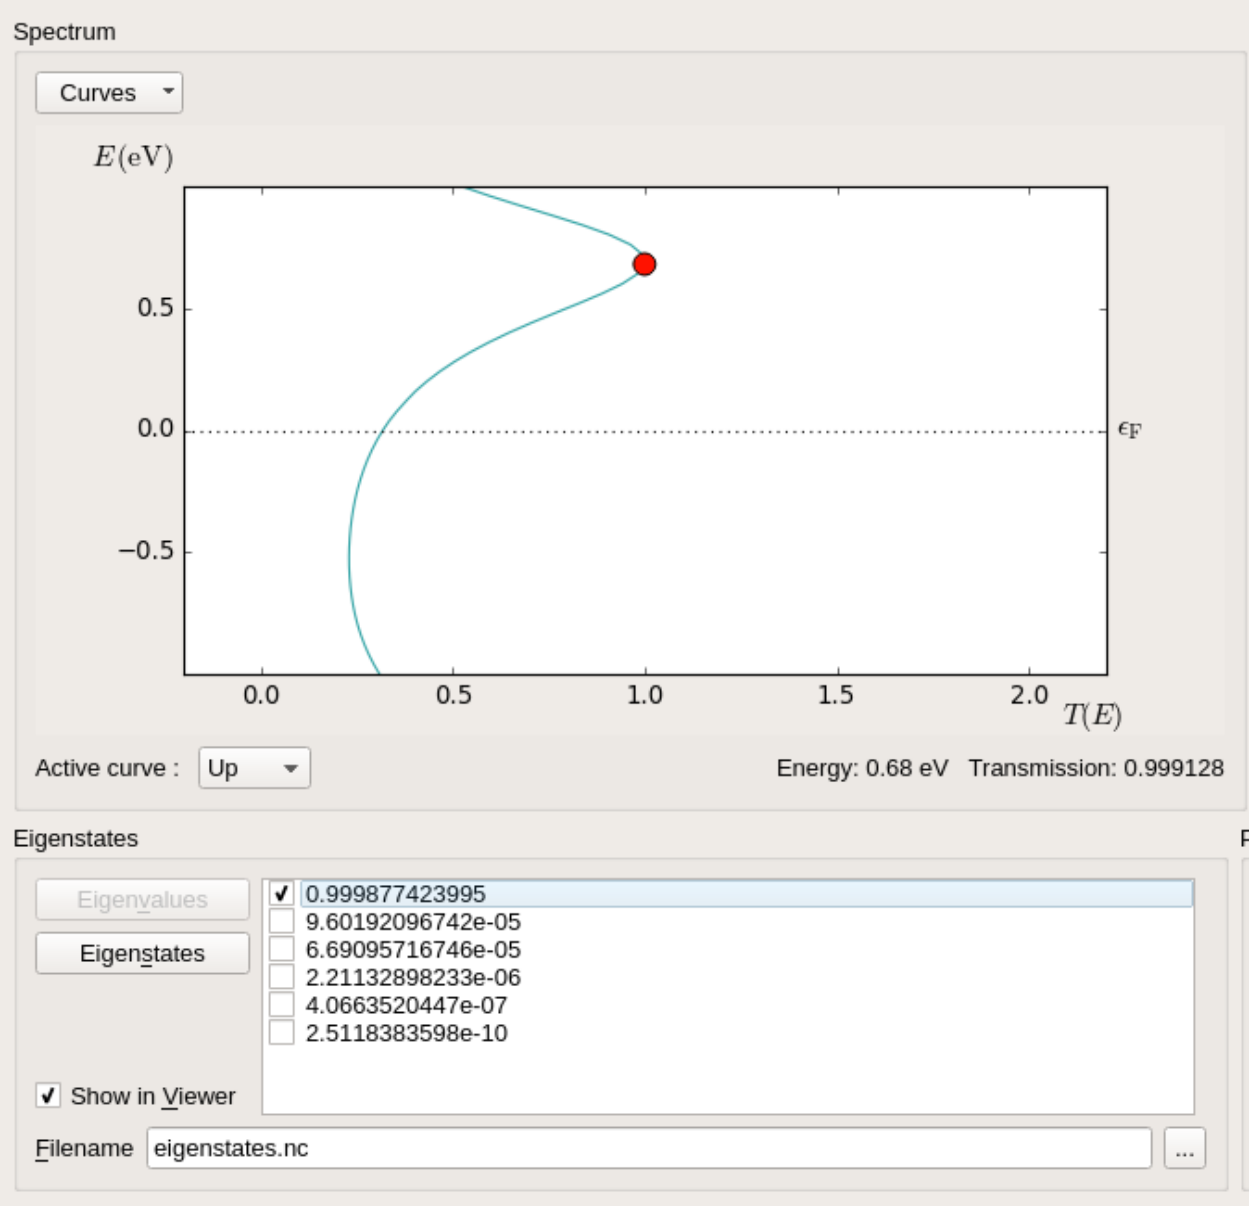
Running the calculations

Use the pre-made QuantumATK Python script `au_dtb_au.py`, which defines the Au–DTB–Au device configuration, performs a DFT-SE calculation using the extended Hückel method, and computes the -point transmission in an energy range ± 1 eV around the Fermi level. The calculations will finish in a few minutes.

Analyzing the transmission

Once the calculation has finished, the file `au_dtb_au.hdf5` will appear on the LabFloor. Select the **Transmission-Spectrum** item and open the **Transmission Analyzer**.

The -point transmission spectrum has a peak 0.68 eV above the Fermi level. Select this peak using the mouse, and click **Eigenvalues** to calculate the transmission eigenvalues. There is one dominating eigenvalue very close to 1, and several negligible eigenvalues.



Remove the tick from all except the highest eigenvalue, and click the **Eigenstates** button. This will calculate the scattering eigenstate in real space, and the Viewer will pop up with a visualization of it – choose the isosurface visualization option if prompted. You can then use the *Properties* → *Isosurfaces* options to tune the visualization.

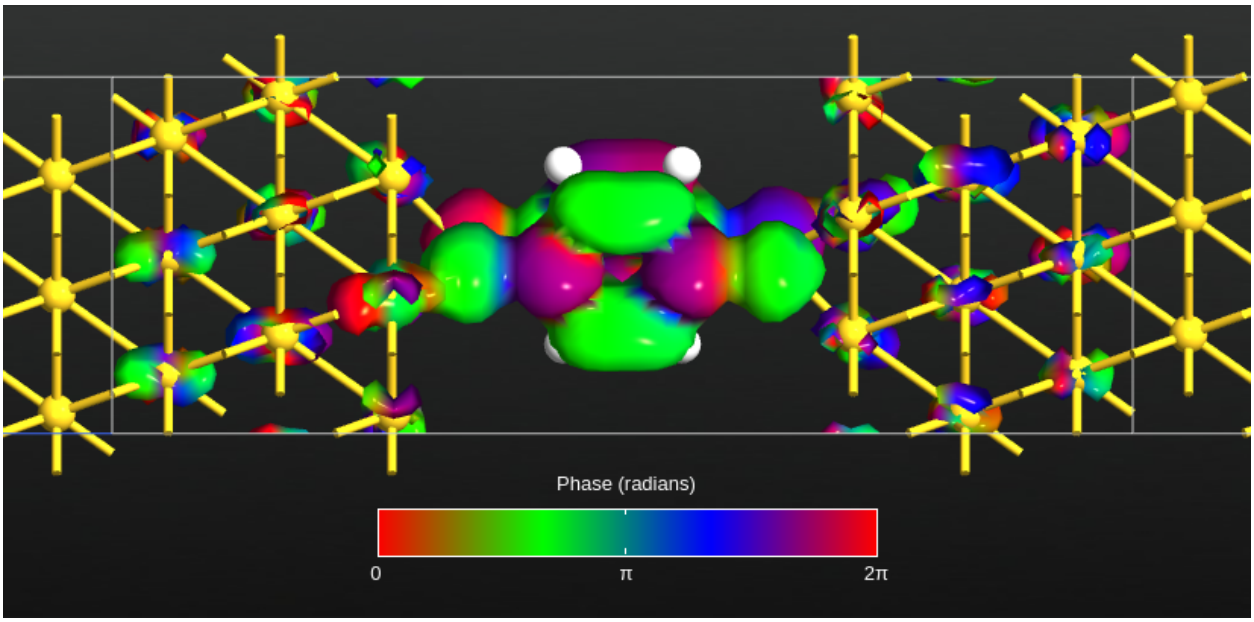


Fig. 3.117: Largest transmission eigenstate for energy 0.68 eV. The isosurface indicates an absolute value of 0.05 Å$^{-3/2}$, and the colors indicate the phase of the eigenstate.

Projecting the transmission

We would now like to project the transmission eigenstate onto the MPSH states of the molecule, to find the orbitals that carry the transmission.

The scattering state, $\psi(\mathbf{r})$, is expanded in basis orbitals, $\phi_i(\mathbf{r})$, through expansion coefficients v_i,

$$\psi(\mathbf{r}) = \sum_i v_i \phi_i(\mathbf{r}).$$

We now diagonalize the self-consistent Hamiltonian projected onto DTB,

$$H^{\mathrm{DTB}}\mathbf{c}_\alpha = \varepsilon_\alpha S^{\mathrm{DTB}}\mathbf{c}_\alpha,$$

where $\mathbf{c}_\alpha$ are the expansion coefficients of the MPSH states.

Next, we expand the projection of the scattering state of the DTB molecule in the MPSH states,

$$\mathbf{v} = \sum_\alpha a_\alpha \mathbf{c}_\alpha,$$

where the expansion coefficients are given by $a_\alpha = \mathbf{c}_\alpha^\dagger S^{\mathrm{DTB}}\mathbf{v}$. Through the magnitude of each a_α, we can get the relevance of each MPSH state, and

$$\sum_\alpha |a_\alpha|^2 = \mathbf{v}^\dagger S^{\mathrm{DTB}}\mathbf{v}.$$

Below is given a script, `projection.py`, which calculates the largest eigenvalue scattering state[3] at energy 0.68 eV, and calculates the projection weight of each MPSH state,

$$p_\alpha = \frac{|a_\alpha|^2}{\mathbf{v}^\dagger S^{\mathrm{DTB}} \mathbf{v}}.$$

```
from QuantumATK import *
from utilities import vectorToGrid, scatteringStates, averageFermiLevel
import scipy

# Read the configuration
device_configuration = nlread('au_dtb_au.hdf5', DeviceConfiguration)[0]
# Get H and S

# Project the eigenstate onto the DTB molecule
ev_dtb = eigenvector[orbital_index]
# Get the norm of the projected eigenstate
norm_ev = numpy.dot(numpy.conj(ev_dtb.transpose()), numpy.dot(S_dtb, ev_dtb))

# Loop over all MPSH
for i in range(len(w)):
    # Resolve the eigenstate into the MPSH states
    coeff = numpy.dot(numpy.conj(v[:,i].transpose()), numpy.dot(S_dtb, ev_dtb))
    # Find the strength of the MPSH projection
    p = numpy.conj(coeff)*coeff
    p = numpy.abs(p/norm_ev)
    # Print out the weight of each non negligible projection
    if p > 0.001:
        print(i, p)
```

The script uses some utility functions from the script `utilities.py`.

[3] M.ăPaulsson and M.ăBrandbyge. Transmission eigenchannels from nonequilibrium Greens functions. *Phys. Rev. B*, 76:115117, Sep 2007. doi:10.1103/PhysRevB.76.115117.

Running the scripts

Save both scripts, and execute `projection.py` using the Job Manager or from command line. It will generate the following output:

```
8 0.00686834365658
11 0.00467610628863
15 0.981647336721
17 0.00670447660685
```

The MPSH state number 15 is clearly the one with the largest projection.

Plotting the MPSH states

The script `mpsh.py` shown below will save MPSH states 8, 11, 15, and 17 into the HDF5 data file `mpsh.hdf5`. The script uses the function `vectorToGrid()`, which performs the folding of the eigenvector with the basis functions.

```
from QuantumATK import *
from utilities import vectorToGrid, averageFermiLevel
import scipy

# Read the configuration
device_configuration = nlread('au_dtb_au.hdf5', DeviceConfiguration)[0]
# Get H and S
H, S = calculateHamiltonianAndOverlap(device_configuration)
H = H.inUnitsOf(eV)

# Calculate average Fermi level
average_fermi_level = averageFermiLevel(device_configuration)

# Get index of orbitals on the Phenyl ring
projection_list = ProjectionList(elements=[Carbon, Hydrogen])
orbital_index = projection_list.orbitalIndex(device_configuration)
# Project H, S onto the Phenyl ring
H_dtb = H[orbital_index,:][:, orbital_index]
S_dtb = S[orbital_index,:][:, orbital_index]

# Calculate the eigenfunctions
w, v = scipy.linalg.eigh(H_dtb, S_dtb)
# Calculate eigen energies relative to the fermi level
eigen_energies =  (w*eV-average_fermi_level)

# Save eigenstates number 13-17
for i in [8, 11, 15, 17]:
    print('eigenenergy ', i,  eigen_energies[i])
    # Put the eigenvector into a vector of length of all orbitals
    number_orbitals = H.shape[0]
    eigenvector = numpy.zeros(number_orbitals, dtype=complex)
    eigenvector[orbital_index] = v[:,i]
    grid = vectorToGrid(eigenvector, device_configuration)
    nlsave('mpsh.hdf5', grid)
```

Run the script, and when finished drag and drop the object with ID `gID002` from `mpsh.hdf5` onto the Viewer.

Then add the device configuration to the plot by drag and dropping it from `au_dtb_au.hdf5`. By adjusting the plot properties, you should be able to get the image shown below.

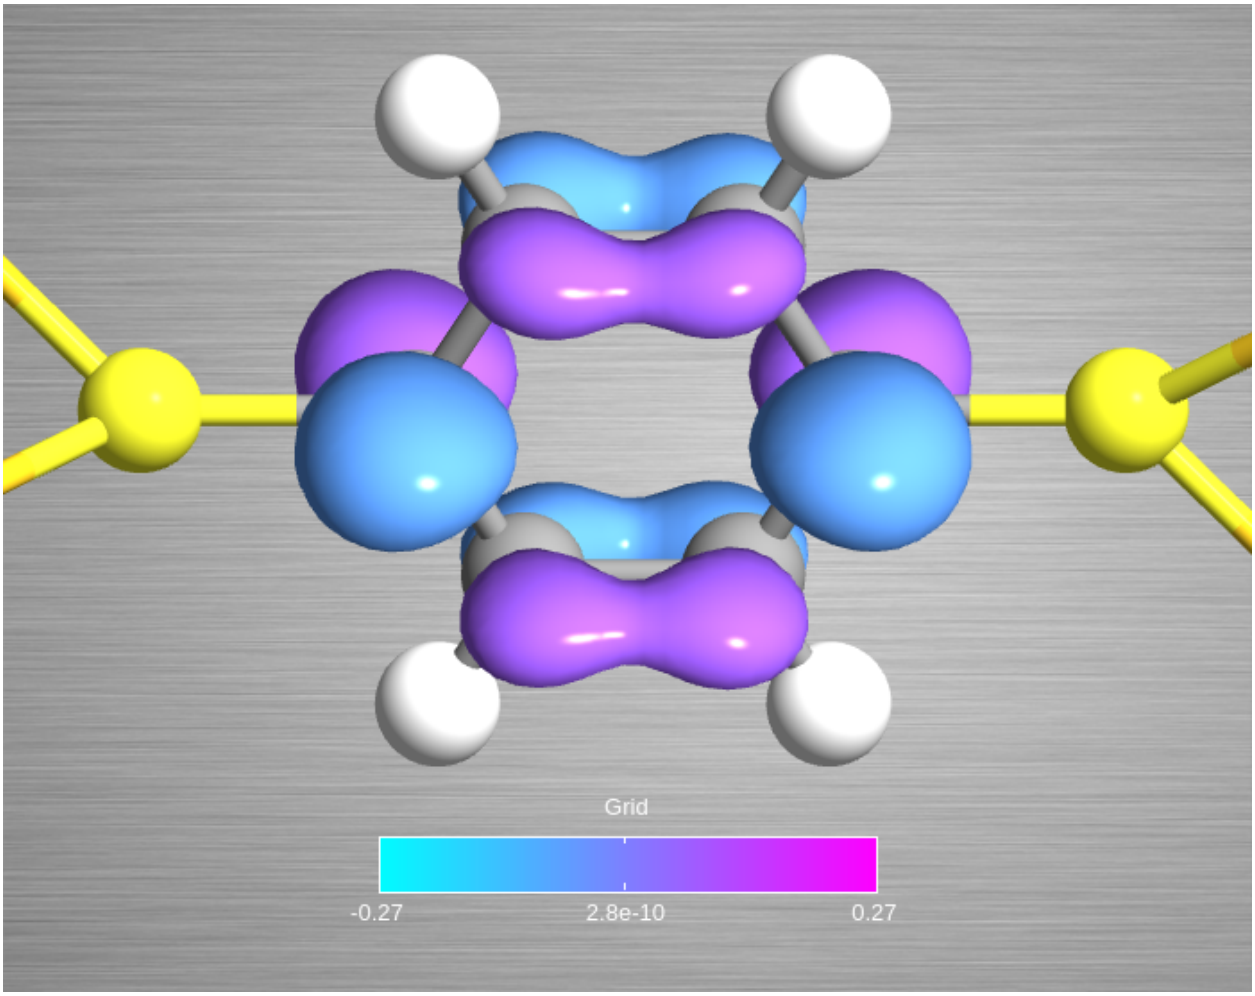

Fig. 3.118: Isosurface with isovalue 0.07 $Å^{-3/2}$ for MPSH state number 15.

Note: The `vectorToGrid()` method uses a finer grid spacing than the value set by the HuckelCalculator. This is why the image above has high-quality resolution.

AC conductance

The scripts presented in this section can be used to calculate the AC conductance of a nanodevice within the wide-band limit. The implementation follows closely the work by Yamamoto *et al.*[4].

We will here consider the (10,10) carbon nanotube device illustrated below, and use again the extended Hückel method with a π-model. Use `cnt_device.py` to perform the ground state device calculation.

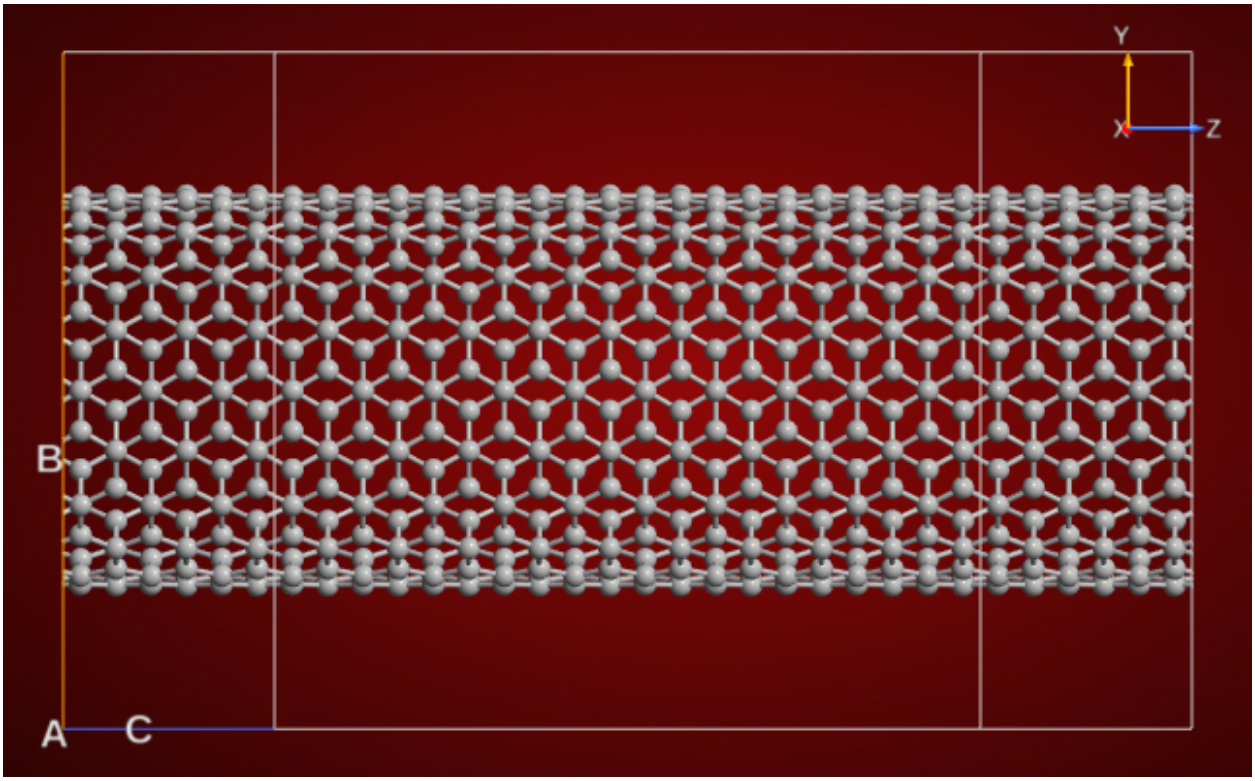

Fig. 3.119: (10,10) CNT device configuration with a central region length of 24.61 Å.

The **admittance** is defined as the inverse of the impedance, and is a measure of how easily a device will allow a current to flow. Download the scripts `cnt_admittance.py` and `admittance.py` to your QuantumATK project folder. Then execute `cnt_admittance.py`, which computes and plots the real (G) and imaginary (B) parts of the AC admittance for the CNT device.

Note: Since the implementation of the AC conductance is done in Python and uses dense matrices, the calculation is computationally inefficient, and for systems with a large number of orbitals the calculation can take substantial time.

---

3.12.3 Slater-Koster tight-binding models in ATK-SE

Version: 2017.0

ATK-SemiEmpirical (**ATK-SE**) comes preloaded with Slater-Koster parameters for simple systems like Si and GaAs, using a couple of different nearest-neighbor models like sp^3s^* and $sp^3d^5s^*$. One very important feature of ATK-SE is, however, that it is possible to **manually** define custom Slater-Koster parameters, e.g. found in scientific literature, and this will be demonstrated in this tutorial.

The tutorial considers a nearest-neighbor Slater-Koster model for hydrogen-passivated silicon, which can for example be used to simulate H-terminated Si nanowires.

Introduction

There are two primary ingredients in a Slater-Koster (SK) model for electronic structure calculations:

1. The values of the **onsite** matrix elements for each element (or atom types) in the model.
2. The values of the **offsite** (hopping) matrix elements for each pair of atom types in the model, and how these depend on the distance between the atoms.

These points will be discussed extensively in this tutorial.

Nearest-neighbor model for silicon with placeholder hydrogen atoms

We will use the Boykin-type $sp^3d^5s^*$ model by Zheng *et al.*[1], which is a commonly used Slater-Koster parametrization for studying Si nanowires. The model extends an earlier parametrization of Si and Ge[2], which in turn builds on the original $sp^3d^5s^*$ models by Jancu *et al.*[3]. The latter is available as a built-in basis set in QuantumATK (denoted Bassani).

Note: The Boykin-type Slater-Koster model implemented in this tutorial will be available as a built-in basis set in QuantumATK as of the 2018 release.

The first step is to define the SK model for Si according to Ref.[Page 1697, 2], then the hydrogen matrix elements will be added to the model in a second step according to Ref.[1]. These are used to remove spurious electronic states due to dangling Si surface bonds, so they basically constitute a numerical trick.

Onsite matrix element

First, consider the onsite matrix element. Here you need to specify the **angular momenta**, **number of valence electrons**, **ionization potentials** and **spin-orbit split** of the basis orbitals. The onsite **Hartree shift** and **spin split** are taken from built-in databases in QuantumATK.

The ionization potentials and spin-orbit split can be taken directly from Ref.[2]. There are four types of valence orbitals (3s, 3p, 3d, and an excited s-type orbital, commonly denoted s* in literature). The onsite Hartree shifts can be extracted from a built-in database; for the *unoccupied* orbitals 3d and s* will use the values from the *occupied* valence orbitals. The spin splits are also obtained from a built-in database.

The onsite matrix elements for each element in the basis set are specified as instances of the *SlaterKosterOnsiteParameters* ATKPython class. For the present silicon SK model, we use the variable `onsite` for an instance of this class:

```
# Define ionization potentials
Es    = -2.15168*eV
Ep    =  4.22925*eV
Ed    = 13.78950*eV
Es1   = 19.11650*eV

# Define spin-orbit split
split =  0.01989*eV

onsite = SlaterKosterOnsiteParameters(
            element                     = Silicon,
            angular_momenta             = [0,1,2,0],
            number_of_valence_electrons = 4,
            filling_method              = SphericalSymmetric,
            ionization_potential        = [Es,Ep,Ed,Es1],
            onsite_hartree_shift=ATK_U(PeriodicTable.Silicon, ["3p"], 'ncp')[0],
            onsite_spin_split=ATK_W(PeriodicTable.Silicon, [ "3p", "3p", "3p", "3s" ]),
            onsite_spin_orbit_split=[0.0,2*split, 0.0, 0.0]*eV,
           )
```

Note that the `element` for which these onsite parameters apply to is a **required argument**.

Tip: Occupations: What actually happens when specifying `number_of_valence_electrons = 4` is that the four electrons are equally distributed among all the 10 available orbitals. This gives the following electron occupations of the Slater-Koster orbitals:

3s
(4/10) electrons * 1 s-type orbital = 0.4

3p
(4/10) electrons * 3 p-type orbitals = 1.2

3d
(4/10) electrons * 5 d-type orbitals = 2.0

s*
(4/10) electrons * 1 s-type orbital = 0.4

These occupations could also have been directly specified in the *SlaterKosterOnsiteParameters* instead of specifying the total number of electrons:

```
onsite = SlaterKosterOnsit+eParameters(
            element                       = Silicon,
            angular_momenta               = [0,1,2,0],
            # number_of_valence_electrons = 4,
            occupations                   = [0.4, 1.2, 2.0, 0.4],
```

Offsite matrix elements

A Slater-Koster model is in general not based on the concept of neighbors – the offsite (hopping) matrix elements are instead defined in a range of distances around each atom, possibly using a scaling function to specify the distance-dependence of the Hamiltonian matrix element. A cut-off distance should also be specified, above which atoms do not interact (the matrix element is set to zero beyond this distance).

The hopping matrix elements are therefore tabulated in an interval around the silicon nearest-neighbor distance, using values from Ref.[Page 1697, 2]:

```
from math import sqrt

# ----------------------------------------------------#
#                     Silicon                         #
#-----------------------------------------------------#

# a is the cubic lattice constant
a = 5.431*Ang

# Nearest neighbor distance
d_n1 = sqrt(3.0)/4.0*a
# Second-nearest neighbor distance
d_n2 = sqrt(2.0)/2.0*a

# Setup list of distances
epsilon = numpy.linspace(-0.20, 0.20, 41)
distances = [ d_n1*(1.0+x) for x in epsilon ] + [ 0.5*(d_n1+d_n2) ]

# Setup hopping elements
si_si_sss   = [ -1.95933*eV for x in epsilon ]
si_si_s1s1s = [ -4.24135*eV for x in epsilon ]
si_si_ss1s  = [ -1.52230*eV for x in epsilon ]
si_si_sps   = [  3.02562*eV for x in epsilon ]
si_si_s1ps  = [  3.15565*eV for x in epsilon ]
si_si_sds   = [ -2.28485*eV for x in epsilon ]
si_si_s1ds  = [ -0.80993*eV for x in epsilon ]
si_si_pps   = [  4.10364*eV for x in epsilon ]
si_si_ppp   = [ -1.51801*eV for x in epsilon ]
si_si_pds   = [ -1.35554*eV for x in epsilon ]
si_si_pdp   = [  2.38479*eV for x in epsilon ]
si_si_dds   = [ -1.68136*eV for x in epsilon ]
si_si_ddp   = [  2.58880*eV for x in epsilon ]
si_si_ddd   = [ -1.81400*eV for x in epsilon ]
```

Note that the cut-off distance is taken at the midpoint between the first and second nearest neighbors (the separate element added to the list), where the corresponding matrix element is set to zero.

Important: The hopping matrix elements defined above are only valid for silicon with a lattice constant of 5.431 Å.

However, the scaling function for the matrix elements could also be fitted to allow calculations for more irregular structures. In that approach, it is commonly assumed that the matrix elements $ijk(d)$ follow a power law,

$$ijk(d) = ijk(d_0)\left(\frac{d_0}{d}\right)^{n_{ijk}},$$

where d_0 is the ideal neighbor distance. Harrison[4] originally used a general exponent of $n_{ijk} = 2$ for all matrix elements ijk, but later work, e.g.[Page 1697, 3] and[5], extends this to fit an individual exponent for each matrix element.

Defining the full Slater-Koster table

In QuantumATK, the Slater-Koster basis set should be implemented as an instance of the *SlaterKosterTable* ATKPython class. As explained in detail in the *ATK Manual*, the onsite and offsite matrix elements in the *SlaterKosterTable* are defined using special keyword arguments.

Onsite parameters

The onsite matrix element for Si is simply passed to the *SlaterKosterTable* using the label `silicon`:

```
# Create Slater-Koster table
basis_set = SlaterKosterTable(silicon     = onsite,
```

Offsite parameters

All the offsite matrix elements defined above are given as individual keyword arguments when setting up the *SlaterKosterTable*. As explained in the *ATK Manual*, these arguments must be on the form `element1_element2_XYZ=list`, where `X` and `Y` are the labels of the orbitals on the first and second elements (both can be `s`, `p`, `d`, or `f`), while `Z` is the type of interaction (`s`, `p`, or `d` for σ, π, or δ, respectively).

Thus, for example, the $\mathrm{sd}\pi$ offsite matrix element between carbon and silicon in some hypothetical SK model would be set with the keyword `si_c_sdp`.

In the present case of pure silicon, the full Slater-Koster table definition, including both onsite and offsite parameters, becomes as follows:

```
# Create Slater-Koster table
basis_set = SlaterKosterTable(silicon     = onsite,
                              si_si_sss   = zip(distances,si_si_sss),
                              si_si_s1s1s = zip(distances,si_si_s1s1s),
                              si_si_ss1s  = zip(distances,si_si_ss1s),
                              si_si_sps   = zip(distances,si_si_sps),
                              si_si_s1ps  = zip(distances,si_si_s1ps),
                              si_si_sds   = zip(distances,si_si_sds),
                              si_si_s1ds  = zip(distances,si_si_s1ds),
```

[5] T.ăB. Boykin, M.ăLuisier, M.ăSalmani-Jelodar, and G.ăKlimeck. Strain-induced, off-diagonal, same-atom parameters in empirical tight-binding theory suitable for [110] uniaxial strain applied to a silicon parametrization. *Phys. Rev. B*, 81:125202, 2010. doi:10.1103/PhysRevB.81.125202.

(continued from previous page)

```
                                si_si_pps   = zip(distances,si_si_pps),
                                si_si_ppp   = zip(distances,si_si_ppp),
                                si_si_pds   = zip(distances,si_si_pds),
                                si_si_pdp   = zip(distances,si_si_pdp),
                                si_si_dds   = zip(distances,si_si_dds),
                                si_si_ddp   = zip(distances,si_si_ddp),
                                si_si_ddd   = zip(distances,si_si_ddd),
                               )
```

Note: **Some additional remarks:**

- The order of the element labels `X` and `Y` matters, if there is more than one element in the model. The orbital `i` is associated with the element `X` orbital, and `j` with `Y`.
- The element labels are not case-sensitive and may be abbreviated. Thus, `Si`, `si`, or `Silicon` are all accepted for silicon.

Tip: This present SK basis set contains two s-type orbitals (3s and s^*). To distinguish orbitals of the same angular momentum, there are two things to keep in mind:

- For the onsite elements, the identification is made by the ordering of the ionization potentials vs. the occupations and angular momenta, etc.
- For the offsite elements, a running index is added, so the first s-orbital is s0, the second one s1, etc. The 0 for the first orbital can be omitted to reduce the notation, so as you see above, the $s * p\sigma$ matrix element will be defined by the keyword `si_si_s1ps`, etc.

Full script

The full script defining the silicon Slater-Koster basis set combines all of the script snippets shown above:

```
from QuantumATK import *

'''
Generate a Slater-Koster basis set for silicon based on

                                si_si_ddd   = zip(distances,si_si_ddd),
                               )
```

SiBasisSet.py

Silicon band structure

A simple test case for the custom silicon Slater-Koster model is to compute the band structure of silicon:

```
# -*- coding: utf-8 -*-
# ------------------------------------------------------------
# Silicon
# ------------------------------------------------------------
lattice = FaceCenteredCubic(5.431*Angstrom)
elements = [Silicon, Silicon]
fractional_coordinates = [[ 0.  ,  0.  ,  0.  ],
                          [ 0.25,  0.25,  0.25]]
bulk_configuration = BulkConfiguration(
    bravais_lattice=lattice,
    elements=elements,
    fractional_coordinates=fractional_coordinates
    )
# ------------------------------------------------------------
# Calculator
# ------------------------------------------------------------
from SiBasisSet import basis_set
k_point_sampling = MonkhorstPackGrid(9,9,9,force_timereversal=False)
numerical_accuracy_parameters = NumericalAccuracyParameters(
    k_point_sampling=k_point_sampling,
    density_mesh_cutoff=10.0*Hartree,
    )
calculator = SlaterKosterCalculator(
    basis_set=basis_set,
    numerical_accuracy_parameters=numerical_accuracy_parameters,
    spin_polarization=SpinOrbit,
    )
bulk_configuration.setCalculator(calculator)
nlprint(bulk_configuration)
bulk_configuration.update()
nlsave('si_bs.hdf5', bulk_configuration)

# ------------------------------------------------------------
# Bandstructure
# ------------------------------------------------------------
bandstructure = Bandstructure(
    configuration=bulk_configuration,
```

(continues on next page)

(continued from previous page)

```
    route=[['L', 'G', 'X', 'W', 'K', 'L', 'W', 'X', 'U'],['K', 'G']],
    points_per_segment=50
    )
nlsave('si_bs.hdf5', bandstructure)
```

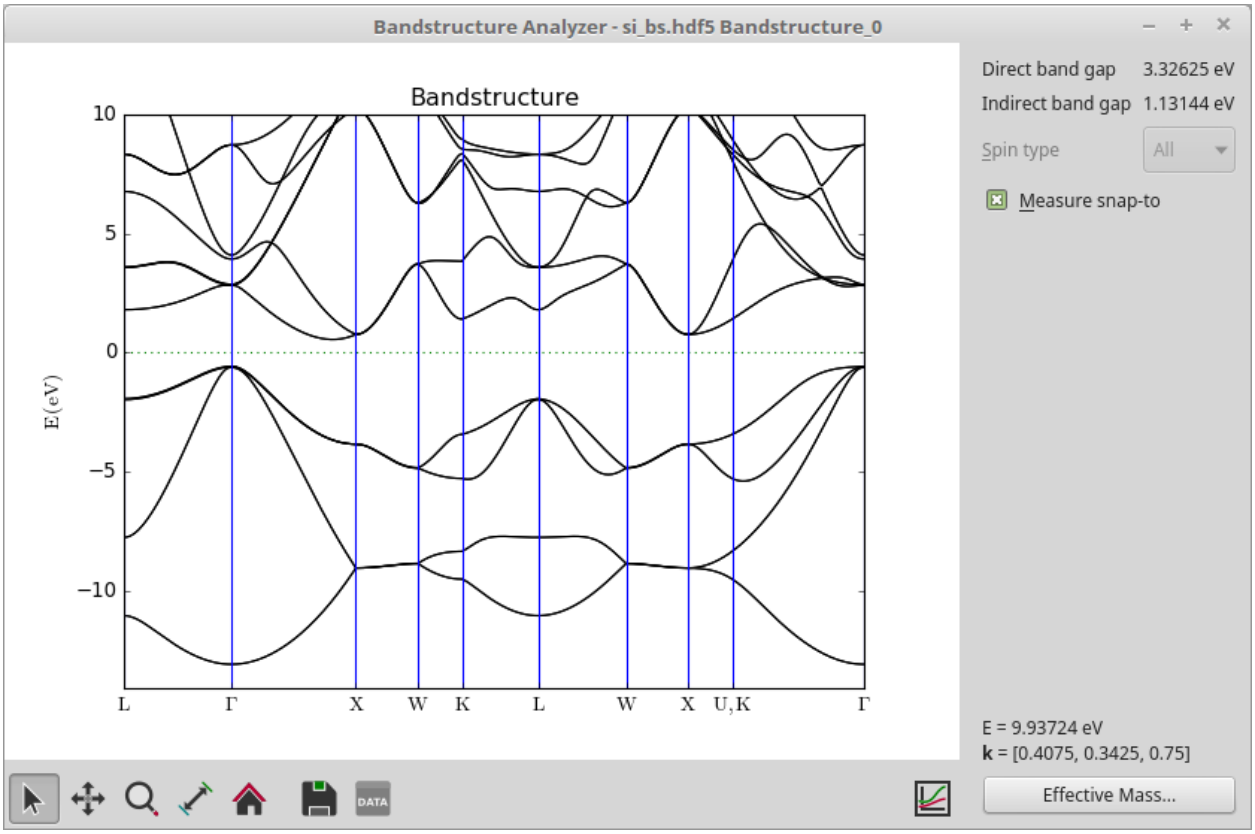
`si_bs.py`

Download this script, as well as the script `SiBasisSet.py` containing the Si basis set, and save them in your QuantumATK Project Folder.

Use the **Job Manager** to run the script `si_bs.py`, or run it from a terminal:

```
atkpython si_bs.py
```

The job should finish in a few seconds, and produces a very accurate band structure of silicon with an indirect band gap of 1.13 eV.



Note: The energy bands in Si are degenerate at the U and K points, and by the special way we construct the band structure route in the script, the band structure plot makes a discontinuous break in the route between these points, i.e. it goes from X to U, then jumps to K and continues to Γ.

Adding hydrogen

The goal of this tutorial is to enable modeling of H-terminated Si nanowires, so we need to expand the Slater-Koster table with the parameters for hydrogen from Ref.[Page 1697, 1]. As previously discussed, the role of the hydrogen atoms is to eliminate the effects of the unsaturated Si bonds on the surface of the wire, not to represent real hydrogen atoms. In an experiment it is of course quite possible that hydrogen atoms, or other atoms, will attach themselves to these dangling bonds, but that is not the point here.

The **onsite** matrix element for hydrogen is added like this:

```
# Define ionization potentials
Es_H    =  0.999840*eV

onsite_H = SlaterKosterOnsiteParameters(
                element                 = Hydrogen,
                angular_momenta         = [0],
                occupations             = [1.0],
                ionization_potential    = [Es_H],
                filling_method          = SphericalSymmetric,
                onsite_hartree_shift    = ATK_U(PeriodicTable.Hydrogen, ['1s']),
                onsite_spin_split       = [[0.0]]*eV,
                onsite_spin_orbit_split = [0.0]*eV,
                vacuum_level            = 0.0*Hartree,
```

Specifying the **offsite** parameters is done like this:

```
# reference distances
d_h_n1 = 1.4*Angstrom
d_h_n2 = 2.2*Angstrom

# Setup list of distances
h_distances = [d_h_n1 * (1.0+r) for r in epsilon] + [0.5 * (d_h_n1+d_h_n2)]

# Setup hopping elements
h_si_sss  = [ -3.999720*eV / 1.0 for r in epsilon ]
h_si_ss1s = [ -1.697700*eV / 1.0 for r in epsilon ]
h_si_sps  = [  4.251750*eV / 1.0 for r in epsilon ]
h_si_sds  = [ -2.105520*eV / 1.0 for r in epsilon ]
```

The onsite and offsite parameters are then simply added to the already prepared silicon *SlaterKosterTable*:

```
from QuantumATK import *

'''
Generate a Slater-Koster basis set for silicon based on
T. B. Boykin et al., PRB 69, 115201 (2004)
http://dx.doi.org/10.1103/PhysRevB.69.115201
'''

from math import sqrt

# ------------------------------------------------#
#                     Silicon                     #
#-------------------------------------------------#
```

(continues on next page)

(continued from previous page)

```
# a is the cubic lattice constant
a = 5.431*Ang

# Nearest neighbor distance

                onsite_hartree_shift    = ATK_U(PeriodicTable.Hydrogen, ['1s']),
                onsite_spin_split       = [[0.0]]*eV,
                onsite_spin_orbit_split = [0.0]*eV,
                vacuum_level            = 0.0*Hartree,
               )

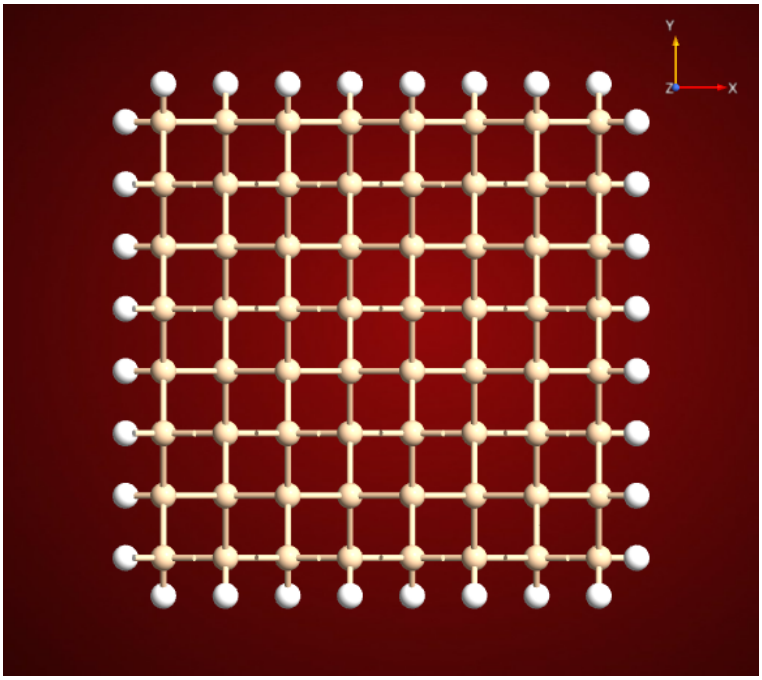
# Create Slater-Koster table
basis_set = SlaterKosterTable(silicon     = onsite,
                              hydrogen    = onsite_H,
                              si_si_sss   = zip(distances,si_si_sss),
                              si_si_s1s1s = zip(distances,si_si_s1s1s),
                              si_si_ss1s  = zip(distances,si_si_ss1s),
                              si_si_sps   = zip(distances,si_si_sps),
                              si_si_s1ps  = zip(distances,si_si_s1ps),
                              si_si_sds   = zip(distances,si_si_sds),
                              si_si_s1ds  = zip(distances,si_si_s1ds),
                              si_si_pps   = zip(distances,si_si_pps),
                              si_si_ppp   = zip(distances,si_si_ppp),
                              si_si_pds   = zip(distances,si_si_pds),
                              si_si_pdp   = zip(distances,si_si_pdp),
                              si_si_dds   = zip(distances,si_si_dds),
                              si_si_ddp   = zip(distances,si_si_ddp),
                              si_si_ddd   = zip(distances,si_si_ddd),
                              h_si_sss    = zip(h_distances,h_si_sss),
                              h_si_ss1s   = zip(h_distances,h_si_ss1s),
                              h_si_sps    = zip(h_distances,h_si_sps),
                              h_si_sds    = zip(h_distances,h_si_sds),
                             )
```

SiHBasisSet.py

Band gaps of passivated silicon nanowires

Due to quantum confinement, the band gap of silicon nanowires usually increase as the wire thickness decreases. You will here demonstrate this using the Si-H Slater-Koster model defined in the sections above.

The script `wires.py` contains 4 silicon nanowire configurations of different thickness. They are all hydrogen passivated, as exemplified below. The wires are perdiodic along the Z direction.



The script `nw_bs.py` loopes over all 4 nanowires and does a nonself-consistent Slater-Koster calculation and a band-structure analysis for each wire. Results are saved in individual HDF5 data files.

```
from SiHBasisSet import basis_set
from wires import wire_2x2, wire_3x3, wire_4x4, wire_5x5

for i, wire in zip([2,3,4,5],[wire_2x2,wire_3x3,wire_4x4,wire_5x5]):
    out = 'wire_%ix%i.hdf5' % (i,i)

    # ------------------------------------------------------------
    # Calculator
    # ------------------------------------------------------------
    k_point_sampling = MonkhorstPackGrid(nc=9,force_timereversal=False)
    numerical_accuracy_parameters = NumericalAccuracyParameters(
        k_point_sampling=k_point_sampling,
        density_mesh_cutoff=10.0*Hartree,
        )
    calculator = SlaterKosterCalculator(
        basis_set=basis_set,
        numerical_accuracy_parameters=numerical_accuracy_parameters,
        spin_polarization=SpinOrbit,
        )

    wire.setCalculator(calculator)
```

(continues on next page)

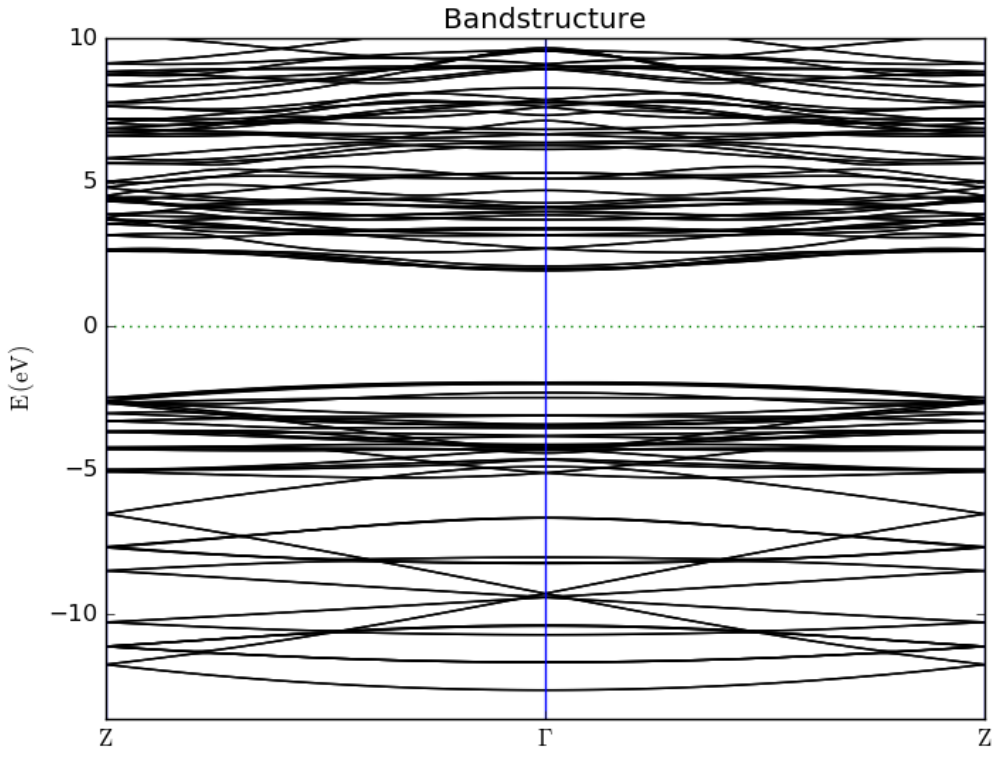
(continued from previous page)

```
nlprint(wire)
wire.update()
nlsave(out, wire)

# ------------------------------------------------------------
# Bandstructure
# ------------------------------------------------------------
bandstructure = Bandstructure(
    configuration=wire,
    route=['Z', 'G', 'Z'],
    points_per_segment=50
    )
nlsave(out, bandstructure)
```

Download both `wires.py` and `nw_bs.py`, and save them in your QuantumATK Project Folder, which should also contain `SiHBasisSet.py`. Then execute the script `nw_bs.py` using the Job Manager or a terminal – the calculation may take up to 10 minutes to run.

The resulting bandstructure analysis objects should appear on the LabFloor, and you can use the **Bandstructure Analyzer** to visualize the nanowire band structures. You will find for all 4 wires that the fundamental gap is located at the Γ point, and is significantly larger than the (indirect) band gap of bulk Si.



You can also use the script `nw_gaps.py` to extract the direct band gaps and compute the nanowire thicknesses, and to plot the data.

```
# Read data
gaps = []
lengths = []
for i in [2,3,4,5]:
    out = 'wire_%ix%i.hdf5' % (i,i)
    bandstructure = nlread(out, Bandstructure)[0]
    gap =bandstructure._directBandGap().inUnitsOf(eV)
    gaps.append(gap)
    wire = nlread(out, BulkConfiguration)[0]
    coordinates = wire.cartesianCoordinates().inUnitsOf(nanoMeter)
    indices = numpy.where(numpy.array(wire.symbols())=='Si')[0]
    coords = coordinates[indices][:,0]
    length = max(coords)-min(coords)
    lengths.append(length)

# Plot data
import pylab
pylab.figure(figsize=(8,4))
pylab.plot(lengths, gaps, 'bo-')
pylab.xlabel('Nanowire width (nm)')
pylab.ylabel('Nanowire band gap (eV)')
pylab.tight_layout()
pylab.savefig('nw_gaps.png')
pylab.show()
```

`nw_gaps.py`

Running the script produces the plot shown below. The nanowire band gap increase significantly for thicknesses of 1 nm or less, also also found in Ref.[Page 1697, 1].

3.12.4 Linear response current – how to compute it, and why it is often not a good idea

Version: 2016.2

In this tutorial, you will learn a simple way to calculate the **linear response current** and how it is different from the self-consistent result, the latter of which is necessary to exhibit **negative differential resistance** (NDR).

The question sometimes arises, why it is necessary to compute the I-V curve using finite-bias NEGF calculations – cant one just use the zero-bias transmission spectrum (which is much cheaper to compute) and calculate the finite-bias current from that? This is indeed possible, but the result – the linear response current – is in most cases radically different from the current evaulated from a finite-bias self-consistent solution. The reason is fairly simple: **The transmission spectrum is bias-dependent**.

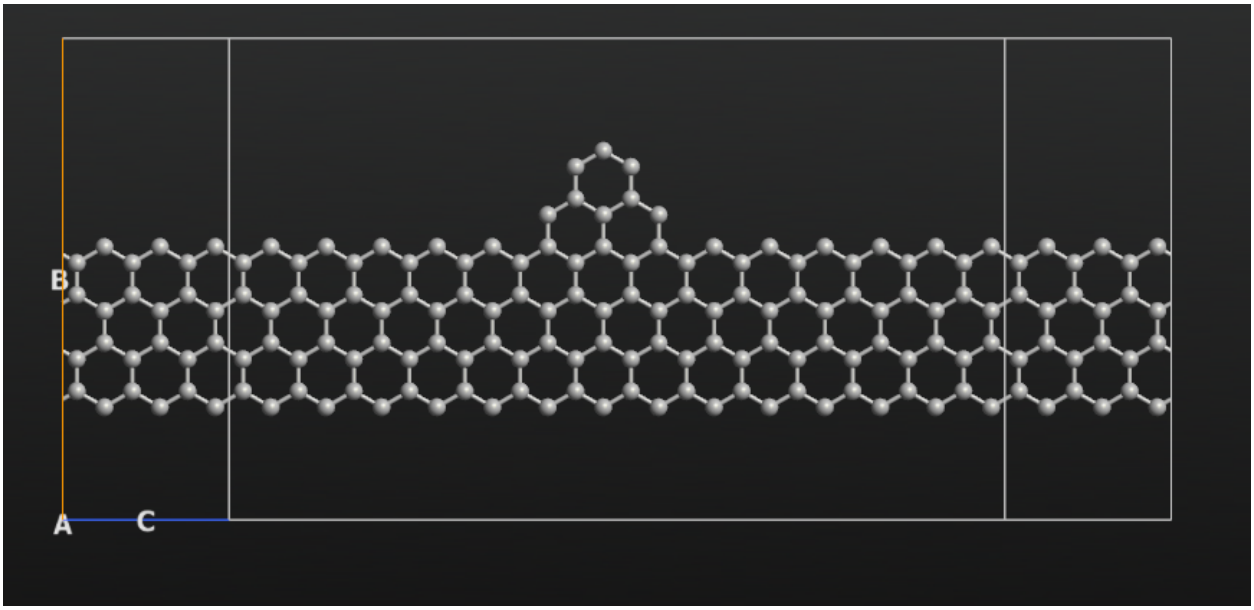
Important: In the linear response case, it is not possible to obtain negative differential resistance, since the current can only increase as the bias window opens up and you integrate an increasingly large part of the transmission spectrum. NDR is an important effect for applications, and is observed in a wide range of cases, but can only be obtained using a self-consistent finite-bias NEGF calculation.

Here well will demonstrate with a relatively simple example how to obtain the linear response current, and how it is different from the self-consistent result. The inspiration is taken from a recent work performed with QuantumATK by Yipeng An *et al.*[1]; in the article the authors used DFT, but we will consider the same system (specifically, the GE1 geometry) using a simple Slater-Koster tight-binding π-model.

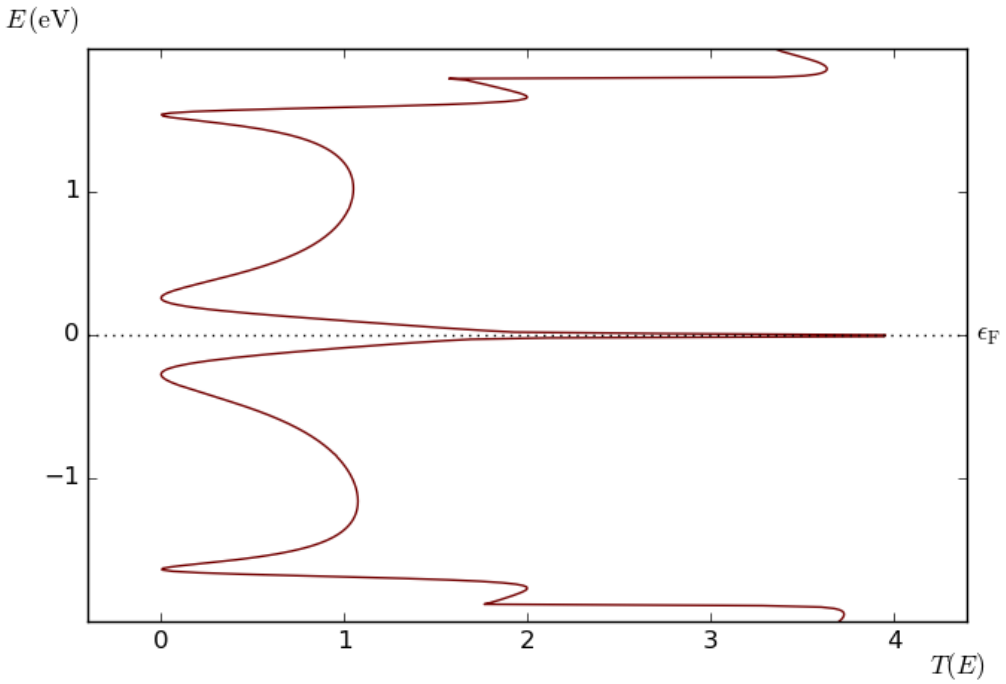
The geometry is shown below. We will not go into the details of how to create it; its farily easy, using the **Builder**:

Create a large graphene sheet and remove the atoms you dont need. Note that for the Slater-Koster model we dont use any terminating hydrogen atoms.

[1] Yipeng An, Wei Ji, and Zhongqin Yang. Z-like Conducting Pathways in Zigzag Graphene Nanoribbons with Edge Protrusions. *JPC C*, 116(9):5915–5919, 2012. doi:10.1021/jp3003646.



We can now compute the zero-bias transmission spectrum of this device. Use a pre-made QuantumATK Python script for this: `zero_bias.py`. The script takes less than a minute to run, even if there are 120 atoms in the central region. The resulting transmission spectrum is shown below (select the `Sum` spin channel in the *Curves* drop-down menu). The spectrum exhibits a pronounced peak at the Fermi level, which is to be expected since the electrodes are zigzag graphene nanoribbons.



At this point, we can compute the linear response I-V curve by integrating the transmission spectrum in an increasingly wide bias interval. QuantumATK supports this calculation via a built-in method on the *TransmissionSpectrum* object. Normally when you ask for the current,

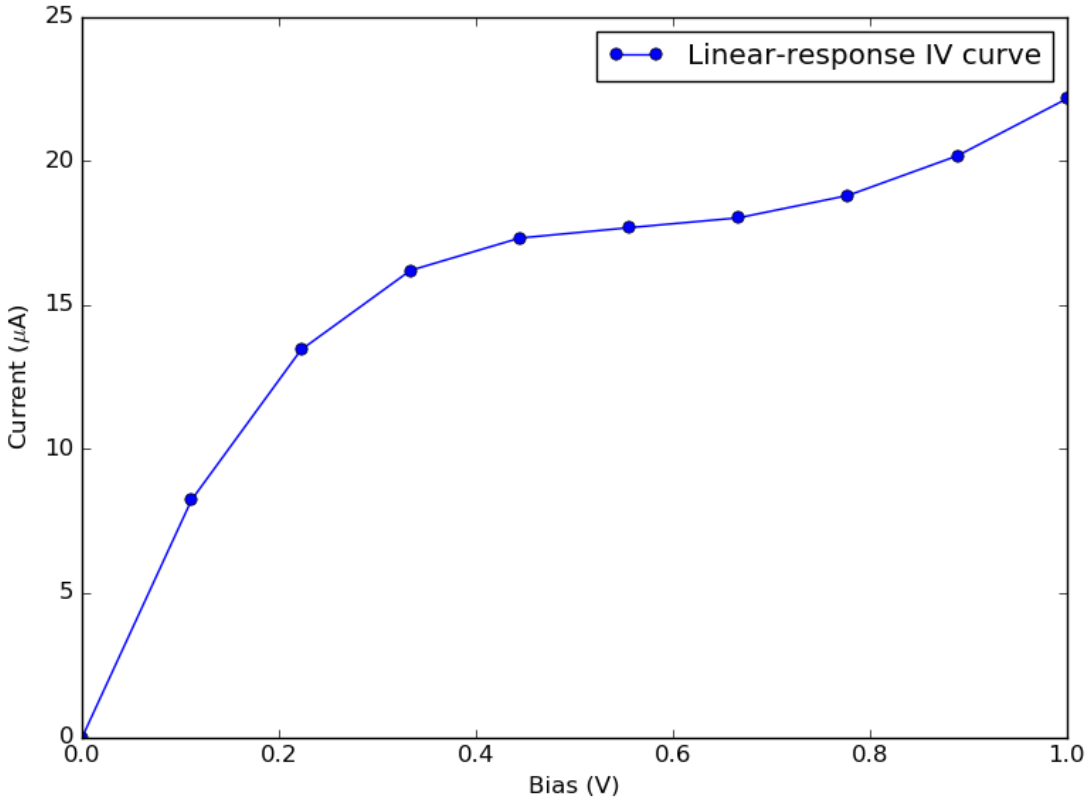
```
current = transmission_spectrum.current()
```

it will be evaluated for the bias that was used when computing the transmission spectrum. However, it is also possible to specify another set of electrode voltages, which will then be used instead. Thus, if the transmission spectrum, as in our case, was computed for zero bias, you can use

```
current = transmission_spectrum.current(electrode_voltages=[-0.5,0.5]*Volt)
```

to get the linear response current at 1 V bias. You can therefore extract an entire linear response I-V curve by looping over a range of bias points and compute the linear response current at each bias.

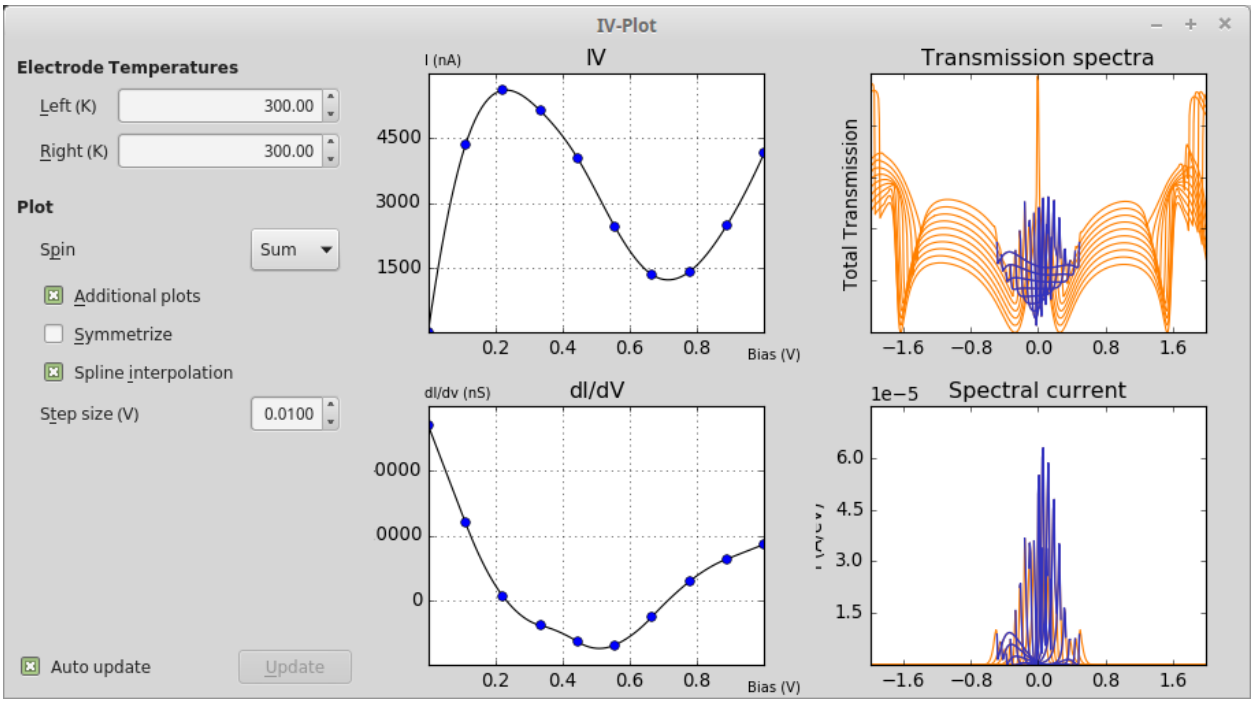
Download the script `linear_response.py` and execute it. The script computes and plots the linear response I-V curve. The result is shown below.



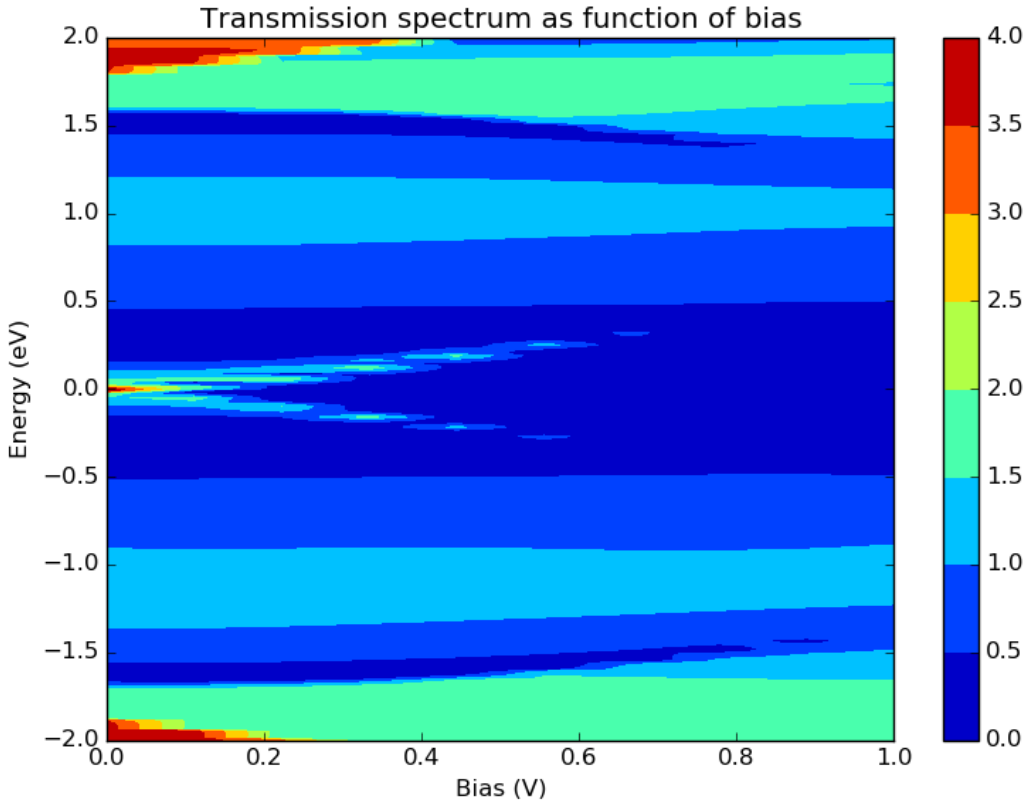
As expected, the current rises monotonically with the voltage – this is the only possible I-V curve that can be obtained this way, since we are integrating a non-negative function (the transmission spectrum) over an increasingly broad interval.

However, we know from[Page 1711, 1] that this system exhibits negative differential resistance, so something is not correct. Therefore, we will next compute the self-consistent transmission spectrum for each bias. Use this script: `iv.py`. It should take less than 5 minutes to run on a modern PC.

The script uses the `IVcurve` analysis object. From the QuantumATK LabFloor, select the generated **IVCurve** item and click the **IV-Plot** plugin from the right-hand plugins bar to visualize the results. Tick the boxes named *Additional plots* and *Spline interpolation*.



In this case we do indeed see NDR – the differential current is shown in the lower-left plot, and it does become negative – and from the upper-right plot of the transmission spectra we can see why. The individual transmission spectra are strongly bias-dependent. To illustrate this point even more clearly, we generate a contour plot of the transmission spectra as a function of energy and bias, using a simple script: `transmission_contour.py`.



Clearly, the assumption of a bias-independent transmission spectrum is invalid in this system, and as mentioned above indeed in most device configurations.

3.12.5 Make Movies from QuantumATK Trajectory Files

ATK: gif animations Platforms: Prerequisites: Know how to create NEB or MD structures in QuantumATK `NEBmovie.hdf5` *In this tutorial you will learn how to make nice movies from Trajectory, NudgedElasticBand (NEB) or MDTrajectory objects.*

Warning: You must already have an existing trajectory file.

Here we report the steps to follow to make a movie from an existing trajectory file. The example is a NEB calculation for a buckled graphene nanoribbon (GNR), but it works exactly the same way for optimization and MD trajectories. There are other tutorials describing how to create and calculate NEB trajectories. Also note that you can also make movies for trajectories computed with other software packages, like VASP, as long as they can be imported.

Creating Animated GIF

You can import your NEB object (here we use the NEB object in `NEBmovie.hdf5`) by simply dragging and dropping the file on the **Viewer**. There you can decorate your structure as you prefer by clicking on the **Properties** button in the right-hand panel. Left-clicking on the structure you have the following four extraction options:

NEBmovie.hdf5

You can download the NEB file from here: `NEBmovie.hdf5`.

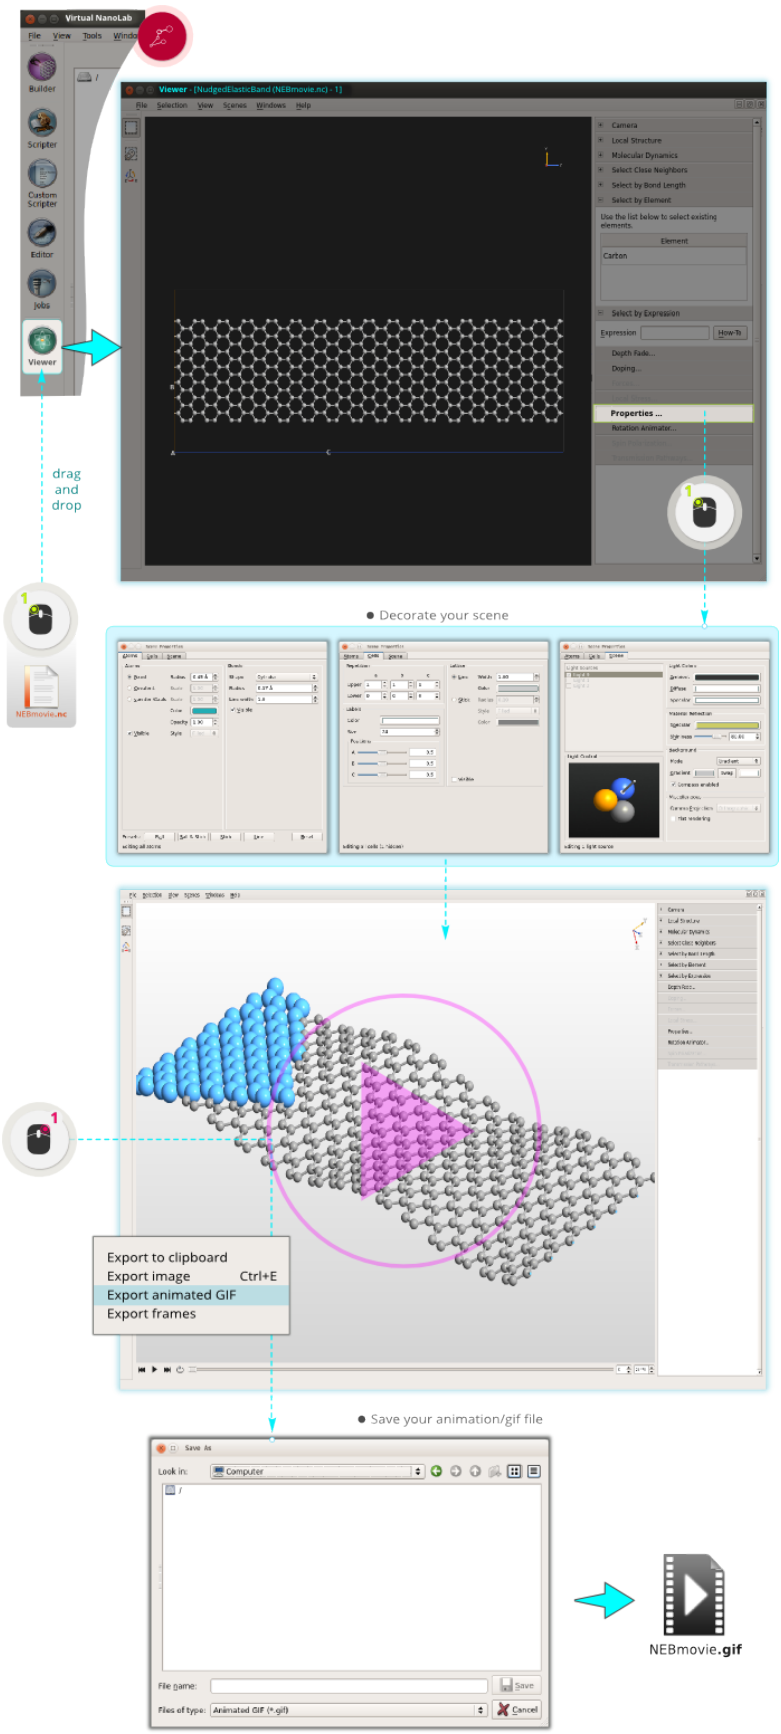
•Export to clipboard

•Export image

•**Export animated GIF**

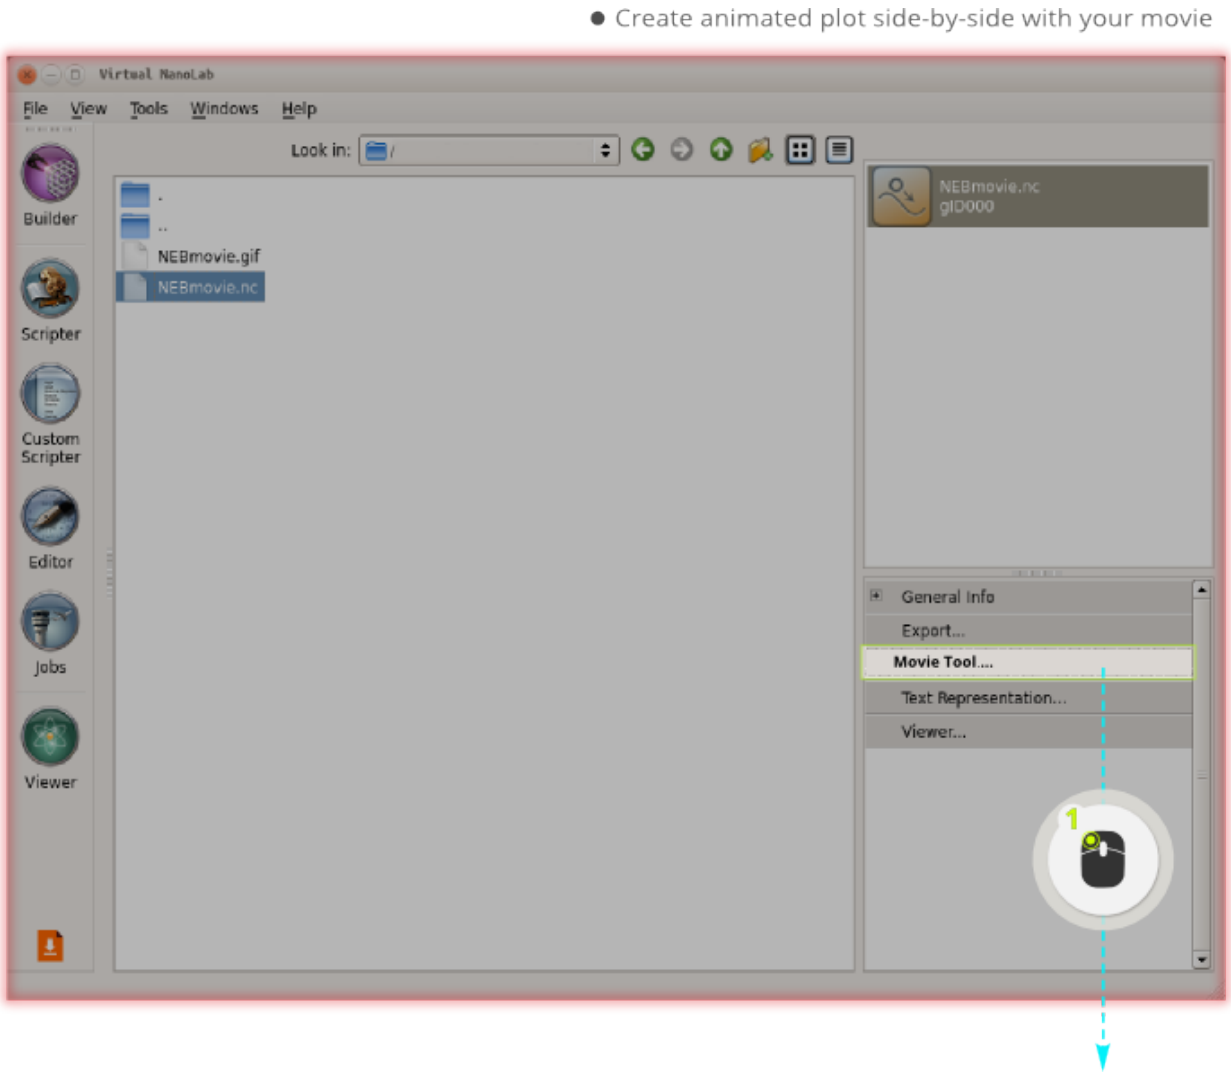
•Export frames

Use the following workflow for exporting an animated GIF:



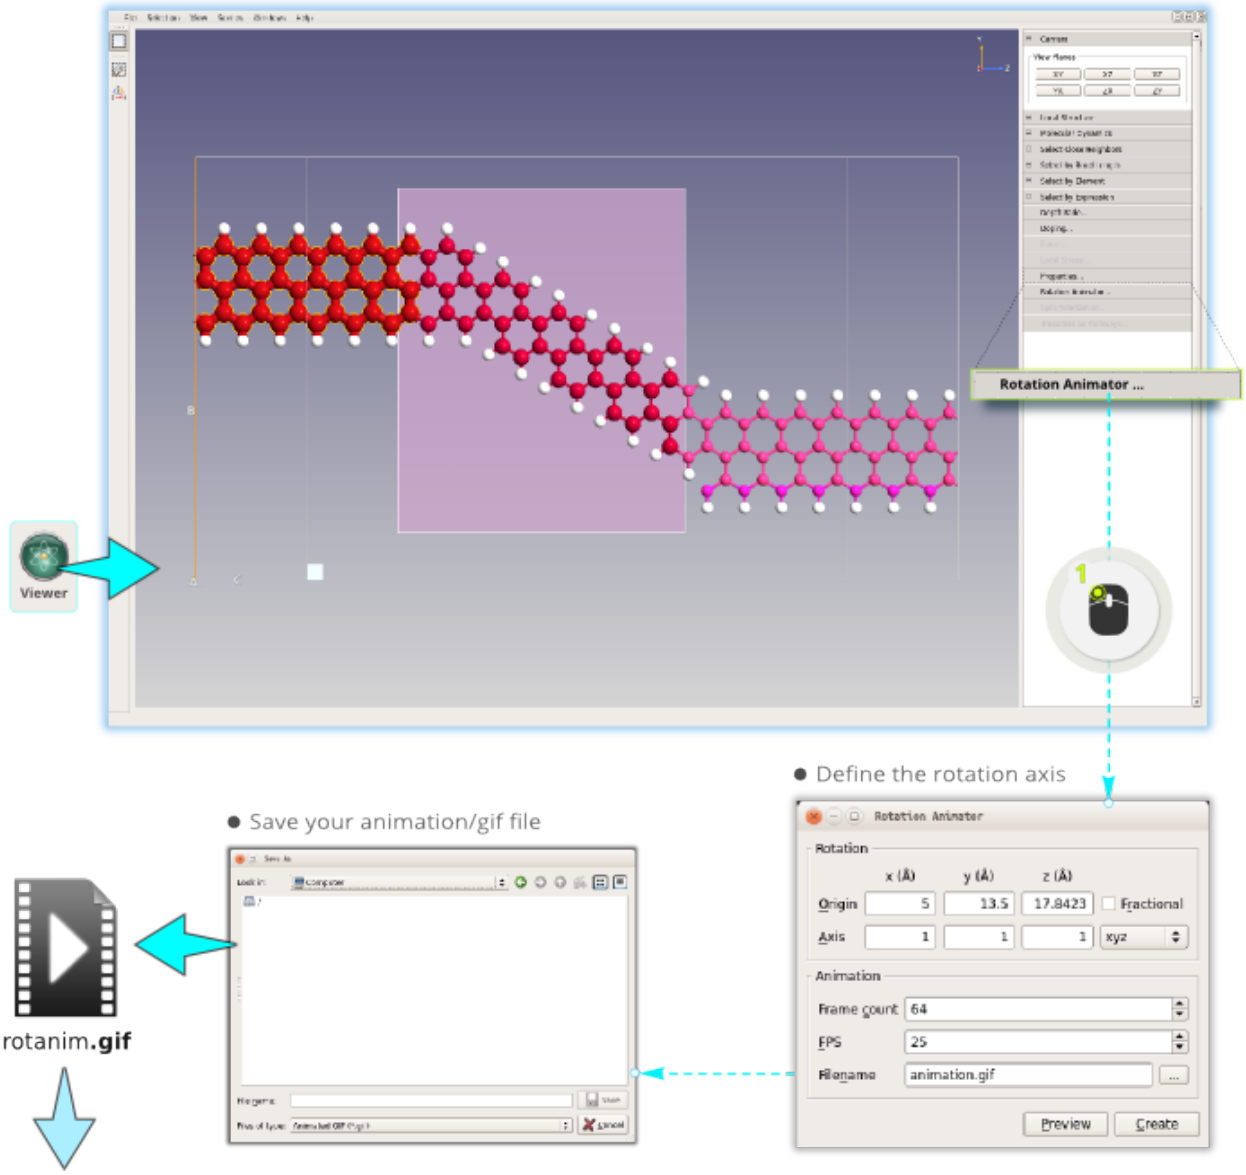
Virtual NanoLab
Builder
Scripter
Custom Scripter
Editor
Jobs
Viewer
drag and drop
Properties ...
Decorate your scene
NEBmovie.nc
Export to clipboard
Export image Ctrl+E
Export animated GIF
Export frames
Save your animation/gif file
Save As
Look in:
Computer
File name:
Save
Files of type:
Animated GIF (*.gif)
Cancel
NEBmovie.gif

The possibilites at this point are endless. If you analyze your NEB or MD simulation with the **Movie Tool**, for example, you can view an animated plot of the relevant quantity:



Rotation Animator

In QuantumATK you can also create a rotation animation (in `.gif` format) of a structure around a specific axis (GIF animation from a static configuration). Just got to *Viewer* → *Rotation Animator*. The functionality of the **Rotation Animator** is quite obvious and easy to understand:

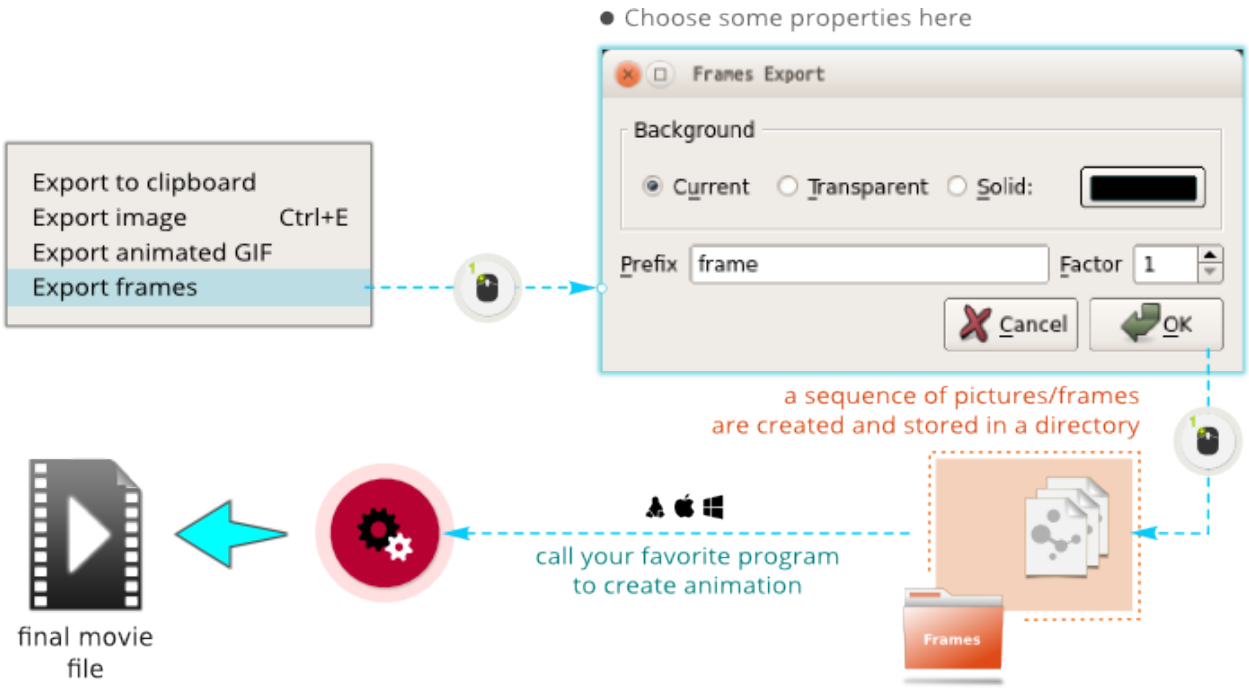


Movie from Trajectory Files

Combining QuantumATK with other (external programs) it is possible to create your animation from a sequence of pictures (in various formats like MP4, FLV, etc.).

Note: Export Frames

In QuantumATK you can extract the set of pictures that correspond to an animated structure. Just right click on the animation/structure in the Viewer and choose **Export frames**.



It may be wise to change the prefix name in case you will export another set of frames later; then you will not overwrite or intermix the image files. When you click **OK**, the movie will start to play in the 3D Viewer. While playing, each frame is actually exported as an image into a directory called **Frames** in your current project. Those images can be stapled together in a movie using some external software! See below for a brief description of making the movie using MPlayer on Linux.

Example: Create a movie with **MPlayer Platforms: Prerequisites:** Linux terminal and MPlayer **Links:** MPlayer *Here we give an example of how to build a movie/animation file using the MPlayer software from the Linux command-line.*

•Open a terminal and navigate to the directory with the frames. Here you will find the PNG files corresponding to your frames, and a file containing the command needed to create the movie (`encode`).

•An example of the encode file is shown below.

•You may run the encode file directly (*./encode*), or choose to modify some option first.

```
$ mencoder mf://GNR_buckle*.png -o atkFrames.avi -ovc lavc -lavcopts \
$ vcodec=msmpeg4v2:autoaspect:vbitrate=2160000:mbd=2:keyint=132:vqblur=1.
↪0:cmp=2:subcmp=2:dia=2:mv0:last_pred=3 \
$ -mf w=800:h=600:fps=5:type=png
```

Some options to consider changing are the aspect ratio (use -mf to set the width (w) and height (h) matching the size of the 3D Viewer window) and the frame rate (fps), and of course the filename of the final movie.

•Now you will have the file **atkFrames.avi** in the Frames directory. The movie should play in most players, but if in doubt, always look to VLC or MPlayer.

•To make an **FLV** file (smaller file size, suitable for online stuff), try:

```
$ mencoder mf://atkFram*.png -o atkFrame.flv -of lavf -oac mp3lame \
$ -lameopts abr:br=56 -srate 22050 -ovc lavc \
```

(continues on next page)

(continued from previous page)

```
$ -lavcopts vcodec=flv:vbitrate=500:mbd=2:mv0:trell:v4mv:last_pred=3 \
$ -mf w=512:h=512:fps=10:type=png
```

Have fun creating cool videos with QuantumATK!

Note: MPlayer is a cross-platform program and you can use it in Windows and Mac as well.

3.12.6 Converting lattices: Rhombohedral to hexagonal and back

Version: 2015.1

As we know, there are 14 Bravais lattices in $\mathbf{R}^3$ space. These determine the translational symmetry properties of a crystal unit cell, and thereby also the symmetry properties in reciprocal space (high-symmetry **k**-points, etc.). Additionally, the space group determines the rotational and other internal symmetry operations of the basis (the atomic coordinates). For the complete symmetry specification we need both, although the lattice symmetry is usually determined by the space group, i.e. each space group is associated with one and only one Bravais lattice.[1]

However, the trigonal crystal system is special, because one can often choose between rhombohedral and hexagonal representation. Trigonal structures found in online databases are often hexagonal, but for computational purposes, the smaller rhombohedral cell will usually be more efficient. In that case, conversion between the two representations is advisable.

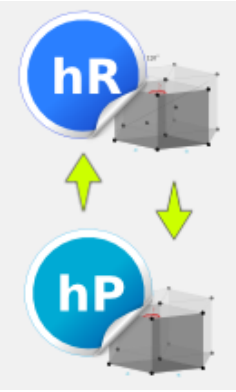
Note: hR (hexagonal) and hP (rhombohedral) crystal systems

The space groups are classified by crystal systems, and any standard book on solid state physics will tell you that there are **7 crystal systems** and **6 crystal families**. Here we focus on the special situation in the hexagonal family, which is the only one that can be subdivided into two crystal systems; the hexagonal and the trigonal.

The hexagonal system comprises 27 space groups. All of these have hexagonal Bravais lattices, labeled hP. The trigonal system is the tricky one, because its 25 space groups (143-167) belong either to the hexagonal (hP, 18 space groups) or the rhombohedral (hR, 7 space groups) Bravais lattice. Now, to make things a bit more confusing, all trigonal crystals with rhombohedral lattices (space groups 146, 148, 155, 160, 161, 166, and 167), can be represented as an equivalent hexagonal system; there is a choice of using a hexagonal or a rhombohedral representation.

Further information on this subject is available in the section *Crystal classifications*.

Conversion between hP and hR representations



[1] ITA: International Tables for Crystallography, Volume A: Space-Group Symmetry, 5th, revised edition, Springer 2005

The hexagonal setting is in fact a supercell with three irreducible rhombohedral units. In the modern so-called *obverse* representation, the origins of these three subsystems are placed at the $\boldsymbol{d}_1, \boldsymbol{d}_2, \boldsymbol{d}_3$ fractional coordinates of the hexagonal lattice.

Tip:

- $\{\boldsymbol{A}_H, \boldsymbol{B}_H, \boldsymbol{C}_H\}_{hP}$: hexagonal (**hP**) lattice vectors
- $\{\boldsymbol{A}_R, \boldsymbol{B}_R, \boldsymbol{C}_R\}_{hR}$: rhombohedral (**hR**) lattice vectors.

Taking into account the symmetries of the crystal structures we can find the following relations among the above vectors:

$$\begin{pmatrix} \boldsymbol{d}_1 \\ \boldsymbol{d}_2 \\ \boldsymbol{d}_3 \end{pmatrix} = \frac{1}{3}\begin{pmatrix} 0 & 0 & 0 \\ 2 & 1 & 1 \\ 1 & 2 & 2 \end{pmatrix}\begin{pmatrix} \boldsymbol{A}_H \\ \boldsymbol{B}_H \\ \boldsymbol{C}_H \end{pmatrix} = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 1 & 1 & 0 \end{pmatrix}\begin{pmatrix} \boldsymbol{A}_R \\ \boldsymbol{B}_R \\ \boldsymbol{C}_R \end{pmatrix}$$

The lattice vectors are connected via the following transformation (direct and inverse):

$$\begin{pmatrix} \boldsymbol{A}_R \\ \boldsymbol{B}_R \\ \boldsymbol{C}_R \end{pmatrix} = \underbrace{\frac{1}{3}\begin{pmatrix} -1 & 1 & 1 \\ 2 & 1 & 1 \\ -1 & -2 & 1 \end{pmatrix}}_{:=\boldsymbol{M}}\begin{pmatrix} \boldsymbol{A}_H \\ \boldsymbol{B}_H \\ \boldsymbol{C}_H \end{pmatrix} \Leftrightarrow \begin{pmatrix} \boldsymbol{A}_H \\ \boldsymbol{B}_H \\ \boldsymbol{C}_H \end{pmatrix} = \underbrace{\begin{pmatrix} -1 & 1 & 0 \\ 1 & 0 & -1 \\ 1 & 1 & 1 \end{pmatrix}}_{:=\boldsymbol{M}^{-1}}\begin{pmatrix} \boldsymbol{A}_R \\ \boldsymbol{B}_R \\ \boldsymbol{C}_R \end{pmatrix}$$

Choosing now Cartesian coordinates one obtains the following relations:

$$\text{hP:} \begin{cases} \boldsymbol{A}_H = a_H(1, -\sqrt{3}, 0)/2 \\ \boldsymbol{B}_H = a_H(1, +\sqrt{3}, 0)/2 \\ \boldsymbol{C}_H = c_H(0, 0, 1) \end{cases}, \text{ hR:} \begin{cases} \boldsymbol{A}_R = (0, +a_H\sqrt{3}, c_H)/3 \\ \boldsymbol{B}_R = (3a_H, -a_H\sqrt{3}, 2c_H)/6 \\ \boldsymbol{C}_R = (-3a_H, -a_H\sqrt{3}, 2c_H)/6 \end{cases}$$

Warning: The orientation of the last cell with respect to the cartesian axes is different from the standard QuantumATK choice for the rhombohedral cell!

For later use, let us compute the lattice parameters of the rhombohedral cell, i.e. the lengths of the lattice vectors (a_H, c_H, a_R) and their angles (α_R, β). They are all the same, as expected for a rhombohedral crystal, and after some algebra we obtain

$$\begin{cases} a_R = a_H\beta/3 \\ \alpha_R = 2\arcsin(3\beta/2) \\ \text{where: } \beta := \sqrt{3 + (c_H/a_H)^2} \end{cases} \Rightarrow \begin{cases} a_H = 2a_R\sin(a_R/2) \\ c_H = a_R 3\sqrt{1 + 2\cos a_R} \end{cases}$$

Now, what to do in practice, if you have recevied a rhombohedral crystal in the hexagonal supercell representation, but want to convert it to the smaller rhombohedral system? We give the recipe in the next section.

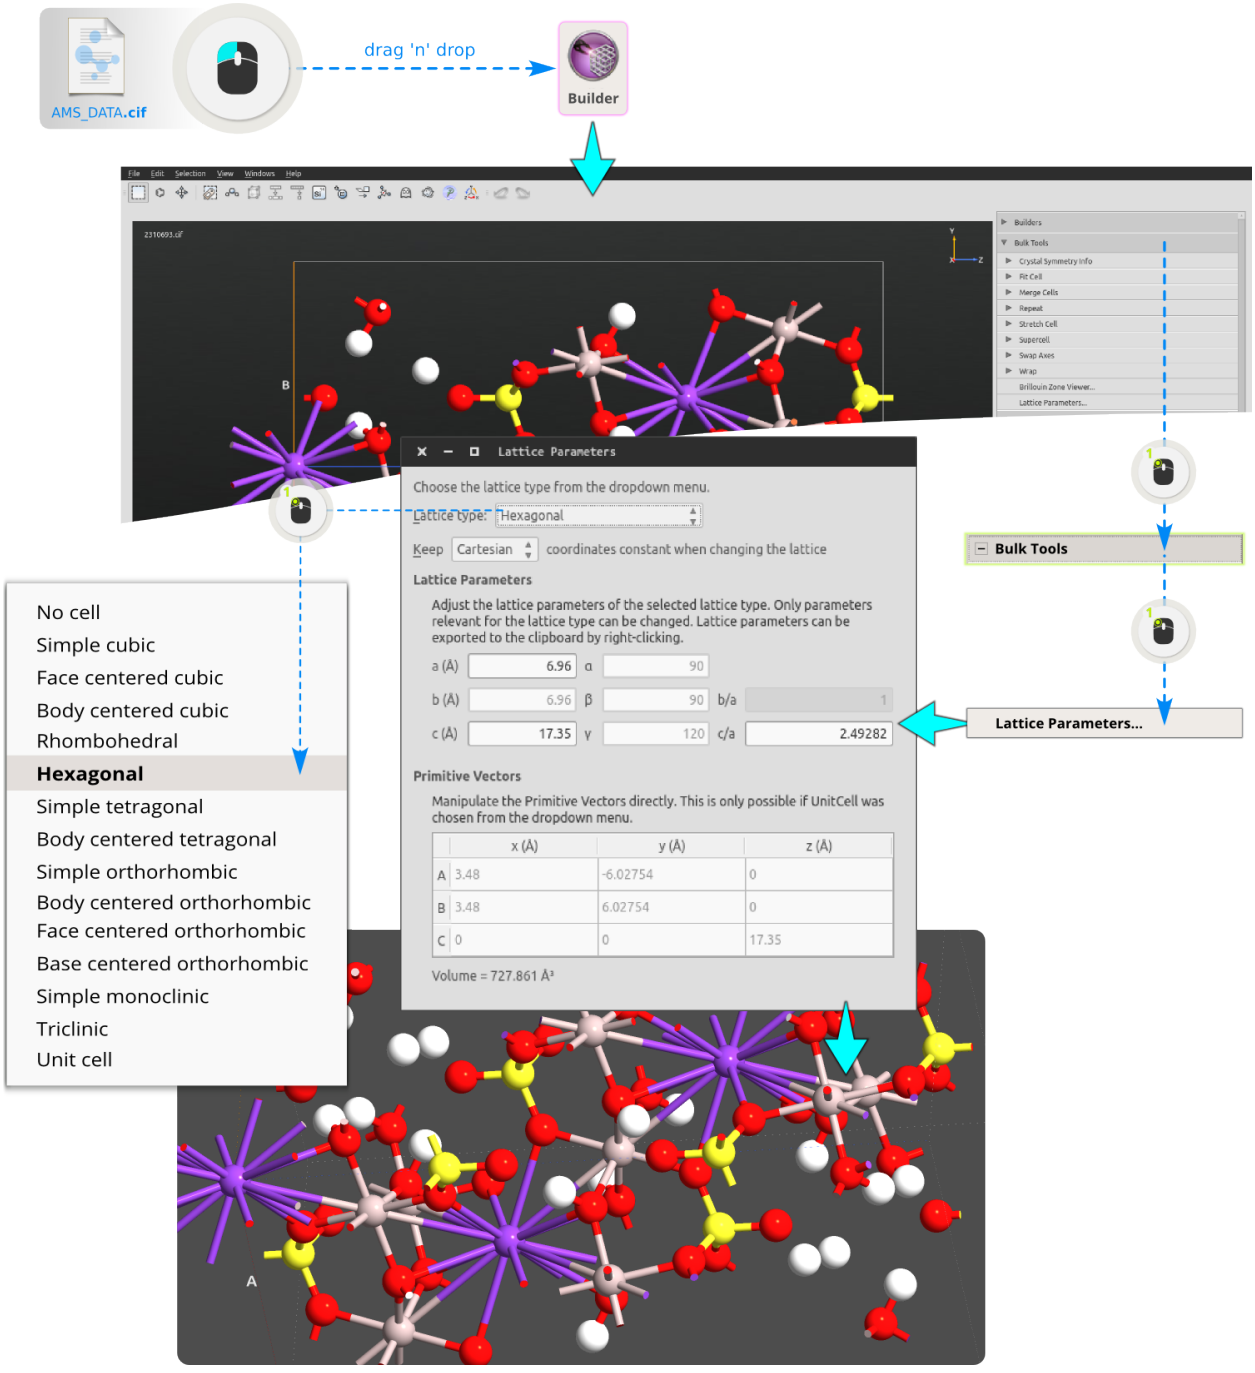
Converting hP supercell to hR primitive cell

Assume you have found a structure in some online database: Hilgardite, $KS_2Al_3O_{14}H_6$. Download the CIF file and save it: `AMS_DATA.cif`.

- **Step 1:** Drag and drop (or use *Add* → *From Files*) the `AMS_DATA.cif` file on the **Builder** .

- **Step 2:** You can read off the lattice parameters via *Bulk Tools* → *Lattice Parameters* (or you can read them in the CIF file):

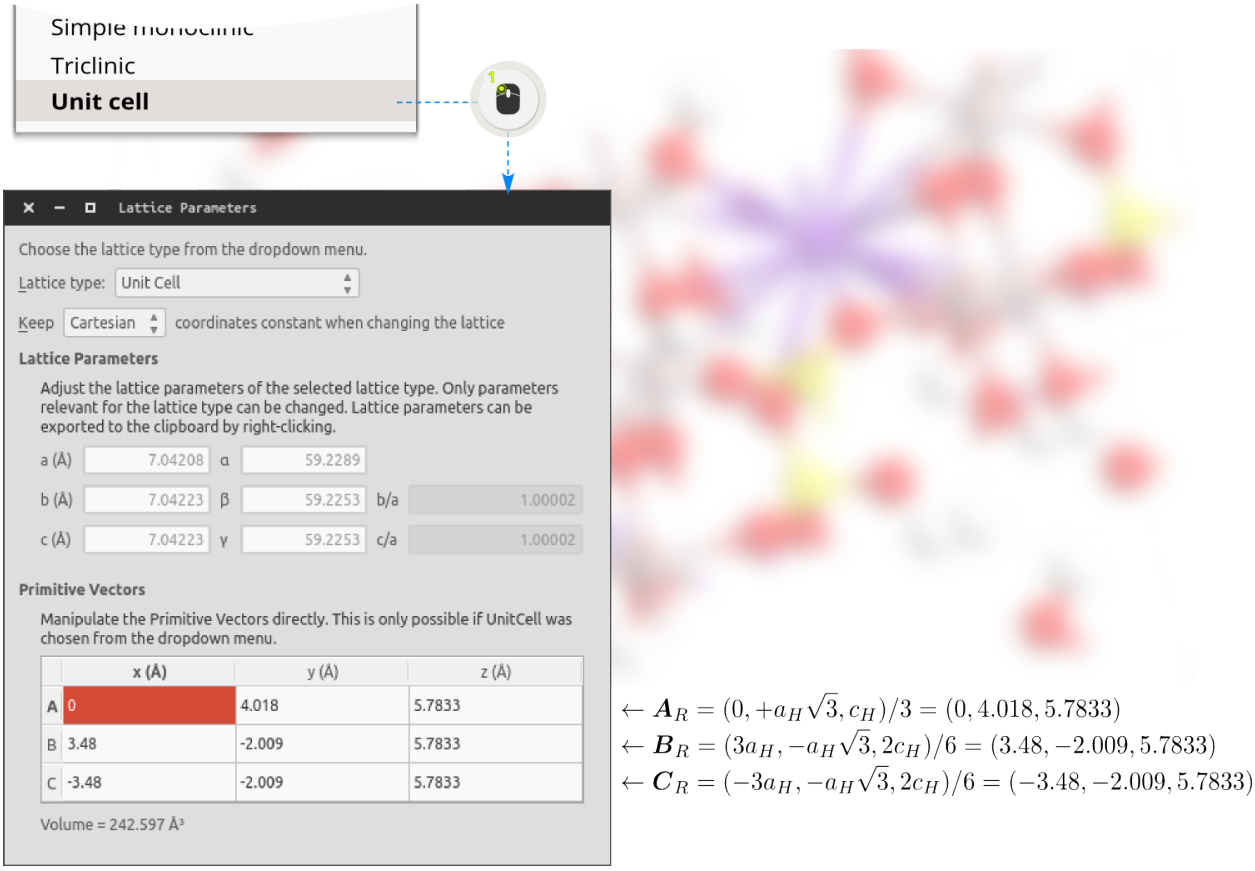
$$a_H = 6.96 \text{ Angstroms}$$
$$c_H = 17.35 \text{ Angstroms}$$



•**Step 3:** To change the lattice to rhombohedral (hR), start by changing the Lattice type to Unit cell, and select to Keep Cartesian coordinates constant when changing the lattice. The rhombohedral primitive vectors are given by the relations from above and inserting the hexagonal lattice constants, you obtain:

$$\text{hR:} \begin{cases} \boldsymbol{A}_R = (0, +a_H\sqrt{3}, c_H)/3 \\ = (0, 4.018, 5.7833) \\ \boldsymbol{B}_R = (3a_H, -a_H\sqrt{3}, 2c_H)/6 \\ = (3.48, -2.009, 5.7833) \\ \boldsymbol{C}_R = (-3a_H, -a_H\sqrt{3}, 2c_H)/6 \\ = (-3.48, -2.009, 5.7833) \end{cases}$$

Insert these numbers, component by component, in the Primitive Vectors table. (At this point you will see that the K atoms sit close to the corners of the unit cell, indicating that we have indeed made a reasonable transformation.)

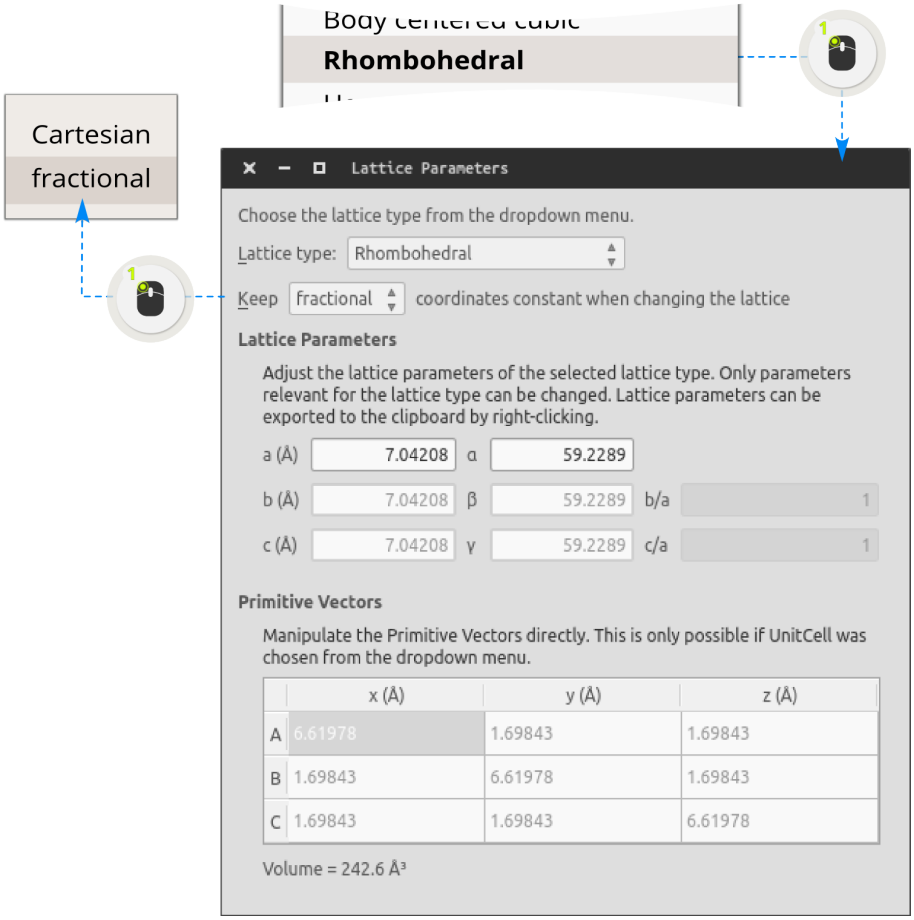


$\leftarrow \boldsymbol{A}_R = (0, +a_H\sqrt{3}, c_H)/3 = (0, 4.018, 5.7833)$
$\leftarrow \boldsymbol{B}_R = (3a_H, -a_H\sqrt{3}, 2c_H)/6 = (3.48, -2.009, 5.7833)$
$\leftarrow \boldsymbol{C}_R = (-3a_H, -a_H\sqrt{3}, 2c_H)/6 = (-3.48, -2.009, 5.7833)$

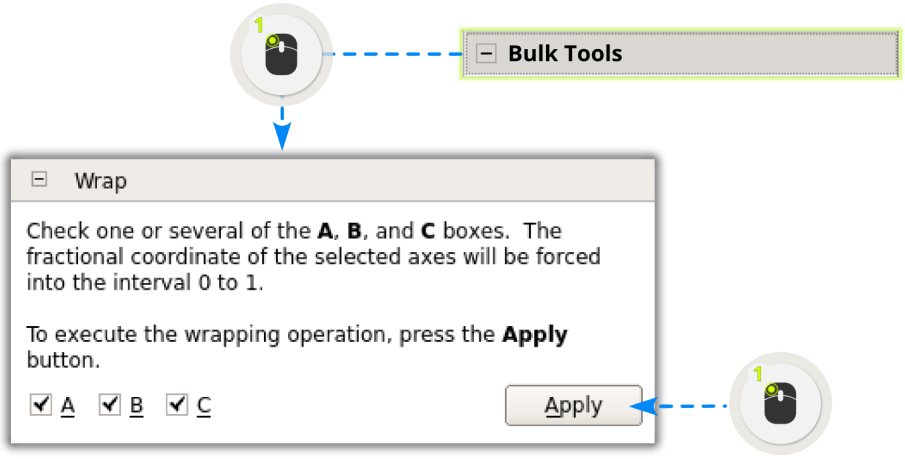
- **Step 4:** As mentioned above, the orientation of this new cell with respect to the Cartesian axes is different from the standard QuantumATK choice for the rhombohedral cell. The next step is therefore to **reorient the cell to fit the standard cell**.
- To do this, switch to Keep fractional coordinates constant when changing the lattice. This ensures we do not distort the geometry while reorienting the cell.
- Change the Lattice type to Rhombohedral. This operation preserves the lengths of the primitive vectors, but aligns them into the standard orientation (and also uses the Rhombohedral lattice class, so you have access to the relevant symmetry points for band structure calculations, etc). As a verification of this, you can compute the lattice constants by hand:

$$\begin{aligned} \beta &= 3.03548 \\ a_R &= a_H\beta/3 = 7.0423 \text{ Angstroms} \\ \alpha_R &= 2\arcsin(3\beta/2) = 59.228^\circ \end{aligned}$$

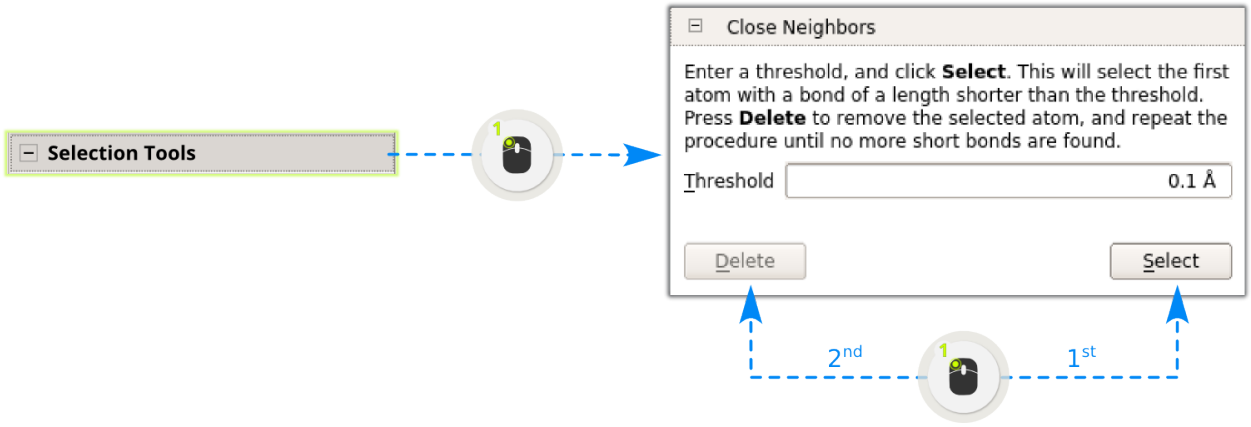
which is close to the values shown in the Lattice Parameters widget (some rounding error will occur due to the number of decimals used for the lattice vector components).



•**Step 5:** There are still too many atoms (three times too many). These extra atoms are however all sitting in symmetry equivalent positions of the rhombohedral lattice, and thus by **wrapping them into the cell**, they will fall on top of the minimal basis. Thus, go to *Bulk Tools* → *Wrap*, ensure all directions A, B, C are ticked, and click **Apply**.

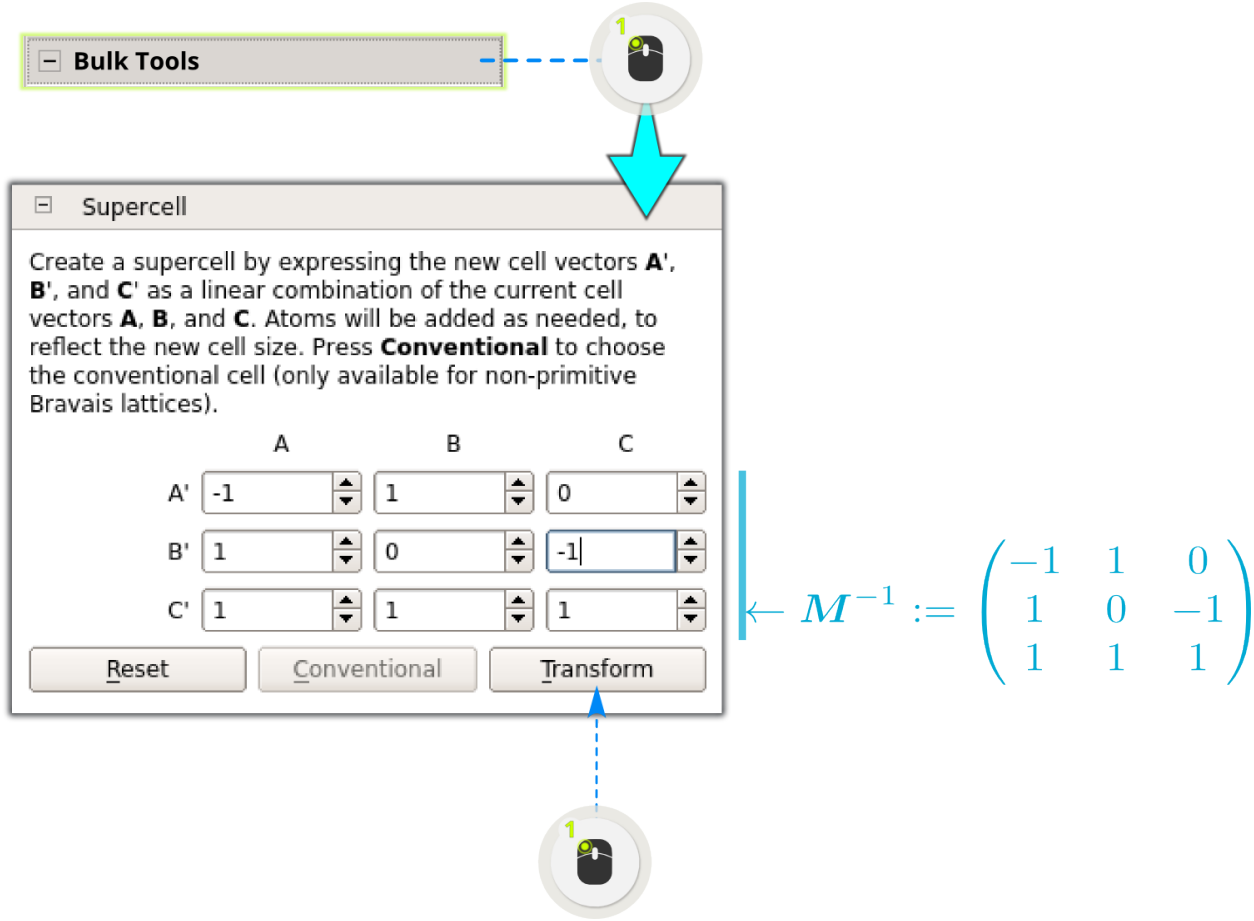


•**Step 6:** Now it may appear as if magically the superfluous atoms were removed. However, they are still there - there are atoms on top of each other now. Such a configuration is not valid for calculations, so the final step is to remove the equivalent atoms. For this, use *Select* → *Close Neighbors*, and click the buttons **Select** and **Delete**.



Inverse case

You can of course also convert the other way, i.e. to the hexagonal supercell from the rhombohedral minimal cell. This is simpler. Looking above, we see that the hP vectors are obtained by hR after the action of the matrix M^{-1} as defined above. This matrix can be implemented **directly in ATK** by choosing *Bulk Tools* → *Supercell* and enter this transformation:



You now have a hexagonal cell, its just not oriented in the usual way, but this is easily fixed just like before: Use *Tools* → *Lattice Parameters*, choose to keep fractional coordinates constant, then change the Lattice type to Hexagonal. The structure is now back to the originally imported file.

3.12.7 Reusing electrodes in device calculations

A typical study of electronic devices with QuantumATK involves systematically studying the influence of various modifications of the device region. The variation can be atomic positions or types of dopants/vacancies in a semiconductor wire, or a different molecule attached to a nanotube, etc. In any case, the electrodes often remain unchanged. One can therefore calculate the electronic structure of the electrodes only once, and then reuse them in other calculations to save computational time.

In this tutorial you will therefore learn how to reuse the devices electrodes for different calculations, thus saving time by only having to calculate the converged state of the electrodes once.

Note: **Methodology** An QuantumATK device calculation is usually a two-step process: First the self-consistent states of the electrodes are calculated, and then the actual device calculation is done. Any post-SCF analysis and other operations are done after those two steps.

Reusing the initial electrode calculations is done like this: Starting out from a Python script designed for a normal device calculation as outlined just above, you split that calculation into two scripts: One script that calculates and saves the self-consistent state of the electrodes, and another script that reuses those electrodes and starts directly on the device calculation.

Warning: **Calculator settings** It is important that the parameters used for the electrode calculators are the same as those that will be used in the final device calculation, or at least very similar. Otherwise the electrode Fermi level alignment vs. the device average Fermi level may change, which can cause problems for SCF convergence.

Therefore, first make a decision on the numerical accuracy parameters, such as exchange–correlation functional, temperature, mesh cut-off, basis set, etc., and then stick to these for the whole sequence of calculations.

Moreover, it is absolutely necessary that the electrode and device **k-point sampling** match each other in the A and B directions! You can not use 3 k-points along A in the device but 7 k-points along A in the electrodes.

Separate scripts for electrodes and device

A bit of scripting is required, but mostly copying/pasting existing lines of Python code:

1. Start by setting up the full device calculation as you would normally with some representative central region. Use the Script Generator for this task, and make some good chices for the numerical accuracy parameters to be used.
2. Save two copies of the script: `electrode.py` and `device.py`.
3. Open `electrode.py` in the Editor and scroll down to where the `device_configuration` is defined. It usually looks like illustrated below. **Remove** those lines.

```
device_configuration = DeviceConfiguration(
    central_region,
    [left_electrode, right_electrode]
    )
```

Tip: The script `electrode.py` is only used to compute the electrodes. You may want to remove the definition of the

central region altogether to keep things tidy, but its not strictly necessary.

4. Now scroll down towards the end of the script, and remove everything that has to do with the device calculator. That is, **remove** all lines from the following comment lines to the end of the script:

```
#----------------------------------------
# Device Calculator
#----------------------------------------
```

5. **Add** instead the following lines at the end of the script, and save the script as `electrodes.py`.

```
left_electrode.setCalculator(left_electrode_calculator)
left_electrode.update()
nlsave('left_electrode.nc', left_electrode)
right_electrode.setCalculator(right_electrode_calculator)
right_electrode.update()
nlsave('right_electrode.nc', right_electrode)
```

Note: In the case of identical electrodes, delete the three lines involving the right_electrode, and remove the left prefix from all the remaining variables:

```
electrode.setCalculator(electrode_calculator)
electrode.update()
nlsave('electrode.nc', electrode)
```

6. **Run** the electrode script, e.g. Job Manager .

7. Now start modifying the script `device.py`. Starting from the top, remove all the lines involving the left and right electrode configurations, i.e. **delete** all lines until (but not including)

```
# ------------------------------------------------------------
# Central region
# ------------------------------------------------------------
```

8. Instead, **add** the following lines at the top of the script, which will read the saved electrodes from file:

```
left_electrode = nlread("left_electrode.nc")[0]
right_electrode = nlread("right_electrode.nc")[0]
```

Hint: In the case of identical electrodes, if only a single electrode calculation was executed and saved, in e.g. `electrode.nc`, use this file for loading *both* electrodes.

9. It is recommended, but not strictly necessary, to also remove the definition of the electrode calculators, including the lines in the device calculator:

```
electrode_calculators=
    [left_electrode_calculator, right_electrode_calculator],
```

Thats it! You have successfully separated the electrode and device calculation into two scripts. When the electrode calculation is done, you can run `device.py`, and see that it completely bypasses the electrode calculation.

Tip: Whats next? For each new central region geometry to be computed with these electrodes, just replace the definition of the `central_region` in `device.py`, and run the device calculation. Make sure to check the device parameters such as bias voltage, etc.

Alternatively, you can apply steps 7–9 above to any complete device calculation script, keeping the points about the numerical accuracy parameters in mind.

3.12.8 Initialize from a converged state

Version: 2016.0

In this tutorial, you will learn how to save time in calculations by using a previously converged calculation as the starting point of a new calculation. This is useful, for example, when scanning the lattice constant, applied bias, or checking the convergence of various parameters, like k-point or mesh cut-off.

In many calculations you can save a lot of time by using a converged calculation as a starting guess for another calculation. In fact, for finite bias calculations of complicated transport systems, it may sometimes be the only way to obtain stable convergence.

Introduction

The default start guess for a self-consistent calculation in **ATK** is based on neutral atoms, i.e. the basis orbitals are populated as if each atom was isolated in space. This can, in many cases, be quite far from the real state of the atoms, even in a simple crystal; so it seems obvious that you could save a lot of time by providing a better starting guess. Similar systems, with only one parameter slightly different, will commonly be a better starting guess of a calculation and is especially useful in the following scenarios:

- Looping over a particular variable to see how much the results change. Therefore, we can apply this method to obtain good convergence at finite bias, which is done automatically when using the IVCurve object
- Checking convergence in various parameters, like k-points or mesh cut-off.
- Determining equilibrium lattice constant for a bulk system, or a coordinate for one or several atoms.
- As a special case: to initialize the anti-parallel configuration in a magnetic tunnel junction.

Since the initial guess is applied to the density matrix, it is a requirement that the original configuration/calculation (to be used to initialize the new one) and the new one have exactly the same sets of basis orbitals. Thus, the two configurations must have:

- the same atoms, element by element and in the same order
- the same basis set, atom by atom.

The atoms do not have to be in the same geometric positions, but the electronic density will not be adjusted to accordingly, so if the atoms have moved too far between configurations, the initial guess is likely to be worse than using neutral atoms.

The way to initialize one calculation from another is to add a keyword *initial_state* to the *setCalculator()* method on a configuration. The initial state object is typically read from a HDF5 file, or a variable in the script if you are looping over e.g. k-points or bias. We will also show how to do this using the **QuantumATK** GUI.

It is probably easiest to understand how to do this by looking at a couple of examples.

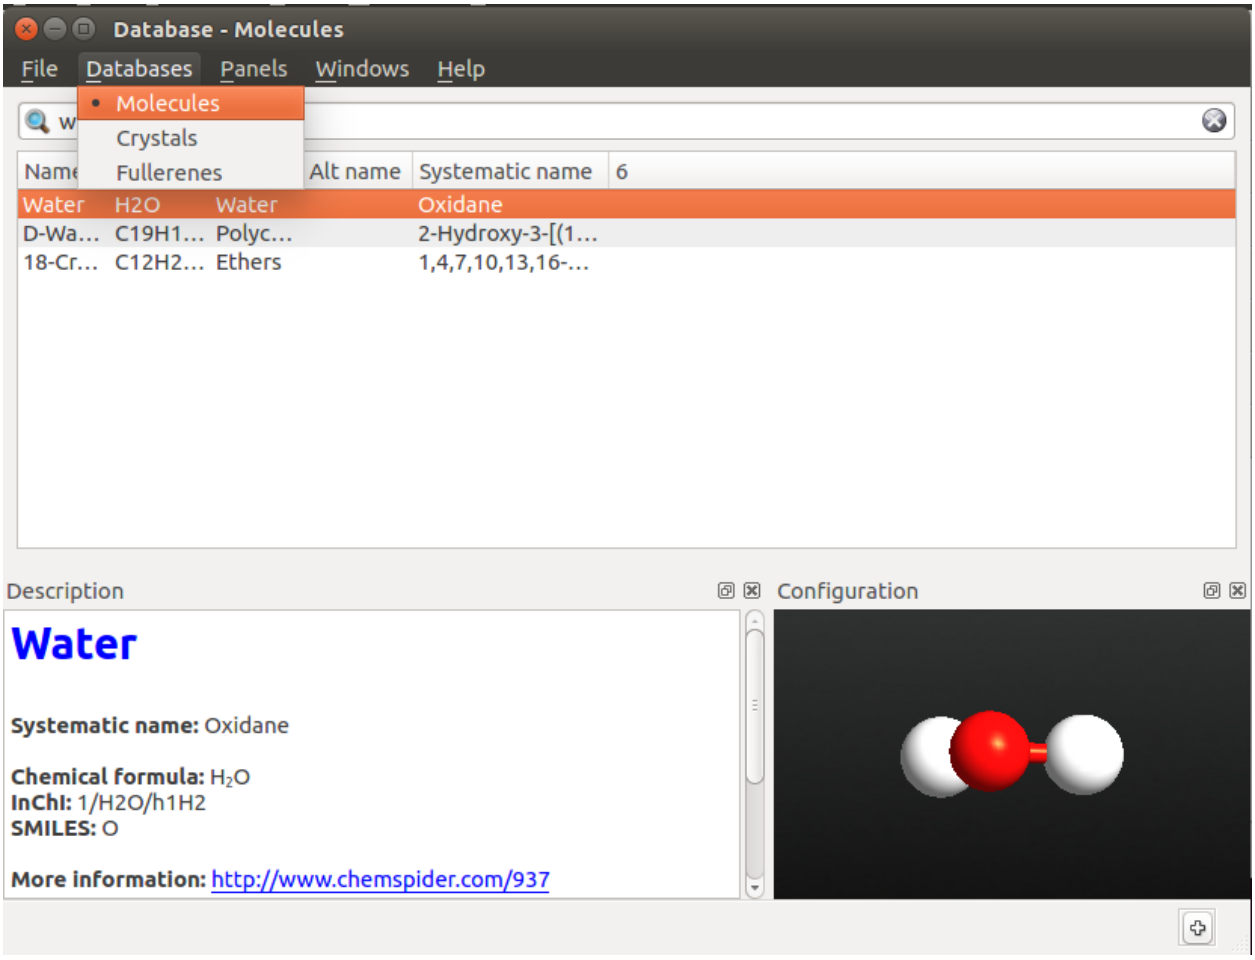
Examples

Water molecule example

We will demonstrate how to save computational time for a high accuracy calculation by doing it in two steps, for a simple case of a water molecule.

Calculation with low accuracy:

•Open the **Builder** and add water from *Database* → *Molecule*.



•Send the structure to the **Script Generator** with the **Send To** icon at the lower right corner.

•Add a **New Calculator** and change the *mesh cut-off* to 40 Hartree.

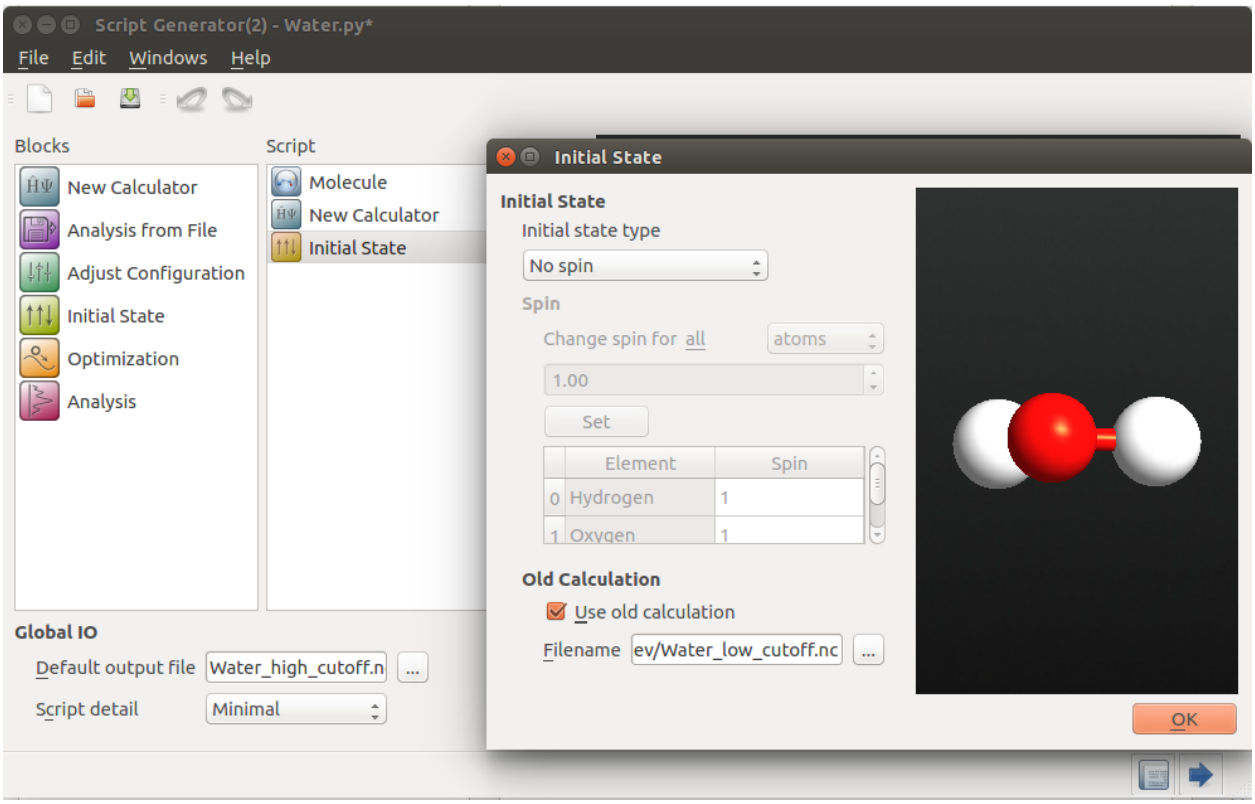
•Change the output name to `water_low_cutoff.hdf5`.

•Send the job to the **Job Manager** and run the calculation.

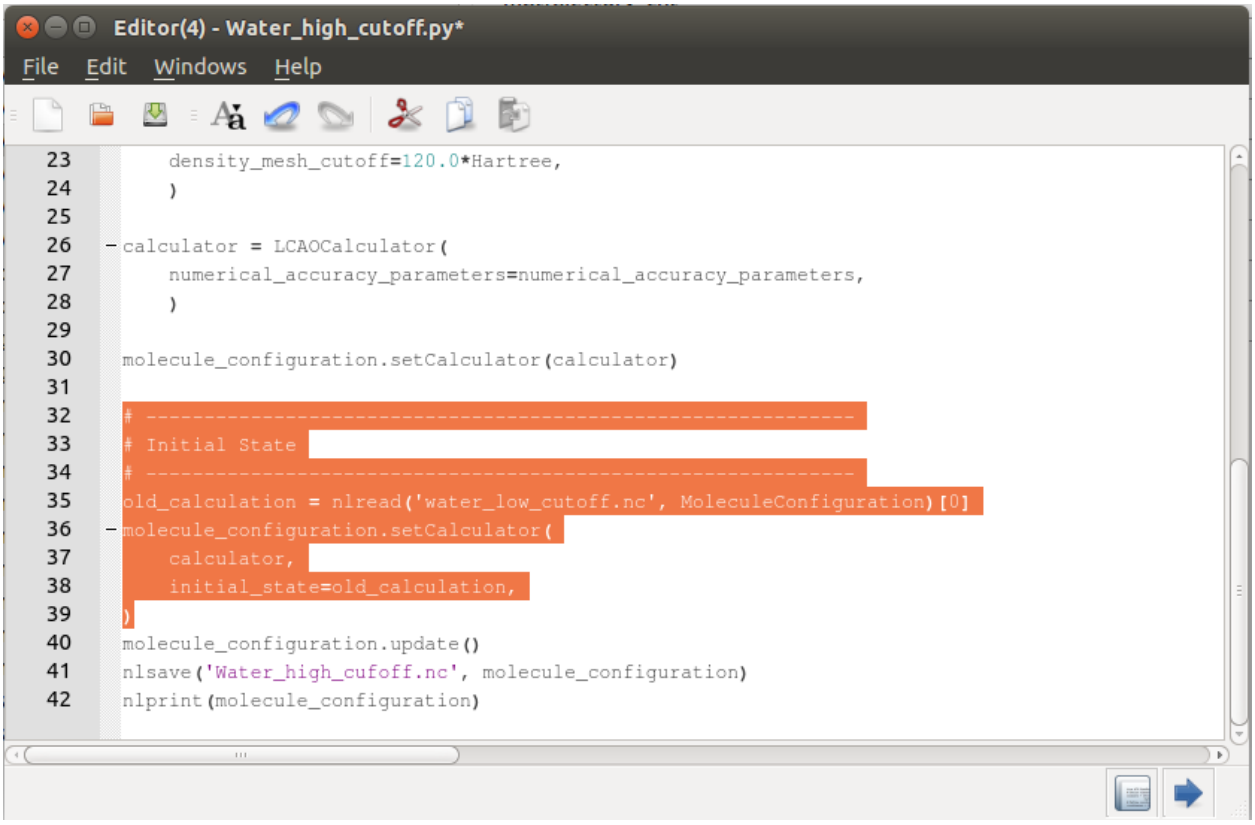
Calculation using the low accuracy result

•In the previous **Script generator** , open the **New Calculator** block and change the *mesh cut-off* to 120 Hartree.

•Add an **Initial State**. Tick the checkbox *Use old calculation*, and locate the file `water_low_cutoff.hdf5`.



This inserts an *initial_state* variable to *setCalculator()*, as mentioned above. Send the script to the **Editor** by the **Send To** icon at the lower right corner. You will find the lines in the script. Send it to the **Job Manager** and run the calculation.



You will find that the low accuracy calculation takes 6 self-consistent iterations to converge and the high accuracy calculation takes only a single iteration. If you run the high-accuracy calculation without initialization, it also needs 6 iterations. In this example, as the system is very small, there is not any time save by using this method, due to overhead from initialization etc. But for a realistic system, the high accuracy calculation could be much more time consuming than the low accuracy ones, saving time overall by using this method. We can save a lot of computational time by reducing the number of high accuracy iterations using this strategy.

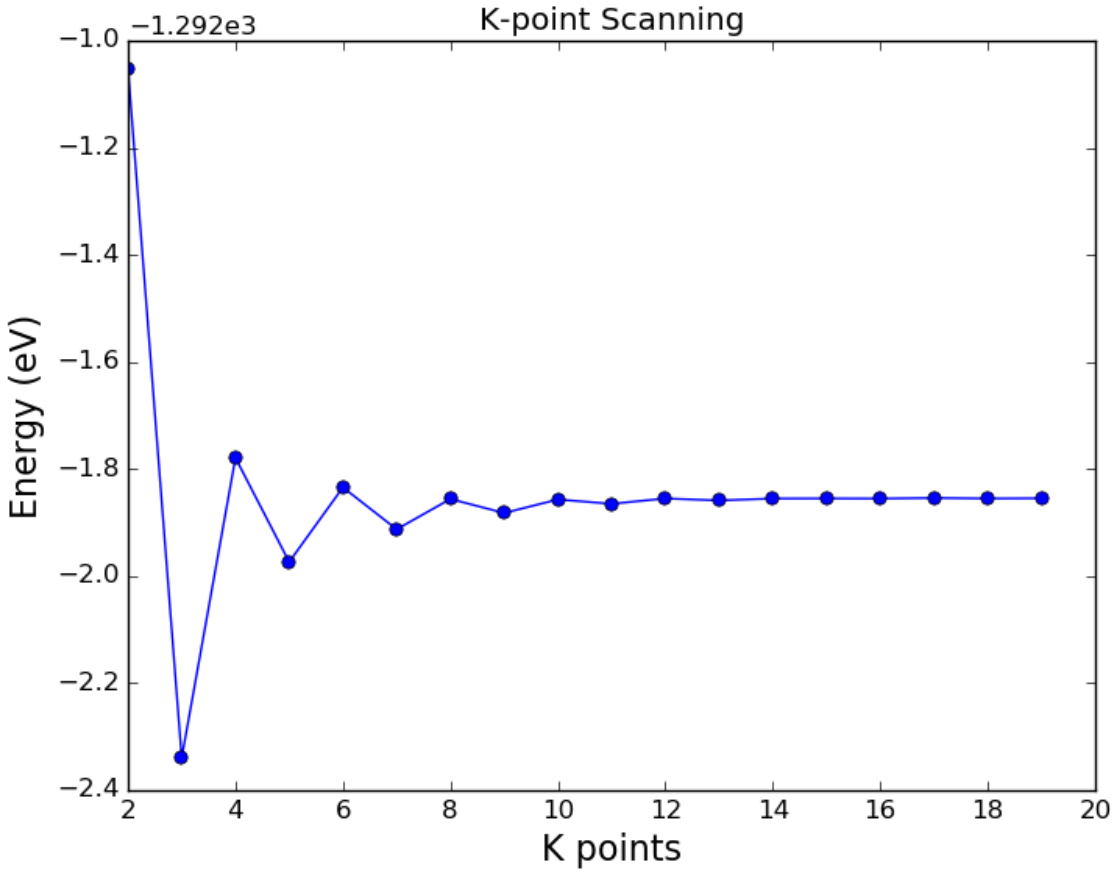
Note: The first calculation also takes some time and the efficiency of this method varies strongly from case to case. It is only effective if the result from the first calculation is good enough to reduce the number of iterations in the second calculation significantly.

Looping over parameters

Usually, there are numerical parameters which you do not initially know how to choose optimally, that is, the values of parameters which gives a desired balance between calculation time and accuracy. This applies to parameters like k-point sampling and mesh cut-off. Besides using some reasonable physical insight to get a rough idea, a more reliable way is to try different values and see how the results change. This can often be done on a small testing system, and the results can then be applied to a real and larger system of interest.

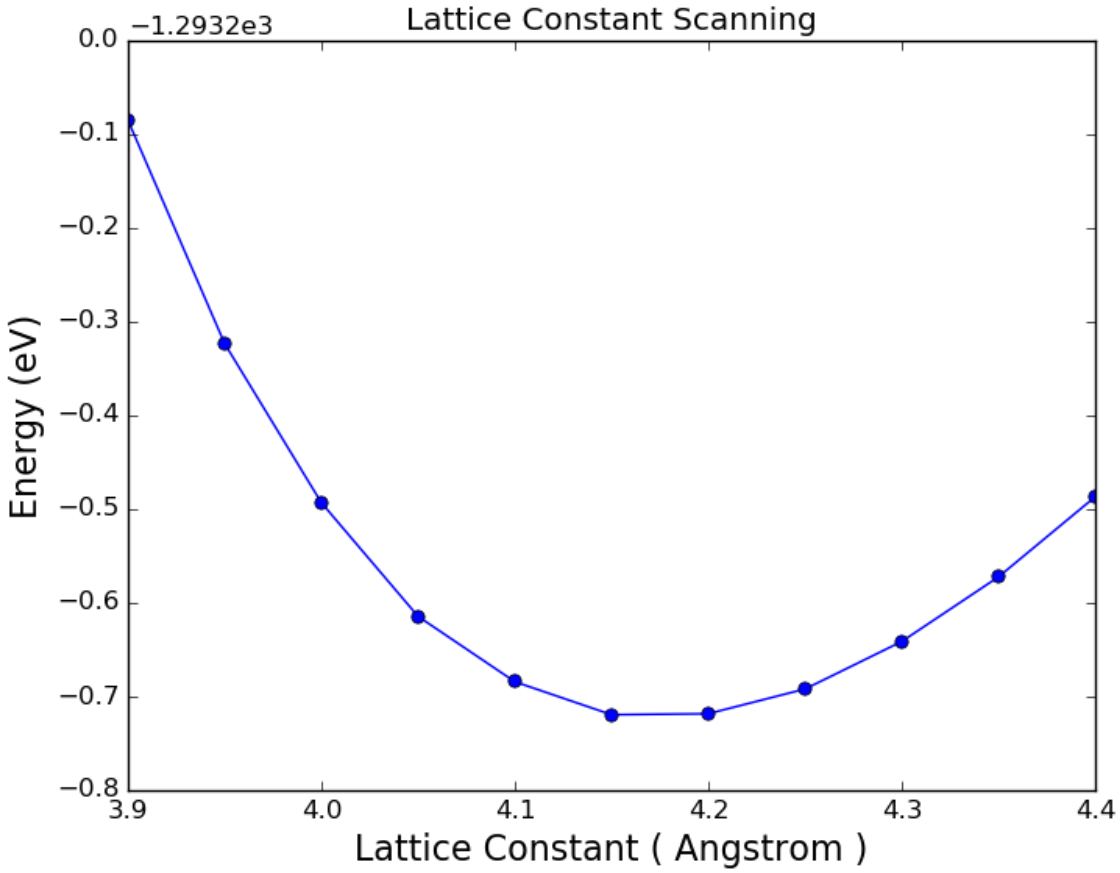
The script `kpoint_looping.py` checks how many k-points are needed to get a good value for the total energy of a gold crystal. When doing parameter scanning, it is a good idea to lower the tolerance of the self-consistent loop, which increases the accuracy of the solution. In this script we set it two orders of magnitude lower than default.

Running this script, you will get the following plot, from where you find that a sampling of 12 or 13 k-points along each axis is sufficient for good total energies for gold (valid for this specific combination of basis set, etc).



If you compare to the same calculation without any initial state, i.e. if each calculation is started from neutral atoms, the number of self-consistent iterations is typically more than two times larger, especially when the number of k-points is large (i.e. the most time-consuming parts of the script); thus the benefit of using an initial state in this type of loop is very obvious.

Another very common task is to loop over a variable, like a lattice constant, to find the lowest total energy for a configuration. This script `lattice_const_looping.py` is for finding the equilibrium lattice constant of gold.



Note: To optimize the unit cell size for a system like this, it is often more efficient to use the **OptimizeGeometry** method in **ATK**, which can optimize th lattice parameter(s) using an efficient algorithm. The calculation above is still meaningful, however, since it also gives an idea of the error we make by having a non-optimized cell. Furthermore, the values can be used to compute the bulk modulus if you do a more proper 3rd degree polynomial fitting.

In these examples the results are not saved. If you want to do some further processing, like compute the band structure for each configuration and compare those, add such statements inside the loop and store the results in a HDF5 file.

The result of fitting the parabola is a =4.17 Å; if we use GGA instead of LDA ,the value changes to 4.19 Å, i.e. in both cases about 2-3% above the experimental value of 4.08 Å. It is not expected that DFT always gives the experimental value, so this is not an error. A more relevant comparison is, for instance, what a corresponding high-accuracy plane-wave calculation gives, and these typically also overestimate the lattice constant of gold by 1-3%[1].

[1] K.ăLeung, S.ăB. Rempe, P.ăA. Schultz, E.ăM. Sproviero, V.ăS. Batista, M.ăE. Chandross, and C.ăJ. Medforth. Density Functional Theory and DFT+U Study of Transition Metal Porphines Adsorbed on Au(111) Surfaces and Effects of Applied Electric Fields. *Journal of the American Chemical Society*, 128(11):3659–3668, 2006. doi:10.1021/ja056630o.

Stepping up in bias

In the tutorial of Molecular Device, the I-V curve is obtained by climbing in bias using the converged previous state as the initial state.

Special example: anti-parallel spin in MTJs

This strategy has also been used in the magnetic tunnel junction (MTJ) calculation, where it is used initialize a calculation with a new spin configuration compared to the original calculation. This allows you to converge the calculation with a simpler spin-state and use that as a starting point. **ATK** will rescale the converged density matrix into an initial density matrix for the new calculation according to the distribution of spin up and spin down as given by the *initial spin* setting of the new calculation.

3.12.9 Restarting a stopped calculation

Version: P-2019.03

Saving the checkpoint file

It may happen that a calculation terminates before converging, for instance due to a power outage, or if a job runs over its allocated walltime in a queue. It may also be that convergence is not reached within the set number of maximum iterations. In these cases you will want to restart the job from the point it stopped.

For this purpose, QuantumATK saves the current state of the calculation to a **checkpoint file** at regular intervals. The default is to save it every 30 minutes. The name of the checkpoint file is always written in the log file.

```
+------------------------------------------------------------------------------+
| Checkpoint Handler                                                           |
| Filename : /tmp/checkpoint28146777.nc                                        |
| Interval : 0.5 h                                                             |
+------------------------------------------------------------------------------+

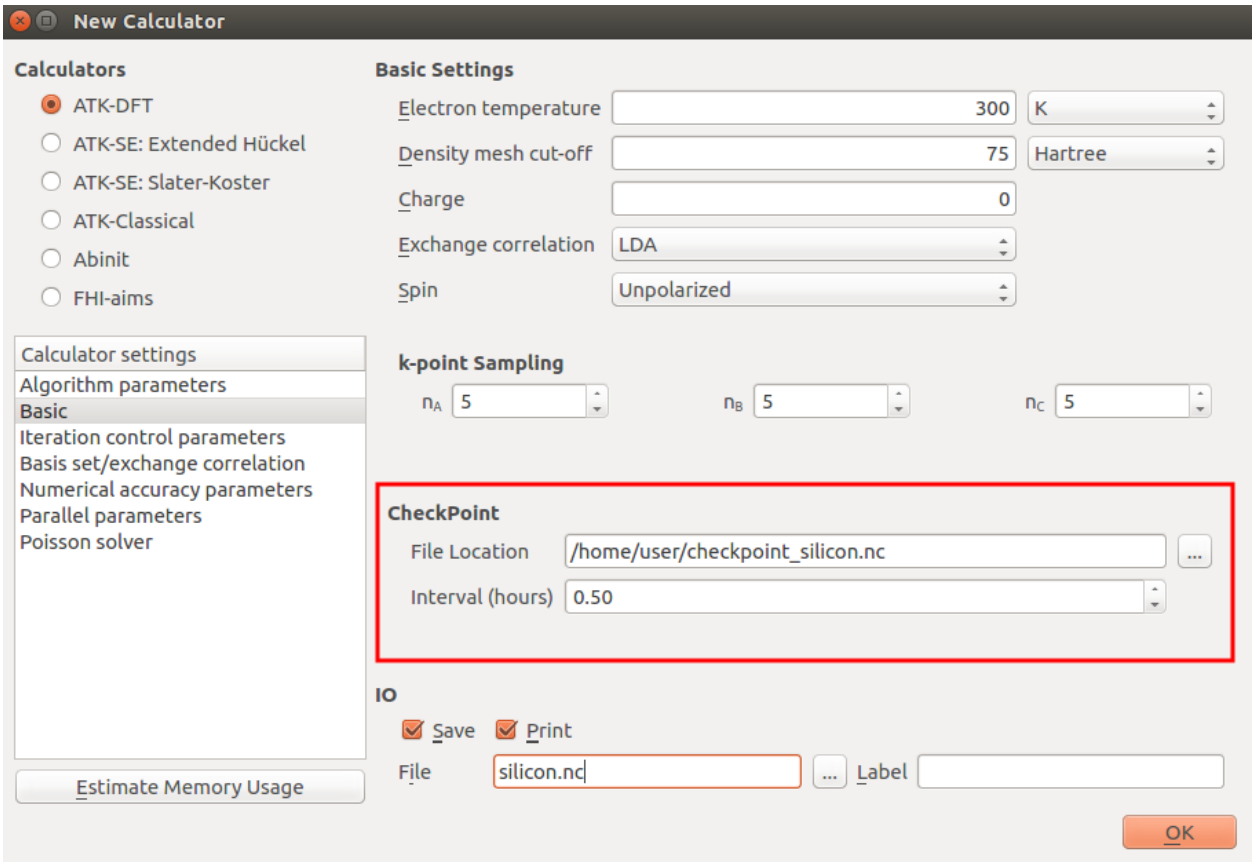
                            |-------------------------------------------------|
Calculating Eigenvalues    : ================================================
Calculating Density Matrix : ================================================

+------------------------------------------------------------------------------+
| Density Matrix Report                       DM[U]     DM[D]      DD          |
+------------------------------------------------------------------------------+
|   0  Fe   [  0.717 ,  0.717 ,  0.716 ]    5.39789   2.59547  -0.00664        |
```

Note: The default location of the checkpoint file is in the directory specified by the environment variable TEMP. If you are running on a large cluster, you may not have permission to write to the TEMP directory, and even if you do, any files you create in this directory may be deleted automatically when your job finishes – even if the QuantumATK calculation did not converge. In this case it is important to specify the location of the checkpoint file manually, e.g. in your HOME directory.

Specifying the location of the checkpoint file

The image below shows how you can set the saving interval and the name of the checkpoint file using the **New Calculator** block in the QuantumATK **Script Generator**.



If you wish, you can refer to the QuantumATK Reference Manual to get more information on how to set these parameters or turn off the checkpoint handler.

Restarting the calculation from the checkpoint file

The quickest way to restart a calculation from a checkpoint file is to read the configuration from the checkpoint file and then call update on the configuration.

```
configuration = nlread("checkpointfile.hdf5")[0]
configuration.update()
nlsave("file.hdf5", configuration)
```

The argument to `nlread()` should of course be set to the actual checkpoint file name.

The disadvantage of this approach is that if the *original* script contained any analysis blocks (e.g. to compute the band structure), you need to manually insert those blocks to the bottom of the restart script.

Restarting the original script

Conceptually, a better approach would be to rerun the script you already have, but tell it to start not from scratch, but from the checkpoint file. This would also retain all analysis blocks, as defined in the original script. This is possible; you just need to insert the lines of code shown above in the appropriate way.

Let us assume that you have a standard script, produced by the Script Generator, without too many elaborate steps. That is, a straightforward sequence of Configuration and New Calculator, followed by analysis blocks. In other cases, you can always modify the script in the same way as described here, but you have to take more care to preserve the logic. Special care needs to be take if the script contains an **InitialState** block.

Open your original script in the **Editor** and locate the line

```
device_configuration.update()
```

Tip: For bulks or molecular calculations, the variable will be called `bulk_configuration` or `molecule_configuration` instead.

Then add the following line before that line:

```
device_configuration = nlread("checkpointfile.hdf5")[0]
```

Again, the argument to `nlread()` should of course be the actual checkpoint file name.

Now you can rerun the script.

Note:

- The checkpoint file is not written exactly at the specified interval, but only when a step in the self-consistent loop has been completed and the requested time interval has passed.
- The history of the self-consistent loop is not written to the checkpoint file. Therefore, convergence might become more difficult when restarting, since the mixing algorithm has less information to work with than normally.

Restarting geometry optimizations

Restarting a geometry optimization is much more complicated. For a lengthy relaxation it is therefore always a good idea to use a trajectory file; if the calculation is interrupted you can take out some of the later images and set up a new optimization using this geometry as a starting point. Note, however, that some images in a QuasiNewton geometry optimization are test balloons, which may correspond to very large forces (i.e. a very bad guess), especially during the first 5–10 steps. So, it can be important to choose an image that does not have too large forces.

3.12.10 Compute quantities from converged simulations

Version: 2016.0

In this tutorial, you will learn how to start a converged calculation to add additional functions. In this way a lot of simulation time can be saved.

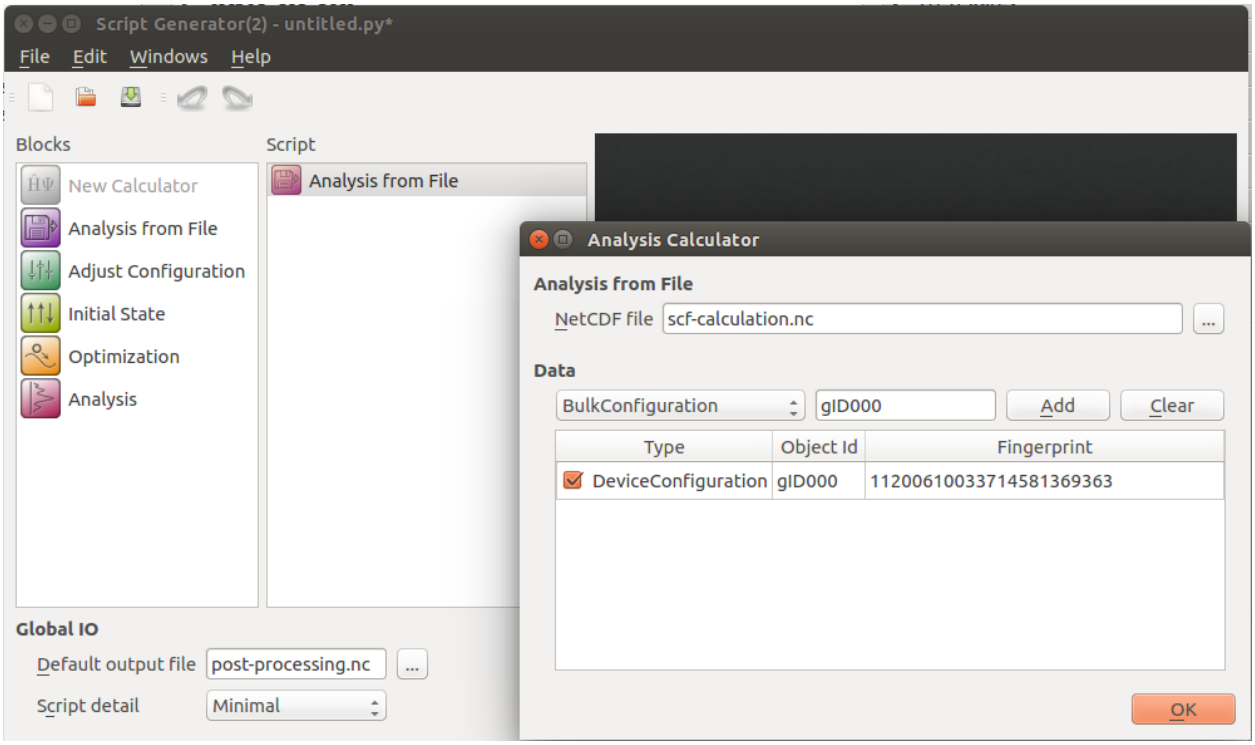
What can you do if you forgot to add the Bandstructure analysis to your script when you set it up? Or you discover you probably need more k-points to get a converged transmission spectrum? Do not worry - with **ATK** you dont have to compute all quantities together with the self-consistent calculation. You can always compute them later on, by reading the converged state of the calculation from the HDF5 file.

Using the **Script Generator** is usually the easiest way to do post-processing analysis, especially for small calculations. The post-processing can take some time, however, especially to compute the transmission spectrum or DOS with many k-points. In those cases you might want to run the script in parallel on a cluster (the analysis calculations usually parallelize linearly up to very many nodes). If so, it is still very handy to set up the script using the **Script Generator**, and then save it. That is - just like you would do it for the main self-consistent calculation itself.

Start a new **Script Generator** from the **QuantumATK** toolbar. When you open it without dropping any configuration on it, the only available block is *Analysis from File*, which is precisely what we want - to perform analysis based on a HDF5 file. Double-click this block to insert it into the script.

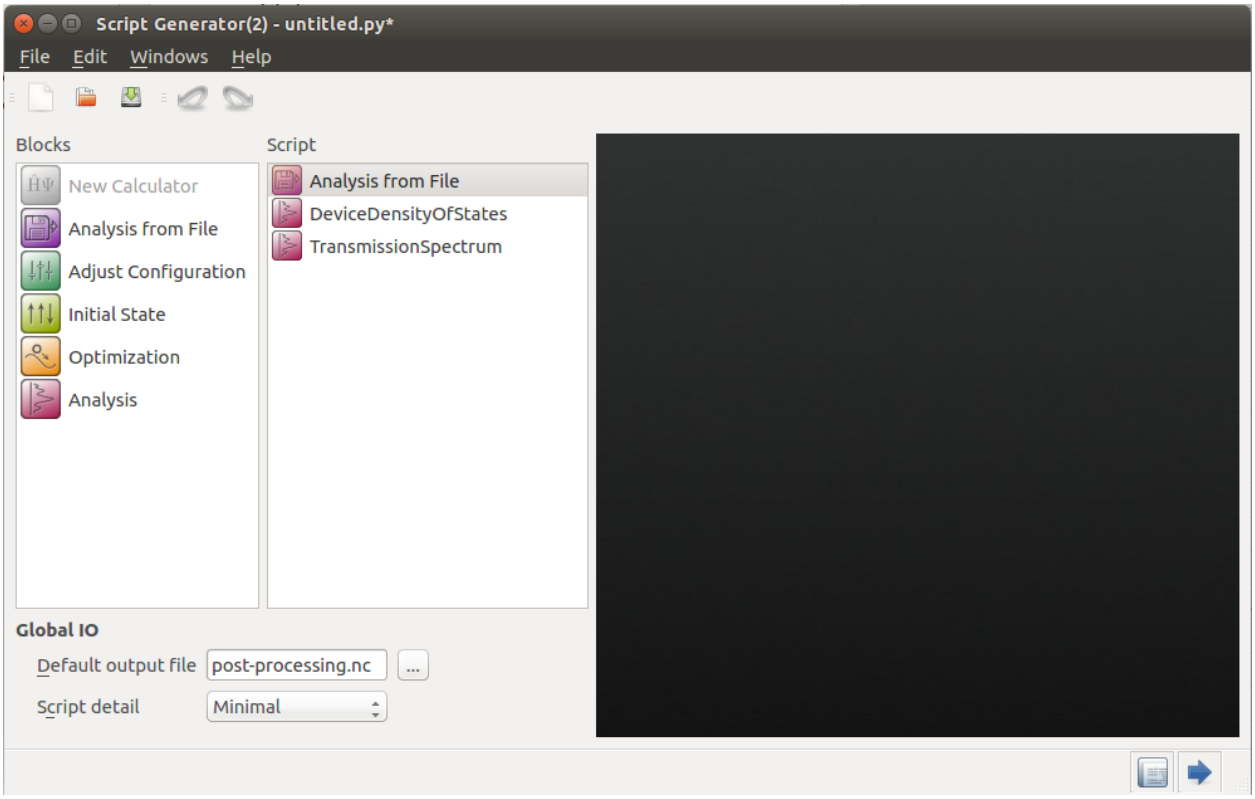
Open it, then browse and select the relevant HDF5 file.

Note: If you intend to run the script on another computer, from the command line (e.g. in parallel) you must naturally copy both the script and the HDF5 file to it. Make sure to place the two files in the same directory, and only specify the name of the input HDF5 file, without any path.



Next, check that the Object id corresponds to the self-consistent calculation you want to base the analysis on. If your calculation was a standard run, then most likely the default *gID000* is the one you want. However, if you did a geometry optimization, *gID000* corresponds to the initial geometry, and the optimized geometry will be *gID001*. You can inspect the contents of the HDF5 file, and the object ids, in the *LabFloor* in the main **QuantumATK** window.

Click **OK**, and then add all the *Analysis* quantities you want to compute, and set the parameters as appropriate.



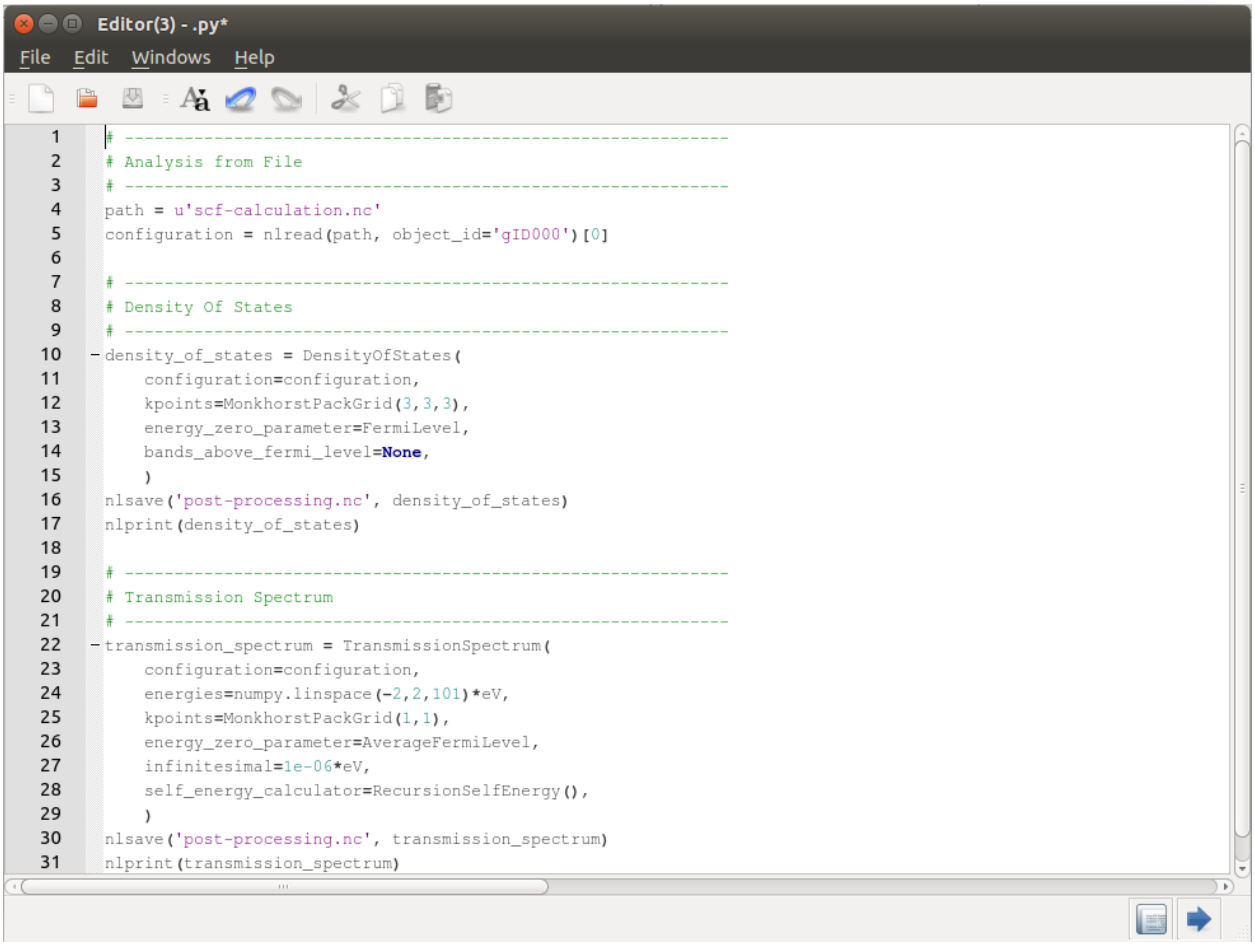
Finally, give a name and location at the blank *Default output file*.

Note: As above, if you will run the script from the command line on a different computer, just set a name without a path, in order to save the file in the running directory.

Tip: You might want to save the computed analysis quantities in a separate HDF5 file, in order not to make the original HDF5 file too big.

Now either send the script to the **Job Manager** by using the *Send To* button at the lower right corner, as usual, or save the script and copy it (with the HDF5 file!) to the cluster and run it from the command line.

If you havent looked into the Python scripts used by **ATK**, this is an excellent type of script to start with. If you send the script to the **Editor** , you will see the following.



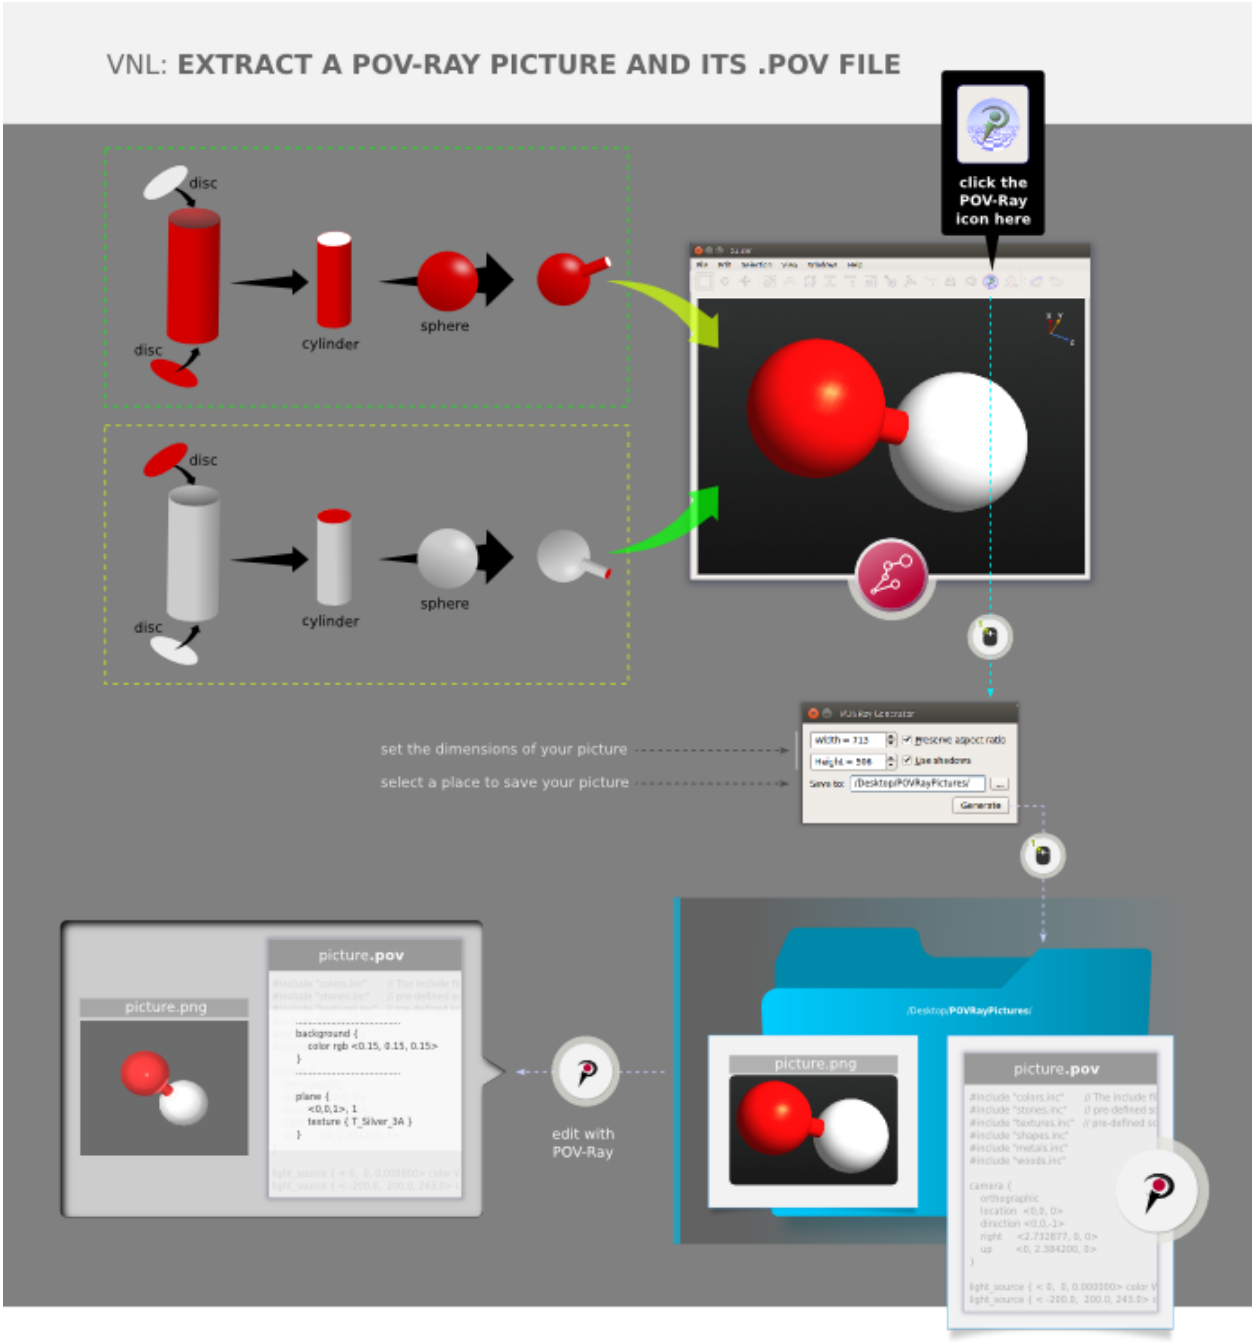
You will see that each function of the script is separated into blocks and under each block, there are lines to setup the detail parameters of the simulation. The line that does the main trick is at the very top, using the function *nlread()* to read the configuration from the HDF5 file.

Note: *nlread()* can in principle read many objects at once from a HDF5 file. Object ids must however be unique, so by using the object_id keyword, you are guaranteed to get only one object back. However, nlread() always returns a list of objects, even if there is only one match, so we need the [0] to pick out the first/only configuration matching the object_id.

3.12.11 POV-Ray images from QuantumATK

Elementary functionalities through an example

In this simple example (diatomic molecule) we are going to present how to edit an image of a molecule composed by two atoms (red and white). Also, it is a good opportunity to introduce some basic POV-Ray concepts we are going to use. The whole process is shown schematically below:



•**Step 1: Create a structure in QuantumATK.** The first step is to create this structure using the QuantumATK Builder. At this point it is good to analyze what our structure has. Here in this example we have two atoms represented by two spheres (white and red colors) connected with a single bond that represented by a thin cylindrical object. This object is composed by two cylinders (white and red cylindrical surfaces) and their top and bottom caps (white and red discs). Namely,

Structure Composition:

1.sphere (red atom)

2.sphere (white atom)

3.cylinder (red atom bond-part)

4.cylinder (white atom bond-part)

5.disc (red bottom cap of the red atom bond-part)

6.disc (white top cap of the red atom bond-part)

7.disc (red bottom cap of the white atom bond-part)

8.disc (white top cap of the white atom bond-part)

•**Step 2: Extracting POV-Ray files.** Once we are ready with the molecule in QuantumATK we are ready to extract it as a POV-Ray file (POV-Ray files have the **.pov** extension). It is quite easy to do that; just click the POV-Ray icon at the top-right of the Builders toolbar. A pop-up window appears asking you to give a name to the .pov file. Lets name it as **picture.pov**. Clicking the Generate button we extract our diatomic molecule in a POV-Ray file and our rendering in picture.png format.

> **Attention:** *It is important to mention here that the extracted .pov files (from QuantumATK) cannot be modified with QuantumATK. We can do that only with the POV-Ray program changing and importing parameters and properties.*

Examining the .pov file

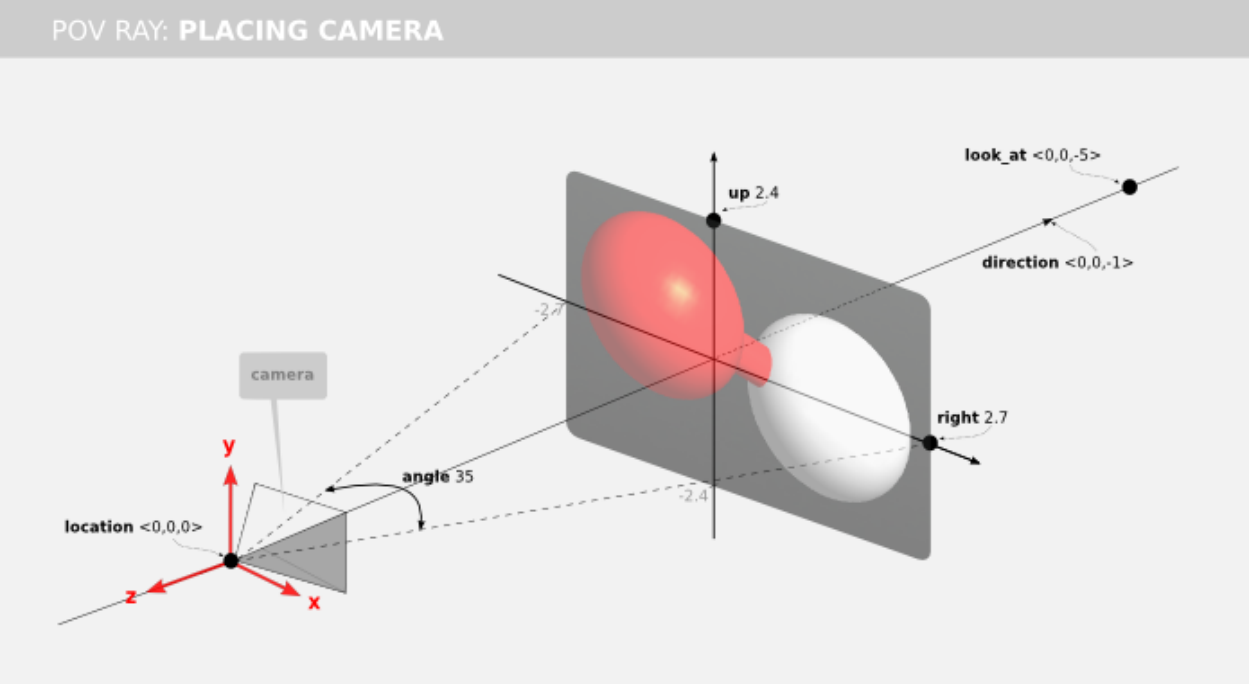
•**Header Files.** *Opening the picture.pov file we see a C++ code that describes each element and every detail of our picture. In the first lines of the code we include some .inc header files that are responsible for handling various colors, textures and shapes. Their role is obvious and it is not necessary to get into more details about that now:*

```
#include "colors.inc"
#include "stones.inc"
#include "textures.inc"
#include "shapes.inc"
#include "metals.inc"
#include "woods.inc"
```

•**Camera(s).** *The next few lines describe the properties of the camera. The camera element is very important because the rendering of the picture is depending on it.*

```
camera {
    orthographic
    location  <0,0, 0>
    direction <0,0,-1>
    right     <2.7, 0, 0>
    up        <0, 2.4, 0>
}
```

The above lines of code describe the camera view that we have used to extract our diatomic molecule from QuantumATK. The following picture shows some basic camera properties in the 3D space. For more information on editing cameras and their properties look at .



•**Light Source(s).** *The next important element is the light_source element. One may control this element by importing and/or changing various light source attributes. In the present example we have two light sources where their locations and their color lights have defined:*

```
light_source { < 0,  0, 0> color White }
light_source { < -200.0,  200.0, 243.0> color White shadowless}
```

•**Background(s).** *This element is used to assign a color to all rays that do not hit any object. Here we have defined a grey background providing the proper RGB color coordinates:*

```
background { color rgb <0.15, 0.15, 0.15> }
```

•**QuantumATK Object(s).** *The next part of the code includes the description of the various objects that we have created and rendered in QuantumATK. Namely, the elements and their properties (like textures, colors, relevant positions, radii, etc.) that are mentioned in step 1 above. It is easy to see in these code lines that we have indeed: two spheres, two cylinders and four discs and their properties are defined between the curly brackets. For example, the red atom/sphere is described by the following sphere:*

```
sphere {
    <-0.3, 0.2, -2.1>,  0.4     // center and radius
    texture {
        pigment { color rgb <1. 0.06 0.06> }
        finish {
             ambient .2
             diffuse .4
             specular .75
             roughness .001
             reflection { .6, metallic}
        }
    }
}
```

In line 2 we can see the location (in Cartesian <x,y,z> coordinates) of the center of the sphere. The next number

after the comma is just the radius of the sphere. The rest lines describe the texture of the sphere. In **pigment** we can clearly see the color definition (red) while with the (staring in line 7) we have a more realistic impression of the object. **Finish** is quite useful identifier since it gives us the option to control many properties (like roughness, diffusion and reflection effects, and many more) of the surface(s) of an object in a more detailed level. The final result of all these texture-terms are highly correlated with the light sources and the camera view of course. This means that when we change a parameter in **finish** identifier we must always take into account the light properties that we have already set in our scenery according to our camera view (different camera views give us different impressions of the same object since the light reflections are changing). Cylinders and discs are defined in a similar way.

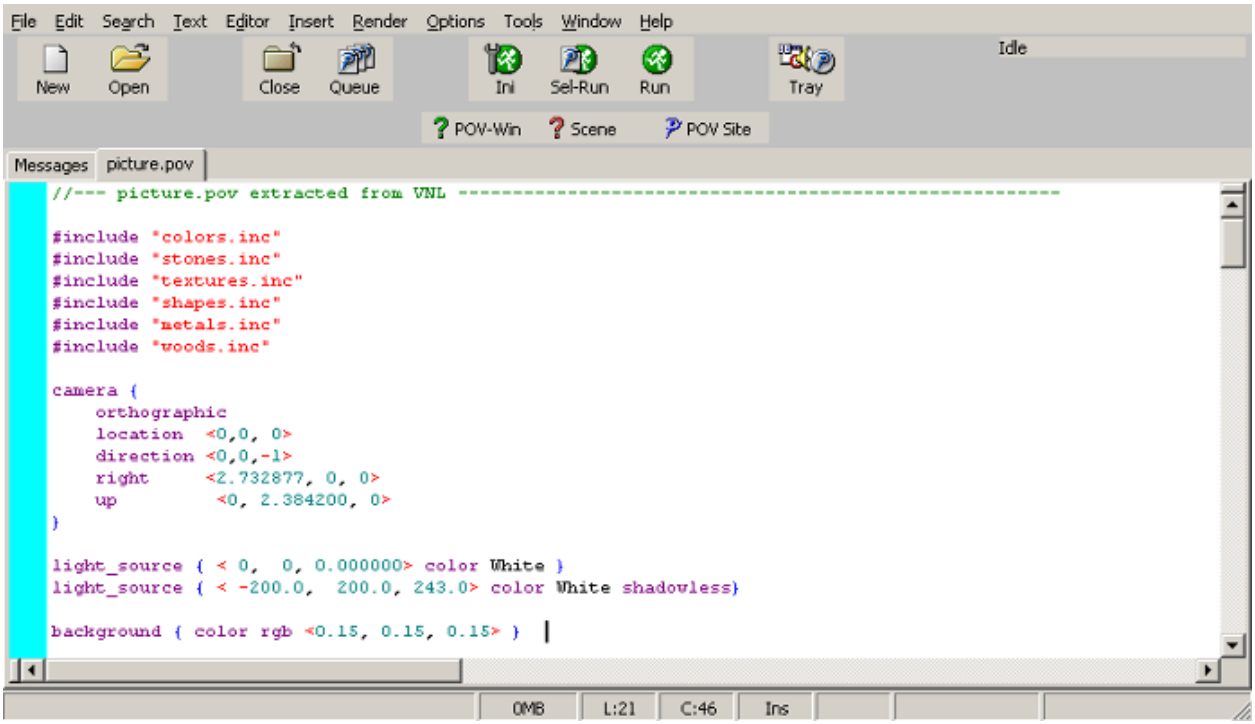
•**Step 4: Editing POV-Ray Files.** Now we are ready to update our picture. Editing the example1.pov file we are able to control many parameters, to add objects and to create many artistic effects in general (using the POV-Ray program). In our example we just add a plane. The we want to have is described by the following lines of code:

```
plane {
    <0,0,1>, 1                          //This represents the plane 0x+0y+z=1
    texture { T_Silver_3A }   //The texture comes from the file "metals.inc"
}
```

Exporting pictures with POV-Ray

Note: The content of this paragraph refers to the general use of POV-Ray as an independent program and does not restricted by QuantumATK or any other software. QuantumATK just has the ability to export complex structures as .pov and .png extensions.

In order to be able to export an edited picture you must have already installed POV-Ray on your system. You can find detailed instructions about this topic at the . So, assuming that you have already a [filename].pov file (in our example here [filename] stands for picture) follow the steps below:



| POV-Ray on Windows

•**Step 5.1:** Click the POV-Ray application icon and the POV-Ray interface opens (see picture above).

•**Step 5.2:** Click **Open** button, and navigate to your files to import your [filename].pov file you prefer (picture.pov for instance). Now you can see and edit the code according to your preferences. Once you are ready just click the green **Run** button and in some seconds you will create your [filename].png picture.

| POV-Ray on Linux

•**Step 6.1:** Open the [filename].pov with a text editor, make the changes you want (if any) and save it.

•**Step 6.2:** Open a terminal and type `povray [path/to/pov/file]`. For example if the picture.pov file is on the Desktop, then type:

```
$ cd Desktop/
$ povray Desktop/picture.pov
```

or directly

```
$ povray Desktop/picture.pov
```

If you want specific picture size type:

```
$ cd Desktop/
$ povray picture.pov -w320 -h240 +a0.3
```

Where **-w**, **-h**, **+a** numbers define the **width**, the **height** and the **aspect ratio** respectivelly.

`zn-zno-zn.py` `zero-bias.py` `analysis.py` `finite-bias.py` `iv-curve.py`

This tutorial introduces you to one of the most important functionalities in **QuantumATK**, namely electron transport calculations.

The system you will investigate is a Zn|ZnO|Zn junction, which is selected for demonstration purposes, in order to make calculations relatively fast. However, this system does encapsulate many of the relevant and interesting physical effects present in more realistic devices, and these will be discussed in the tutorial.

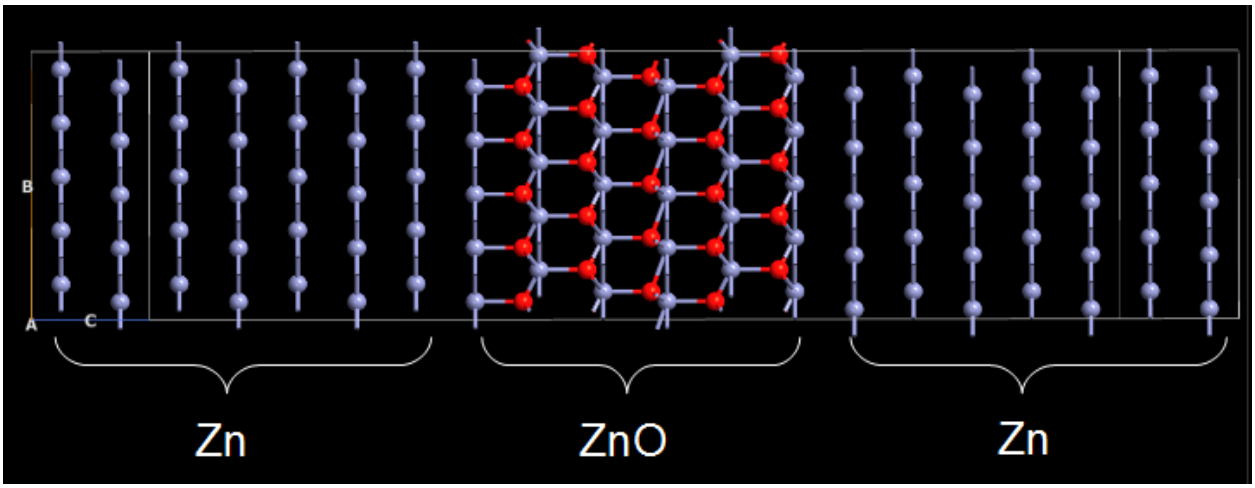

Fig. 3.121: The Zn-ZnO-Zn system to be studied in this tutorial. Note that the configuration is repeated 5 times along the B axis to improve the visual clarity.

Note: In order to run the calculations in this tutorial, you must have a license for the **ATK-SE** tight-binding engine. If you do not have one, you may obtain a time-limited demo license by contacting us via our website: Contact QuantumATK.

Attention: This tutorial was prepared using QuantumATK version 2016.3. Downloadable scripts and output files may therefore not work with QuantumATK 2015 and earlier.

Introduction

In this tutorial, the electronic structure of the Zn-ZnO-Zn junction will be calculated using a **tight-binding** (TB) model in combination with the **non-equilibrium Greens function** (NEGF) technique for the actual calculation of the electron transport through this junction. A detailed description of technical aspects of the computational parameters and models can be found in the ATK Reference Manual.

To set up the calculations, you will use the graphical interface **QuantumATK** (QuantumATK). If you have never worked with QuantumATK before, it is highly recommended to first go through the Basic QuantumATK Tutorial to become familiar with the basics of how to operate the software.

You will here use a predefined device configuration, but we have many other tutorials that show you how to set up other device geometries.

Tutorial objectives

We will first introduce the central concepts involved in a device calculation, and then present a range of tools that can be used to analyze the electronic transport properties of the device.

After reading this tutorial and performing the calculations, you will be able to:

•Understand the general concept of a device configuration.

•Test convergence of physical quantities with respect to computational parameters.

•Check if a given bulk configuration is suitable as an electrode.

•Calculate the transmission spectrum at zero and finite bias voltage.

•Analyze the transmission spectrum using the Transmission Analyzer.

•Calculate and plot transmission eigenstates.

•Calculate and plot the projected device density of states.

•Calculate the potential profile (voltage drop) across the device.

•Calculate the I–V curve and analyze it.

Geometry for transport calculations

The type of atomic configuration needed for an electron transport calculation is fundamentally different from the configurations used in atomic-scale simulations of periodic and finite structures. This is because an electron transport calculation requires **open boundary conditions** in the transport direction. Open boundary conditions make it possible for incident electrons coming from the source electrode to be partially transmitted through the central part of the device and end up in the drain electrode, and partially reflected back to the source.

One may see the device configuration as a combination of periodic and finite configurations, as shown in the figure below. The left and right bulk (periodic) **electrodes** (source and drain, in a transistor perspective) are attached to the **central region** of the device, which is finite (non-periodic) along the transport direction. The central region is often called the scattering region, because the charge carriers traveling between the two electrodes are scattered by changes to the physical and chemical environment in the central region, for example by interfaces and defects. The central region therefore determines the *functionality* of the device, while the left and right electrodes are modeled as perfect leads that connect the device to the external source and drain.

For reasons of numerical stability during QuantumATK device calculations, there is a region in both ends of the central region where the element types and ionic positions are fixed to match the electrodes – these are the **electrode extensions**. Both must always be an exact replica of the corresponding electrode, and are therefore not allowed to change during geometry optimization of the device.

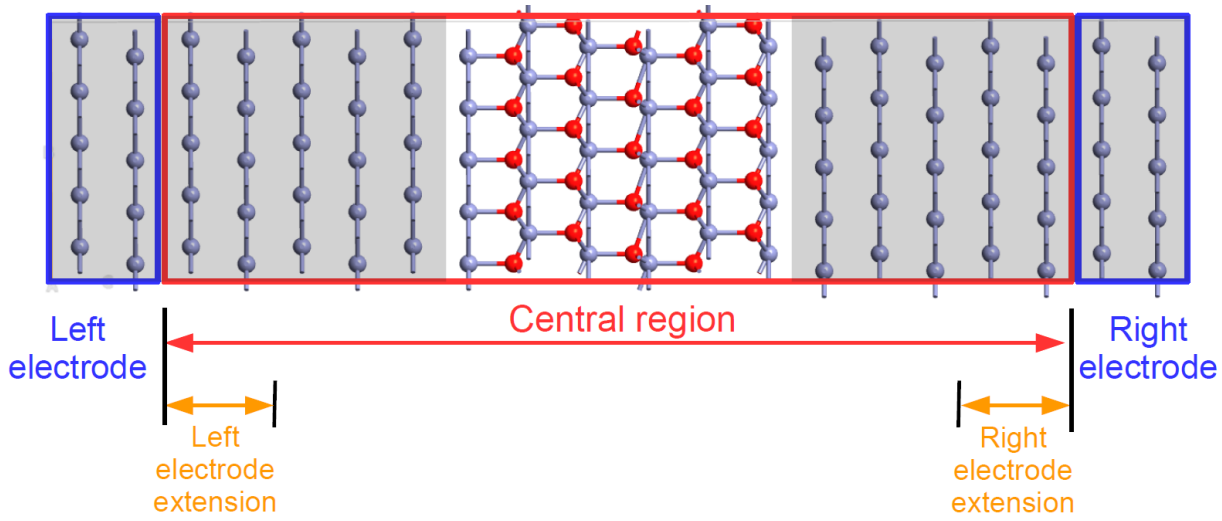

Fig. 3.122: A two-probe device configuration consists of two electrodes and a central region. Both ends of the central region, called the electrode extensions, must be exact replicas of the corresponding electrode structures.

Hint: In both figures above, the device configuration is periodically repeated 5 times along the B axis (which points up in both figures) to improve visual clarity. However, just like in standard atomistic simulations one should always use device configuration with the smallest lateral unit cell area, taking advantage of any structural periodicity of the device in the A and B directions (orthogonal to the transport direction, C).

Important notes

- The C-direction in the device configuration is the **transport direction**, meaning that the electrodes are always connected to the central region in this direction.
- The electrodes are by default assumed to be periodic in the A and B directions, i.e., perpendicular to the transport direction. When simulating transport through 1D or 2D confined systems, such as wires, tubes, ribbons, and sheets, a sufficiently large vacuum padding should be added along the confined direction(s). This allows the electron density and electrostatic potential to decay correctly in the vacuum region, and this also avoids spurious interactions with repeated images of the system.
- The central region can take many different forms. For example, it can be a metal–semiconductor–metal sandwich, as in this tutorial, a molecule between the two electrodes, or a piece of a nanotube or a graphene flake with a defect.
- In the Zn|ZnO|Zn device treated here, the two electrodes are identical, but this is not a general requirement. For example, QuantumATK can easily simulate the electron transport through an interface between two different materials.
- In addition to source and drain electrodes, QuantumATK supports inclusion of **electrostatic gates** for transistor simulations. This will not be covered here, but is addressed in several other tutorials.

The screening region

The central region should normally involve some structural inhomogeneity (interfaces, surfaces, molecules, defects, etc.) that leads to rearrangements in the electron density and hence in the self-consistent potential felt by the electrons. This electronic rearrangement may be further enhanced by structural relaxation effects inside the central region (excluding the electrode extensions, which are not allowed to relax). This deviation of the central region potential from the bulk electrode potential causes the electrons to be scattered, which will cause a voltage drop across the central region at finite bias.

Note: Simulating the transport properties of a perfectly periodic structure is only possible at zero bias (since there is no place for the voltage to naturally drop in a perfectly periodic structure, as there is no scattering), and can moreover be done in a simpler way, using just a periodic bulk configuration

---

The NEGF formalism assumes that the potential in the central region converges smoothly towards the electrode potentials, such that there is no scattering at the two electrode–central region interfaces. In the sketch of the Zn|ZnO|Zn device shown below, the Zn metal regions in both ends of the central region are on a gray background, just like in the electrodes, in order to indicate the so-called **screening regions**, in which the potential and charge rearrangements at the Zn–ZnO interfaces are screened and smoothly approach the electrode potentials. If the screening regions are shorter than the actual (physical) screening length of the system, spurious scattering may take place at the electrode–central region interfaces. This may give rise to poor convergence of the self-consistent calculation and inaccurate results in finite-bias calculations.

The figure above shows the potential profile due to an applied bias voltage of U = -0.5 Volt in the Zn|ZnO|Zn device considered here, meaning that the voltage on the left electrode is 0.5 V lower than that on the right electrode. Most of the voltage drop occurs in the ZnO region while the potential in the metallic screening regions is virtually flat, so no scattering takes place in these screening regions. In the section *Finite-bias calculations* you will reproduce this potential profile.

Attention: In systems with semiconductor electrodes, the screening length can be quite long, and a very long central region may be required before the potential approaches the bulk value. However, in most real situations, the semiconductor electrodes are doped, which brings the screening length down to manageable simulation sizes, provided the doping level is high enough.

Note:

- The entire treatment of electron transport is in this context coherent and elastic, i.e. there is no scattering by phonons.
- The NEGF formalism assumes that the electrodes are in thermal equilibrium, which formally requires that the electrical current through the device is low. This always holds true at low voltage, and may also be a valid assumption at higher voltage, provided that the transmission probability through the central region is sufficiently low.

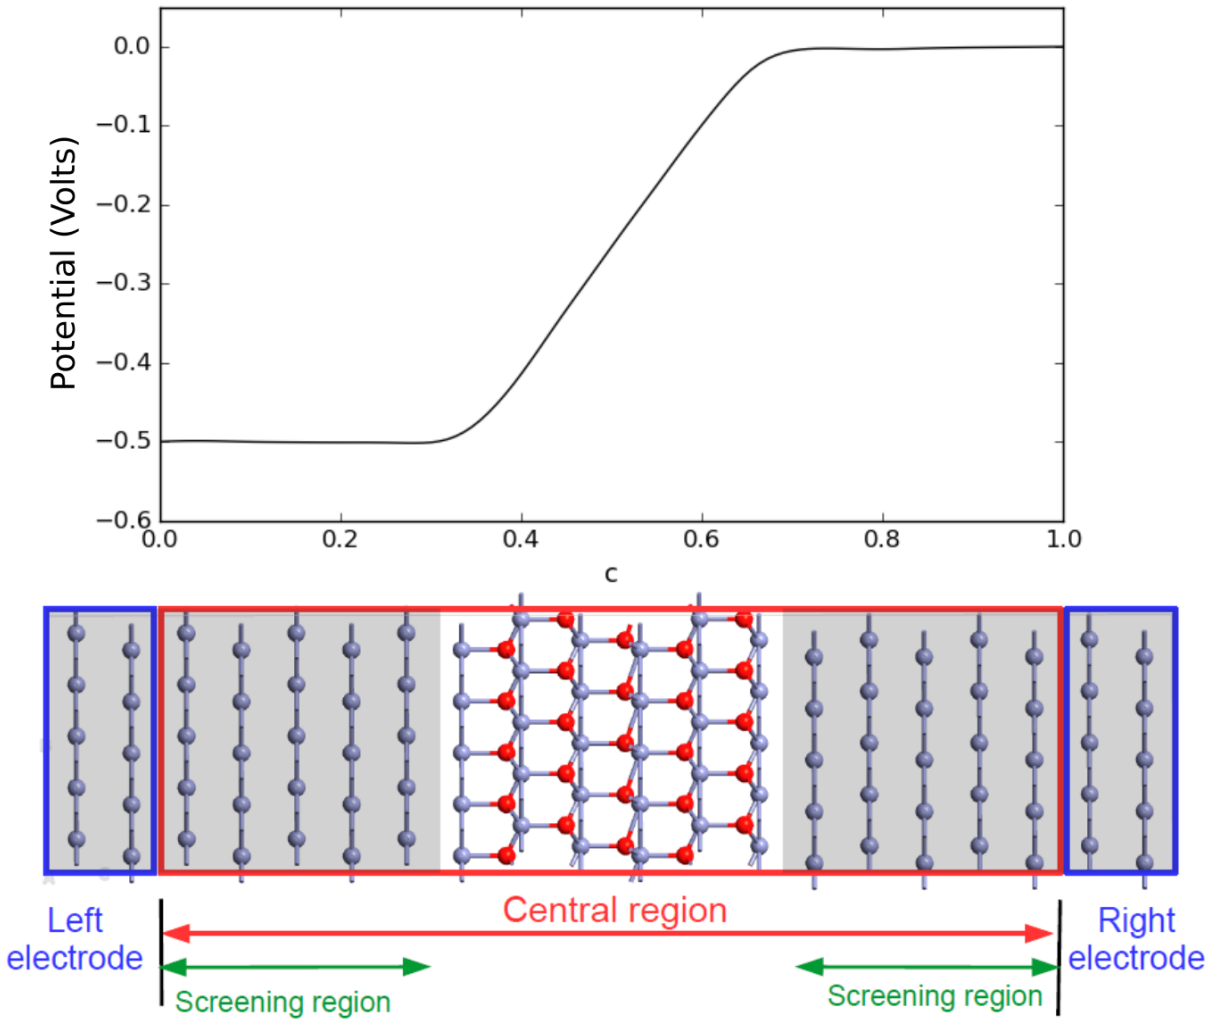

Fig. 3.123: Top: Electrostatic potential along the transport direction. Bottom: Device geometry. The screening regions in the left and right parts of the central region, indicated by gray background, must be longer than the screening length of the system to ensure a smooth transition between the potential of the central region and electrodes.

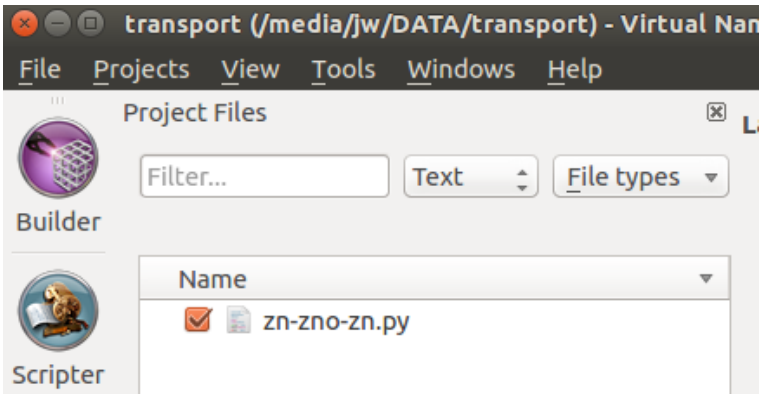
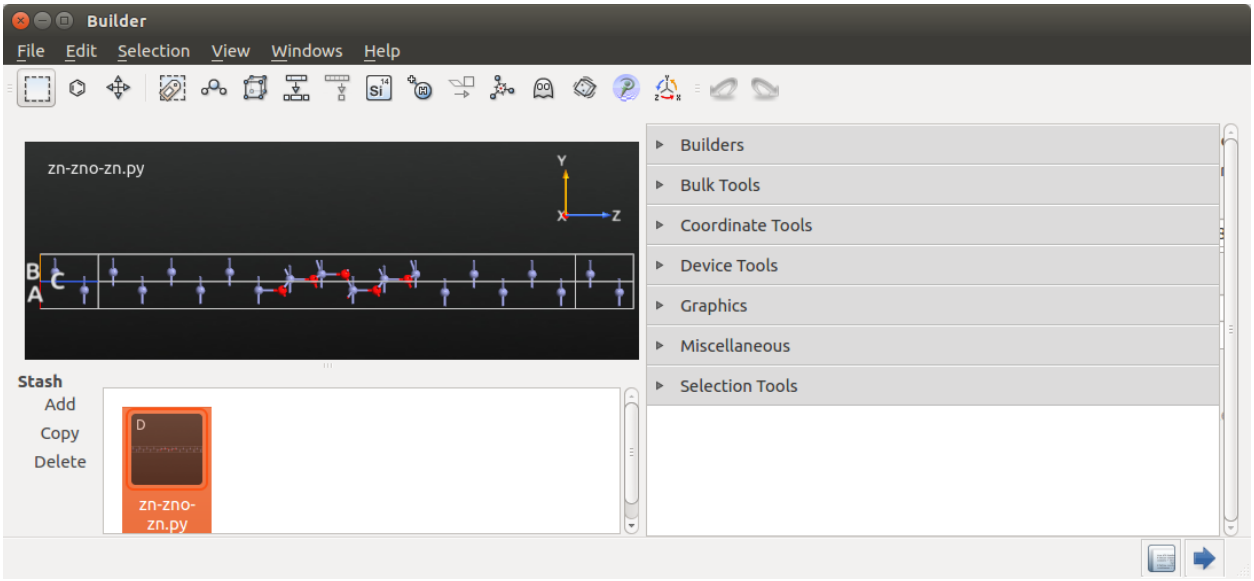
Getting started

Start up **QuantumATK** and create a new project. You would normally use the **Builder** to create the device configuration, but here we will use the Zn|ZnO|Zn device already defined in the QuantumATK Python script `zn-zno-zn.py`. Download the script and save it in the project folder. It will then show up on in the Project Files list.



Drag the script onto the Builder to access a large palette of tools for creating new configurations and modifying existing ones.



Convergence of electrode parameters

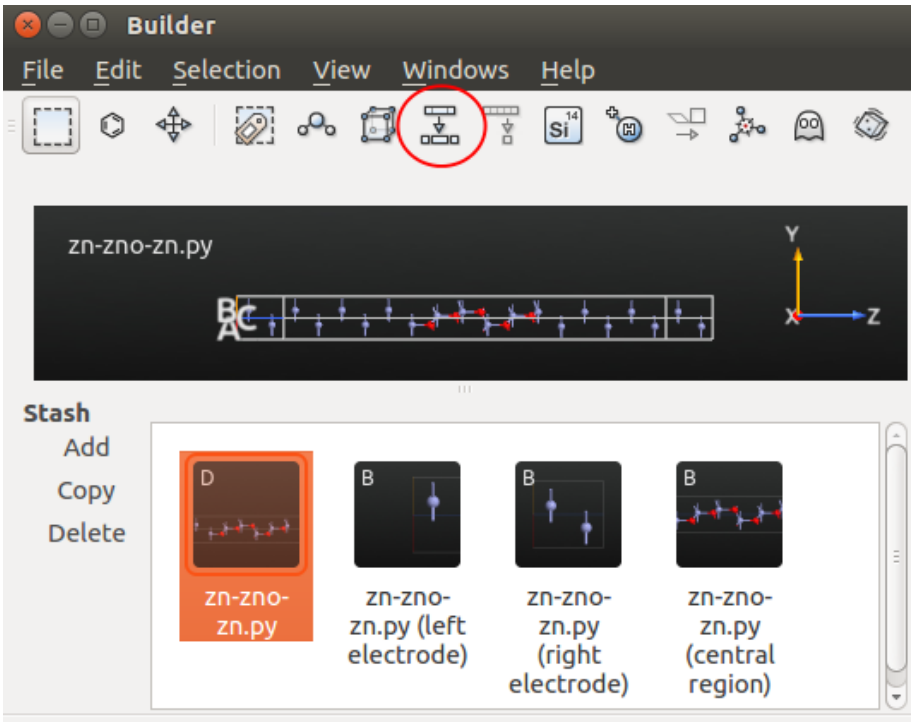
An QuantumATK device calculation is performed in multiple steps. First, the electrode(s) and the central region are treated as (periodic) bulk systems, and the self-consistent electron density is calculated for each of them. The device calculation is then started, using the central region bulk electron density as an initial guess, and matching the electronic structure at the two electrode/central region boundaries to that of the electrodes. Finally, the self-consistent electronic structure of the central region is determined, and thereby of the full device.

It is important to the procedure outlined above that the electrode bulk calculations are well converged, both in electrode lengths and numerical accuracy. The purpose of this section is to demonstrate the convergence of two very important numerical accuracy parameters; the mesh cut-off and the number of k-points in the transverse directions (A and B).

The convergence test will here be performed only on the left electrode, since the two electrodes are (physically) identical. In case the electrodes are not identical, the required mesh cut-off and k-point sampling should be determined separately for both of them. However, since these numerical parameters must be the same in the two electrodes in the device calculation, in the end they need to be chosen large enough that both electrodes are accurately described.

Split the device configuration

Use the *Splitter* tool in the top toolbar to split the device into electrodes and central region. This will add 3 new configurations to the **Stash**, corresponding to the left and right electrodes and the central region.



You can now highlight the left electrode configuration and use the botton to send it to the **Script Generator** and set up a range of bulk calculations for the electrode using different density mesh cut-offs and k-point samplings to study the numerical convergence.

For convenience, scripts have already been prepared for the calculations needed in the two convergence studies. In the following, you should simply download and run them.

Mesh cut-off

The first numerical parameter to converge is the density grid cut-off. This controls the density of the real-space grids in QuantumATK, which represent e.g. the electrostatic potential and real-space electron density. The density cut-off is specified as an energy E; the corresponding distance between the grid points is given by

$$\Delta x = \frac{\pi\hbar}{\sqrt{2mE}},$$

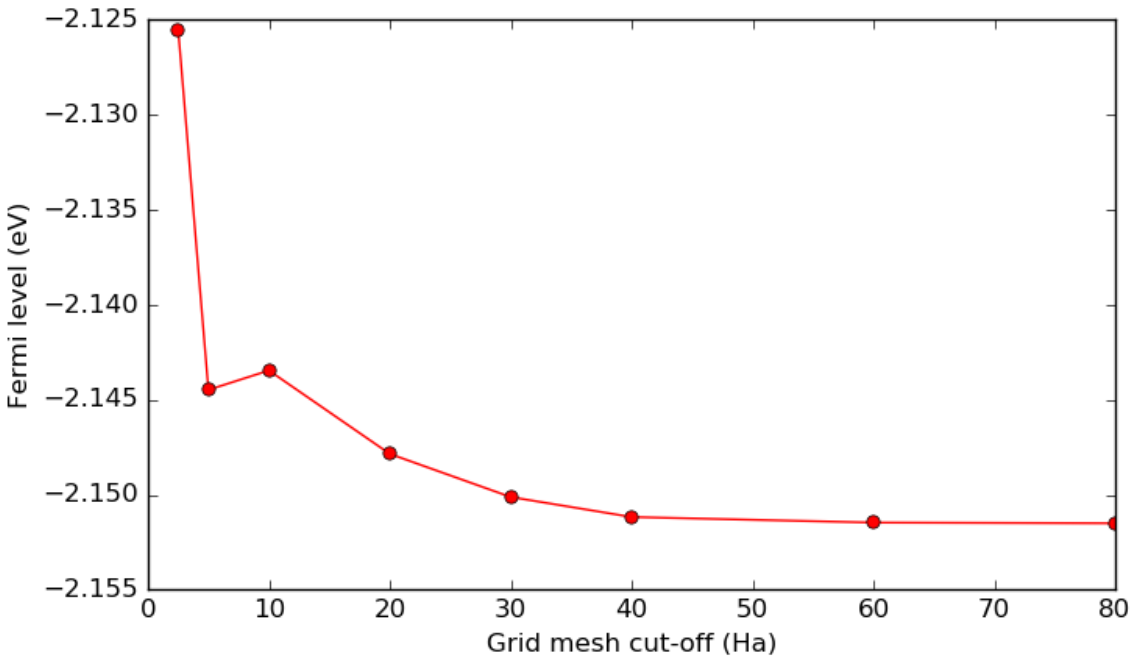
where m is the electron mass.

The script `mesh_loop.py` performs calculations of the ground state of the electrode for different mesh cut-offs ranging from 2.5 Ha to 80 Ha. All other numerical accuracy parameters are kept constant. The convergence observable is the Fermi level (chemical potential) of the electrode.

The script simply loops over the mesh cut-offs, performs the calculation for each value, and finally plots the results. Download the script, and then run it using the **Job Manager**. If you are not familiar with the QuantumATK Job Manager, please refer to the tutorial *Job Manager for local execution of QuantumATK scripts*. You can of course also run the script from command line:

```
$ atkpython mesh_loop.py > mesh_loop.log
```

The plot will automatically appear once the calculations are done (in less than a minute). The plot is shown below. It is clear that the default 10 Ha mesh-cut-off for tight-binding calculations is a perfectly sufficient default, since the Fermi level changes by less than 10 meV when using larger values (which are computationally more expensive), and we will keep it for further calculations.



Attention: This weak dependence of computed quantities on the mesh cut-off is typical of tight-binding models. The same would generally not be true for DFT calculations, where the default mesh cut-off with the cheapest pseudopotentials is 75 Ha.

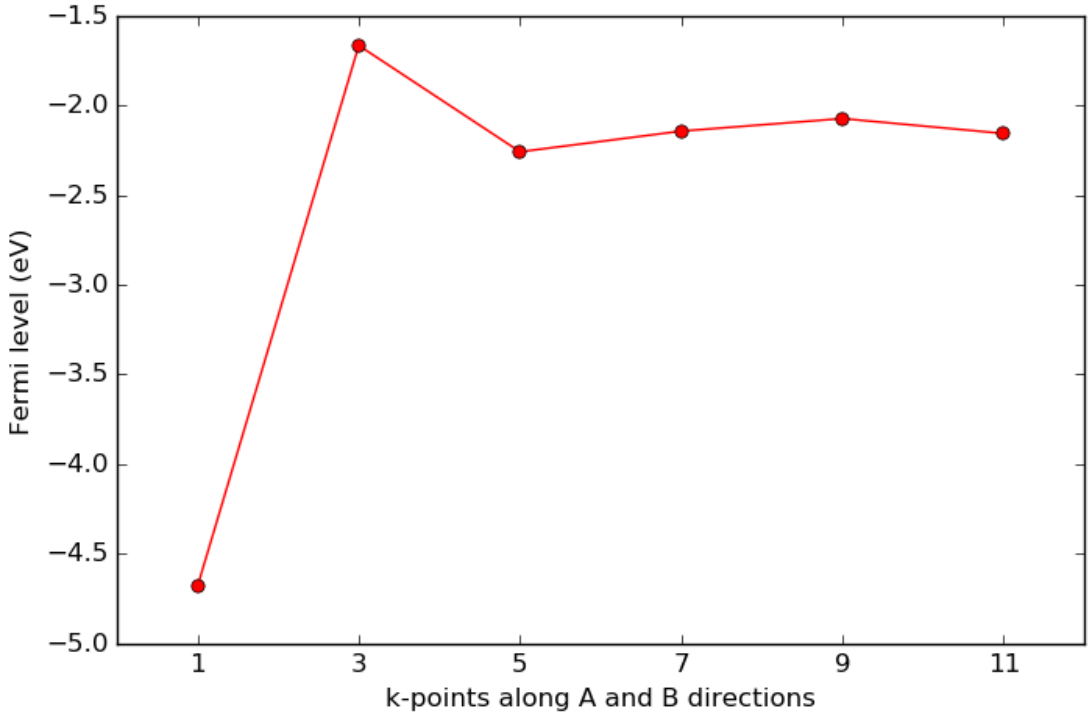
Transverse k-points

In the same fashion as above, you will now study the electrode Fermi level as a function of the number of k-points in the transverse directions (A and B), which are orthogonal to the transport direction (C).

The number of k-points in the transport direction should be quite large in a device calculation, so keep it at n_C = 51. All other numerical accuracy parameters should be kept at their default values, including the grid mesh cut-off (10 Ha).

Use the script `kpts_loop.py` for this convergence study. It is identical to the one used above for the mesh cut-off, but loops over odd transverse k-points in the range 1 to 11.

Download and run the script, which will produce the plot shown below. It is quite clear that the calculation with only 1 k-point along the A and B directions fails completely in describing the periodic Zn electrode bulk, while the calculations with 5 or more transverse k-points are much better.

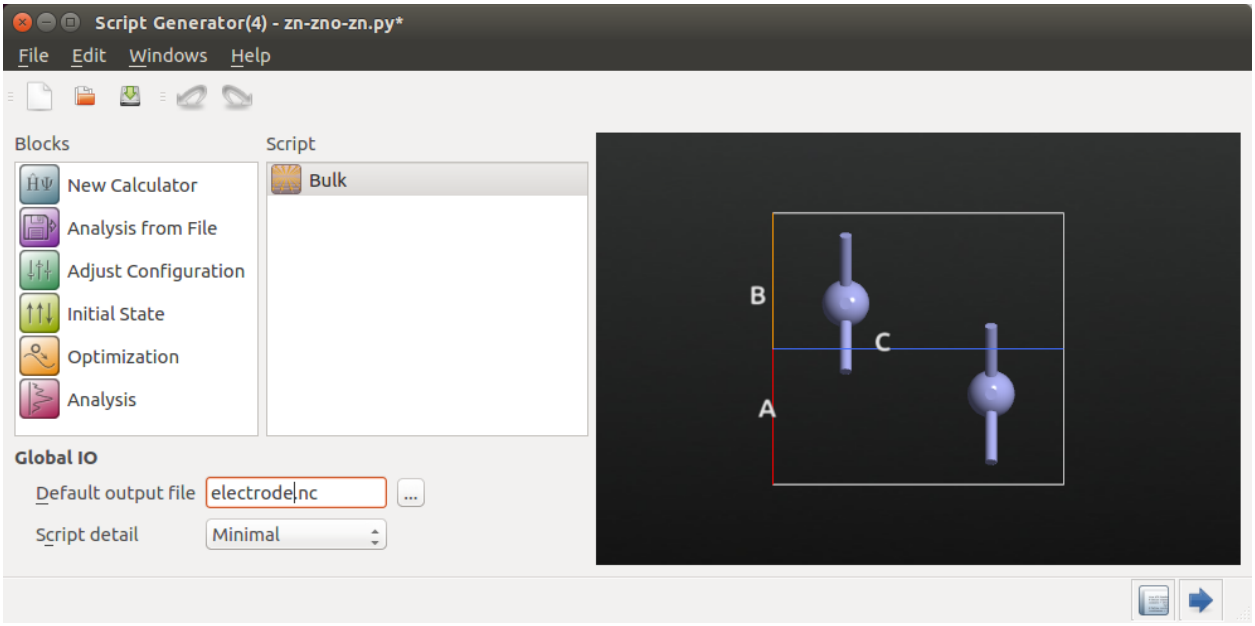


Check the electrode geometry and size

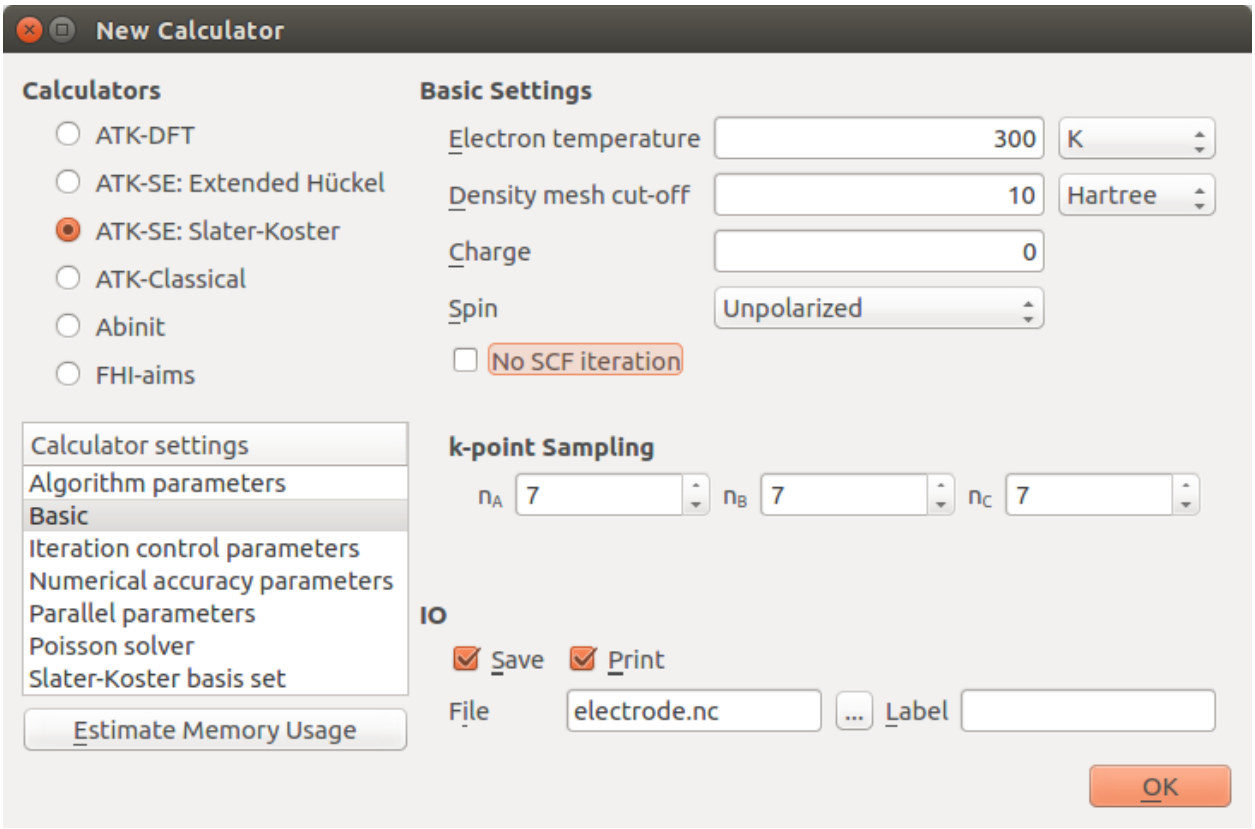
After having performed the electrode calculator convergence tests, the final preparatory step consists of checking the electrode geometry, using the **Electrode Validator** plugin. This tool checks if the electrode configuration has the appropriate geometry (*viz.* if the C axis is parallel to the Z coordinate axis, and if the AB plane is perpendicular to C) and if the electrode is long enough along C.

You first need to do a ground state calculation for the electrode. Follow these steps to set up the calculation:

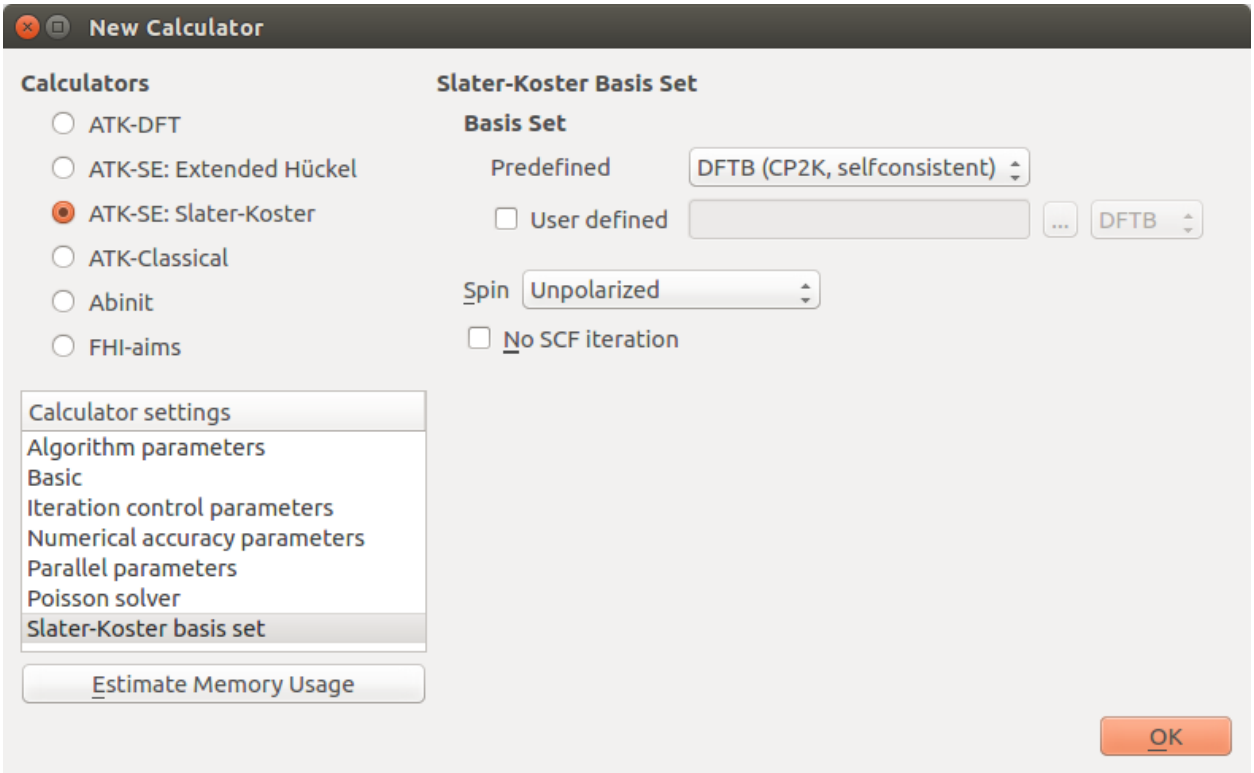
•Open the Builder and select the left electrode. Then use the botton to send the electrode to the **Script Generator**. Change the default output file name to `electrode.hdf5`.



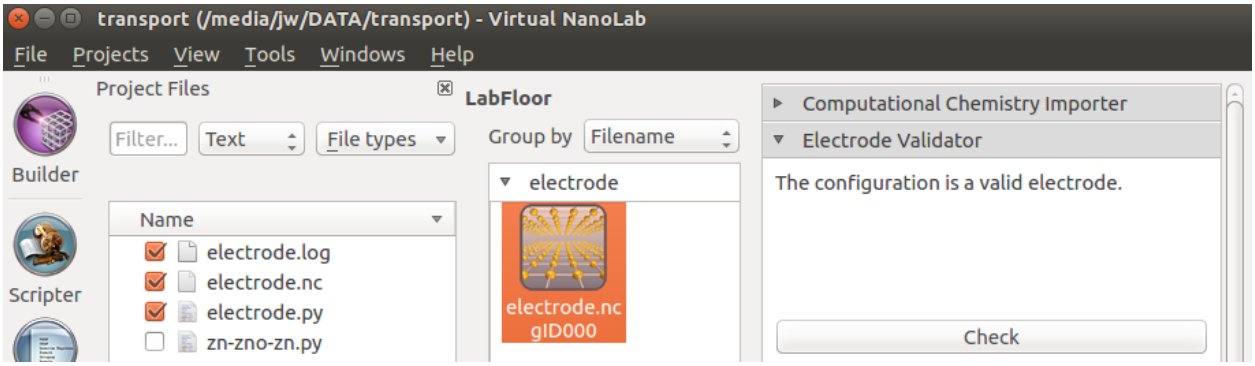
•Add a **New Calculator** block and double-click it to open it. Select the **Slater-Koster** tight-binding calculator engine, make sure No SCF iteration is not checked, and set up a 7x7x7 k-point grid.



•Finally, in the *Slater-Koster basis set* calculator settings, choose the self-consistent DFTB CP2K basis set.



Save the script as `electrode.py` and run the calculation. The script can also be obtained here: `electrode.py`. The results should soon appear on the **LabFloor**. Select the bulk configuration saved in the output file (`electrode.hdf5`), open the Electrode Validator plugin in the right-hand plugins toolbar, and click *Check*.



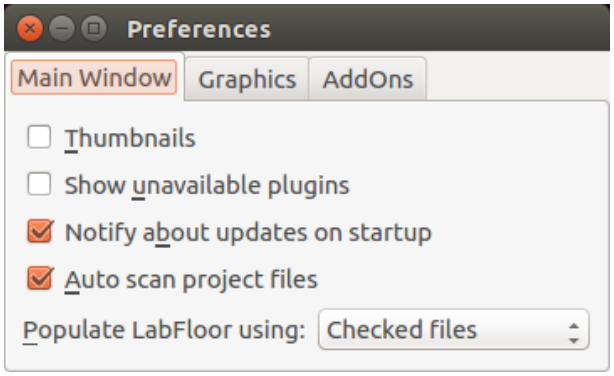
You should see a message saying *The configuration is a valid electrode*, indicating that the electrode geometry and length are fine. In case the electrode for some reason fails the check, a warning and an explanation will be presented.

Note: Whether an electrode is long enough in the C direction depends to some extend on the basis set used. The Electrode Validator uses the criterion that any discarded matrix elements of the Hamiltonian should not exceed 10^{-10} eV.

The reason for this is that only the nearest-neighbor interactions of the electrode along C are kept in the device calculation. Specifically, this is the interaction between the electrode and the electrode extension. This is necessary in order to describe the electrodes as semi-infinite rather than fully periodic along C).

If the electrode is deemed too short, you can still proceed with the device calculation, but, depending on how large the discarded matrix elements are, you risk that the calculation will not converge or that the results are inaccurate.

Tip: The screenshots for this tutorial have been made after unticking the option *Show unavailable plugins* in the *File* → *Preferences* menu in the QuantumATK main window. This causes QuantumATK to dynamically change the list of available plugins in the right-hand plugins bar, such that plugins that are not compatible with the selected LabFloor item are not shown.



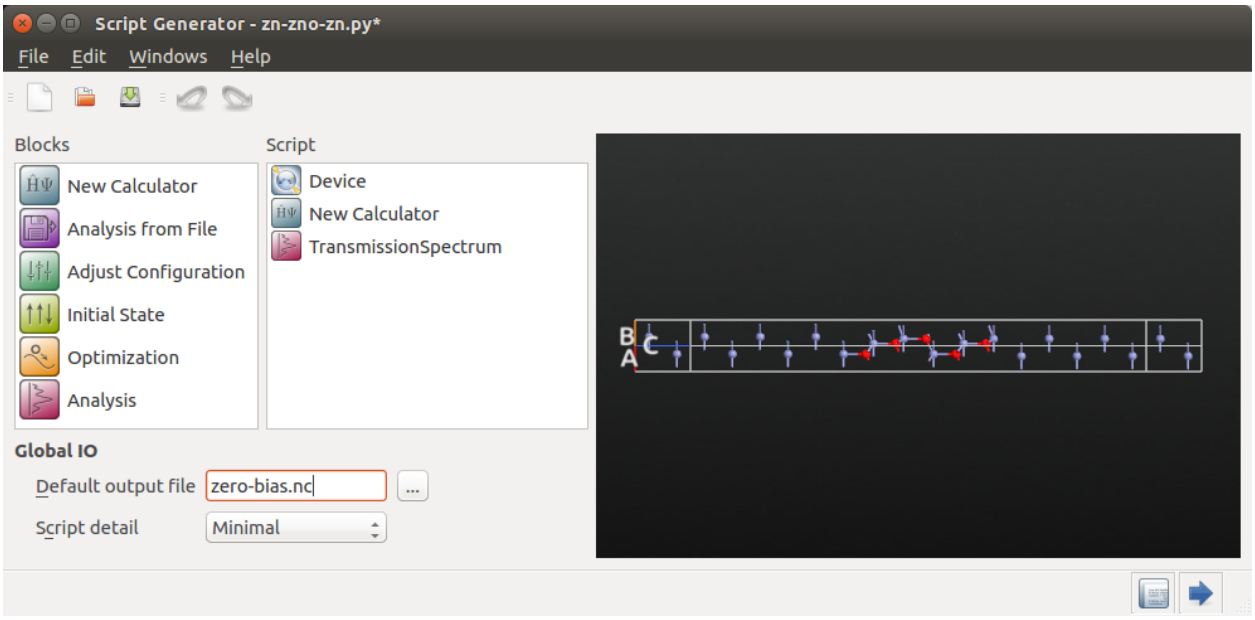
Zero-bias analysis

Having confirmed that the geometry of the electrodes is indeed suitable for QuantumATK device calculations, you are now ready to continue with the actual transport calculations. In the **Builder**, Select the Zn|ZnO|Zn device configuration, named `zn-zno-zn.py`, and send it to the **Script Generator**.

Transmission spectrum analysis

In the Script Generator, follow these steps to set up a script that calculates the electronic transmission spectrum of the Zn|ZnO|Zn device:

- Change the default output file name to `zero-bias.hdf5`.
- Add a New Calculator block to the script.
- Add also the *Analysis* → *TransmissionSpectrum* block.



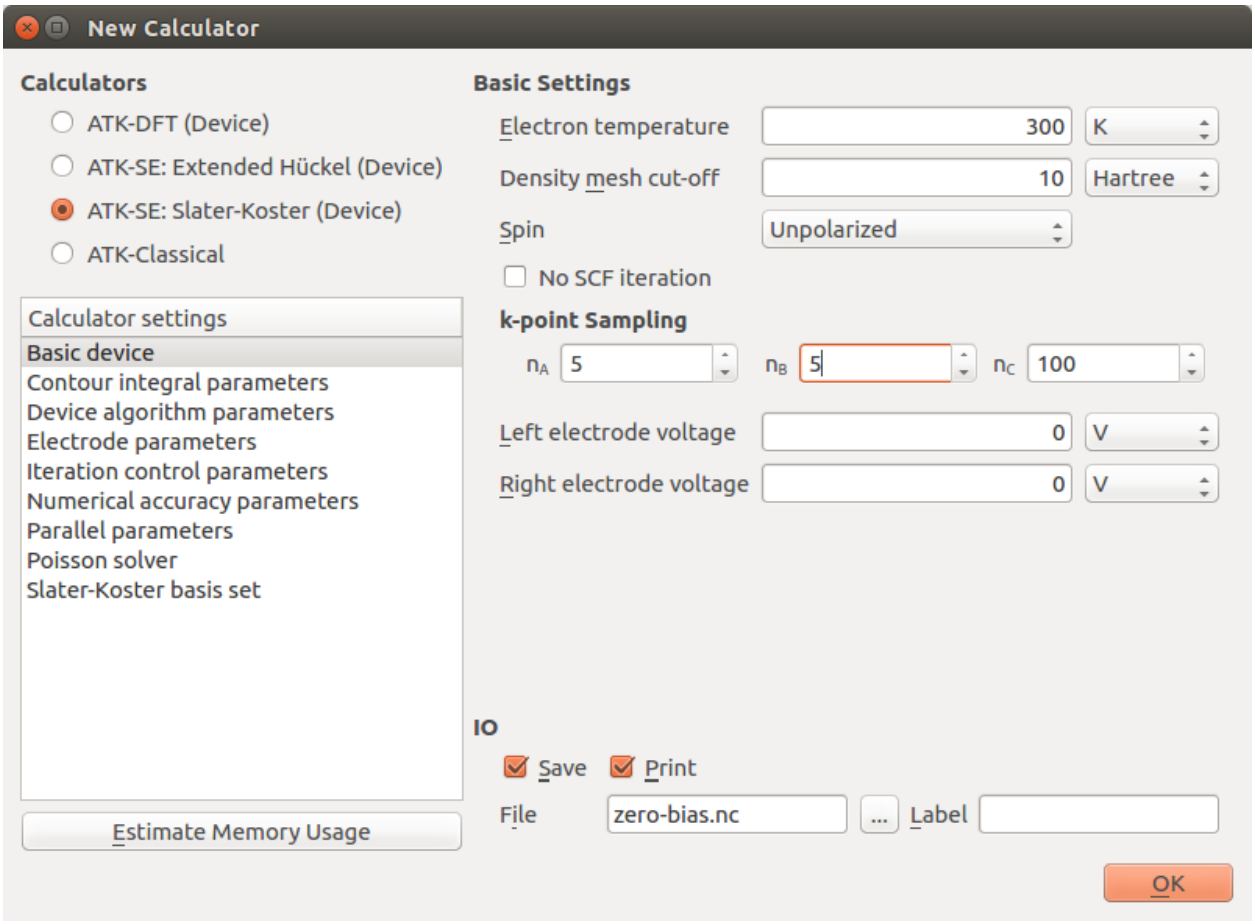
Then edit the calculator settings by double-clicking in the script:

•Choose the **ATK-SE: Slater-Koster (Device)** tight-binding calculator engine.

•Set the transverse k-point samplings (along A and B) to 5.

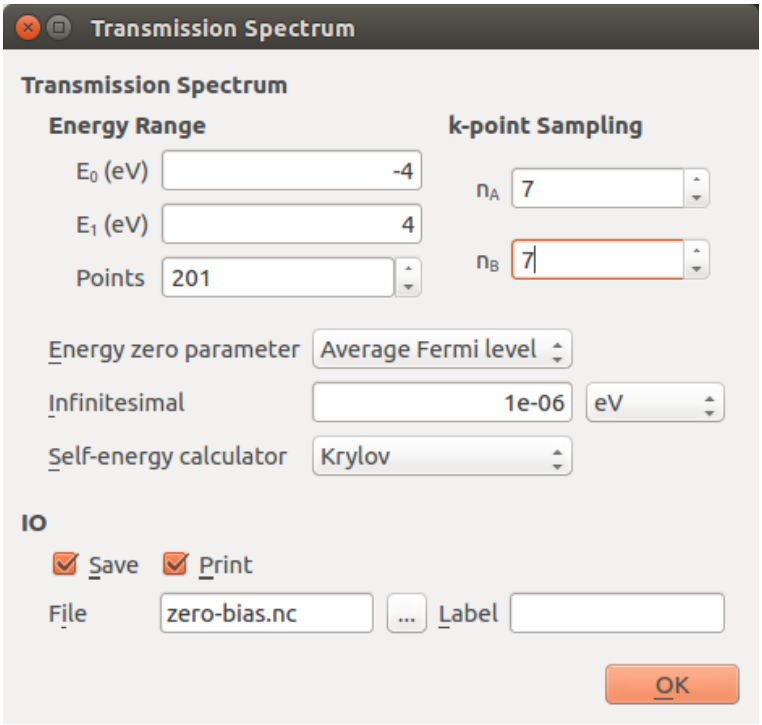
•Uncheck the box *No SCF iteration* to run a self-consistent calculation.

•Verify that the **Slater-Koster basis set** is set to *DFTB CP2K*.



Next, edit the settings in the TransmissionSpectrum block:

- Increase the energy window such that it ranges from -4 eV to +4 eV.
- Increase the number of sampled energy points to 201.
- Set the transverse k-point sampling to 7x7.
- Change the self-energy calculator to *Krylov*.



Note:

- The density of energy points will determine the accuracy of the computed current at finite bias.
- For the energy window, it is recommended to choose a wide interval at zero bias to get a picture of where the transmission peaks are located, but for finite bias, a proper convergence study should be performed, since a too wide energy spacing (too low density of energy points) may mean that narrow peaks in the transmission spectrum are not captured.
- The k-point sampling used in the transmission analysis (and in most post-SCF analysis calculations) does not need to be the same as used in the calculator. Typically, you need more k-points in the transmission analysis than in the SCF calculation.
- The Krylov self-energy calculator is chosen here because it is the fastest method available, but in some cases it can give negative transmission values due to some approximations made.

The script is now ready, so save it as `zero-bias.py`. If needed, you can also download the final script here: `zero-bias.py`.

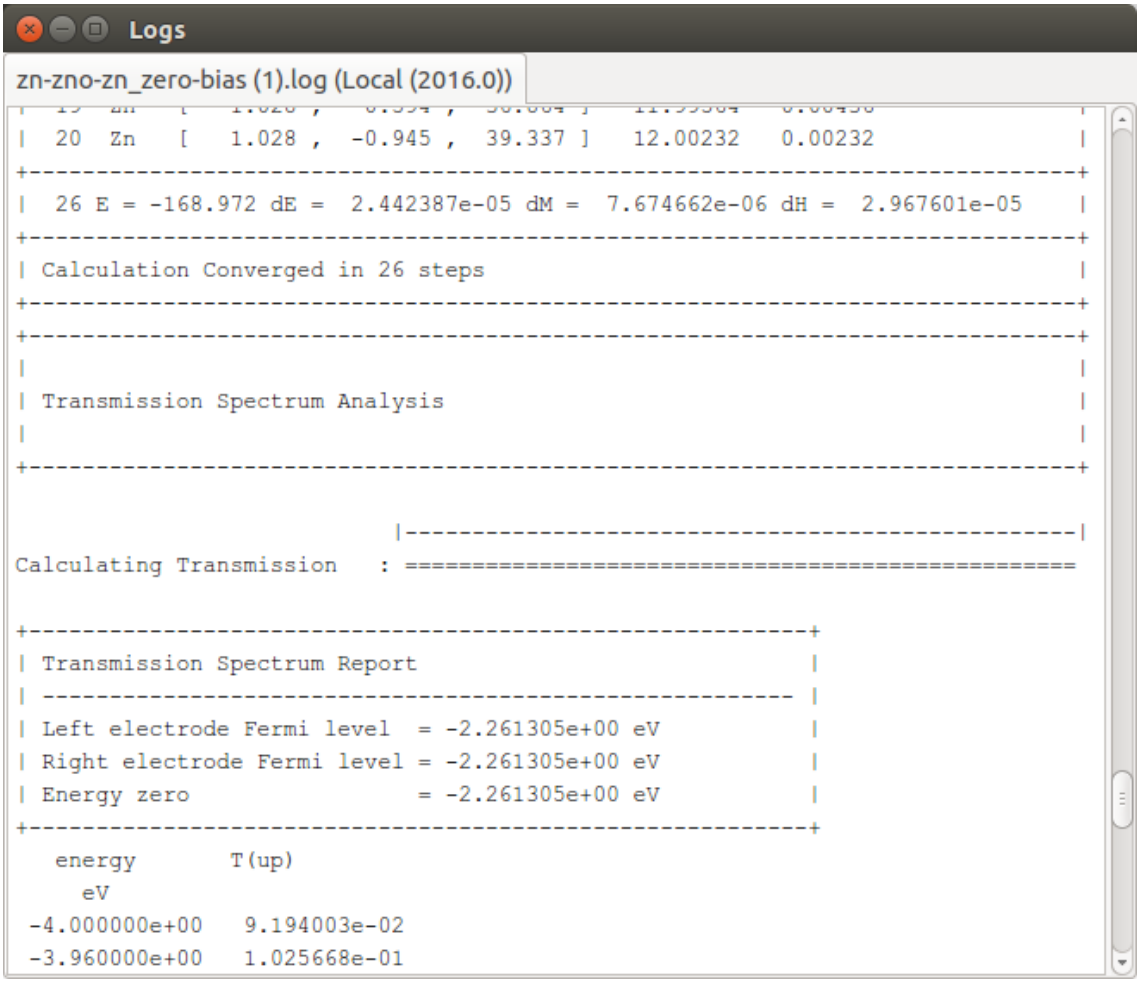
Running the calculation

Execute the script using either the Job Manager or from command line. The calculation should finish in a few minutes.

You should have a look through the job log file to follow the progress of the device calculation. You will see that the following sequence of calculations are carried out:

1. Left electrode SCF (bulk).
2. Right electrode SCF (bulk).
3. Device SCF (NEGF).

4.Transmission spectrum analysis.



Congratulations! You have now performed a complete transport calculation with QuantumATK. The basic work flow is similar for all transport calculations. Please proceed to the next section to visualize and analyze the results.

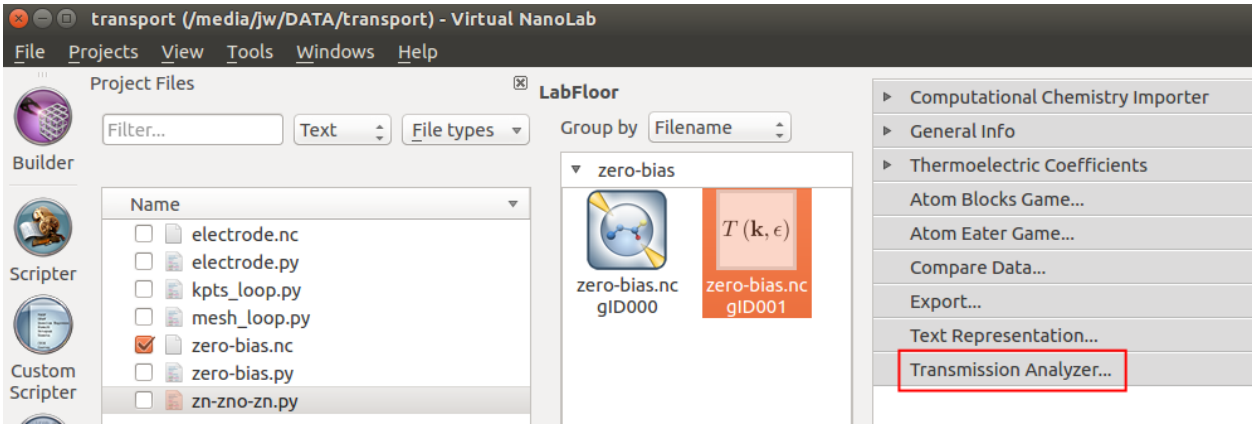
Transmission Analyzer

The calculation output should now have appeared on the **LabFloor**. Locate and select the file `zero-bias.hdf5`. It contains two objects:

DeviceConfiguration contains the two-probe device configuration and the self-consistent state of the attached calculator.

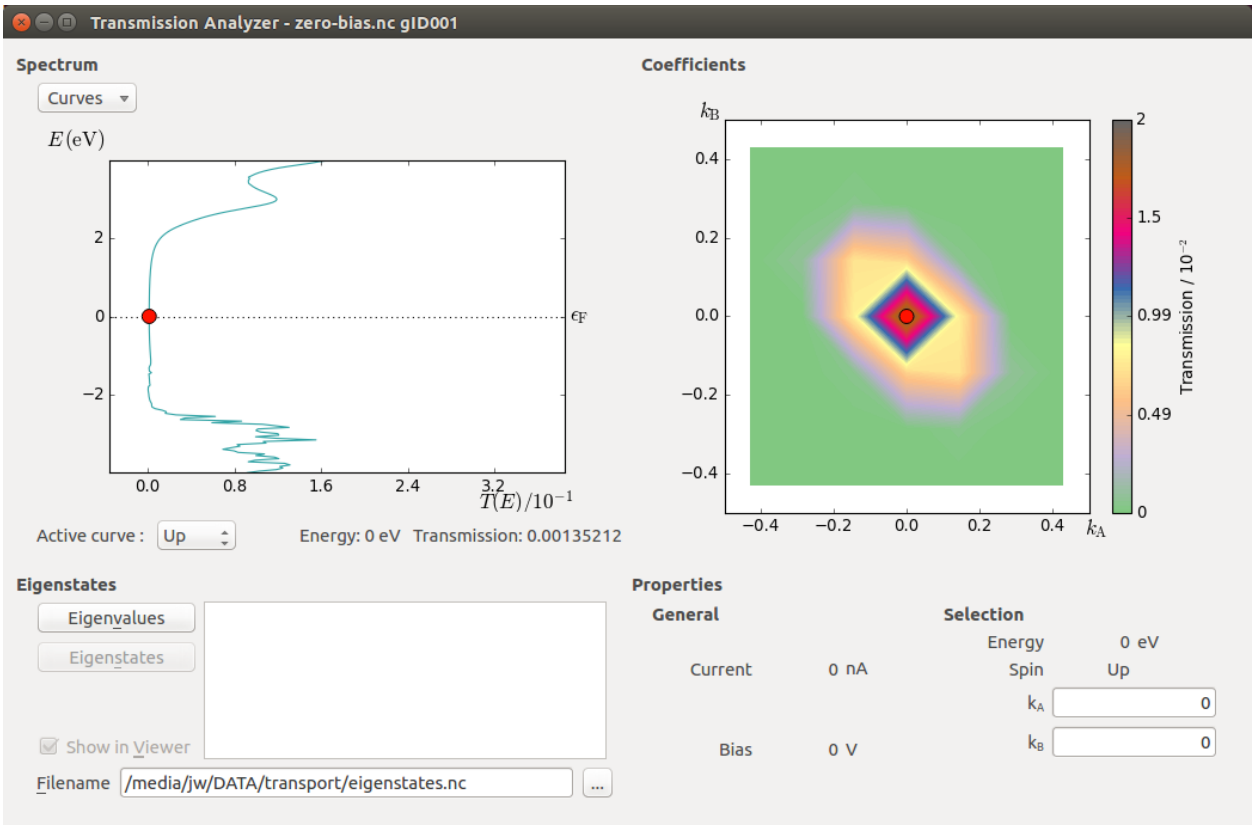
$T(\mathbf{k}, \epsilon)$

TransmissionSpectrum contains all information about the computed transmission spectrum, including settings and results.



Select the TransmissionSpectrum object, and click the **Transmission Analyzer** in the right-hand panel bar.

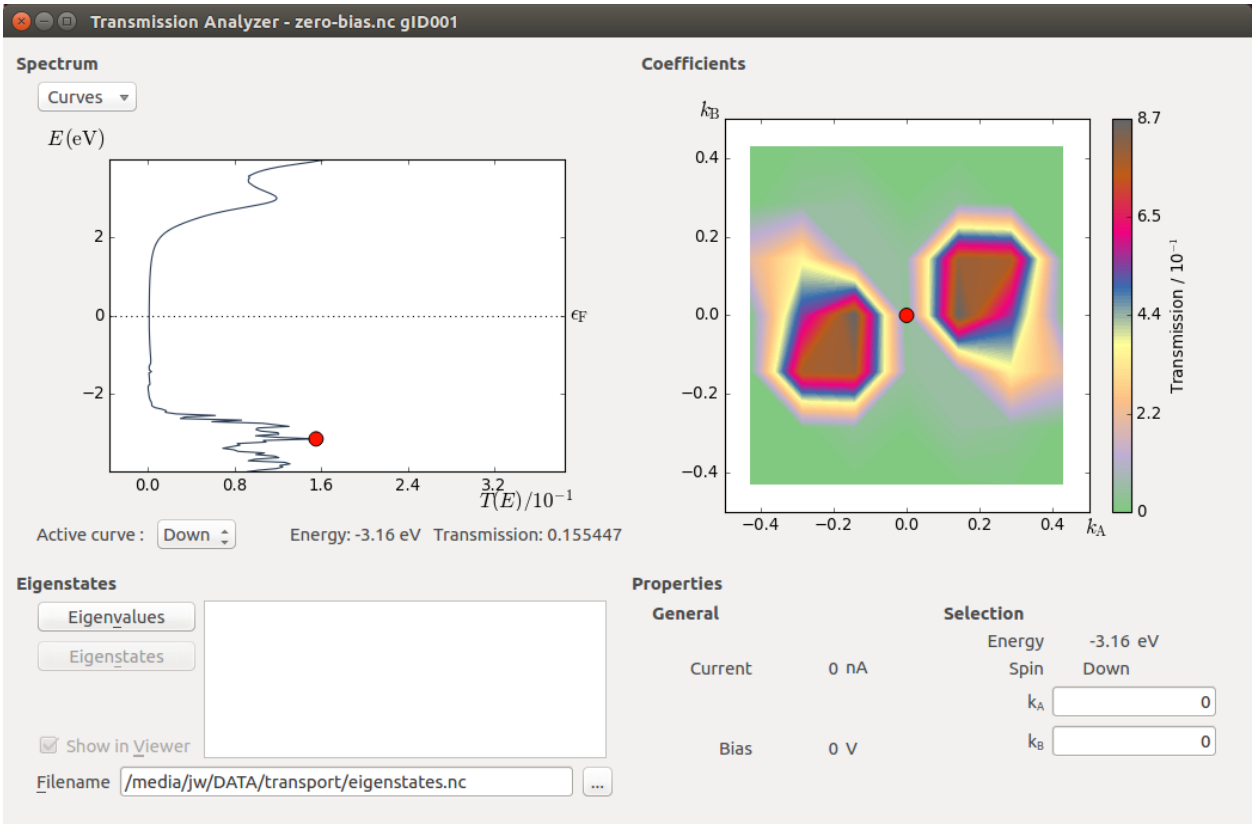
The Transmission Analyzer plugin opens. On the left, named **Spectrum**, is shown the k-point averaged transmission spectrum as function of energy. The average Fermi energy of the two electrodes is set to zero and indicated with a dashed line. It is evident that there is a broad energy range from -2.5 eV to +2.5 eV with very low transmission values. This corresponds to the band gap in the semiconducting ZnO.



The transmission and energy values in the point marked by the red dot are shown below the plot. You can use the mouse to move the dot along the $T(E)$ curve and read off the values. The *Curves* drop-down menu lets you select the spin components to be plotted. Note that the transmission for spin types X, Y, and Z are only non-zero for calculations with noncollinear spin.

At any particular energy (defined by the red dot), the total transmission is computed as an average over the transmission coefficients in the sampled k-points. The right-hand plot, named **Coefficients**, shows an interpolated contour plot of the transmission coefficients vs. reciprocal vectors k_A and k_B.

In the figure above, it is clear that the main contributions to electronic transmission through the Zn|ZnO|Zn device at the average Fermi level come from k-points around the Γ-point, where $k_A = k_B = 0$. The situation is very different at other energies, such as e.g. E = -3.16 eV, as shown in the figure below.



Tip: By increasing the number of k-points sampled in the transmission spectrum calculation, the resolution of the contour plot can be improved – and thereby also the accuracy of the total transmission spectrum. In many devices, a large number of k-points may be required to obtain a converged spectrum.

Transmission eigenstates

By clicking on the contour plot you can also move the red dot to a desired k-point. The chosen k-point is shown in the **Selection** box. At a particular energy and spin (chosen in the **Spectrum** plot) and a particular k-point (chosen on the **Coefficients** contour plot) you can obtain the transmission eigenvalues and eigenstates:

- Select a k-point with high transmission value; (k_A, k_B) = (0.15, 0.05) at energy -3.16 eV.
- Click *Eigenvalues* in the lower left part of the window.

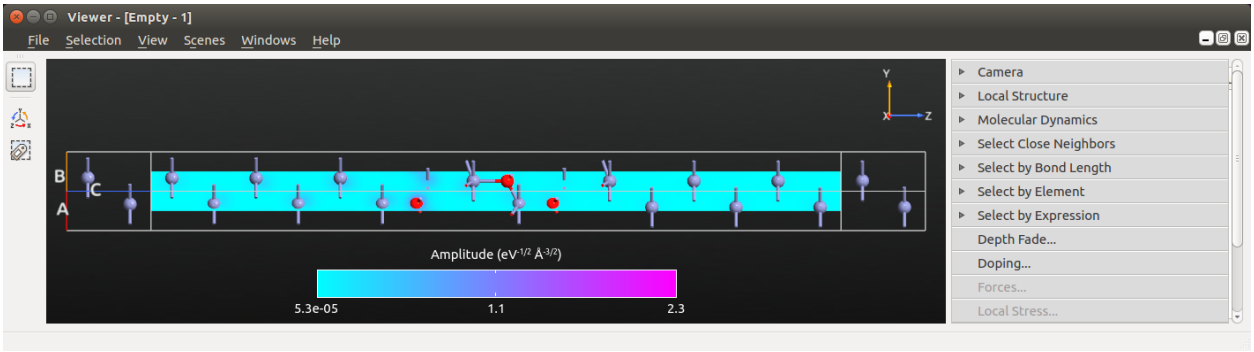
The transmission eigenvalues for the selected energy, k-point and spin are calculated, and after a couple of seconds the eigenvalues are listed.

Hint: If several transmission channels contribute to the transmission, more than one eigenvalue will be shown. Each eigenvalue is restricted to the range [0, 1], but the sum of the eigenvalues, which equals the k-point resolved transmission $T(E, \mathbf{k})$, may be larger than 1, just like the total transmission $T(E)$ can be.

You can now calculate and visualize the transmission eigenstate for each eigenvalue:

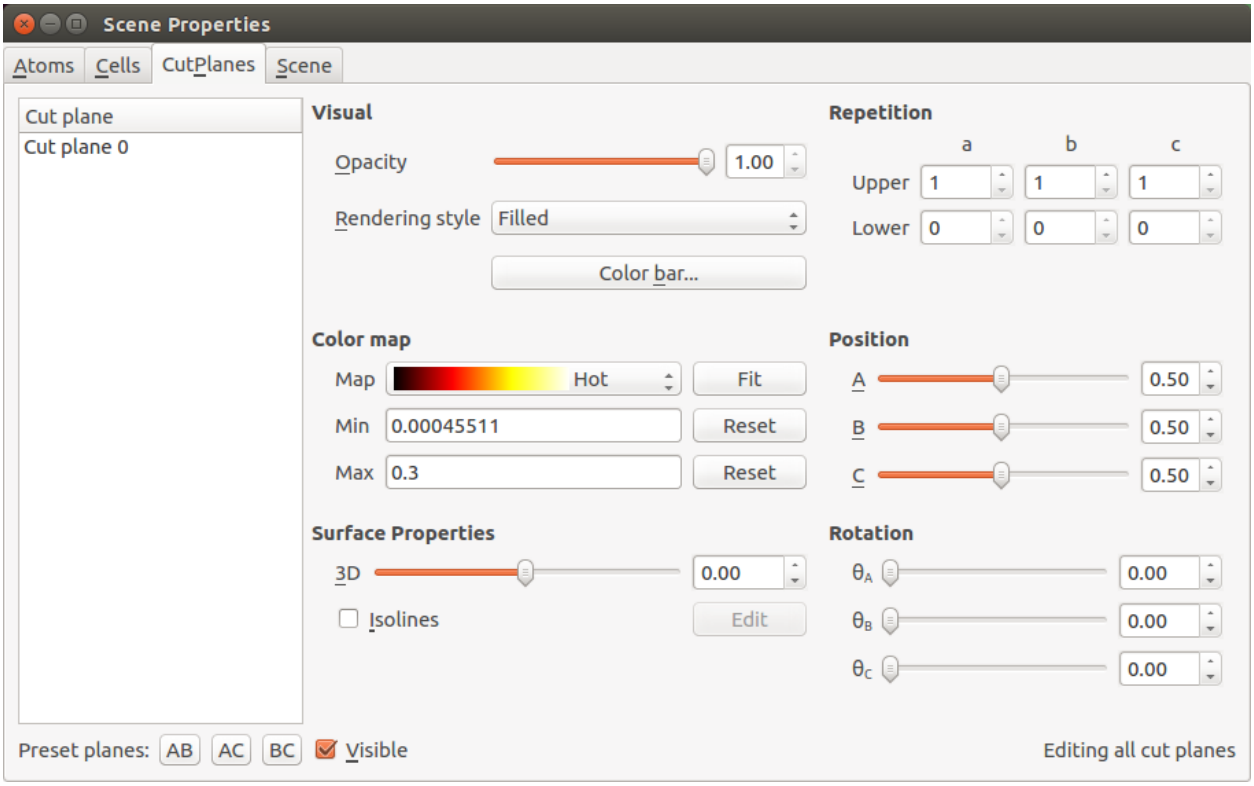
- Select an eigenvalue and click *Eigenstates*. The **3D viewer** opens after a few seconds.
- Select the **Cut plane** plotting type and click *OK*.

The Viewer now displays the Zn|ZnO|Zn device configuration and a cut-plane representation of the transmission eigenstate throughout the device central region.

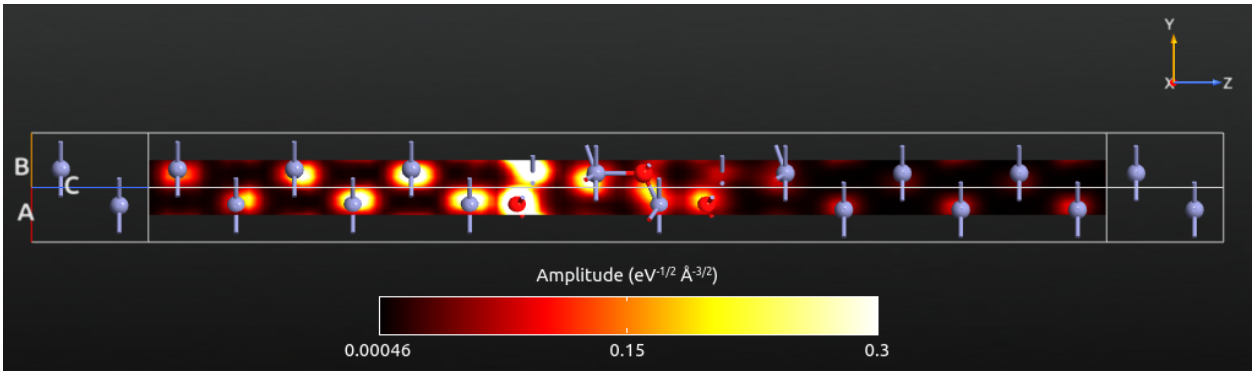


Next, edit the visual properties of the cut-plane to focus the color palette on the finer features of the eigenstate:

- Open the **Properties** editor in the right side of the Viewer.
- In the *CutPlanes* tab, change the colormap to Hot, then click *Fit*, and enter 0.3 for the maximum eigenstate value to be visualized.

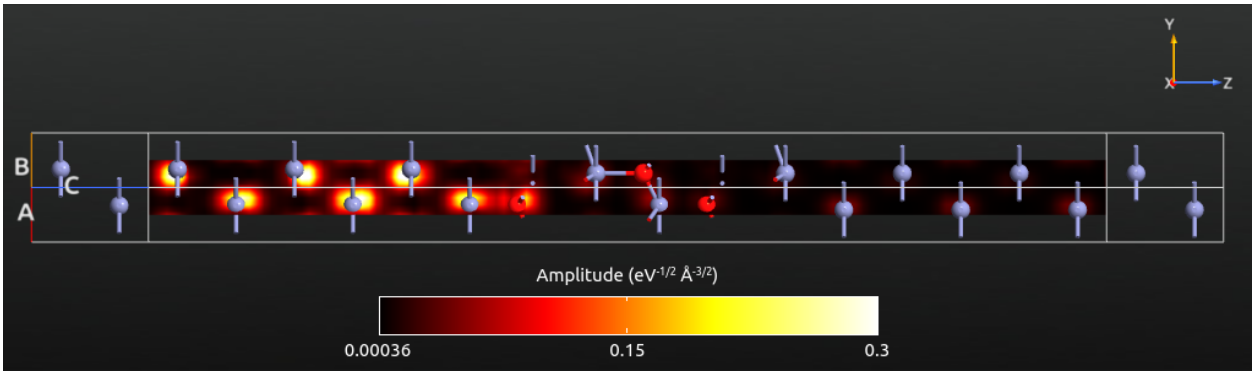


The cut-plane visualization should now look as illustrated below. The eigenstate corresponds to a scattering state coming from the left electrode and traveling towards the right. The eigenstates will therefore always have a large amplitude in the left-hand part of the central region. Eigenstates with a relatively high transmission eigenvalue will also have a relatively large amplitude in the right-hand part of the scattering region. This simply reflects the relatively high transmission probability of an incoming state (at a specific energy, spin, and k-point) that attempts to travel through the central region and into the right electrode.



The transmission eigenstates in the left part of the scattering region are composed of an incoming (right-moving) and a reflected (left-moving) state. This leads to interference effects, which can be observed in the figure above: The eigenstate amplitude around the first Zn atom is relatively small due to destructive interference between the incoming and reflected states. To the right of the ZnO, the eigenstate consists only of the transmitted (right-moving) states, and no such interference effects are observed.

Try yourself to plot the transmission eigenstate at the Fermi level (energy E = 0 eV) and $k_A = k_B = 0$. By adjusting the plot properties you can get a plot similar to the one shown below. Now the eigenstate has a vanishing amplitude in the middle and right parts of the scattering region, due to the low transmission eigenvalue, i.e. only a tiny part of the scattering eigenstate is transmitted, and most of it is reflected at the Zn–ZnO interface.



Tip: If you instead plot the transmission eigenstate as an isosurface, the isovalue corresponds to the magnitude of the wave function, and the phase is used to color the isosurface.

Convergence of k-points for transmission spectrum

As already mentioned, more k-points are typically needed to obtain a well-converged transmission spectrum than for the SCF calculation. As an example, consider the figure below, which shows the total transmission (averaged over all k-points) evaluated at three different energies and plotted as function of the number of k-points in the transverse A and B directions. The figure was generated using the script `transmission_kpts.py`.

The transmission converges very differently at different energies. While the transmission at the Fermi energy is converged with just 5 or 7 k-points in the A and B directions, at -3 eV and +3 eV it looks like at least 13 k-points are needed.

You may recall from above that the transmission spectrum has many sharp peaks in the region around -3 eV. It is typically such, that many k-points are needed when sharp features are present. However, there may also be isolated peaks that are hidden by too low k-point density, so one really needs to study the k-resolved transmission plot to get an idea of the needed k-point sampling.

Additionally, in a region with many (sharp) transmission peaks as function of energy, a large number of energy points are required to converge the integral over energy needed to compute the current.

Further analysis

This section will introduce some further ways to analyze the zero-bias calculation. An important feature in QuantumATK is that you do not have to define all analysis quantities from the outset; you can always calculate additional quantities without having to redo the self-consistent calculation from scratch.

You will now compute the device density of states (DDOS) of the Zn|ZnO|Zn configuration, and the electrostatic difference potential:

- Open a new **Script Generator** window.
- Change the output file name to `analysis.hdf5`, and add three blocks to the script:
  - Analysis from File
  - DeviceDensityOfStates

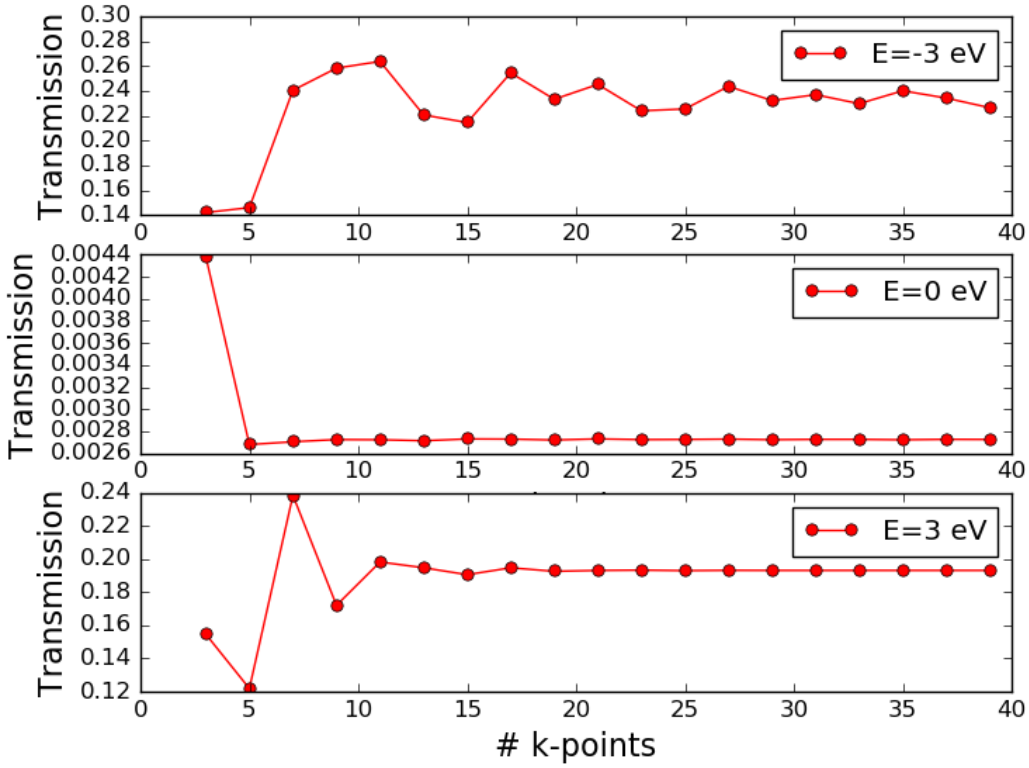


Fig. 3.124: Total electronic transmission vs. the number of k-points in the transverse directions for the Zn|ZnO|Zn device evaluated at three different energies: -3 eV (top), 0 eV (middle), and 3 eV (bottom).

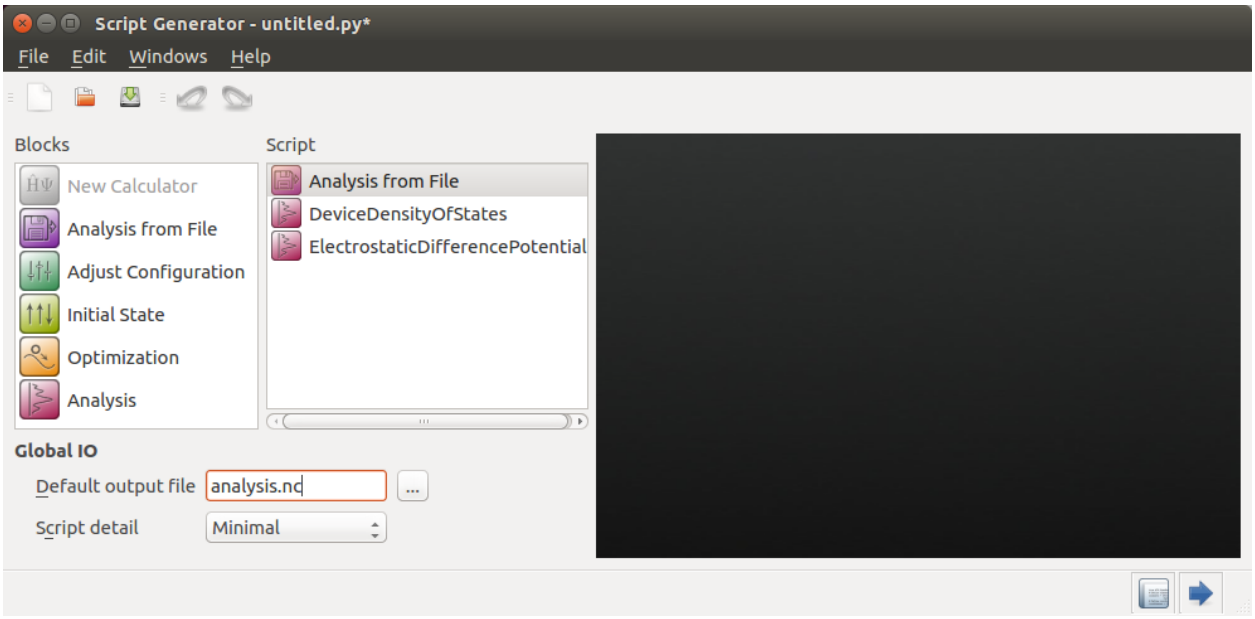
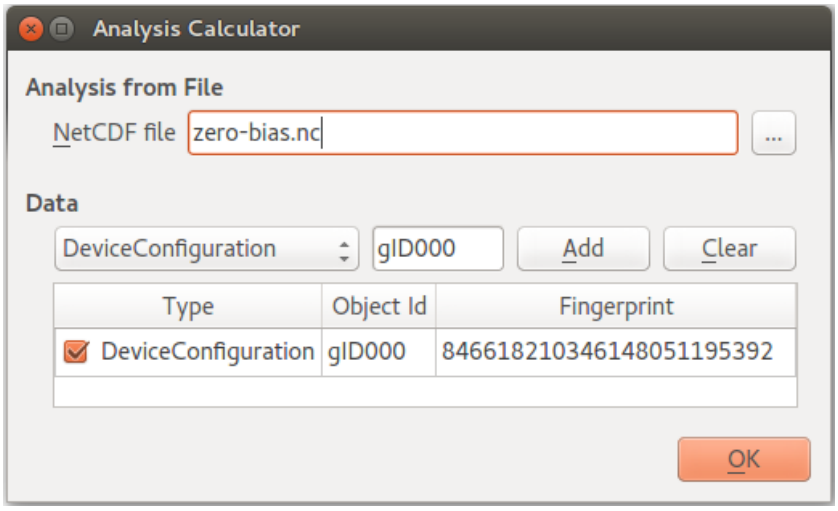
– ElectrostaticDifferencePotential



•Open the Analysis from File block. This is the part of the QuantumATK script that is responsible for reading the converged state of the zero-bias calculation. You need to specify which file and which saved configuration you want to base the following analysis on (there may be several configurations in a single file).

•Select the saved file `zero-bias.hdf5` – the configurations stored in that data file are then automatically detected and listed. Only one configuration is in this case available; it has object ID gID000. Make sure that configuration is ticked, and click *OK*.



Tip: The ID number of each object is indicated below its icon on the LabFloor. To distinguish different configurations in the same file, you can use the **General information** plugin to inspect the most important parameters of the calculation.

•Next, edit the DeviceDensityOfStates settings, which should be similar to the settings used for computing the

transmission spectrum:

–energy range from -4 eV to +4 eV with 201 points.

–7x7 k-point sampling.

–Krylov self-energy calculator.

•No changes need be made to the ElectrostaticDifferencePotential analysis.

The analysis script is now ready. Save it as `analysis.py` and execute it using the Job Manager or from command line – it takes only a few minutes to run. You can also download the script here: `analysis.py`.

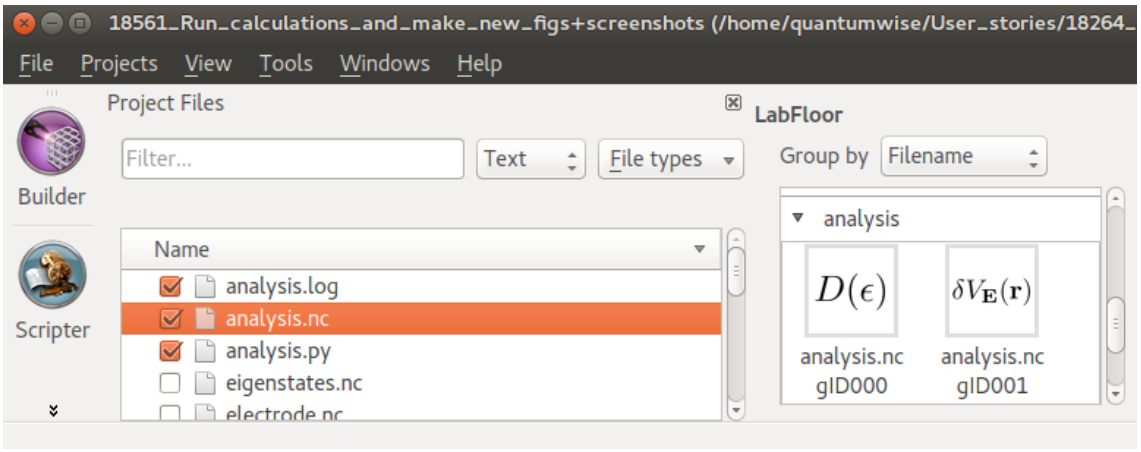
When the job is done, observe that the analysis results have appeared on the LabFloor:

DeviceDensityOfStates

$D(\epsilon)$

ElectrostaticDifferencePotential

$\delta V_{\mathbf{E}}(\mathbf{r})$



Device density of states

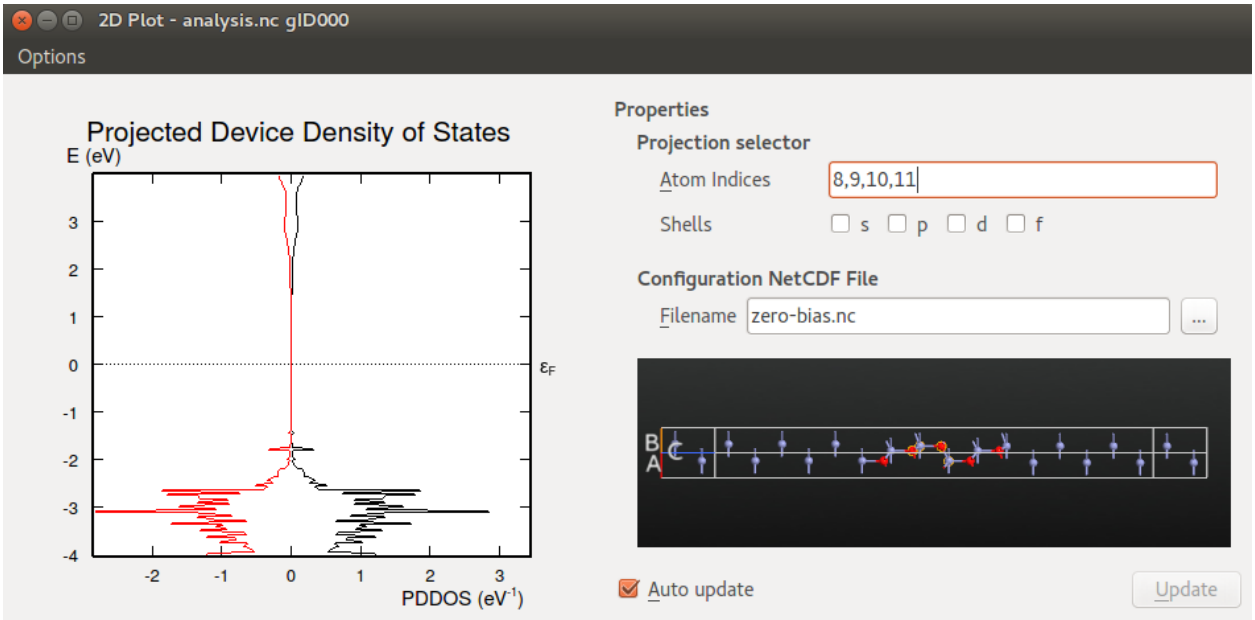
Select the DeviceDensityOfStates object and click **2D plot** in the right-hand plugins bar to visualize it.

The 2D Plot window opens with the DDOS plottet on the left. The right-hand panel allows you to also visualize the configuration and select atoms and orbitals to project the DOS onto:

•Under **Configuration HDF5 File**, select the output file `zero-bias.hdf5` for visualizing the device configuration (which is not saved in `analysis.hdf5`).

•Under **Projection selector**, select atom indices 8,9,10,11 in order to preject the DOS onto the middle part of the ZnO layer.

•Then zoom in on the projected DOS like shown in the figure below.



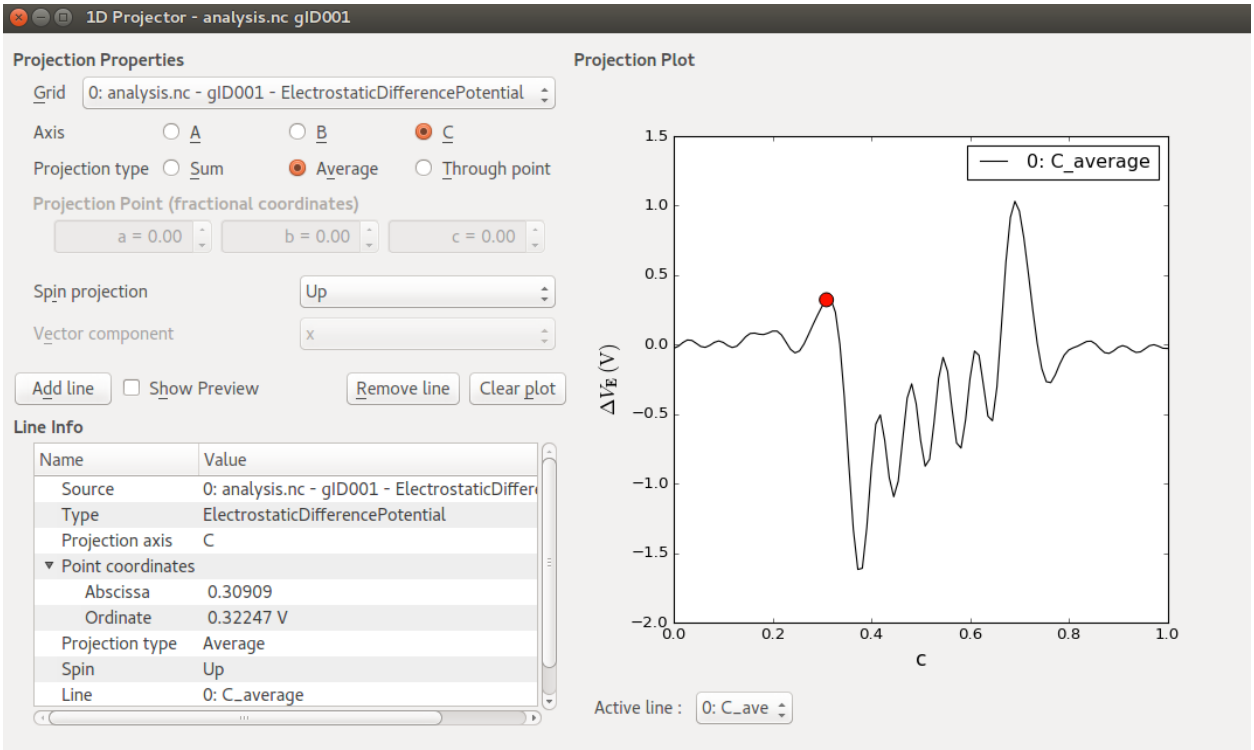
You should notice that the shape of the DDOS resembles the shape of the transmission spectrum analyzed above: Both plots show a broad energy region around the Fermi energy with low values, reflecting the semi-conducting nature of ZnO; for energies below -2 eV there are many sharp peaks; finally, both the transmission spectrum and the DDOS display a broad peak around +3 eV. The correspondence between the transmission spectrum and DDOS is a very general feature often observed in device calculations.

Electrostatic difference potential

The ElectrostaticDifferecePotential object contains a 3D grid that represents the difference between the electrostatic potential of the self-consistent valence charge density (the solution to the Poisson equation with this density) and the electrostatic potential from a superposition of atomic valence densities. You will use this object later when calculating the voltage drop.

You can of course use the **Viewer** to visualize such 3D grids, just like you did for the transmission eigenstates a few sections up. Another way to visualize a quantity represented on a 3D grid is to use the **1D Projector**. With this tool you can project a potential or density along a certain direction, integrated or averaged over the two directions perpendicular to it. For devices, it is often most interesting to plot the potential along the transport direction (C) and to average over the A and B directions.

- Select the ElectrostaticDifferencePotential object on the LabFloor, and open the 1D Projector from the right-hand plugins bar.
- Change Projection type to *Average* and click *Add line*.



You should now see a plot like shown in the figure above, where the electrostatic difference potential, ΔV_E, is plotted against the fractional C-coordinate (ranging from 0 to 1).

A significant charge transfer seems to take place at both Zn–ZnO interfaces, causing the self-consistent electrostatic potential to differ significantly from that of the atomic valence densities. In the metallic Zn regions near the electrodes, oscillations are rather small, indicating that the self-consistent charge distribution is not much different from the atomic valence charges in those regions.

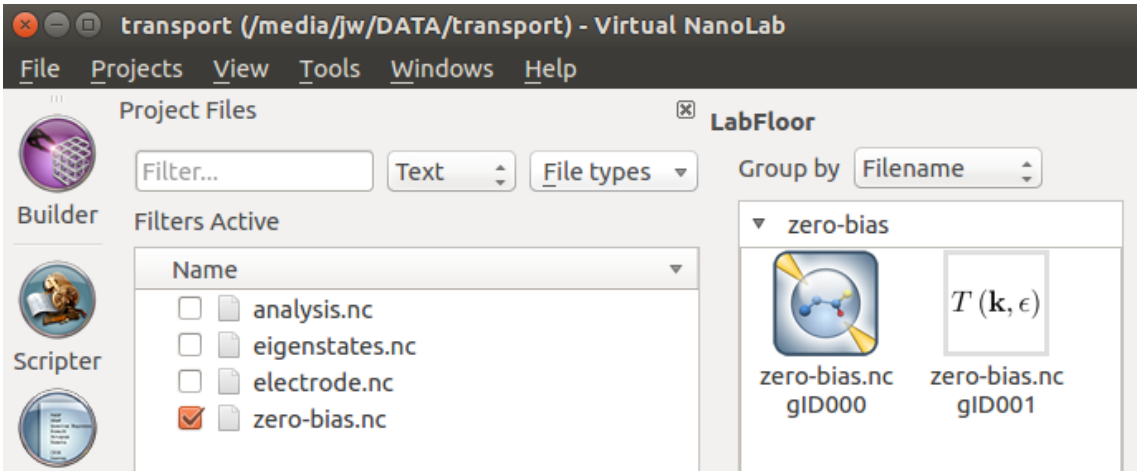
Finite-bias calculations

All calculations performed so far have been with zero voltage on the left and right electrodes, i.e. at zero bias. In this section you will use the zero-bias calculation as a starting point for finite-bias calculations, where the left and right electrode voltages are different. This shifts the left and right electrode Fermi levels relative to each other – a basic mode of operation for electronic devices.

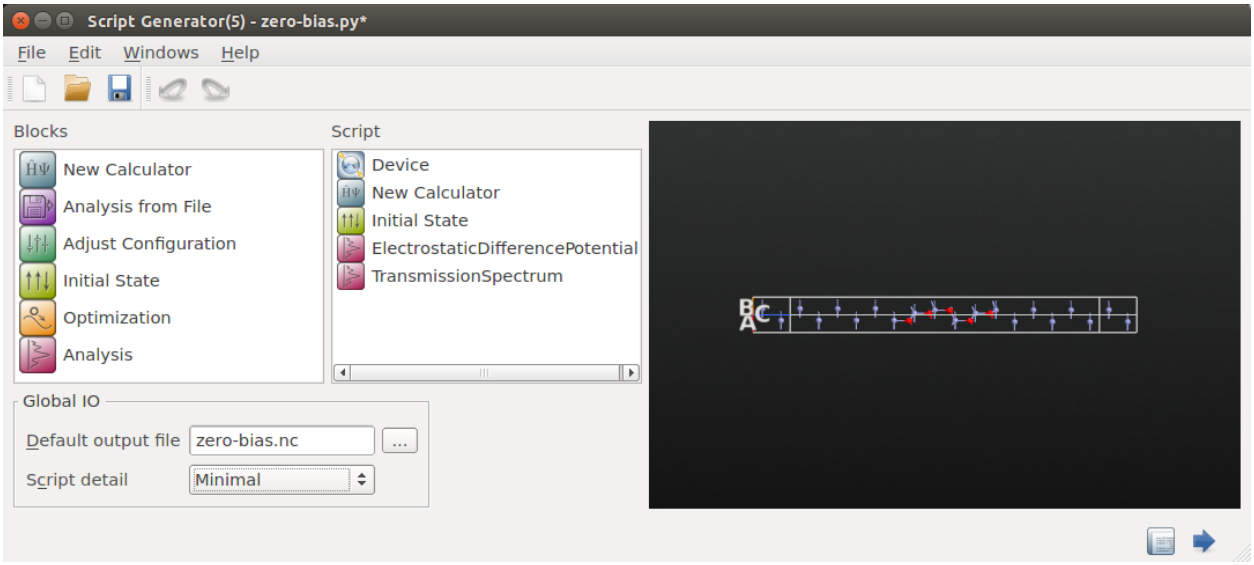
The recommended method for obtaining fast and reliable SCF convergence for finite-bias QuantumATK transport calculations is to start out from a zero-bias calculation and change the bias in small steps. You will now perform a device calculation at -0.5 V bias.

Set up the calculation

In the QuantumATK Project Files list, tick the file `zero-bias.hdf5` to see its contents on the LabFloor, and drag the DeviceConfiguration (*gID000*) onto the **Script Generator**. This will setup the Slater-Koster calculator parameters identically to those used for the zero-bias calculation.

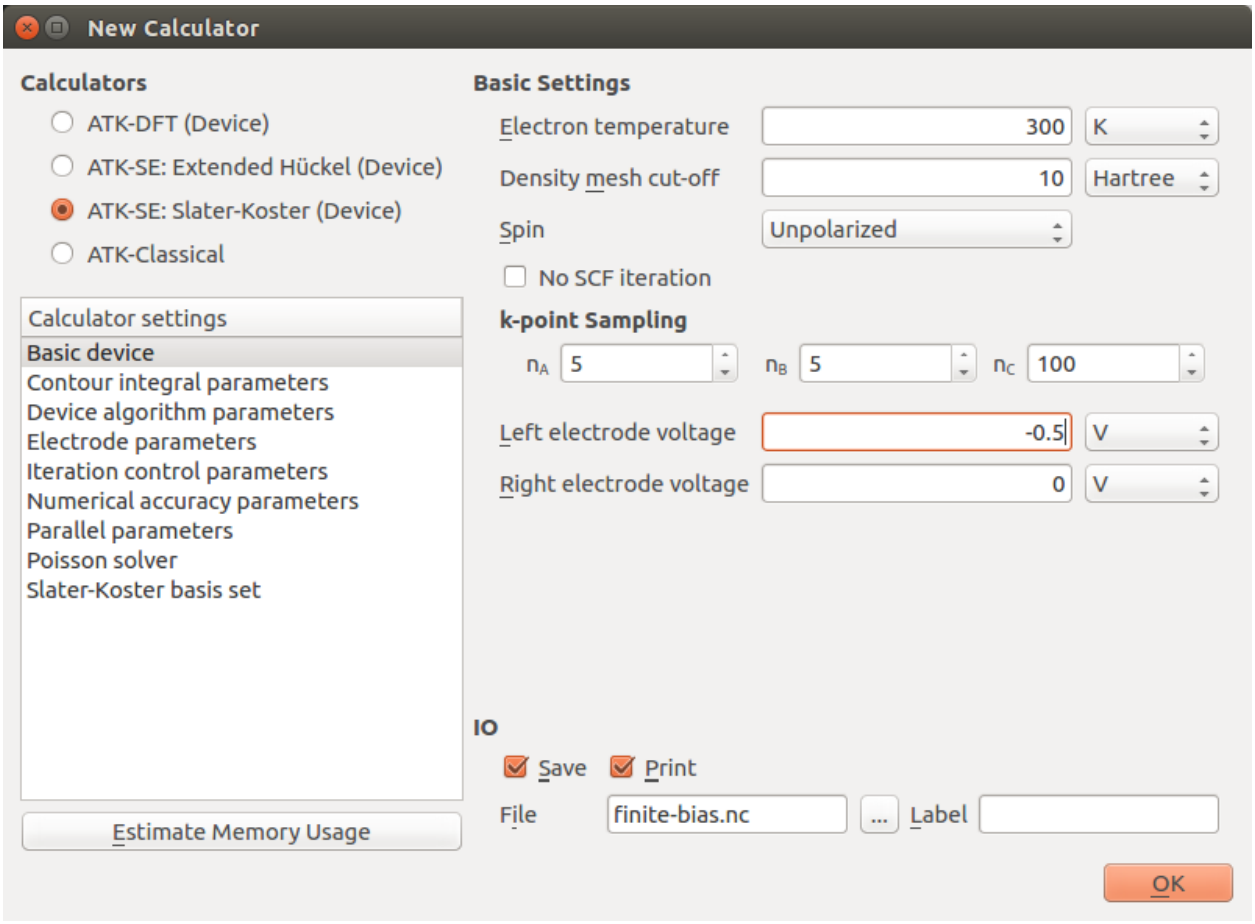


Add three blocks to the script: Initial State, *Analysis → ElectrostaticDifferencePotential*, and *Analysis → TransmissionSpectrum*.



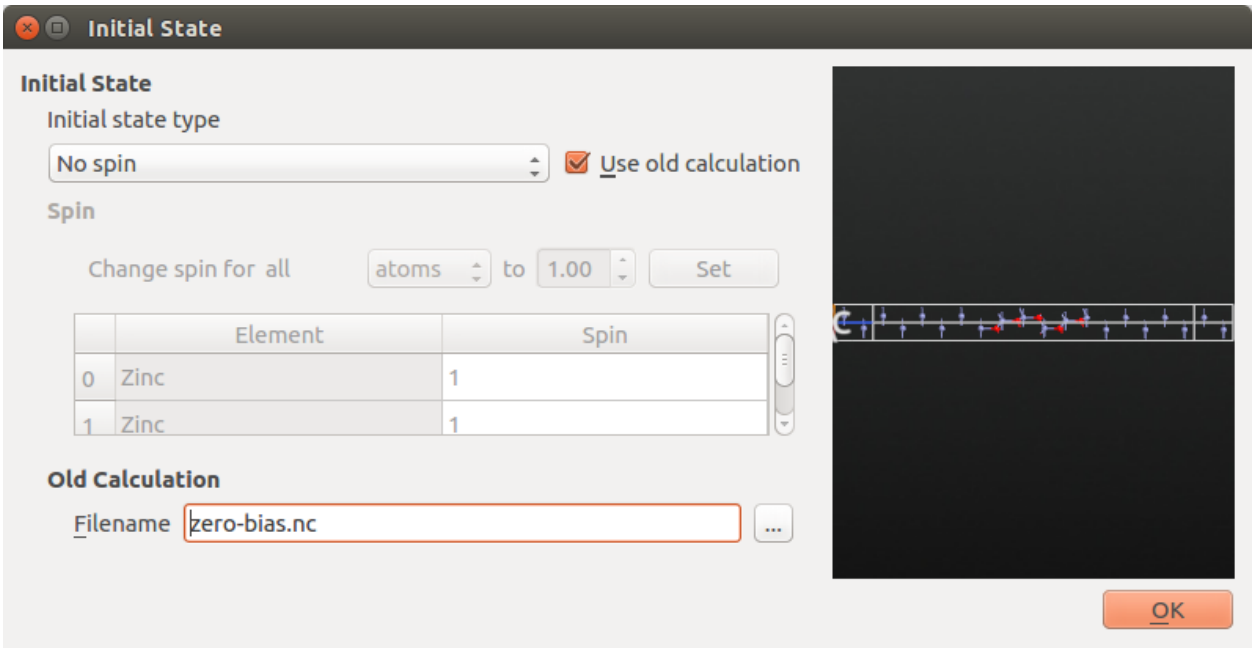
Then change the default output file to `finite-bias.hdf5`, and open the New Calculator to apply a bias:

•Set the **Left electrode voltage** to -0.5 V.



Next, open the Initial State block to instruct QuantumATK to use the zero-bias state as an initial guess for the finite-bias calculation:

- Tick **Use old calculation**, and choose `zero-bias.hdf5` as the filename of the *Old Calculation*.



Lastly, set up the TransmissionSpectrum parameters identically to those used for the zero-bias calculation:

- Energy window of -4 eV to +4 eV with 201 energy points.
- 7x7 transverse k-points.
- Krylov self-energy calculator.

Save the script as `finite-bias.py` and run it. The calculation will take a little more time than the zero-bias calculation. If needed, you can download the final script here: `finite-bias.py`.

Note: Electrode voltages and current In a zero-bias calculation, the local chemical potential is constant throughout the device, including the electrodes. Applying a potential difference $U = V_{\mathrm{L}} - V_{\mathrm{R}}$ between the electrodes is identical to shifting the electrode Fermi levels with respect to each other,

$$eU = e(V_{\mathrm{L}} - V_{\mathrm{R}}) = \mu_{\mathrm{R}} - \mu_{\mathrm{L}},$$

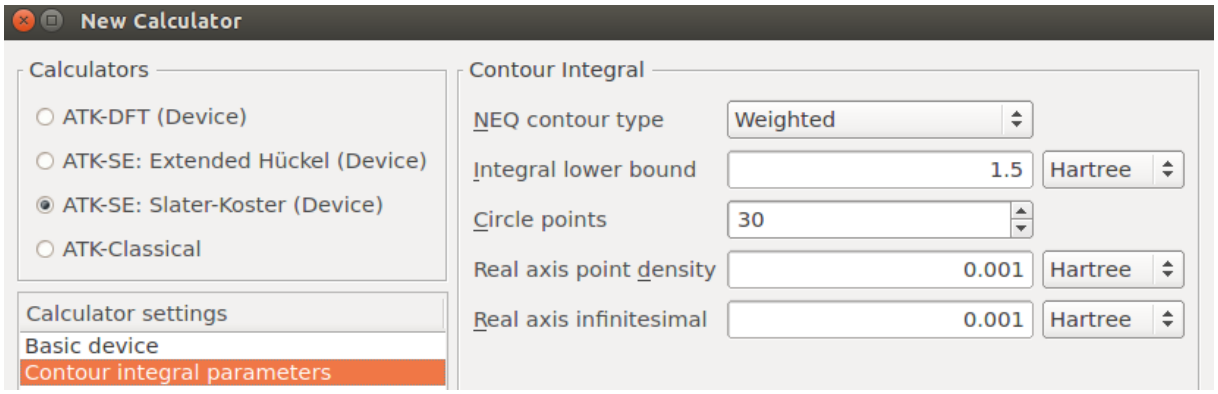
where μ_{L} and μ_{R} are the left and right electrode Fermi levels, respectively, and e the (positive) elementary charge.

The **bias voltage** U is therefore positive when the applied potential on the left electrode is higher than on the right electrode. This situation is also called *forward bias*, and implies that the chemical potential in the left electrode is moved down such that $\mu_{\mathrm{L}} < \mu_{\mathrm{R}}$. Conversely, under *reverse bias*, we have $V_{\mathrm{L}} < V_{\mathrm{R}}$, and therefore a negative bias voltage and opposite ordering of the chemical potentials, $\mu_{\mathrm{L}} > \mu_{\mathrm{R}}$.

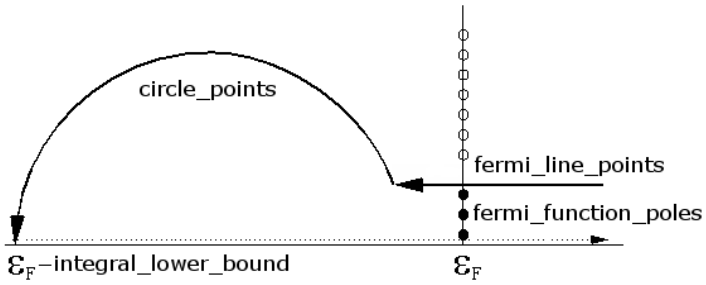
A positive **current** corresponds to charges moving from left to right, meaning that electrons move from right to left (since electrons have a negative charge). The current is therefore *positive under forward bias* and *negative under reverse bias*, so you should expect to get a negative current with the bias setting specified above.

Type	Bias voltage	Electrode potentials	Chemical potentials	Current
Forward	$U > 0$	$V_{\mathrm{L}} > V_{\mathrm{R}}$	$\mu_{\mathrm{L}} < \mu_{\mathrm{R}}$	$I > 0$
Reverse	$U < 0$	$V_{\mathrm{L}} < V_{\mathrm{R}}$	$\mu_{\mathrm{L}} > \mu_{\mathrm{R}}$	$I < 0$

Attention: NEGF contour integral For finite-bias calculations, a potentially important convergence parameter is the *Real axis point density*, which is specified under *Contour integral parameters*. This parameter determines how many energy points are used when integrating the left and right spectral density matrices along the real energy axis between the chemical potentials of the left and right electrodes. For the present calculation you can proceed with the default value, but be aware that a convergence test of this parameter should in general be performed.

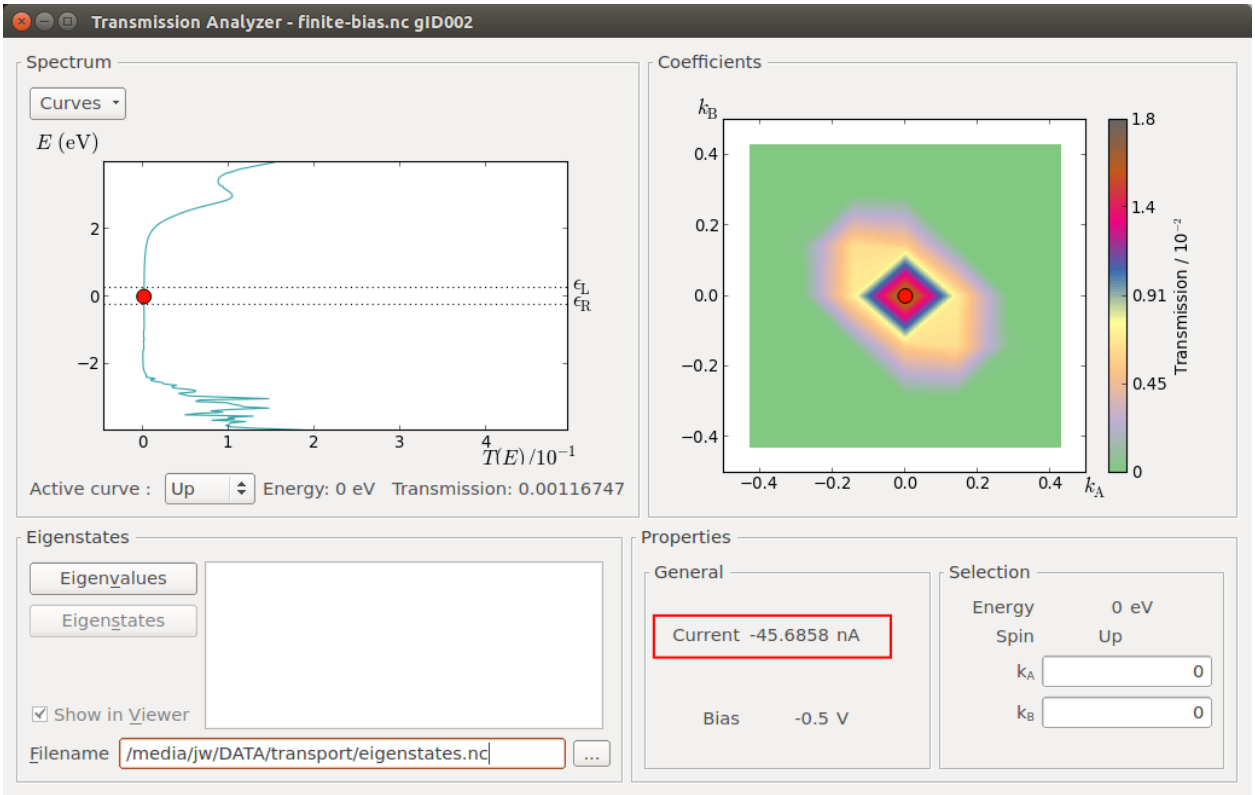


The settings *Integral lower bound* and *Circle points* are another important set of parameters. The NEGF contour integral needs to include all eigenvalues on the energy axis, but these are in general not known *a priori*. The default lower bound for the integral is 1.5 Ha below the Fermi level, but for DFT calculations with hard pseudopotentials (many valence electrons, possibly semi-core states), there may well be eigenvalues deeper than that. In that case, the *Integral lower bound* should be increased, and possibly also the number of circle points. Poor device SCF convergence is often due to such issues.



Analyzing the results

Go to the QuantumATK main window and open `finite-bias.hdf5` on the LabFloor. Use again the **Transmission Analyzer** to plot the transmission spectrum. Notice that the chemical potential of the left and right electrodes are separated by the bias of 0.5 V and distributed evenly around the average electrode Fermi levels, which still is the energy zero reference. Also, you can see that there is a (very small) negative current flowing in this system, consistent with the direction in which the bias was applied.



The finite-bias transmission looks essentially the same as found for zero bias. Recall from the analysis in section *Device density of states* that you found similar shapes of the ZnO DDOS and the transmission function. The shape of the transmission function is thus in this system largely determined by the density of states of the ZnO, and not so much by the electronic structure of the electrodes. Since the transmission values are very small in the bias window, the current is low and hence the change in DDOS in the ZnO is small. This is not necessarily the case in other systems, especially not if the bias is large enough to bridge the band gap of the scattering region.

Voltage drop

Your next task is to calculate the potential profile along the device transport direction at finite bias, also known as the voltage drop or the induced electrostatic potential. This can be computed as the difference between the electrostatic difference potentials at finite and zero bias,

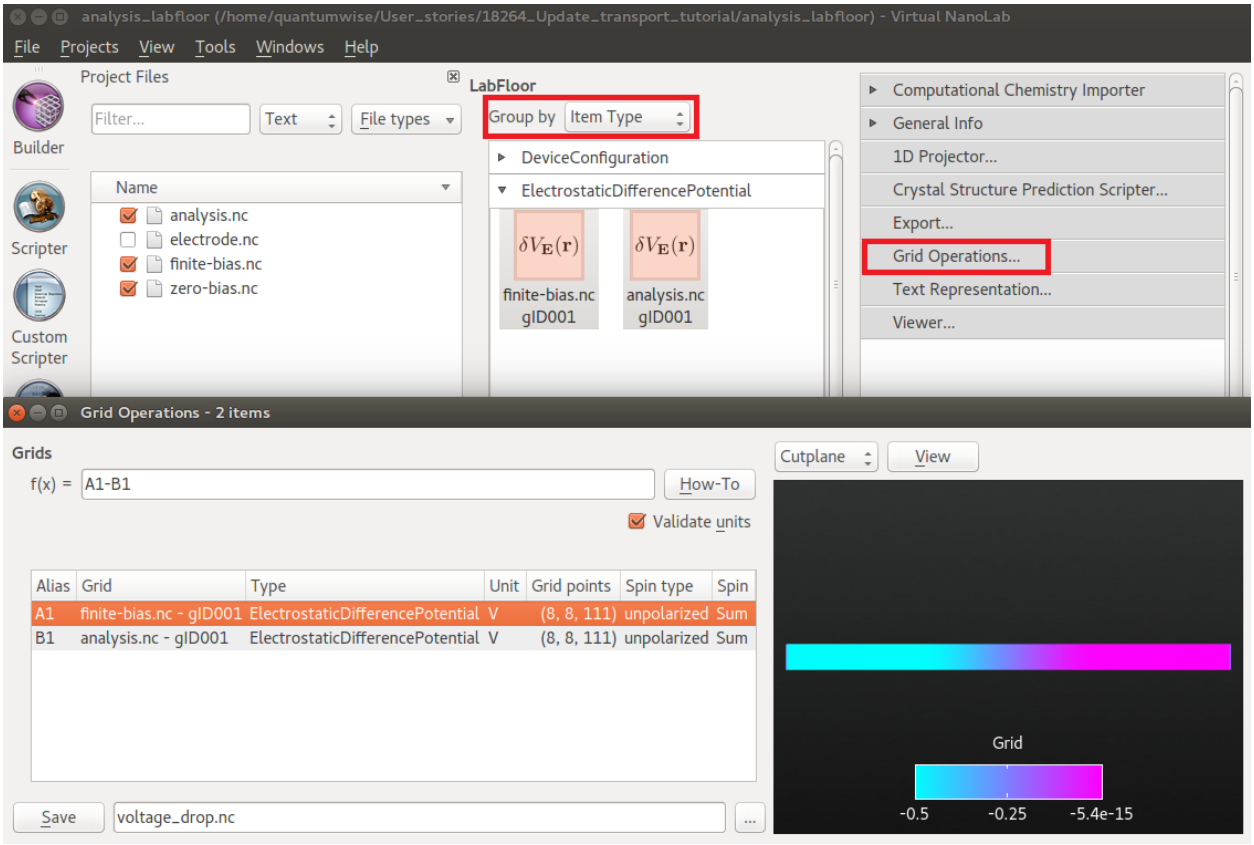
$$\Delta V_E(\mathbf{r}) = \delta V_E^{\mathrm{finite-bias}} - \delta V_E^{\mathrm{zero-bias}}.$$

Hint: Each electrostatic difference potential is the difference between the electrostatic potential of the self-consistent valence charge density and the electrostatic potential from a superposition of atomic valence densities. Since the atomic valence charge densities are the same for the zero and finite bias calculations, the calculated difference, $\Delta V_E(\mathbf{r})$, is the potential due to the differences between the two self-consistent charge densities, which is exactly the voltage drop.

The QuantumATK **Grid Operations** plugin is a very convenient tool. It allows you to perform arithmetic operations on 3D grids, such as addition and subtractions of one grid from another, and also multiplication and division. You will now use the plugin to compute $\Delta V_E(\mathbf{r})$, save it in a file, and then plot it in the **Viewer**:

•By default, the Labfloor groups all items by filename. Change the option **Group by** to *Item Type*.

•Then select the two ElectrostaticDifferencePotential items, and open the Grid Operations tool.



In the Grid Operations tool, the grids are assigned aliases. Depending on the order in which you selected the two items, the finite and zero bias potentials will be called A1 and B1, or opposite. To compute the voltage drop (the induced potential), subtract the zero-bias potential from the finite-bias potential by entering A1-B1 (or opposite) in the box next to *f(x)=* and press *Enter* on your keyboard.

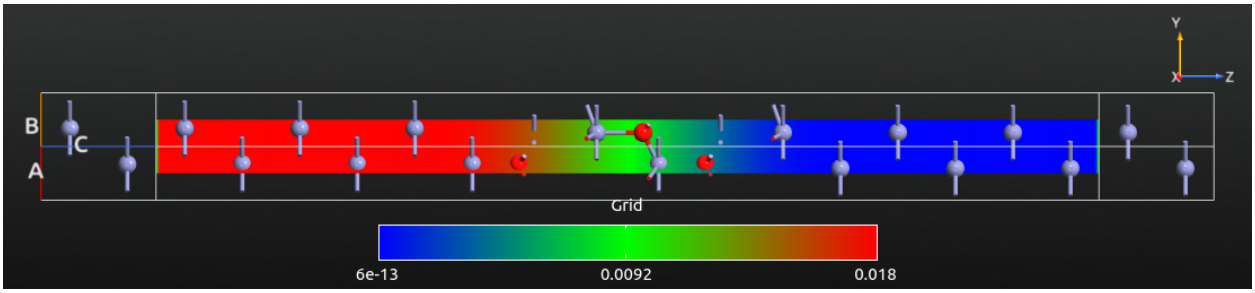
You can then immediately plot the result as a cut-plane or an iso-value contour in the 3D window to the right, and/or save the difference grid in a new HDF5 file by clicking the *Save* button in the lower left corner.

Save the difference grid as `voltage_drop.hdf5`, and observe the GridValues object appear on the LabFloor.

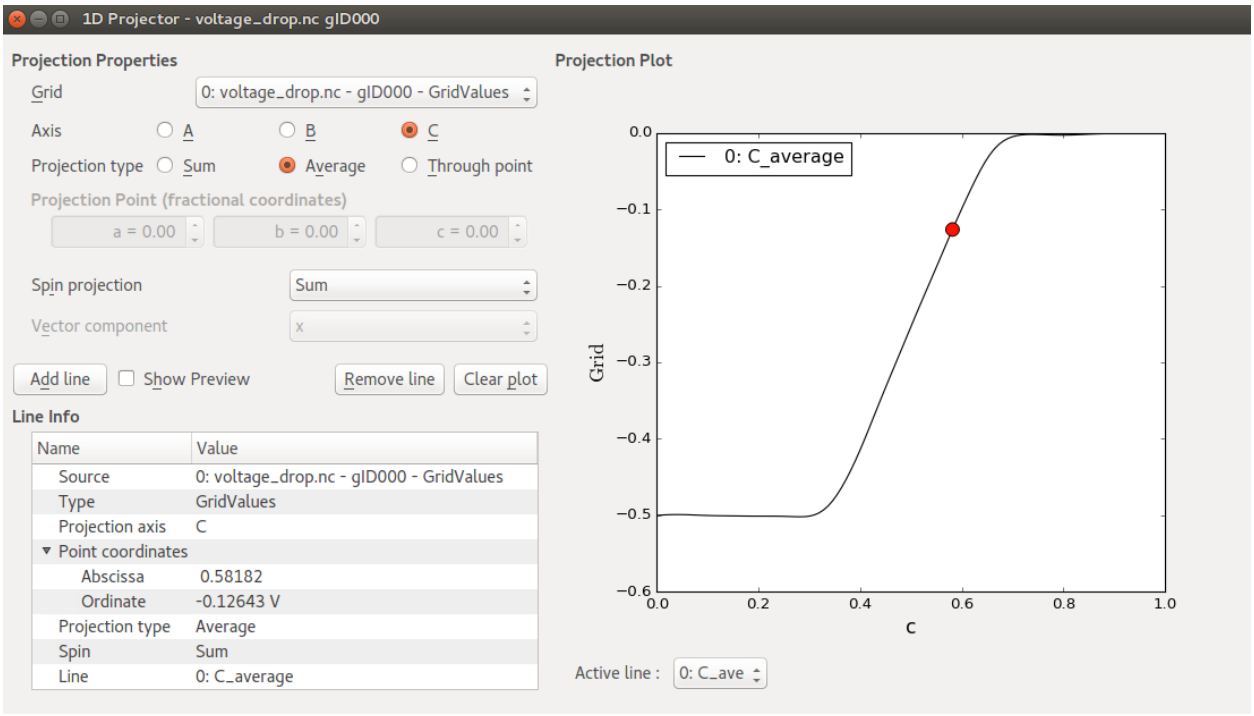
Note: $f(\mathbf{r})$ **GridValues** is a general container for quantities represented on 3D grids.

Select one of the DeviceConfigurations and open it with the **Viewer**. Then drag and drop the GridValues object onto the Viewer canvas in order to visualize it on top of the device configuration. Choose the *Cut-plane* visualization type, and set the color map to *RGB*.

The visualization should look like shown below. The potential drop occurs in the center of the device region, around the ZnO layers, showing that this is where scattering of the electrons takes place.



For a more quantitative analysis, open the saved difference grid with the **1D Projector**, choose *Average* as projection type, and click *Add line*. You should now see a plot like the one shown below. The potential values are given in Volt. The right-to-left potential drop is -0.5 V, which is exactly the applied bias voltage.



Also note that the induced potential is flat towards the electrodes, indicating that the Zn layers in the left and right ends of the central region provide sufficient screening.

I–V curve

The last finite-bias device analysis in this tutorial is the I–V curve. You will first compute it using the **IV Characteristics** analysis in the **Study Objects**, and then visualize it using the **IV-Characteristics Analyzer** plugin.

Attention: The *Study Objects → IV Characteristics* analysis has been implemented since the O-2018.06 version. If you use an older version, you can use the *Analysis → IVCurve* object instead.

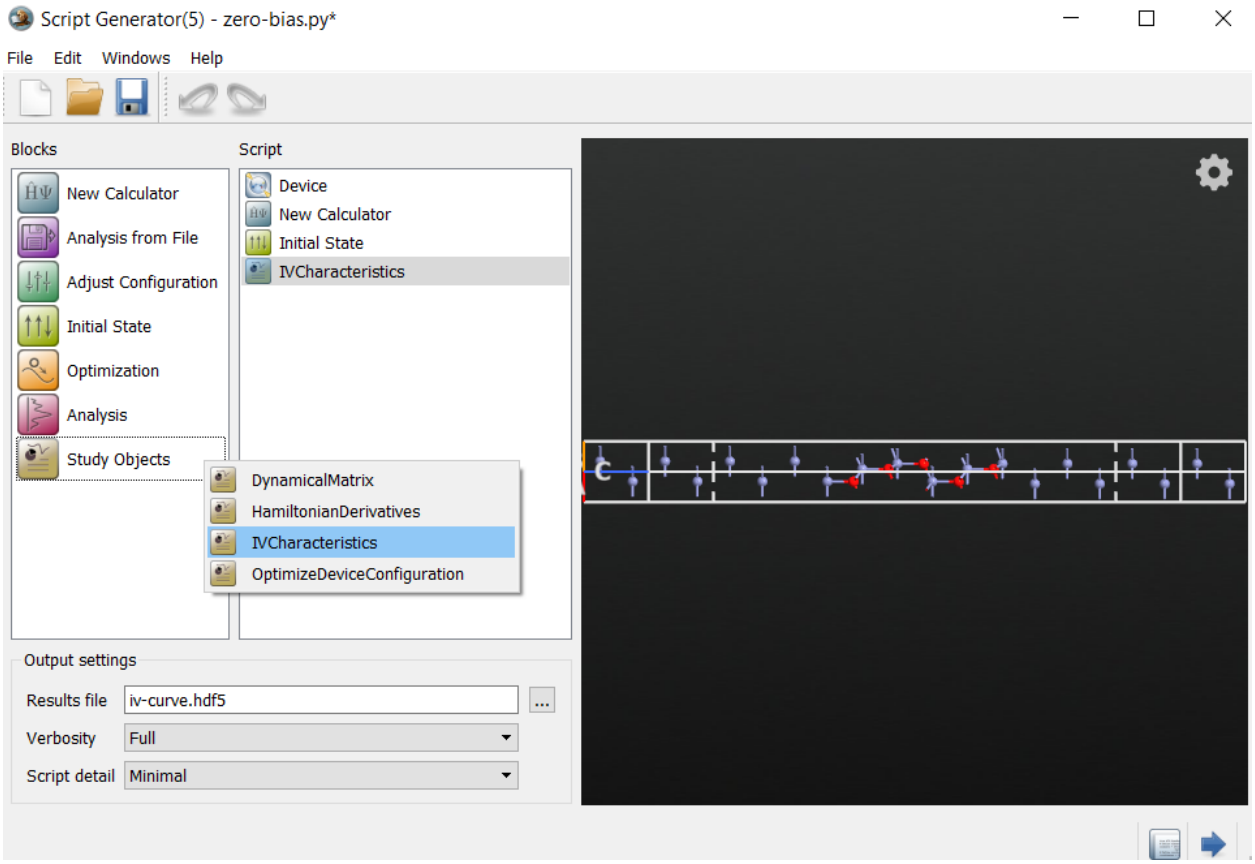
Calculations

Drag and drop the `zero-bias.hdf5` or `zero-bias.hdf5` file onto the **Scripter**. It automatically keeps the settings of the zero-bias calculation. Now do the following:

•Add the Initial State block.

•Add the *Study Objects* → *IVCharacteristics* block.

•Change the default output filename to `iv-curve.hdf5`.

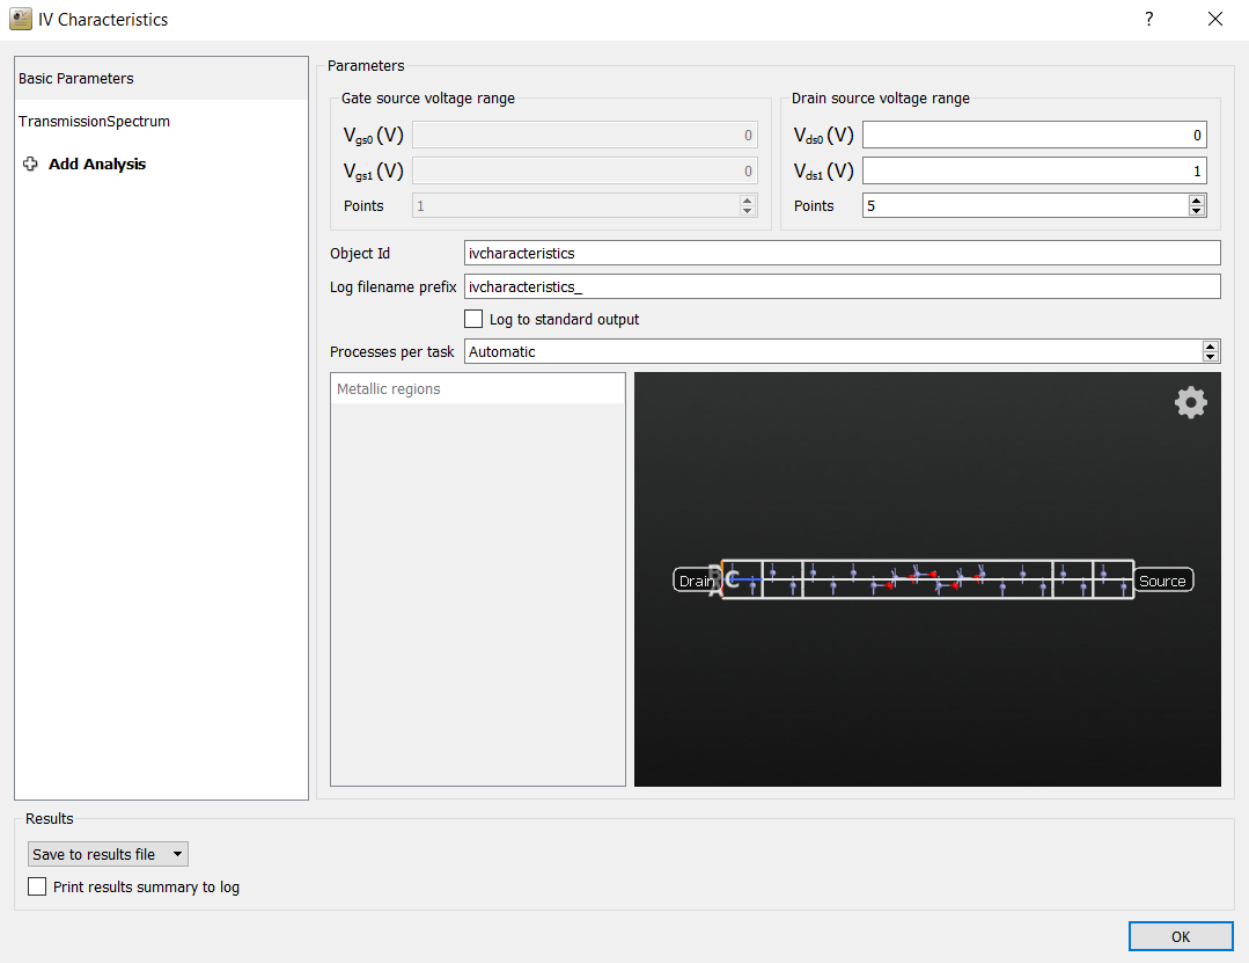


Next, open the Initial State block to instruct QuantumATK to use the zero-bias state as an initial guess for the finite-bias calculation:

•Tick **Use old calculation**, and choose `zero-bias.hdf5` or `zero-bias.hdf5` as the filename of the *Old Calculation*.

Edit the IVCharacteristics block:

•Decrease the number of voltage points to 5 (for speed).



The QuantumATK Python script is now done. Save it as `iv-curve.py` and execute it using the **Job Manager** or from the command line. This calculation will take some time, because a self-consistent calculation and a transmission spectrum analysis must be done at each bias point, so probably around 10 minutes in 16 cpus.

If needed, you can download the script here: `iv-curve.py`. If you do not want to perform the calculation yourself, you can also just download the results: `iv-curve.hdf5`.

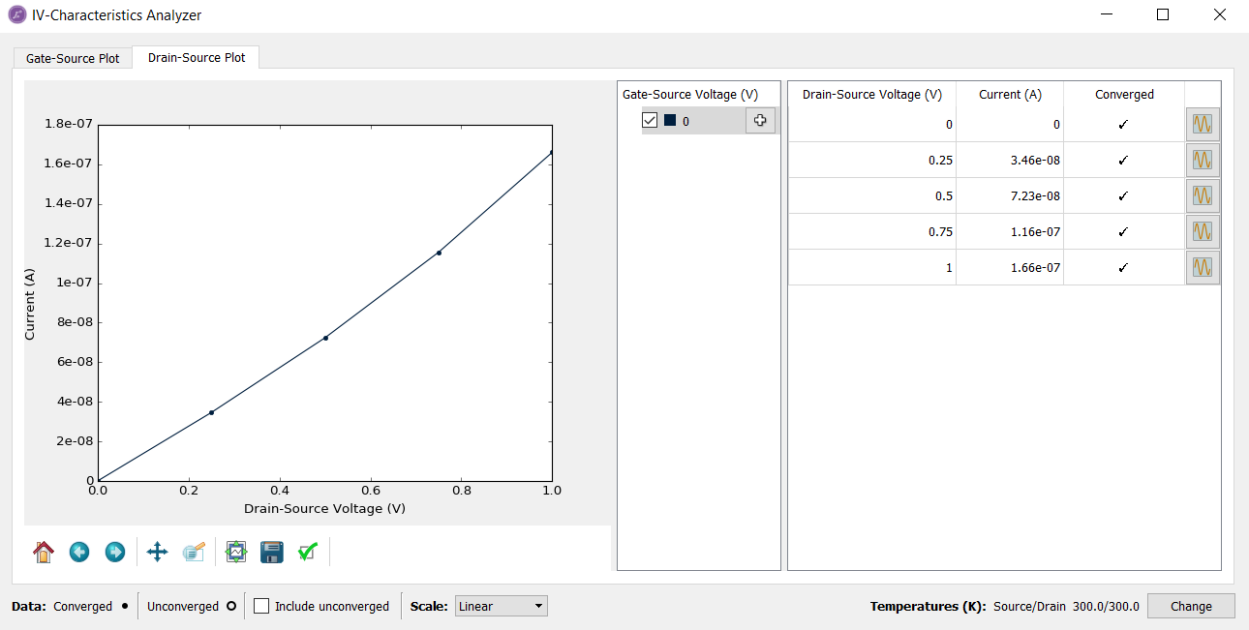
Visualization

The calculation should now be done, and the $I(V_g, V)$ *IVCharacteristics* data item should now be included in the `iv-curve.hdf5` output file. Five new output files were also created, prefixed `ivcharacteristics`; they contain the log file at each bias point.

Note: The $I(V_g, V)$ *IVCharacteristics* item contains the calculated I–V curve, including the transmission spectra computed at each bias voltage.

Select the *IVCharacteristics* item on the LabFloor and click the **IV-Characteristics Analyzer** tool in the $I\,(V_g, V)$ right-hand plugins bar. The I–V curve is plotted in the window that pops up.

Select the *Drain-Source Plot* tab and choose the scale of current by right-clicking and choosing *Customize*. Change the maximum for the y-axis to *1.8e-07* to get the plot shown below.

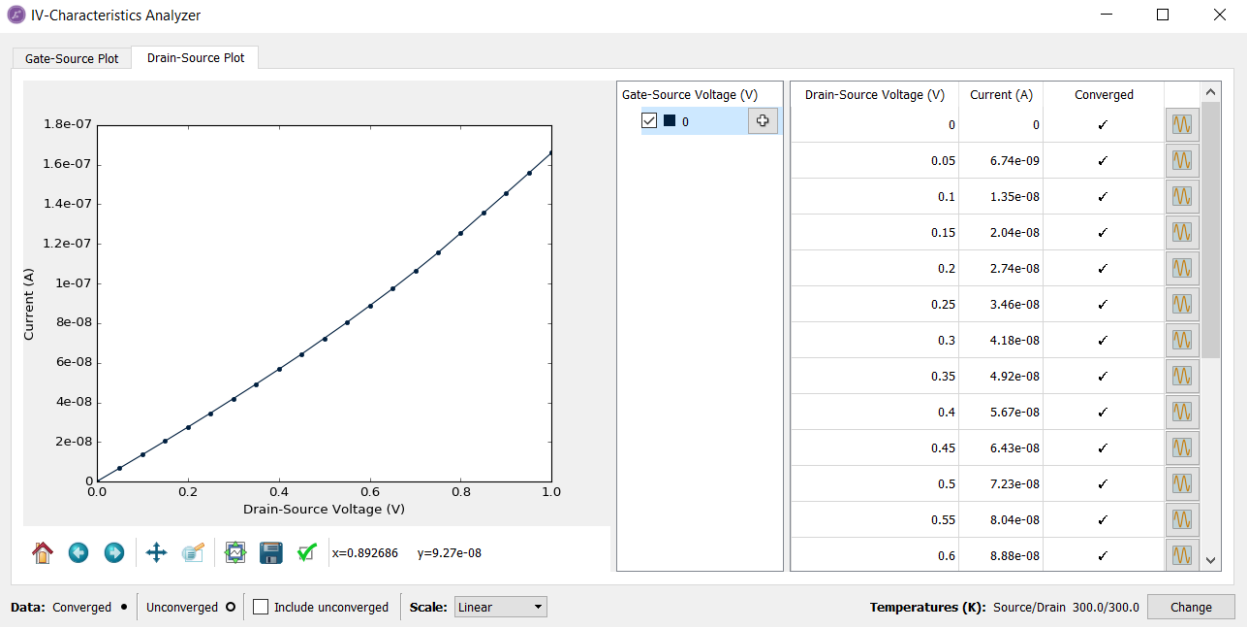


The table in the **IV-Characteristics Analyzer** shows the current and status of convergence at each finite voltage. Once you click the right-hand side plot icon ( ) in the table for the first time, the Analyzer will load in the Transmission spectra from the file. You can the visualize the transmission spectrum corresponding to a specific bias voltage point by clicking the icon and choosing *Transmission spectrum*.

A somewhat finer bias-point sampling would yield a more accurate current. To this end, you should increase the number of bias points to 21, for example, and re-run the script with **IVCharacteristics** study object. It will automatically re-calculate the new points. You can also download the result here: `iv-curve_fine.hdf5`.

Note: The **IVCharacteristics** study object enables addition of more bias points. Simply add more voltage points in the **IVCharacteristics** object with the same calculator settings, then run it in the existing output file directory. The **IVCharacteristics** recognizes the existing bias points smartly, and just runs the additional voltage points. It will be faster and not waste the computational cost. See also the dedicated tutorial: *Electrical characteristics of devices using the IVCharacteristics study object* for more information.

The finely sampled I–V curve is illustrated below. Compare it to the coarsely sampled one shown above even though the IV-curves look very similar.



Summary

You have now been introduced electronic transport calculations with QuantumATK.

- You have gained an understanding of the general structure of a device geometry, and can continue with setting up other device geometries.
- You have learned about important convergence parameters, such as transverse k-points, density mesh cut-off energy, and NEGF contour integral settings.
- You are now able to calculate the transmission spectrum at zero and finite bias voltage, and analyze the results using the Transmission Analyzer.
- You have also been introduced to other analysis tools like projected device density of states, electrostatic difference potential, transmission eigenvalues and eigenstates, and I–V curve using the IV characteristics study object.
- You are also able to visualize 3-dimensional objects with the 3D Viewer or by using 1D projections.

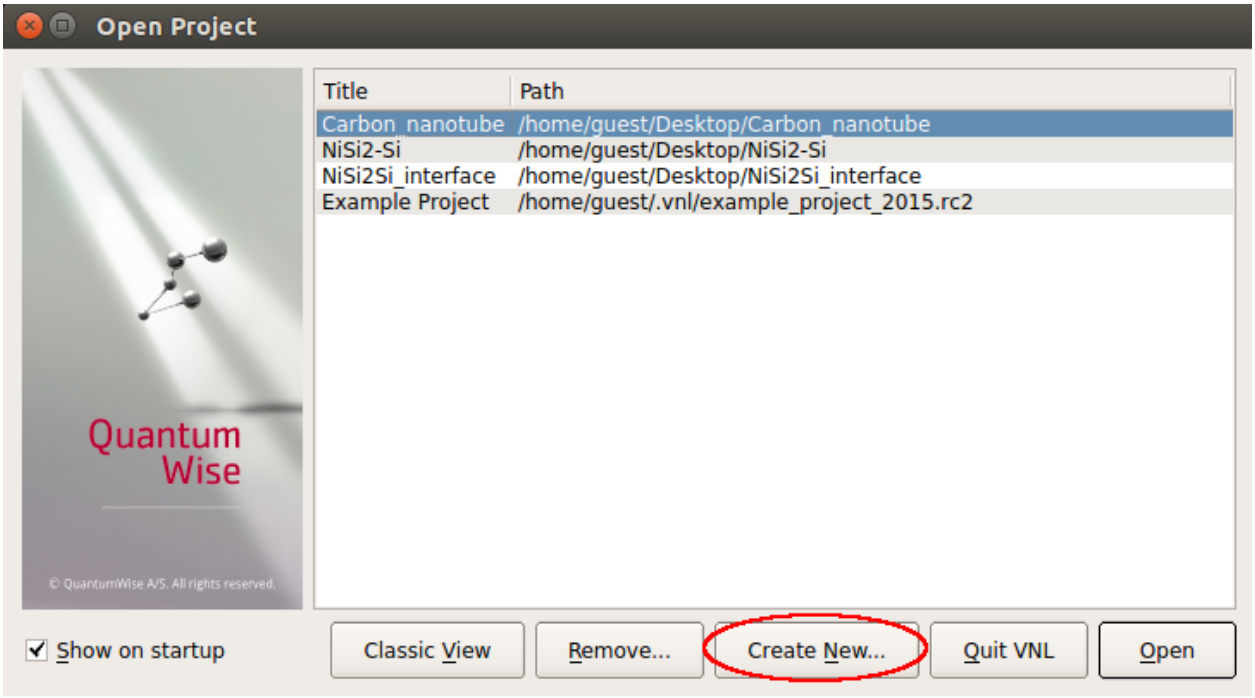
Tip: Whats next? Now that you know the basics of *electron* transport calculations, it would be wise to continue to the tutorial *Phonons, Bandstructure and Thermoelectrics* to learn about simulating *phonon* transport with QuantumATK.

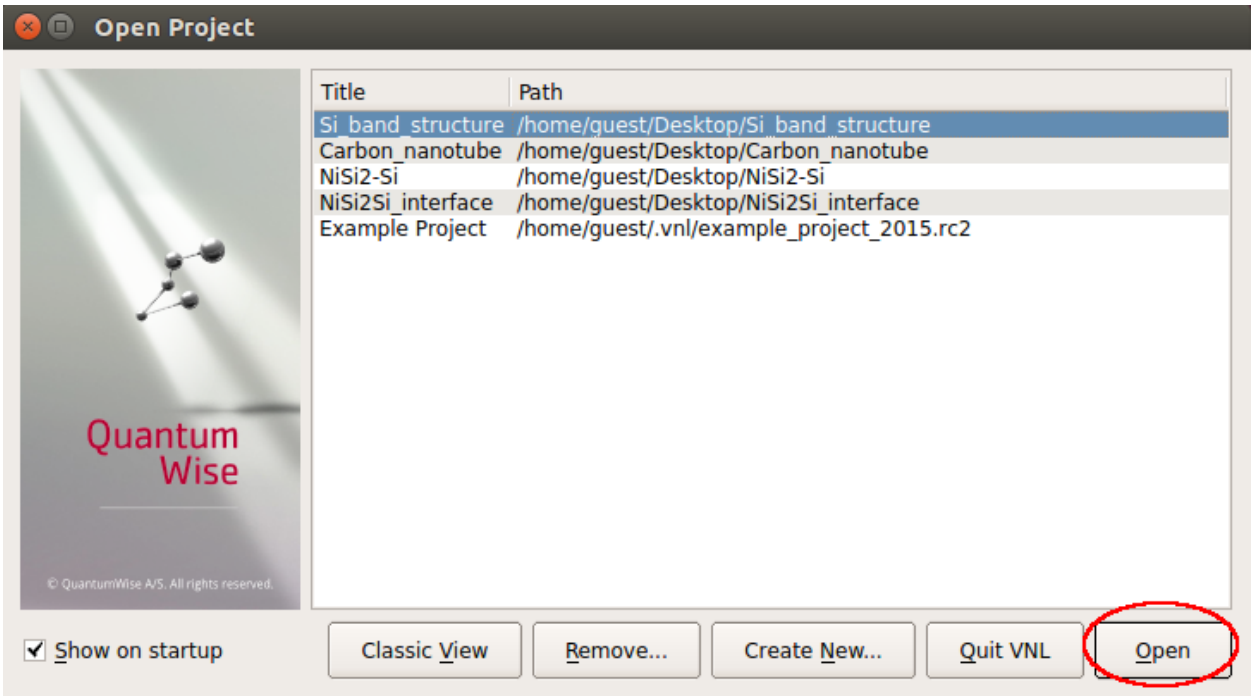
3.12.13 Calculate the band structure of a crystal

In this tutorial, you will learn how to calculate the band structure of silicon by using the extended Hückel method.

Start QuantumATK and create a new project

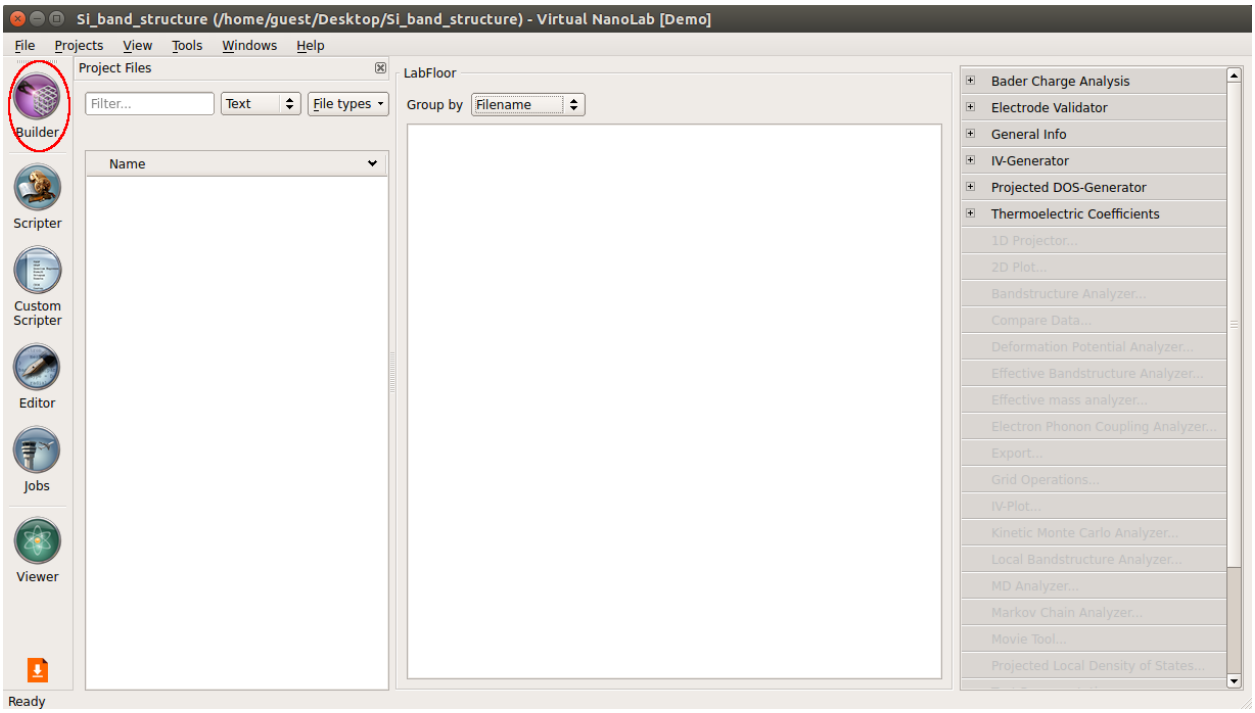
Open **QuantumATK** and create a new project by clicking **Create New**. Give the project a *Title* (here: Silicon_band_structure), select the folder where data will be stored, then click **OK** and **Open** to start the project.





Import the Silicon structure from the Database and send it to the Scripter

1.In the **QuantumATK** main window, click on the icon to open the **Builder**.



2.Go to the **Stash**, click *Add* → *From Database*, and choose *Databases* → *Crystals* from the menu. Type *Silicon* in the filter field at the top and select *Silicon (alpha)* in the list. Click the icon, or double-click its line in the list, to send it to the **Stash**.

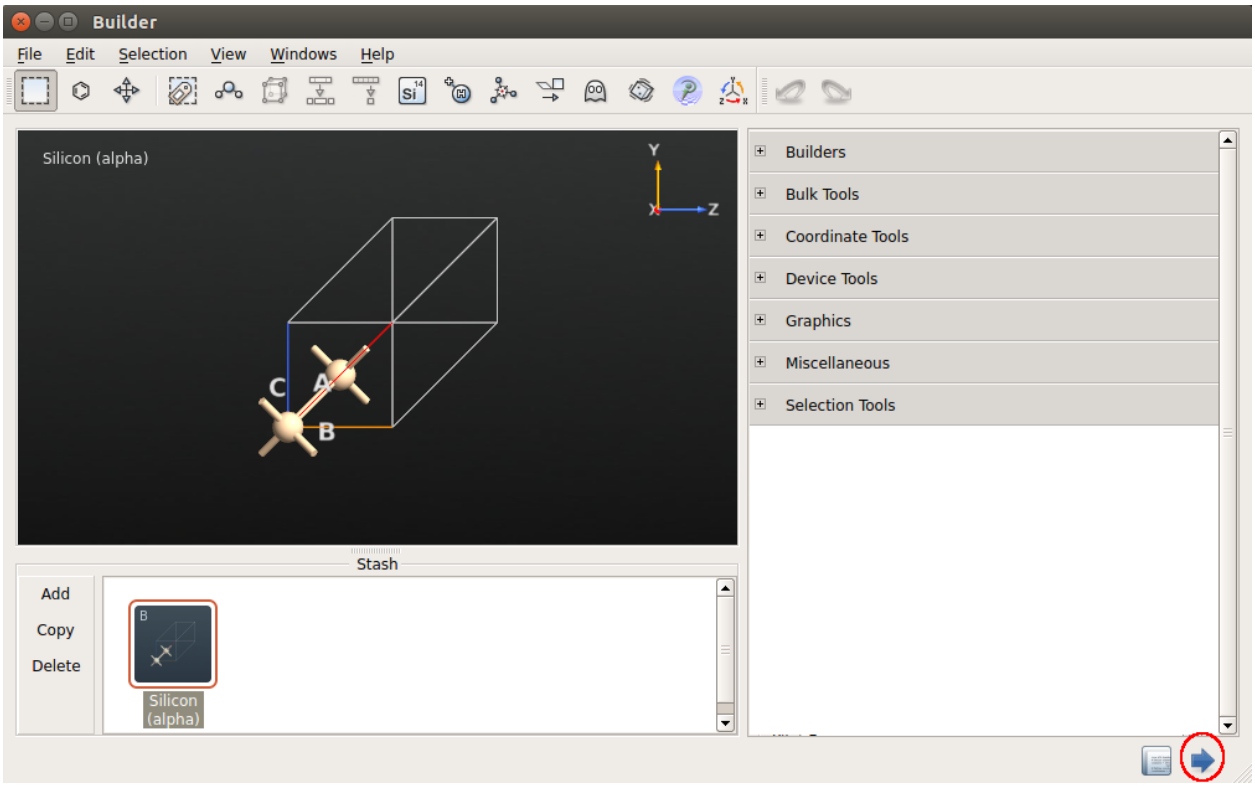
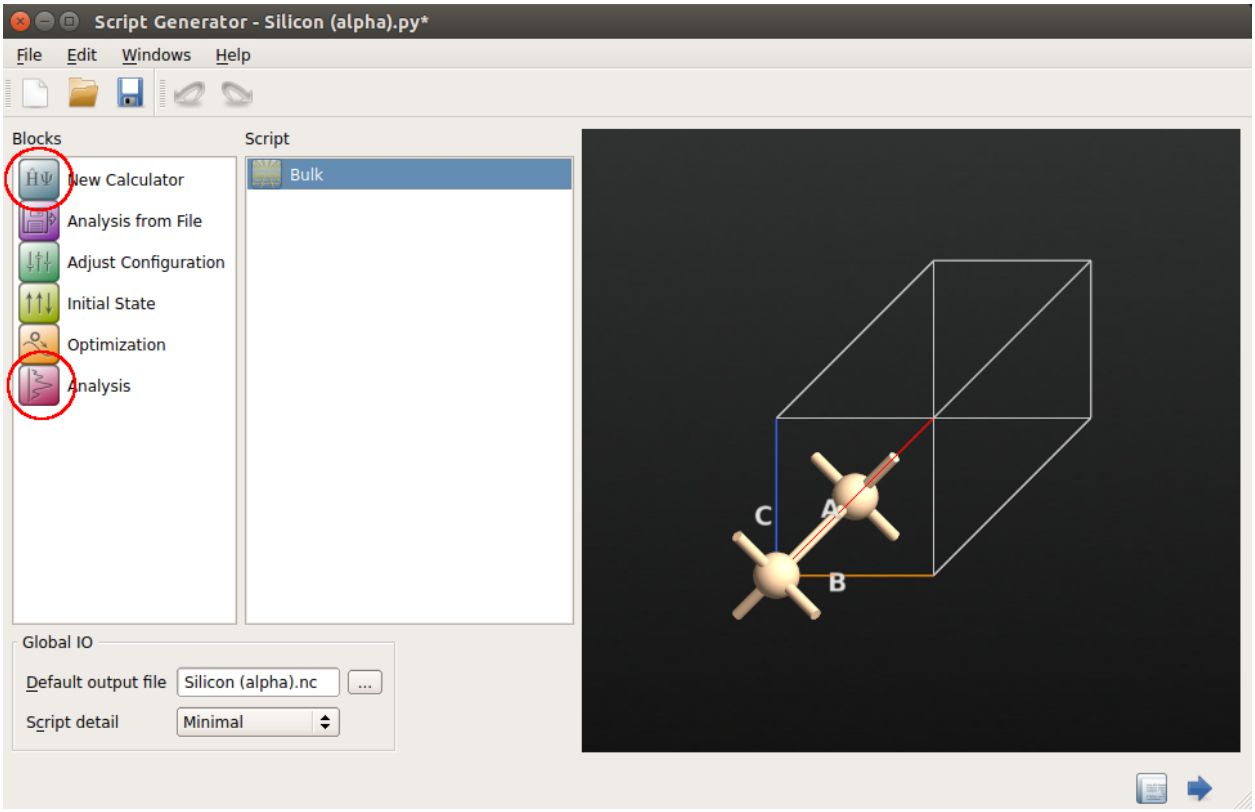
3. Send the bulk structure to the **Scripter**. In order to do that, click the button and choose **Script Generator** from the menu that appears.



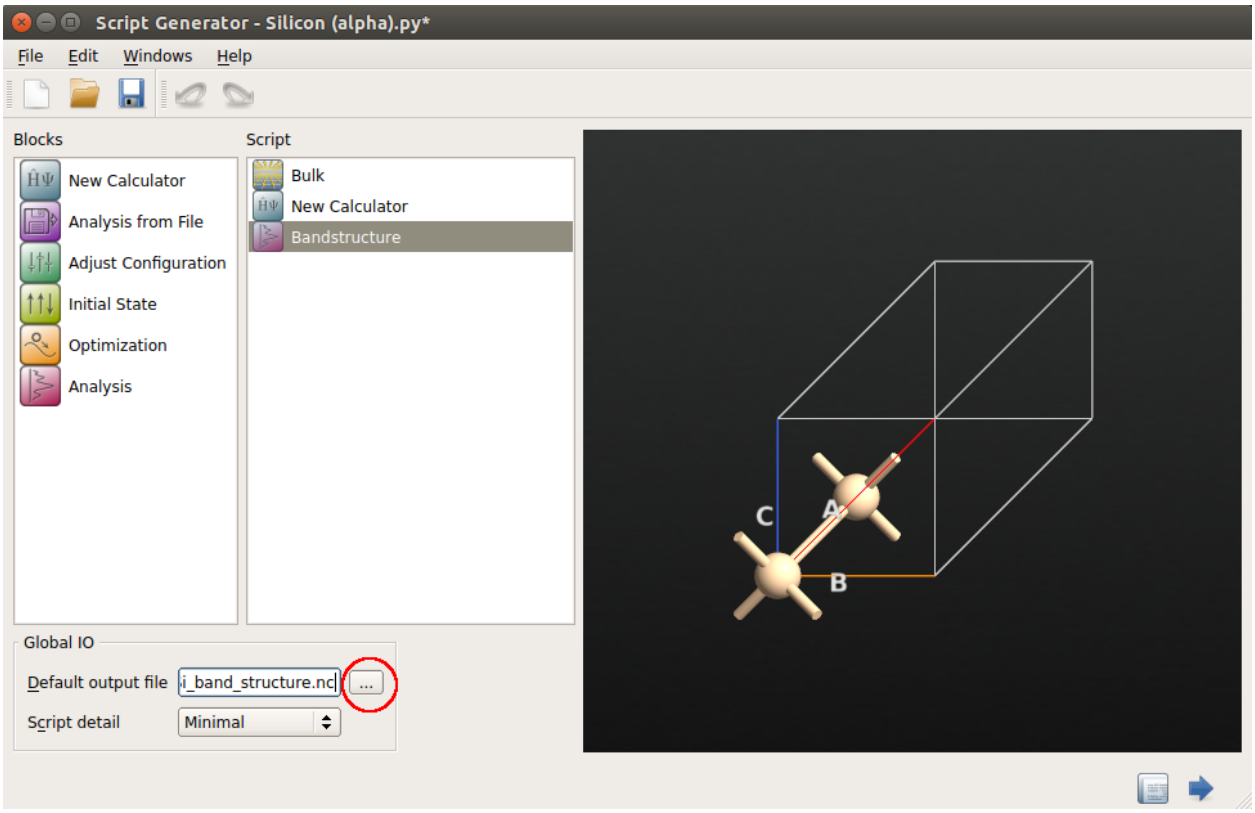
Set up the calculation and analyse the band structure

1.In the Script Generator, use double-clicks to add a New Calculator block.

2.Also add one *Analysis* → *Bandstructure* block.

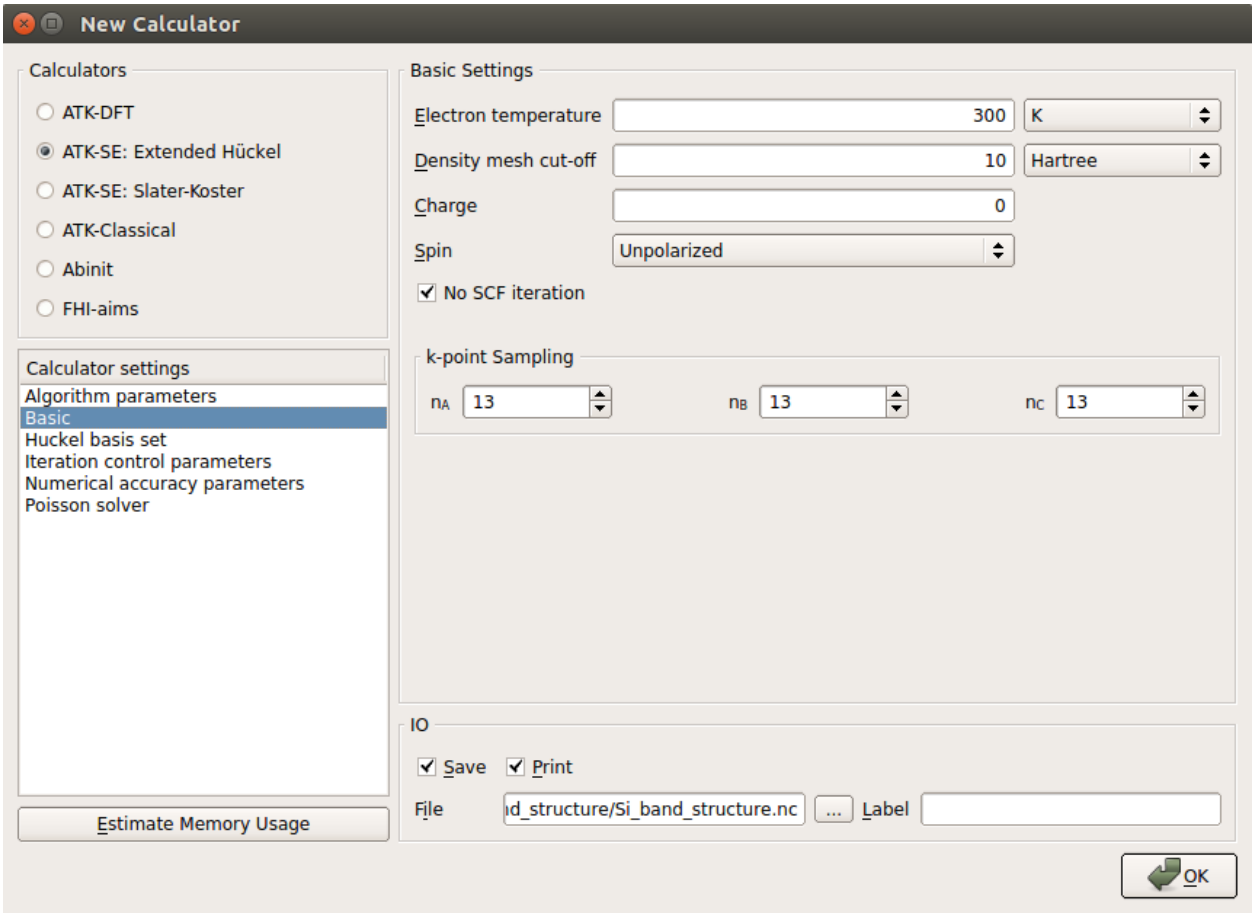


3.Change the default name of the HDF5 file in the **Global IO** options: Type in `Si_band_structure.hdf5`.

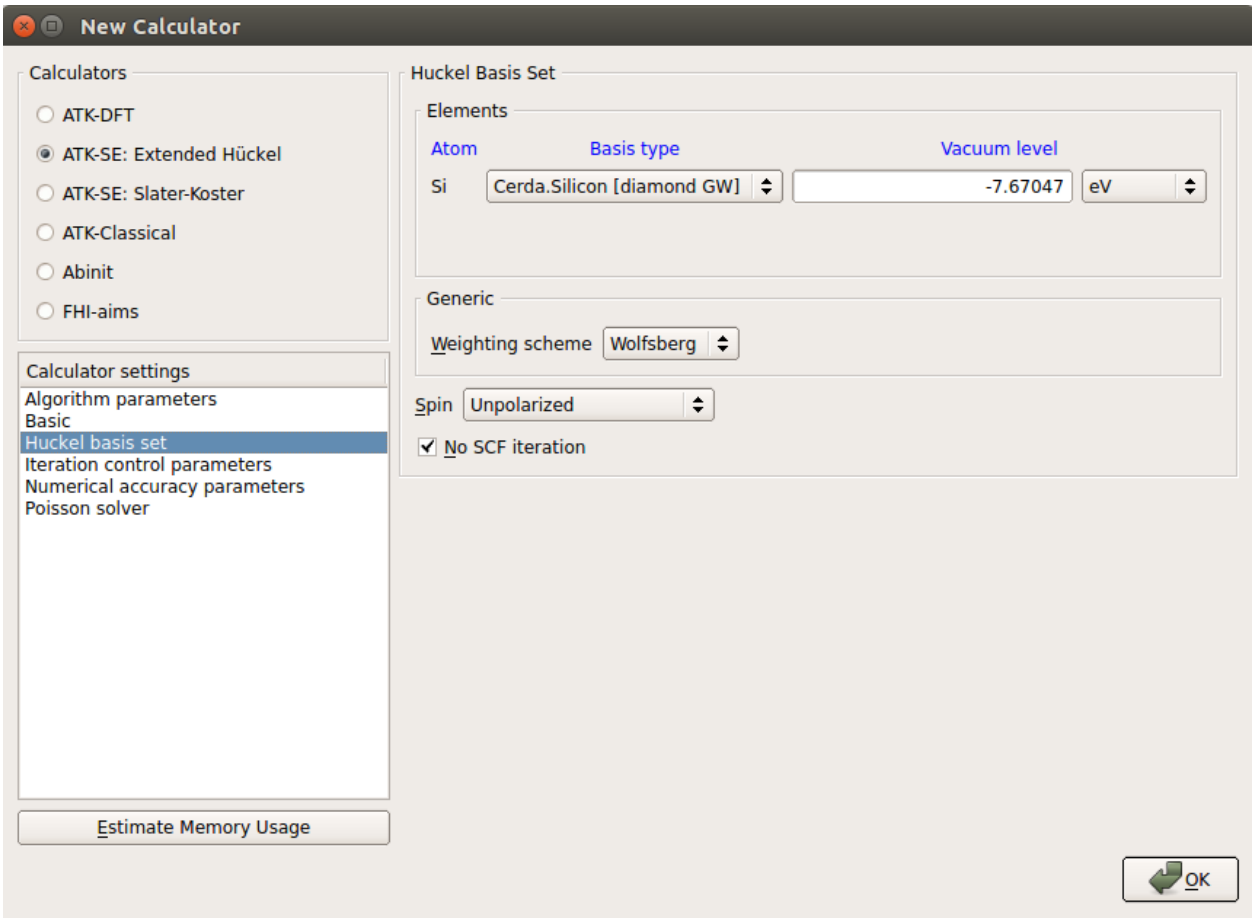


4.Double-click the New Calculator block to define the parameters for the quantum-chemical method:

1.Set the calculator to Extended Hückel (or leave it at DFT if you so prefer), and specify a k-point sampling of $n_A = n_B = n_C = 13$.

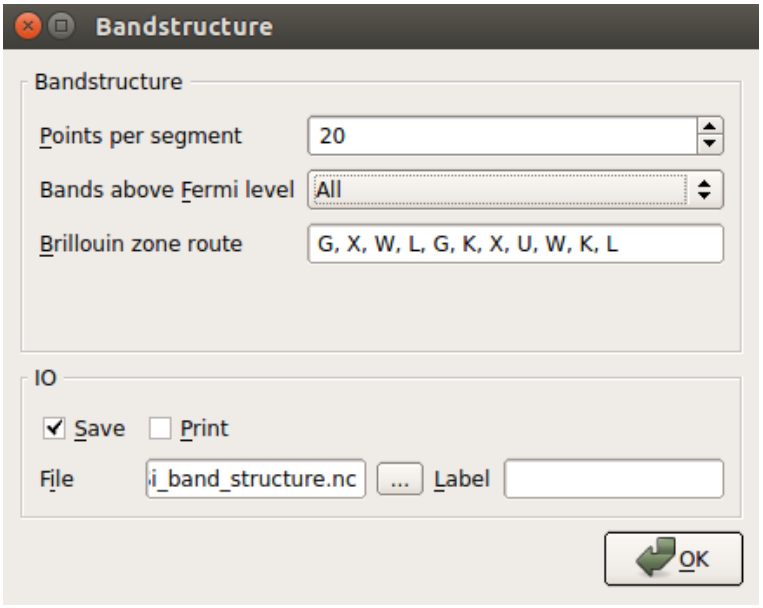


2.If you use the Extended Hückel, you must also change the basis set to *Cerda.Silicon* to get a proper description of the band gap.



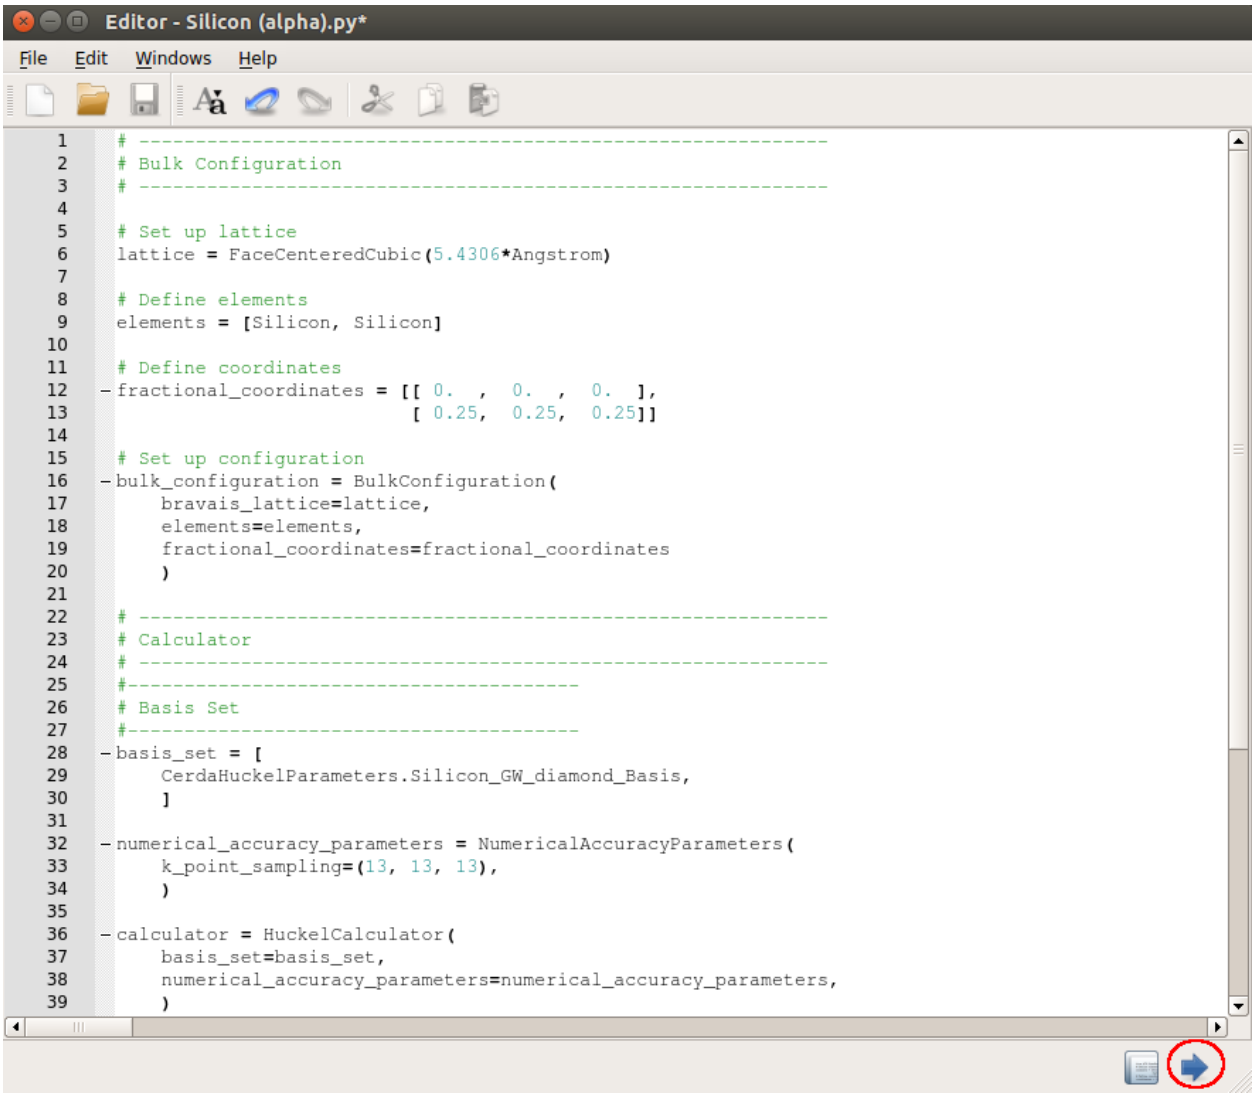
3.Click **OK** to save the changes.

5.Now open the **Bandstructure** block. We will not change anything, but you can see how the path in the face-centered cubic Brillouin zone between the symmetry points G, X, W, L, G, K, X, U, W, K, L, is set up. Click **OK**.

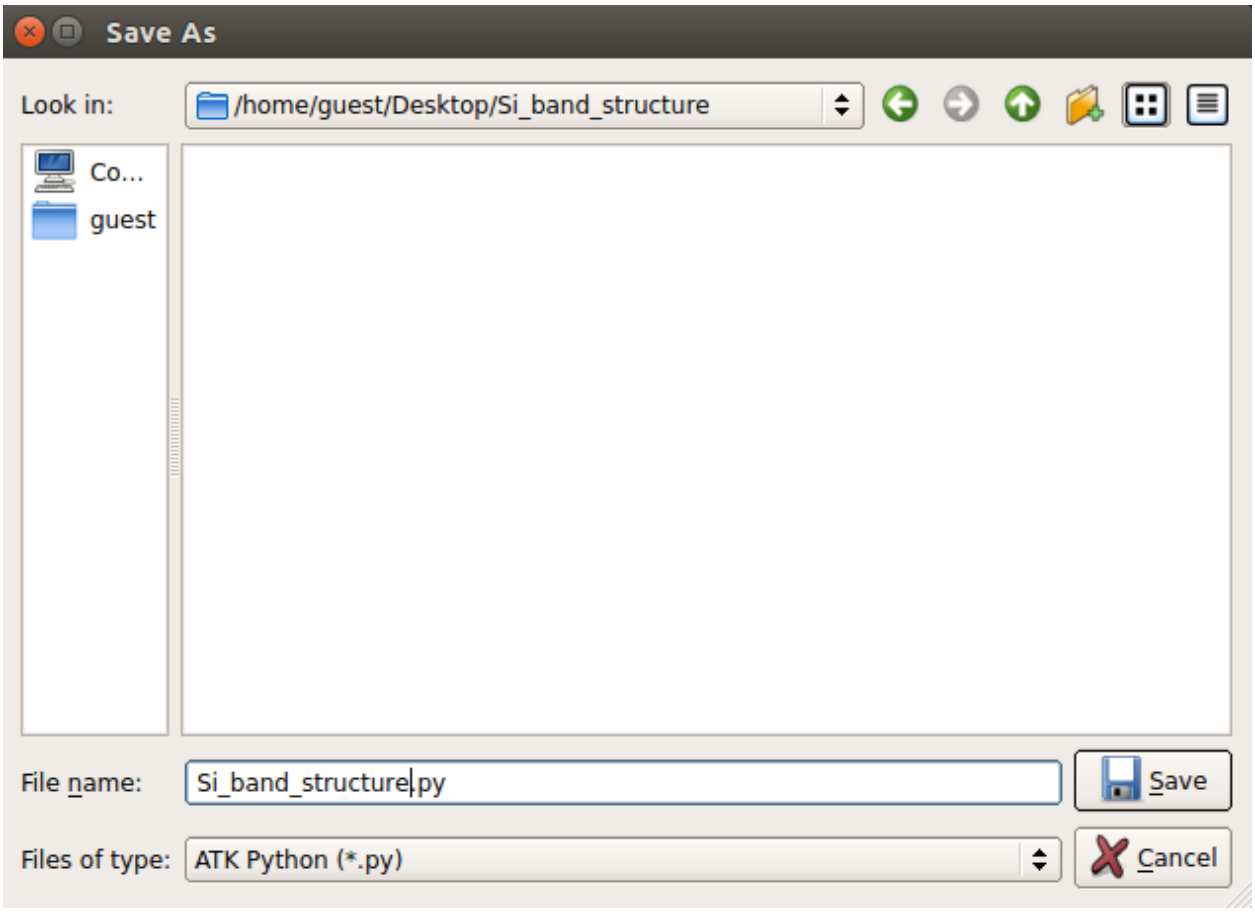


6.If you are interested in inspecting the actual Python script, you can now send the scipt to the **Editor**: Use the button or simply drag and drop it onto . Note that this will minimize the Script Generator window.

7.In order to run the script, you simply send it to the **Job Manager**, again using the button.

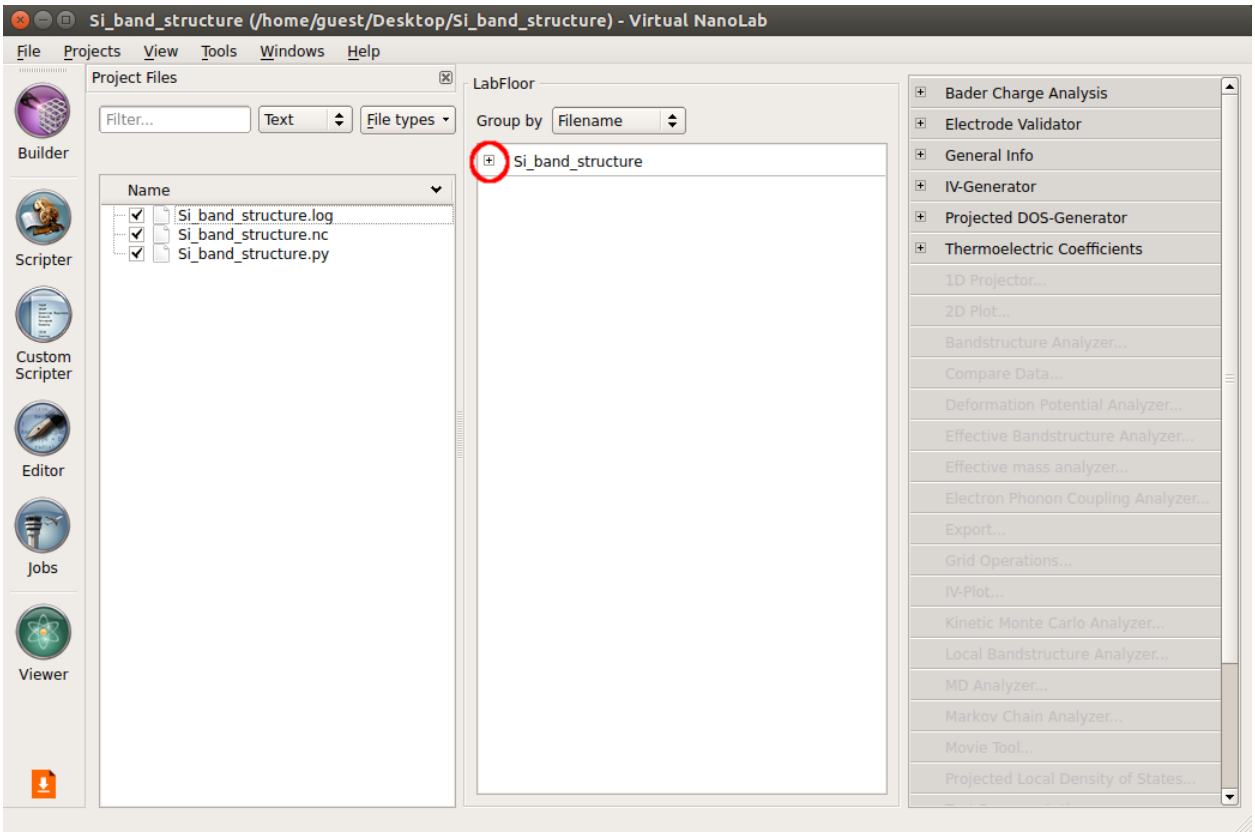


8.Save the script in the window that appears.

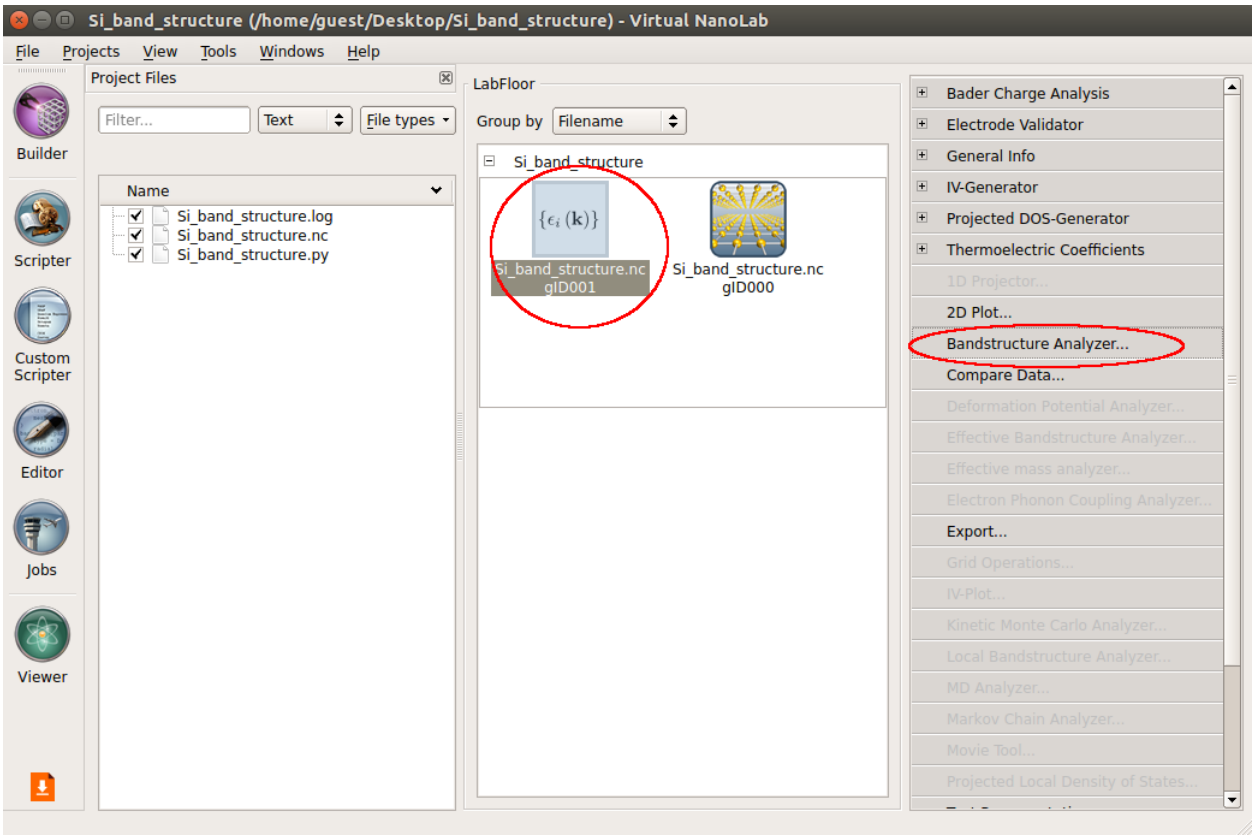


9. In the Job Manager, click ▶ to run the script.

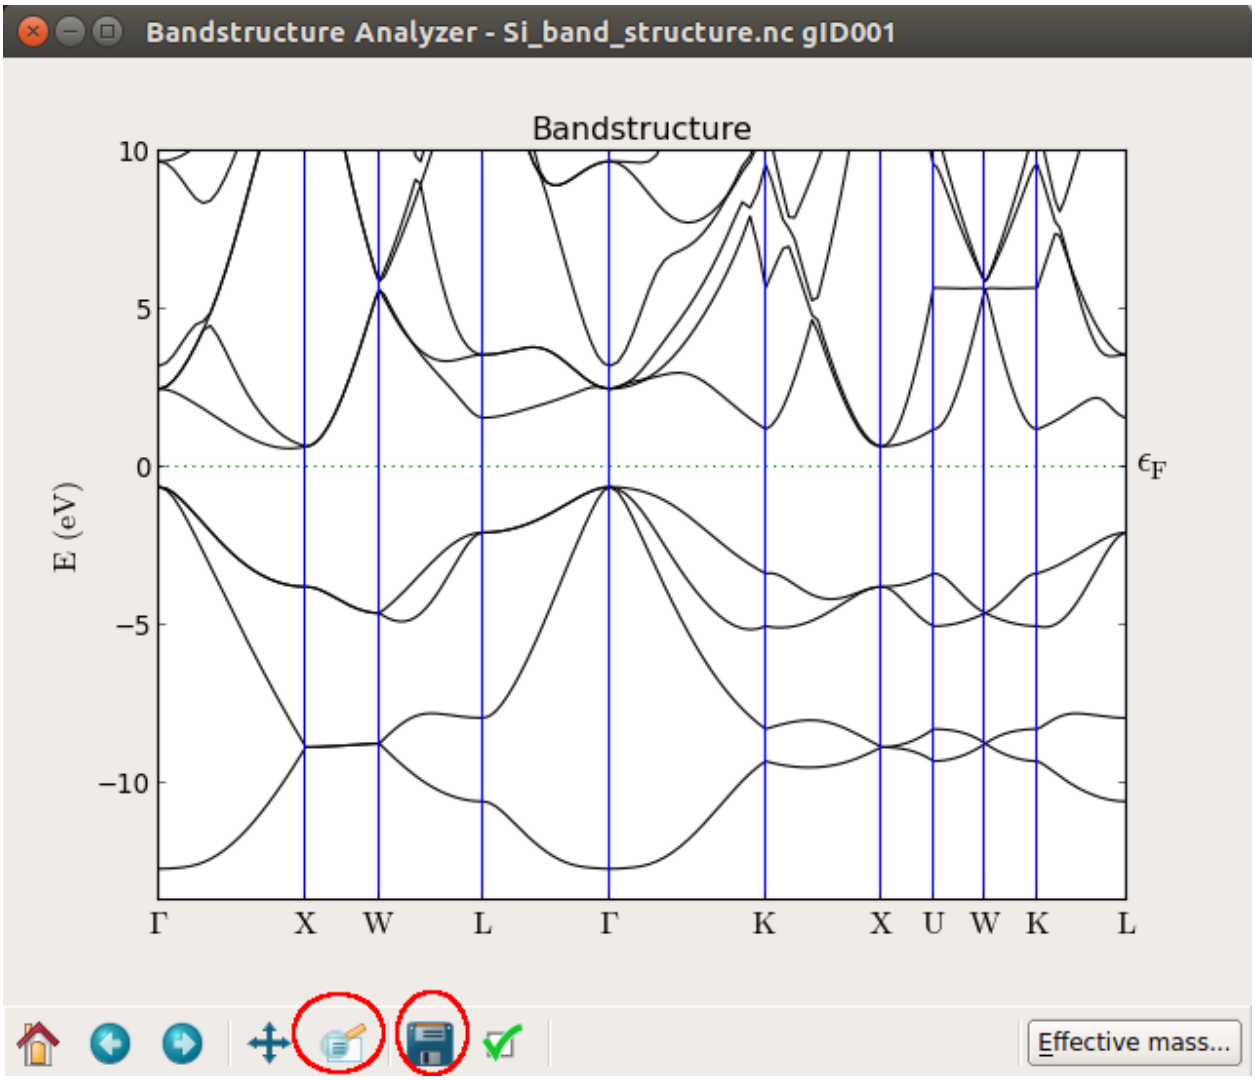
10. When the script has finished (it should only take a few seconds), go back to the main QuantumATK window, and click the tab (⊞) next to your HDF5 file, `Si_band_structure.hdf5`, to see the objects contained in it.



11.Select the Bandstructure object and plot it with the **Bandstructure Analyzer** in the right-hand plugins panel.



12. In the band structure plot that opens, you can zoom in using the **Zoom to rectangle** tool. You can also save the figure by clicking the button.



3.12.14 Introducing the QuantumATK plane-wave DFT calculator

Version: 2017.0

Downloads & Links

`e-cut-conv.py` `restart-e-cut-conv.py` `plot-e-cut-conv.py` `cu-bulk.py`

The ATK-DFT plane-wave calculator was introduced in QuantumATK 2017.0, and this tutorial gives a brief introduction to how to use it. We will look at a simple bulk example to introduce the basic functionalities of this calculator.

Introduction

The central difference between the plane-wave (PW) calculator and the LCAO calculator is that the one-electron eigenstates are expanded in a plane-wave basis set instead of atom-centered basis functions. The plane-wave representation of electronic structure has a long tradition in computational studies of periodic bulk systems, and has the key advantage that the basis set can **systematically be improved** by simply increasing the number of plane waves included in the calculation (albeit at a significantly increased computational cost). This makes the PW calculator an interesting alternative to the usual LCAO calculator for studies of (not too large) bulk systems, and may also be used as a benchmark in investigations of the accuracy of an LCAO basis set for a specific system.

As an example, we will find the lattice constant and band structure of bulk copper, but first we need to converge the size of the PW basis to make sure our results are accurate.

Warning: Note that in the 2017 version of QuantumATK, the plane-wave calculator is still a beta version, so not all functionality has been implemented, and it has a higher risk of bugs. From QuantumATK O-2018.06 it is a finished product with full functionality.

Converging the PW basis

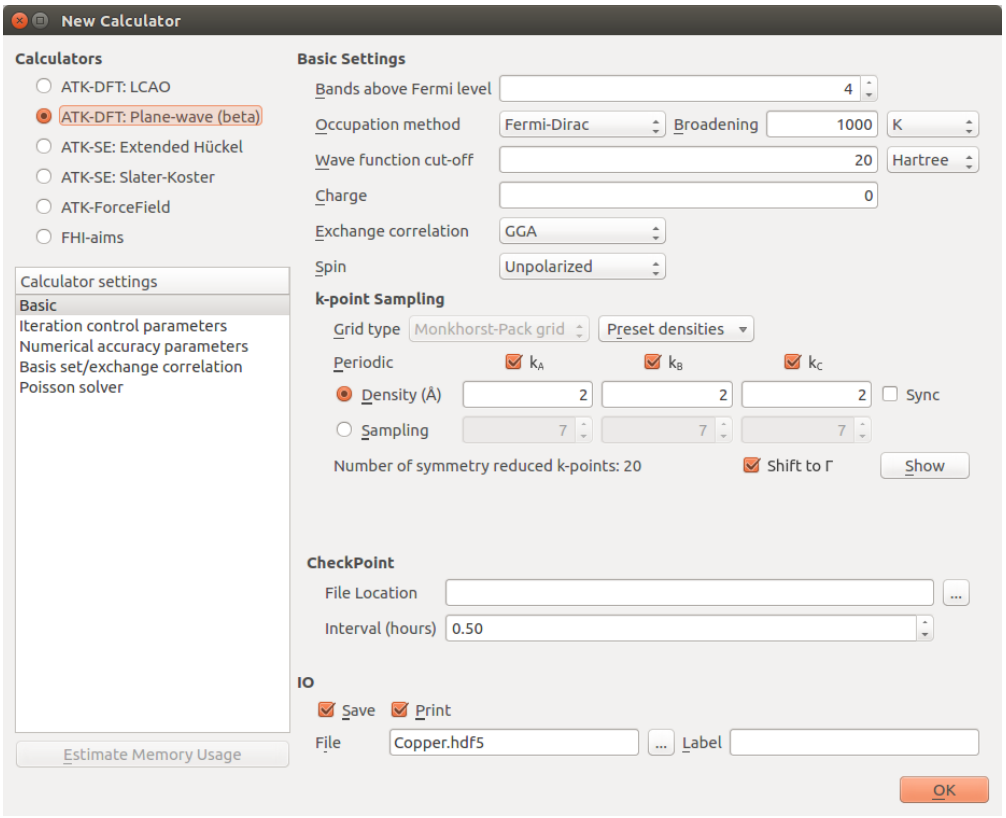
The number of plane waves included in the PW calculation depends on the plane-wave cutoff energy E_{cut}. The accuracy of the PW calculation increases as the number of plane waves increase (larger E_{cut}), but so does also the computational cost. The desired trade-off between computational accuracy and cost must therefore be chosen, and we use a convergence study for this.

To converge the PW basis, we compute some desired property for a range of cut-off energies, here the total energy, in order to investigate how large E_{cut} needs to be in order to get sufficiently accurate results.

To do this, follow these steps:

- Open the **Builder** and click on *Add* → *From database*.
- Type copper to search for pure copper, select it and press the button.
- Now send the configuration to the **Script generator**
- Add **New Calculator** and **Total energy** objects.
- Open the **New Calculator** and change it to *ATK-DFT: Plane-wave (beta)*.

Your **New Calculator** window should look like this:



•Click *Ok* and send the script to the **Editor** by using the .

We now need to create the loop over the PW cutoffs. Insert these lines at the top of the script, after the line specifying the encoding, to calculate the total energy for cutoffs ranging from 10 to 100 Hartree:

```
e_cut_list = range(20,110,10)*Hartree

for e_cut in e_cut_list:
```

You also need to indent everything after these lines.

Tip: You can easily indent many lines in the Editor by selecting them, and pressing the `Tab` key.

Finally, we need to change the values for the cutoffs to the variable that is being used in the `for`-loop. Find the line where the density mesh cutoff is defined, it should be line 37 now, and replace it with the following:

```
        density_mesh_cutoff=e_cut*4,
```

Find the line where the calculator is defined, and insert `wave_function_cutoff=e_cut,` to make the calculator look like this:

```
    calculator = PlaneWaveCalculator(
        wave_function_cutoff=e_cut,
        numerical_accuracy_parameters=numerical_accuracy_parameters,
        )
```

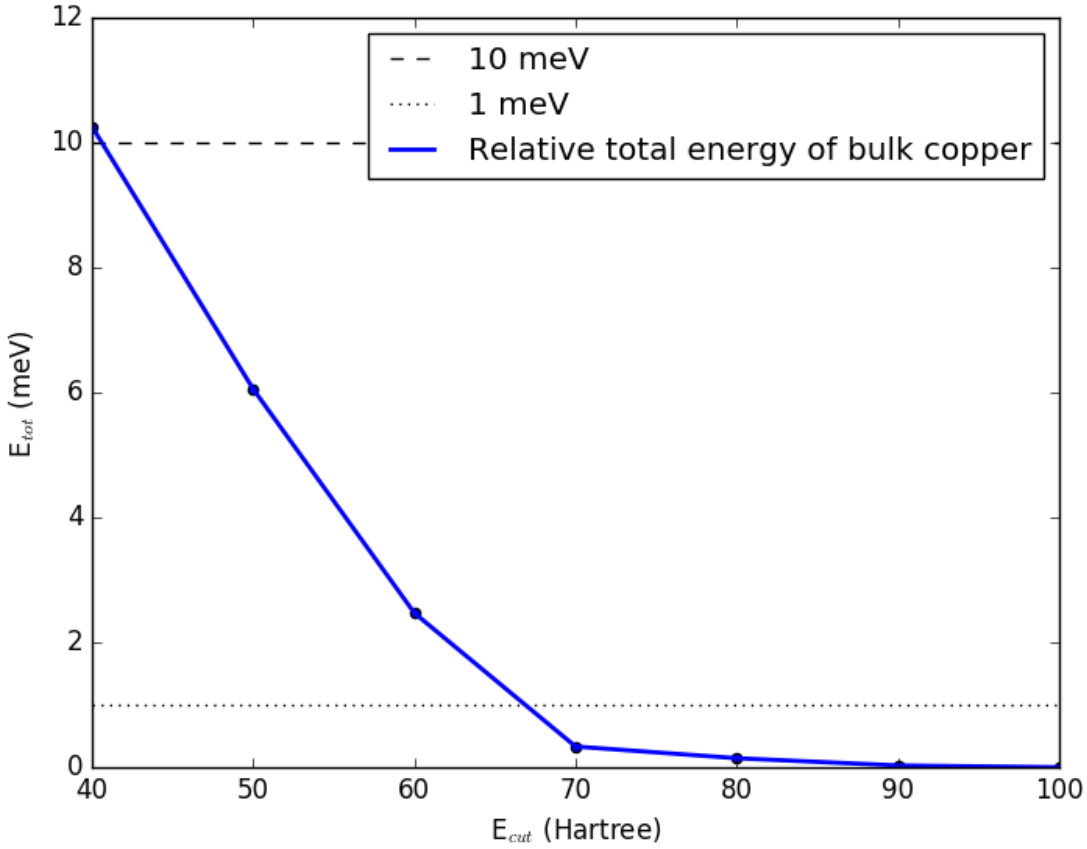
Note: The default mesh cutoff is 4 times the PW cutoff, which ensures that there is no loss of accuracy from this and no unnecessary computational overhead.

Your script should now look like this: `e-cut-conv.py`, and you can run it. It should take no more than half an hour on a modern laptop, and significantly less if MPI parallelization is used.

Tip: We plan to introduce a new feature in 2018 which allows you to set up this process from the Script Generator.

In some cases where you want to redo a previous calculation, but with a higher PW cutoff, it can be beneficial to restart the calculation. It is slightly more complicated to set up the script this way, but in our case it will make the calculation run a little faster, reducing the time required by about a factor of 2. An example of this script can be seen here: `restart-e-cut-conv.py`.

After running the script, we can now plot the total energy of the system vs. the PW cutoff. You can use this simple script to plot the data: `plot-e-cut-conv.py`. It will generate two plots. One for all values of the cutoff, and one where the first values are omitted, to allow for a clearer picture in the region of convergence. The second plot should look like this:



It shows that the total energy has converged to within 10 meV per atom with a cutoff of 50 Hartree, while 70 Hartree is required to converge the energy within 1 meV of the chosen reference calculated with a cutoff of 100 Hartree. The choice of reference and convergence criteria is a decision for the user, and should be based on the needed accuracy, balanced against the computational cost. In this case, we are mostly interested in fast calculations, and so we choose a

cutoff of 50 Hartree.

Tip: The required cutoff depends strongly on both the element and the specific pseudopotential, so you should always test convergence when using a new pseudopotential.

Calculating properties

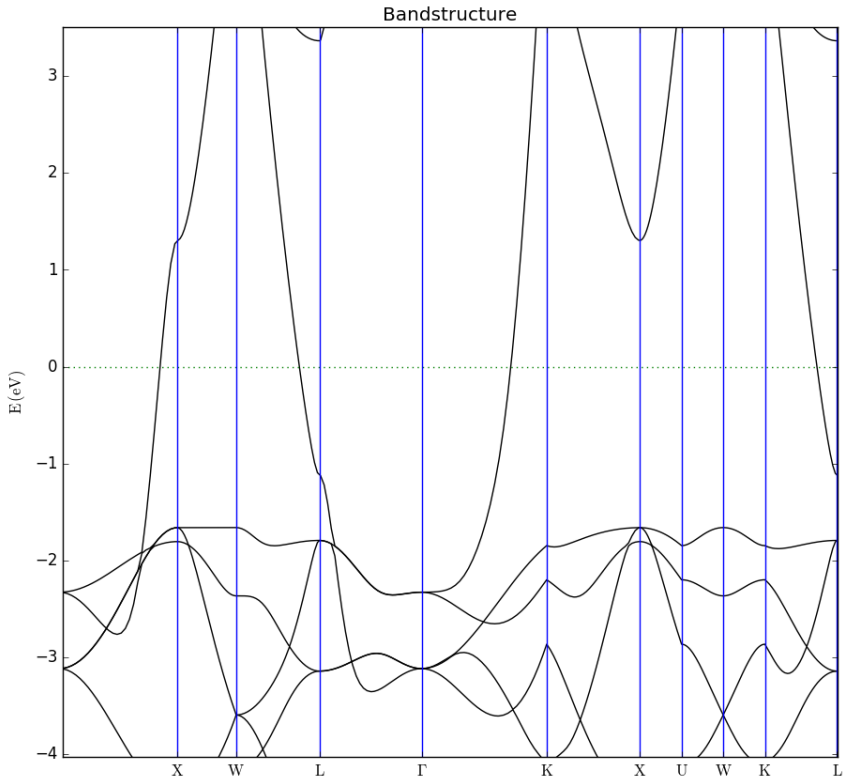
Now that we have found the PW cutoff needed for satisfactory accuracy, we can calculate some properties for bulk Cu. We will do a simple calculation of the lattice constant and the bandstructure. Go back to the Script Generator window.

- Add **OptimizeGeometry** and **Bandstructure** objects.
- Move the objects around to ensure that the is just after the .
- Open the **New Calculator** object and change the cutoff to the 50 Hartree we found previously.
- Open the **OptimizeGeometry** object and un-check *Constrain Lattice Vectors*
- Send the script to the **Job Manager** to run it. It should look like this: `cu-bulk.py`

Running the script took about 10 minutes using 8 MPI processes on an 8-core machine, so anything up to a couple of hours is possible if run on a laptop.

Tip: The ATK-PW calculator uses symmetry to reduce the number of k-points that must be calculated, and it parallelizes over the reduced k-points. In order to get the most efficient parallelization, you should check this reduced number in the Script Generator, and use a number of MPI processes which is as close to a divisor of this number as possible.

You can now inspect the log-file `Copper.log` and the data-file `Copper.hdf5` and verify that we have found a lattice constant for copper of 3.660650 Å after stress and force optimization, a total energy of -4968.92 eV and the following bandstructure, if zoomed in on a range around the Fermi level.



Other analysis objects

Not all QuantumATK analysis objects support the PW calculator in QuantumATK 2017.0, as it is still in beta. However, the **Script Generator** is aware of this fact, and will cross out any unsupported analysis objects, and will omit them when the actual script is generated and sent to the Editor or the Job Manager. If the script is created manually, QuantumATK will give an error message when it encounters an analysis object which does not support the plane-wave calculator.

3.12.15 Build a graphene nanoribbon transistor

In this tutorial, you will learn how to build an advanced device using the QuantumATK **Builder**. We shall consider a nano-scale graphene nanoribbon transistor with a metallic gate separated from the ribbon by a dielectric. This transistor design is inspired by the work presented in[1], where QuantumATK was used to investigate the properties of a similar system.

The device is illustrated in the figure above. It consists of three regions and forms a metal–semiconductor–metal junction. By applying a gate potential across the central region, the system can function as a field effect transistor (FET).

[1] Qimin Yan, Bing Huang, Jie Yu, Fawei Zheng, JiăZang, Jian Wu, Bing-Lin Gu, Feng Liu, and Wenhui Duan. Intrinsic CurrentVoltage Characteristics of Graphene Nanoribbon Transistors and Effect of Edge Doping. *Nano Letters*, 7:1469–1473, 2007. doi:10.1021/nl070133j.

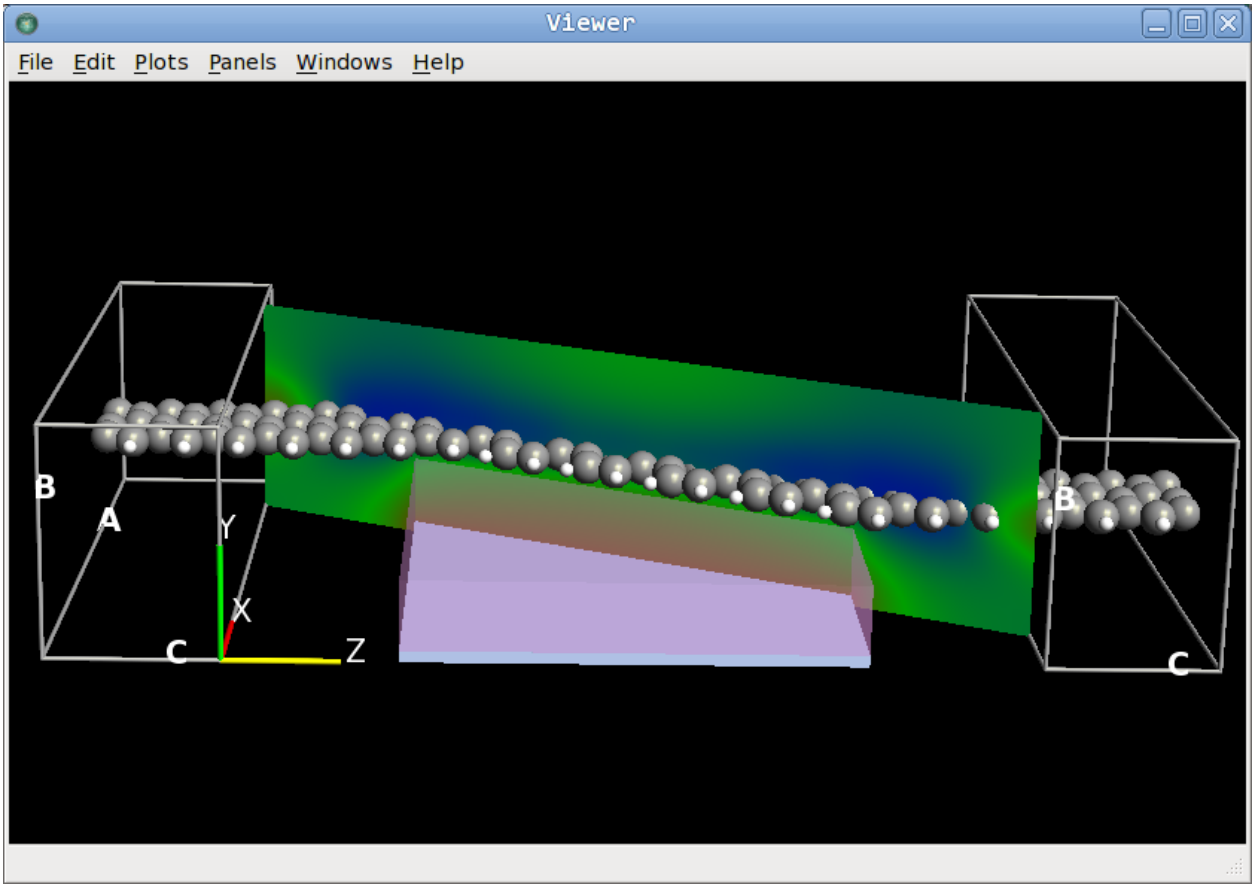


Fig. 3.125: The device system considered in this tutorial consists of a z-shaped graphene nanoribbon on top of a dielectric and controlled by a metallic gate. The contour plot illustrates the electrostatic potential along the transport direction.

Small nanoribbon transistor

The graphene nanoribbon junction device will be of the zigzag–armchair–zigzag type. You will first build the central region (an armchair nanoribbon) and the two electrodes (zig-zag nanoribbons).You will then proceed to merge together the three components and build the complete junction device.

Central region

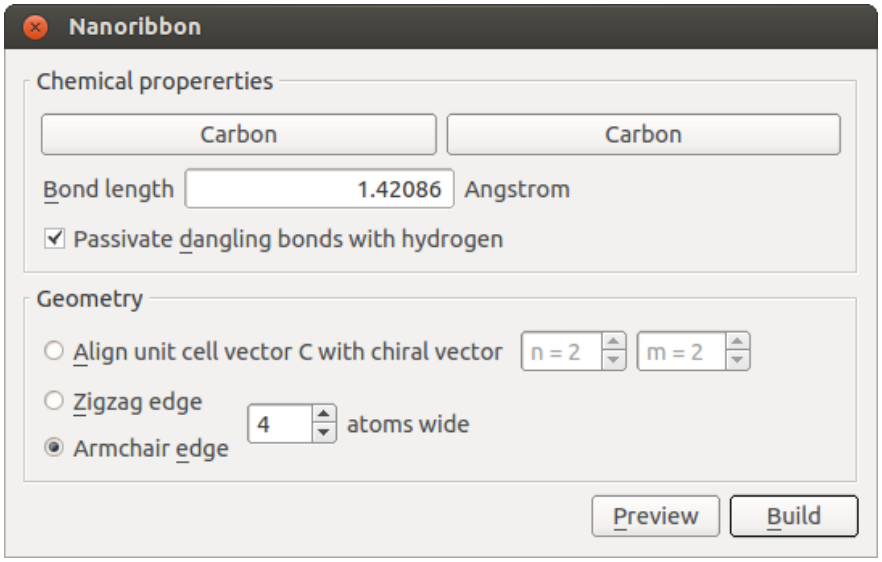
Open the **Builder** and do the following:

•Use the **Nanoribbon plugin** via *Add* → *From plugin* → *Nanoribbon* to create a graphene nanoribbon.

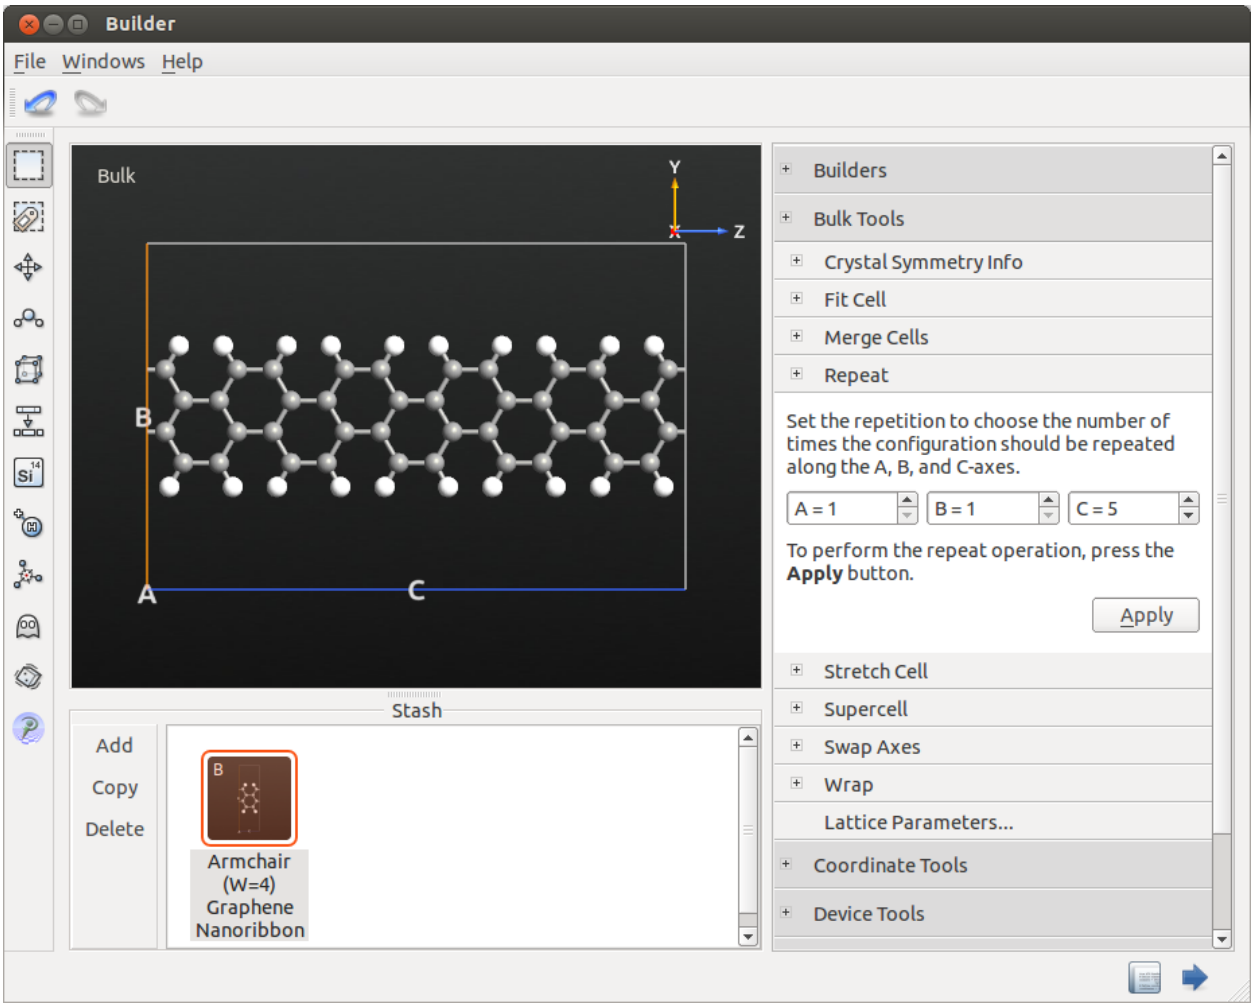
•Tick passivate dangling bonds with hydrogen atoms.

•Choose a width of 4 atoms.

•Choose armchair edge as the ribbon chirality.



•Use *Bulk Tools* → *Repeat* to repeat the ribbon 5 times along the C axis to create the central region.



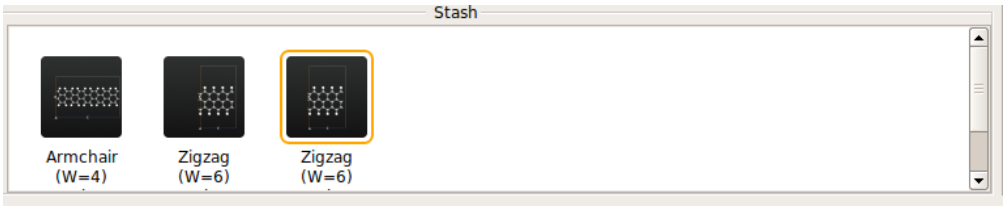
Electrodes

You are now ready to set up the two electrodes, consisting of two identical zig-zag nanoribbons.

•Again, create a ribbon from *Add* → *From Plugin* → *Nanoribbon*. This time you should select a 6 atoms wide zigzag edge nanoribbon.

•Repeat the bulk configuration 4 times along the C axis.

•In order to create two distinct electrodes, make a copy of the newly created zigzag nanoribbon in the Stash.



Merge the three components

Two steps a required:

1. You first create the z-shaped nanoribbon bulk configuration.
2. Then turn the bulk configuration into a **device configuration** used in first principles transport calculations.

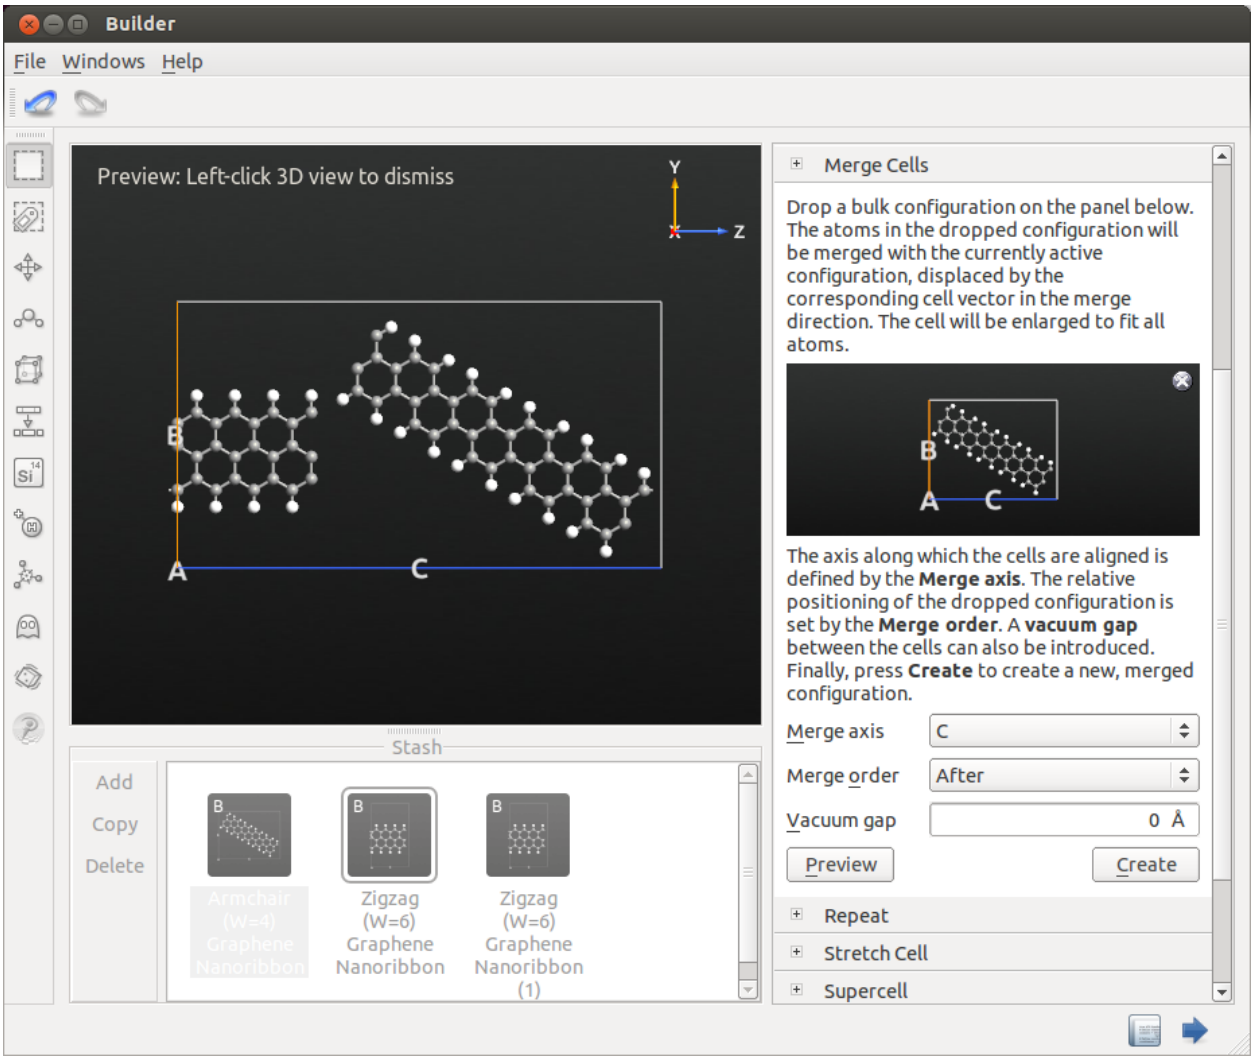
Z-shaped nanoribbon structure

You need to connect the armchair nanoribbon (central part) with the two zigzag nanoribbons (electrodes). First, rotate the central part by 30 degrees:

- Select the armchair nanoribbon from the Stash.
- Use *Coordinate Tools* → *Rotate* to rotate the central region 30 degree around the x axis.
- Go to *Bulk Tools* → *Fit Cell* and fix the cell along the B axis.

Now you can merge the three parts together:

- Select the left electrode by double clicking the configuration on the Stash.
- Select *Bulk Tools*→ *Merge* and drag the central region configuration from the Stash to the small window on the right side as shown below.
- Click **Create**.



•Select all the atoms belonging to the central region and activate the **Move Tool** in the tool bar.

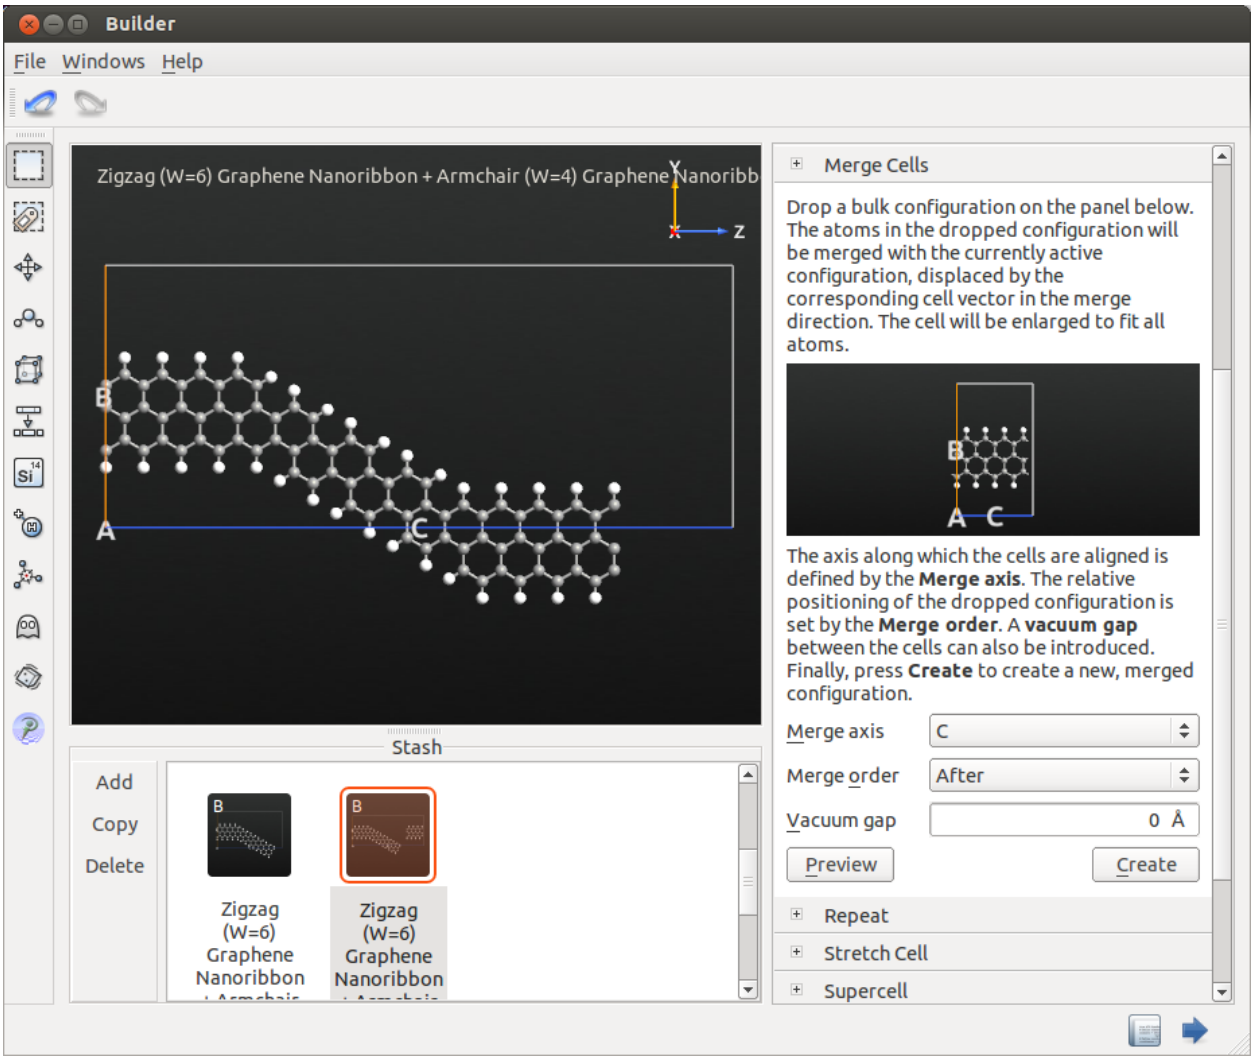
•Select the lower-left edge atom of the central region as shown below. This atom is now the anchor atom which means that all the other atoms will follow this atom when they are moved.

•Be sure that the **Snap** function is selected then drag your anchor atoms close to the right edge atom of your electrode.

•On the Move window you should now be able to see that two atoms are overlapping. Click **Fuse** to delete one atom for each pair of overlapping atoms.

•Close the Move window and **delete** the extra H between the two carbon atoms.

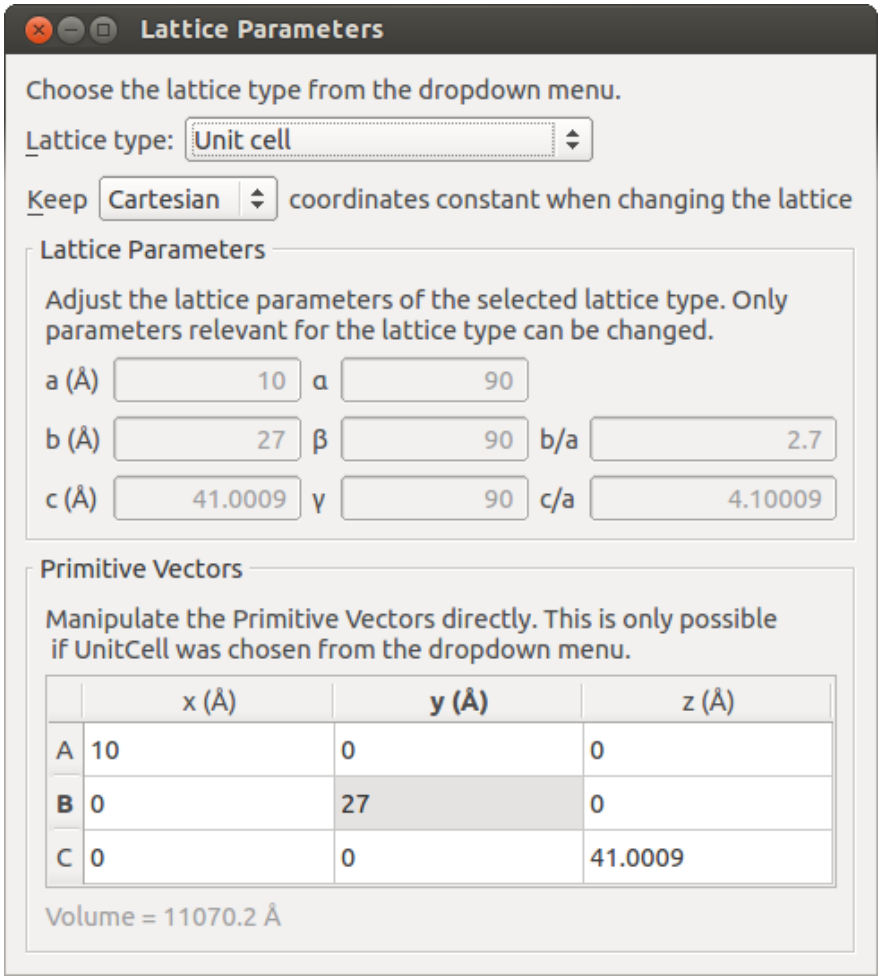
You now have a perfect junction between the left electrode and the central region. Repeat the procedure outlined above to attach the right electrode to the new configuration, and you will have finished the merge.



A proper unit cell

Create a proper unit cell and center the configuration in it:

•Open *Bulk Tools* → *Lattice parameter*, and increase the dimension of the B vector to 27 Å in order to assure sufficient vacuum above and below the configuration.



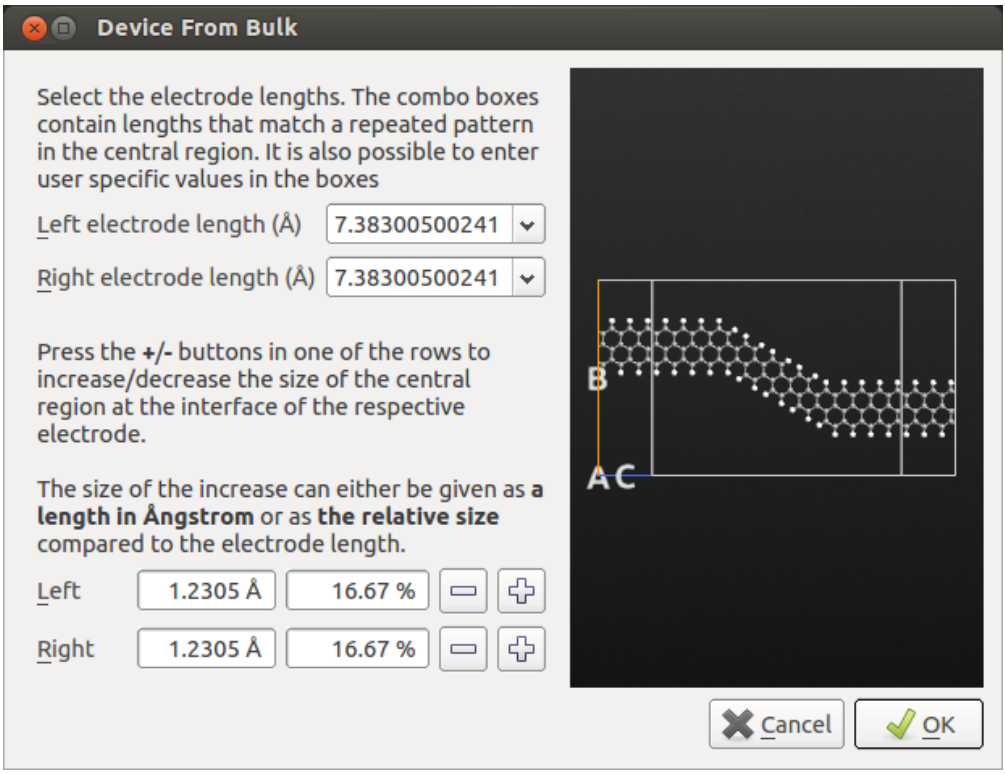
•Use *Coordinate* → *Center* plugin to center the configuration.

The bulk configuration is now finished.

Device from bulk

Transport calculations is a key feature of the QuantumATK platform. The **Device Tools** plugins help you to construct the device with electrodes and gates.

•Highlight the bulk configuration in the Stash, and use the *Device Tools* → *Device From Bulk* tool to construct the graphene nanoribbon device. The tool will automatically select appropriate electrode lengths.



Note: The required length of the electrode cell depends on the computational model employed. Strictly speaking, the length of the cell in the the C-direction should be longer than the interaction distance of the model. For most models a length of about 7 Å will suffice.

Gate and dielectric

Next, add the metallic gate and the dielectrice separator using the **Spatial Regions** tool:

•Open *Miscellaneous* → *Spatial Regions*.

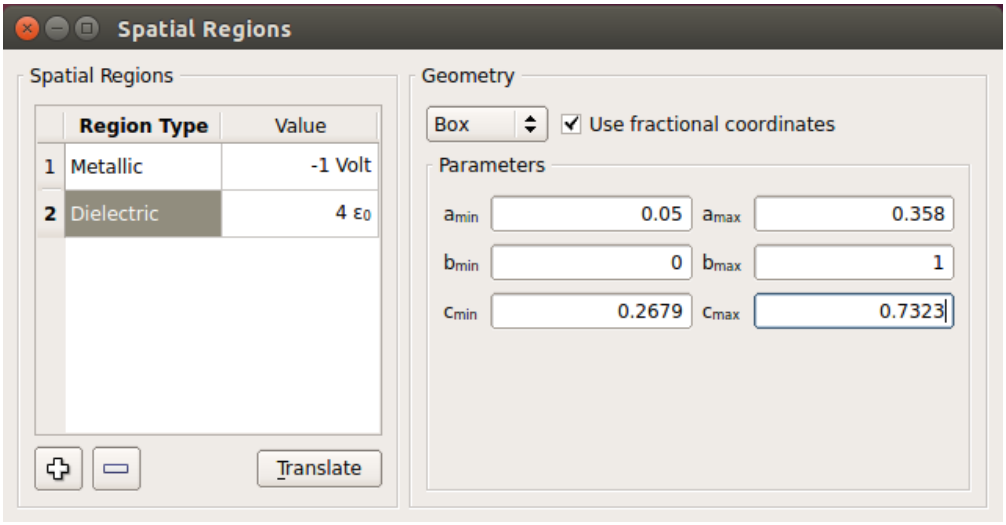
•Click to insert a new spatial region.

•Set the spatial region to be a *dielectric* region and set the dielectric constant to 4.0.

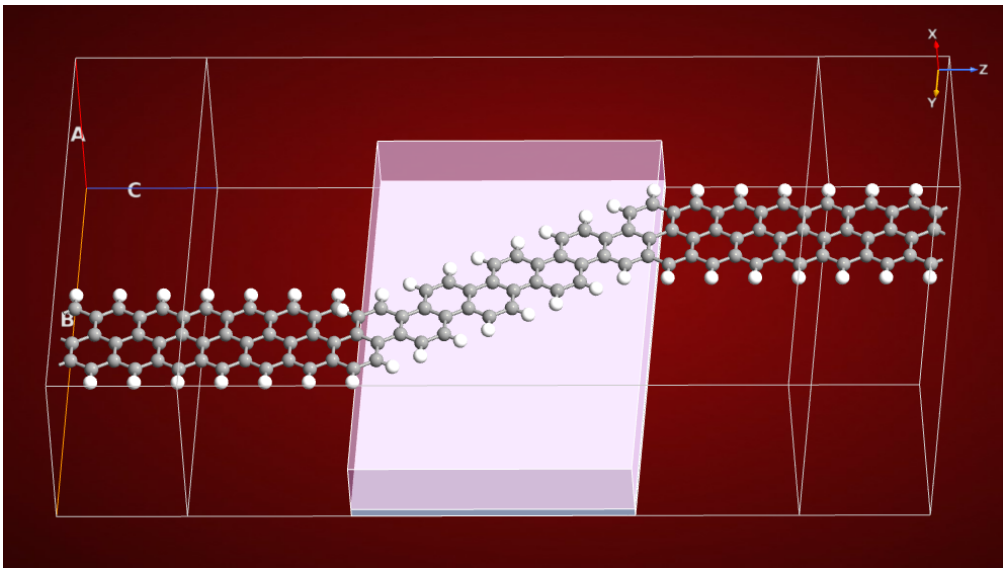
•Use the **fractional coordinate** fields to define the boundaries of the dielectric region: *a:0.05-0.358, b:0-1, c:0.2679-0.7323*.

•Add a second spatial region, set it to be metallic and set the gate potential to -1 V.

•Use the **fractional coordinate** to define the size of the metallic gate: *a:0-0.05, b:0-1, c:0.2679-0.7323*.



Finally, your device should look like illustrated below. You can download a script defining the device configuration here: `device.py`.



Tip: **What next?** You are now ready to perform some transport calculations! For example, check out the tutorial *Graphene nanoribbon device: Electric properties*. It shows you how to compute electron transport properties of the gated graphene nanoribbon device, including the electron transmission spectrum, I–V curve, electron thermal transport, and conductance.

You can also proceed to the next section to learn another way to build a nanoribbon transistor.

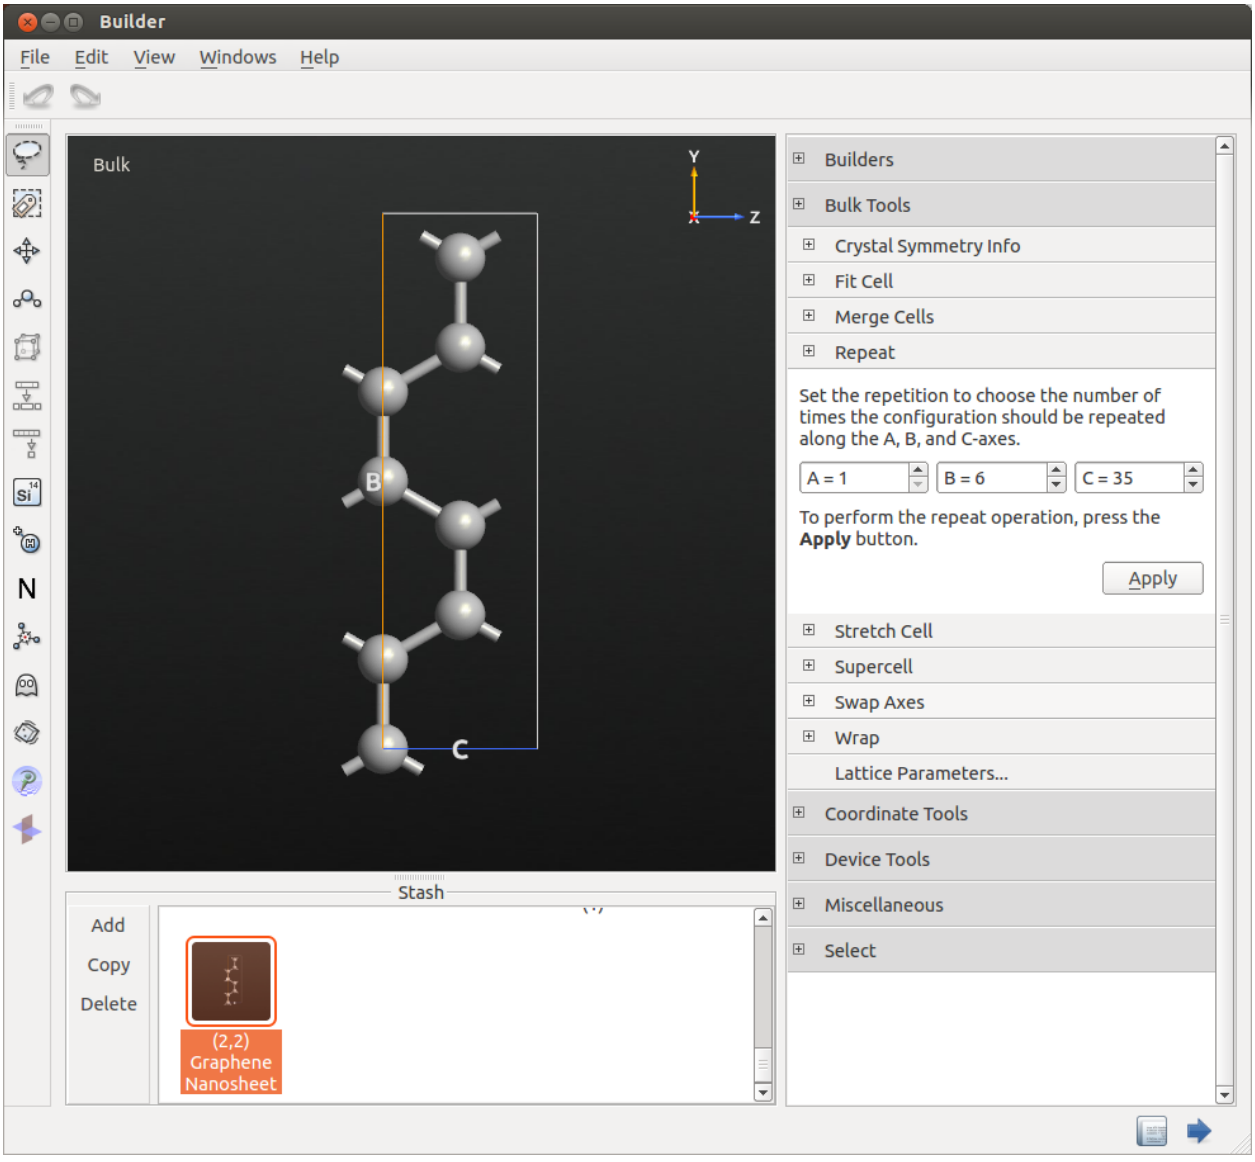
A longer nanoribbon transistor

There are of course several different ways to build a z-shaped graphene nanoribbon device with the QuantumATK Builder. The approach outlined above constructs the three parts of the device separately and then merge them together. Another possibility is to create the device by tailoring an extended graphene sheet. This approach is more flexible, because you can use it to cut out any kind of device based on your needs and imagination.

Use the following this procedure to build a long graphene nanoribbon transistor:

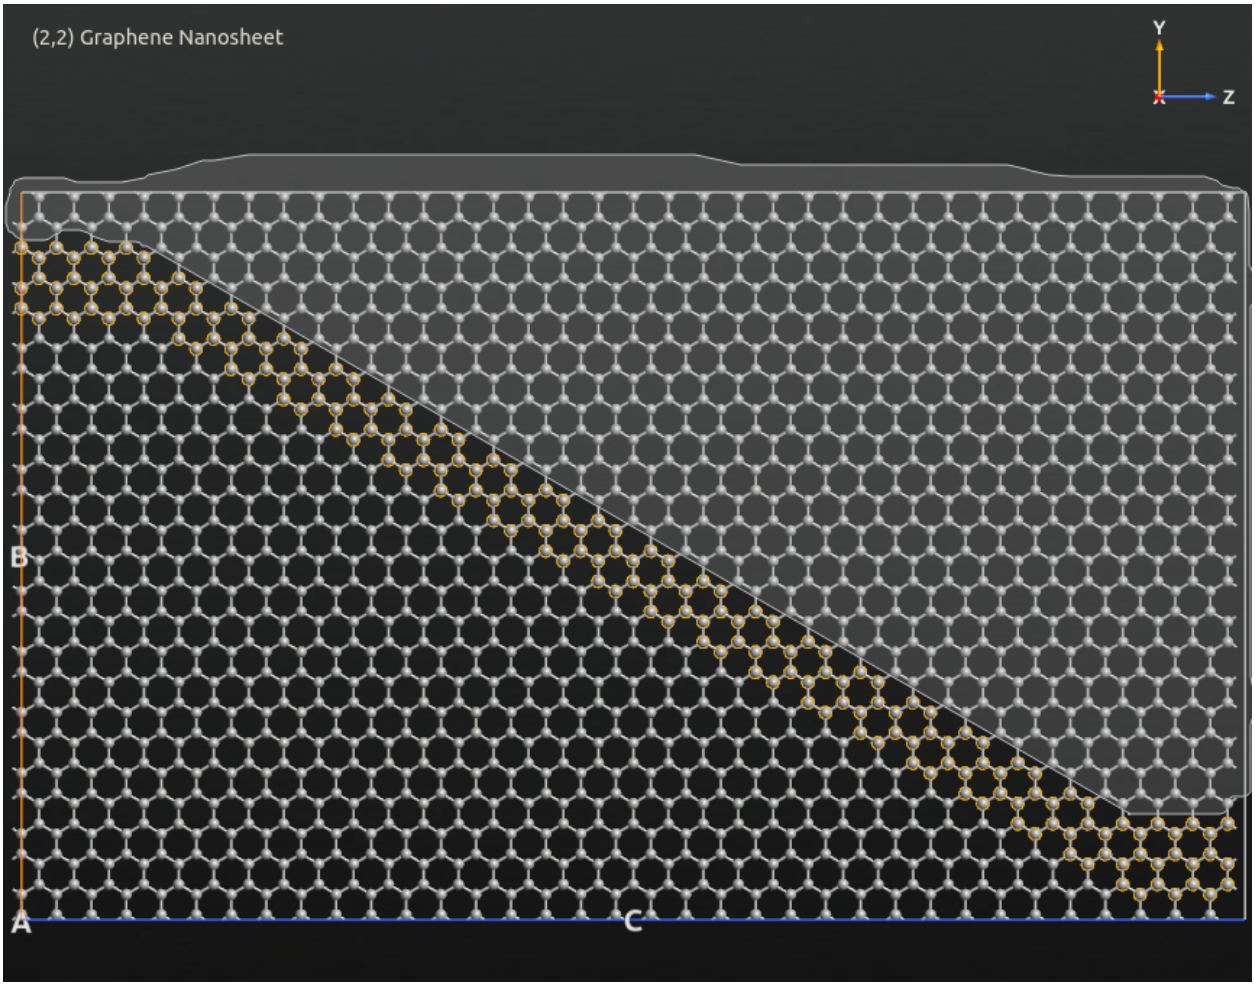
•In the Builder, insert a graphene sheet from *Add* → *From Plugin* → *Nanosheet*. Leave the default parameters unchanged and click **Build**.

•Use the *Bulk Tools* → *Repeat* plugin to repeat the sheet 1, 6 and 35 times along the A, B and C axes, respectively.

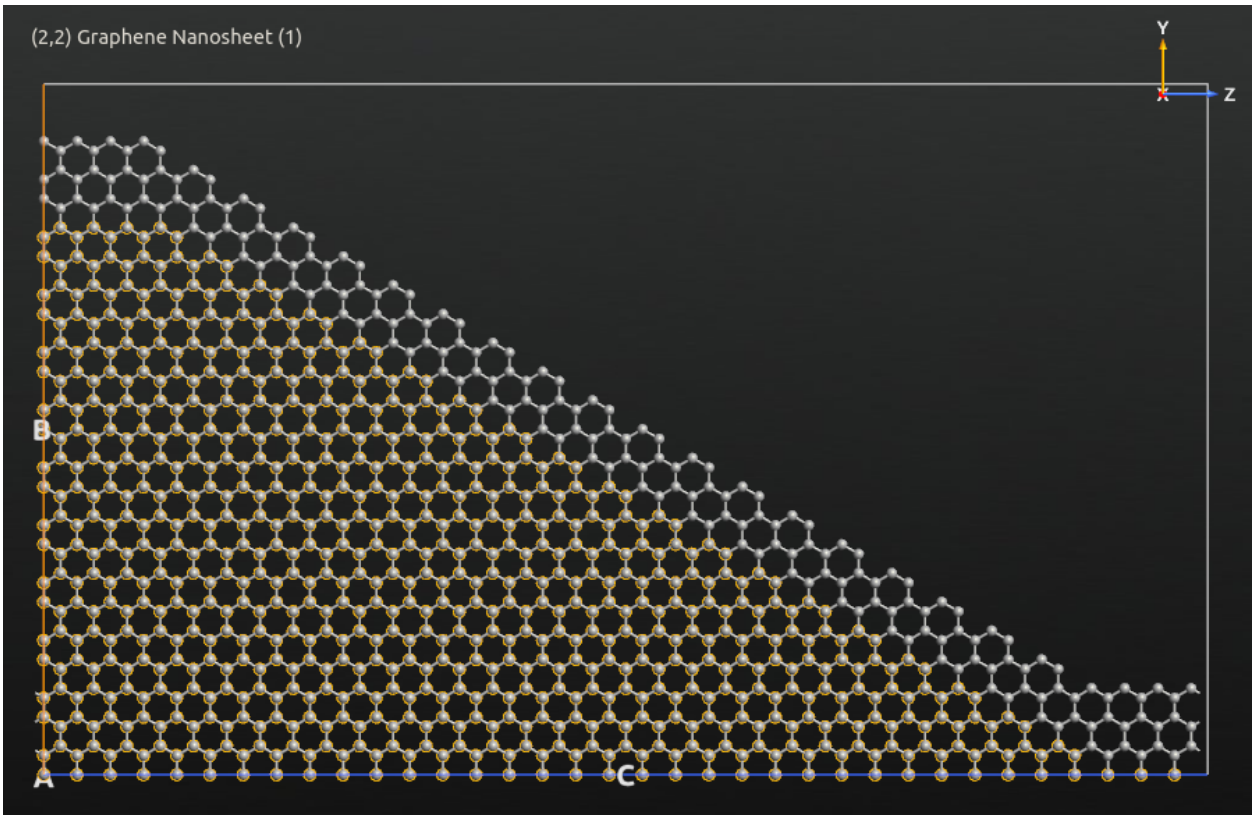


•Open the **Selection Tool** by clicking it and choose the **Lasso** from the pop-up list.

•Use the Lasso to select the regions of atoms you want to cut out, as shown below.



(2,2) Graphene Nanosheet
Y
Z
B
A
C



Tip: You can also use the *Select* → *By Expression* plugin. You will find this tool very handy in case of complicated but geometrically regular shapes. Click the How-To button for more informations about how to use and combine expressions.

To select the atoms that do not belong to the graphene device, use the two following expressions:

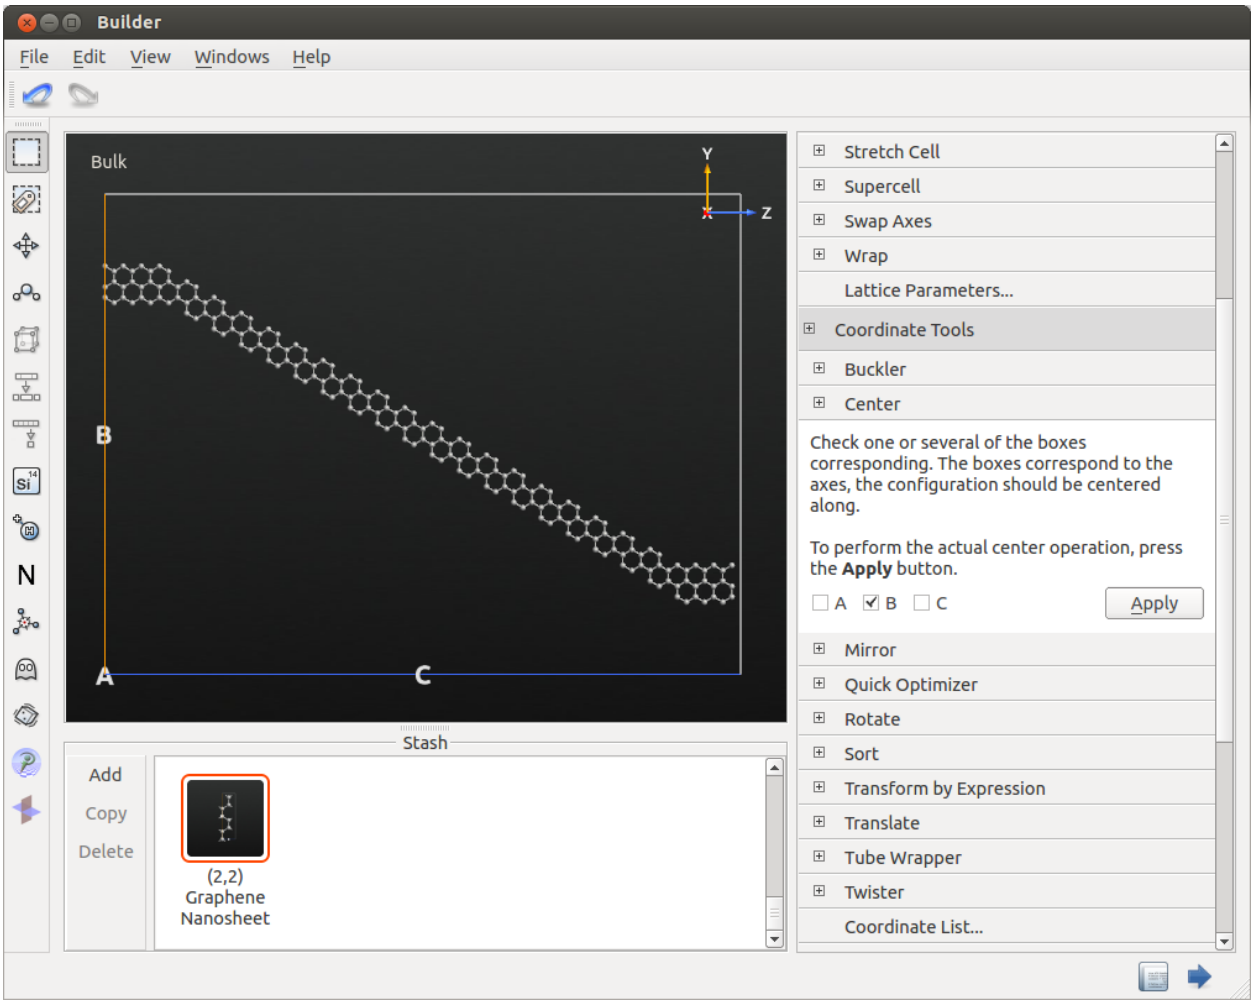
```
(y > 47) or (y > -0.577*z+52 and 7.39 < z and z < 77.5216) or (y > 6.40 and z > 77.5216)
```

```
(y < 1) or (y < -0.577*z+46 and 8.65 < z and z < 77.5216) or (y < 41.91 and z < 8.62)
```

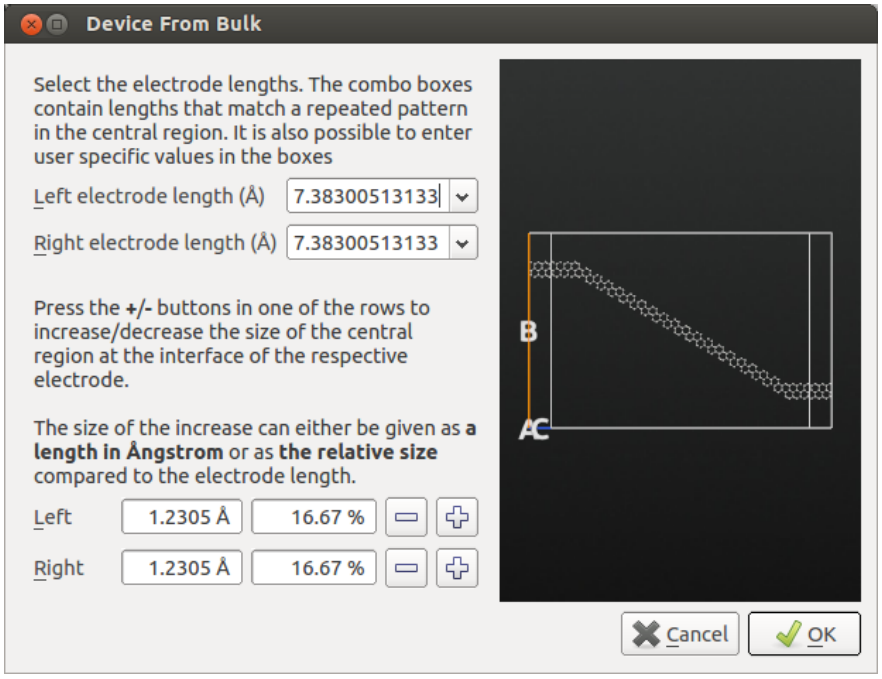
The first expression selects the atoms to delete in the upper part of the device, while the second expression selects the atoms to delete in the lower part.

Whatever method you choose to cut out the z-shaped device, you should now have a nice z-shaped ribbon. Add a bit of vacuum along the B direction:

- Open *Bulk Tools* → *Lattice Parameters* and increase the B vector dimension to 65 Å. Make sure to keep the Cartesian coordinates fixed in this step.
- Use the *Coordinate Tools* → *Center* tool to center the configuration along the B vector.

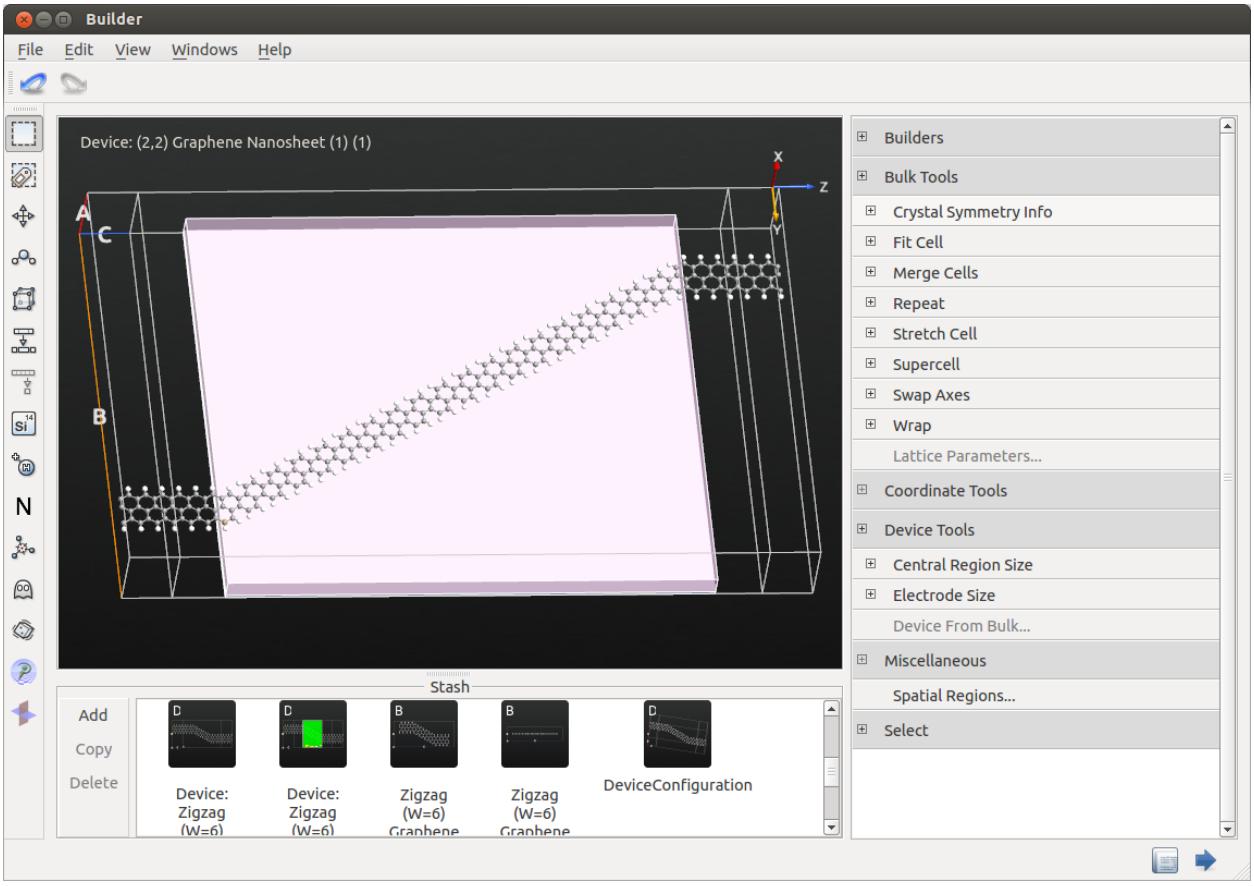


•Next, use the *Device Tools* → *Device From Bulk* tool to create the device configuration. The default electrode lengths are fine.



- The graphene nanoribbon needs to be hydrogen terminated at the edges. Use the Passivate tool to saturate all bonds by hydrogen atoms.
- Next, you should add the metallic gate and dielectric spacer. Open the *Miscellaneous* → *Spatial Regions* plugin and add two regions:
  - Metallic, -1 Volt, fractional coordinates: a:0-0.05, b:0-1, c:0.08-0.92
  - Dielectric, 4, fractional coordinates: a:0.05-0.045, b:0-1, c:0.08-0.92

  You have now created a long z-shaped graphene nanoribbon device on top of a dielectric and controlled by a metallic gate.



Tip: **What next?** The transistor you have just built is used in the second part of the tutorial *Graphene nanoribbon device: Electric properties*. Go directly to the relevant section by following this link: *Comparison to results for a longer device*.

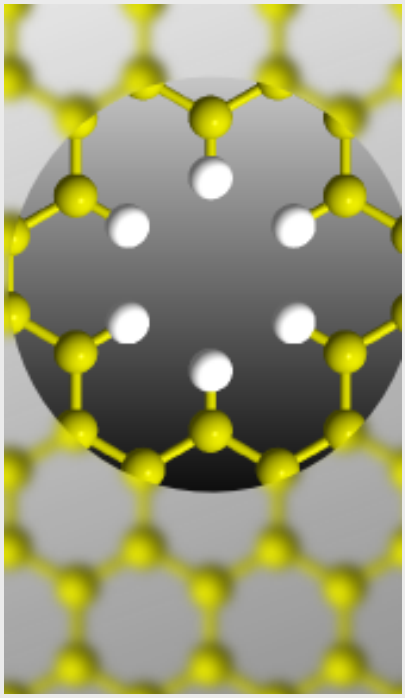
3.12.16 Nanosheet with a hole

QuantumATK: Nanosheet Platforms: *This quick tutorial shows you how to make a small defect in graphene, viz. a hole, and passivate it with hydrogen atoms to saturate all the bonds.*



Here are the instructions:

•**Step 1:** Click *Add* → *From Plugin* → *Nanosheet*.

•**Step 2:** Set **n=1, m=1** and click **Build**. This inserts a simple orthorhombic unit cell of graphene.

•**Step 3:** Use *Bulk Tools* → *Repeat* to make a larger structure. A repetition of 1x6x6 is suitable.

•**Step 4:** Press Ctrl+R in the plot window, to center the view.

•**Step 5:** Switch to the circle select tool .

•**Step 6:** Select a hexagon, press Delete on the keyboard.

•**Step 7:** Click the passivate button on the toolbar.

3.12.17 MoS_2 Nanotubes

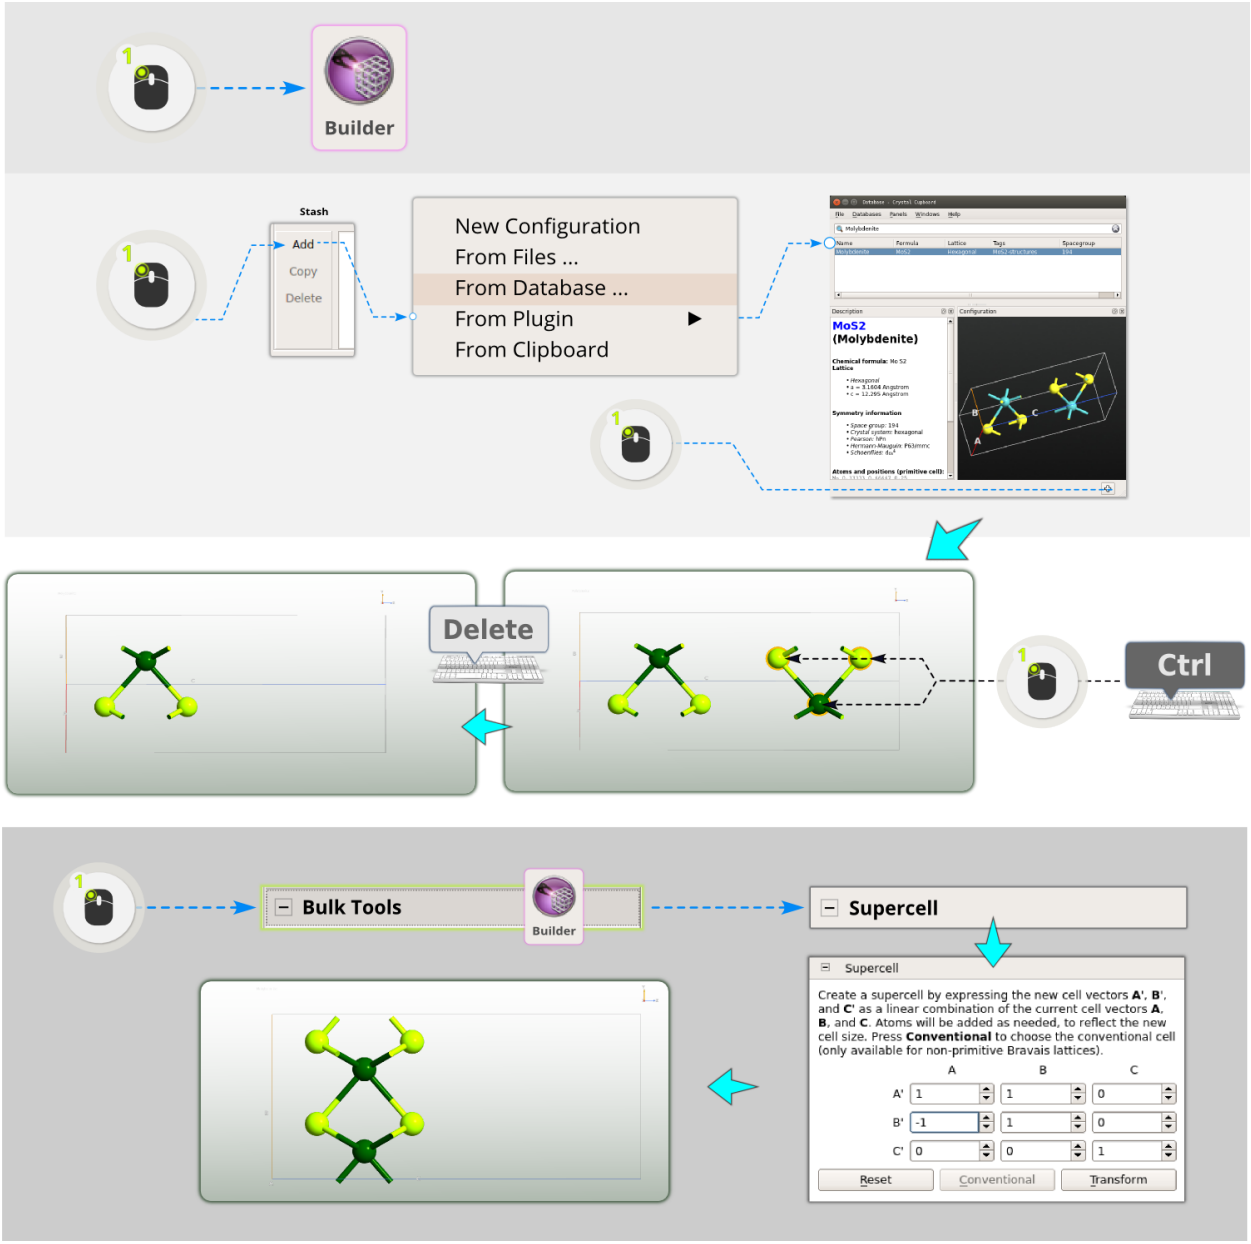
A logical approach seems to be to first make a hexagonal sheet, just like graphene, and then wrap it into the shape of a tube. Indeed, such a **TubeWrapper addon** has been developed, and in this tutorial you will learn how to use it to build MoS_2 and other transition metal sulfide TS_2 nanotubes (T = W, Nb, Re), see Refs.[1] and[2].

> **Attention:** The recipe is simple enough:
>
> 1. Create a bulk crystal of MoS_2.
> 2. Change it into a monolayer.
> 3. Wrap it using the **TubeWrapper addon**.
>
> This approach can then easily be adapted for other TS_2 structures.

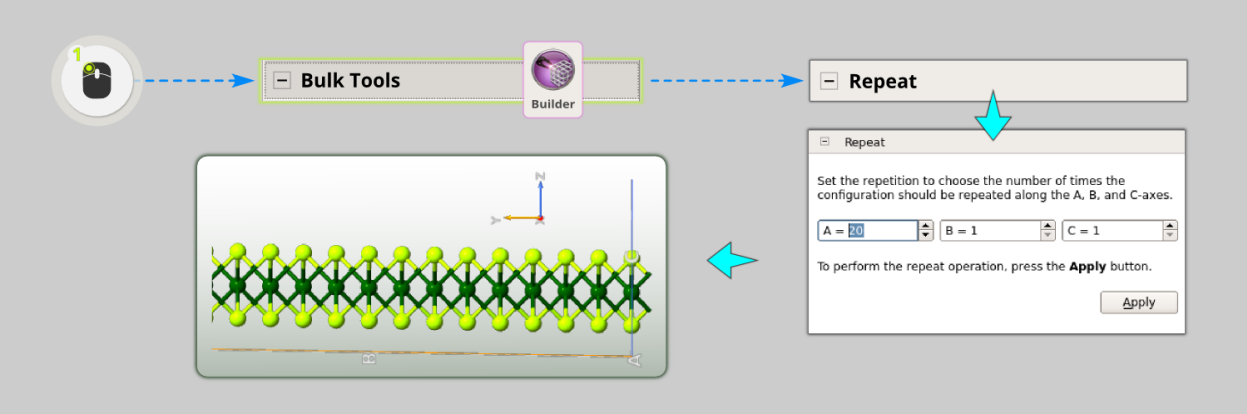
- **Step 1:** Download the `TubeWrapper.zip` file and install the addon following the instructions in the *AddOns* page.
- **Step 2:** Click *Add* → *Add from Database* and locate **molybdenite**. Add it to the Stash (clicking). Use the mouse to select and delete the three atoms to the right in the cell. This leaves a single layer of MoS_2. The cell is hexagonal cell, but to make the tube it is necessary to have an orthorhombic supercell to work with. Therefore, open *Bulk Tools* → *Supercell* and use the settings illustrated below.

[1] A.ăKuc, N.ăZibouche, and T.ăHeine. Influence of quantum confinement on the electronic structure of the transition metal sulfide TS2. *Phys. Rev. B*, 83:245213, Jun 2011. doi:10.1103/PhysRevB.83.245213.

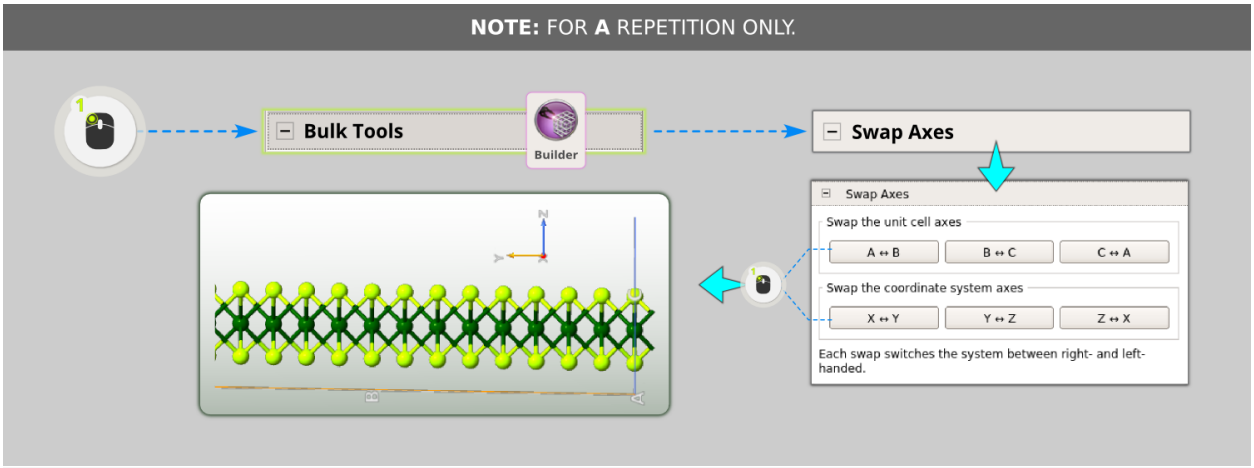
[2] Gotthard Seifert, Humberto Terrones, Mauricio Terrones, Gerd Jungnickel, and Thomas Frauenheim. Structure and Electronic Properties of MoS2 Nanotubes. *Phys. Rev. Lett.*, 85:146–149, Jul 2000. doi:10.1103/PhysRevLett.85.146.



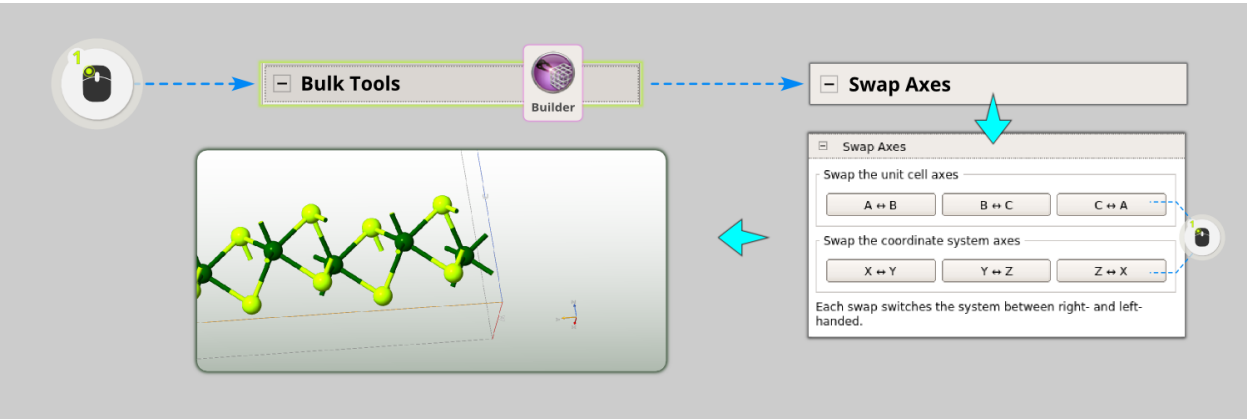
•**Step 3:** Open *Bulk Tools* → *Repeat*. You now have two choices: Repeat in **A** or **B** – this will give either armchair (A) or zigzag (B) tubes. Repeat some decent number, like 20 – the new size of the system in the repeated direction will directly determine the circumference of the tube.



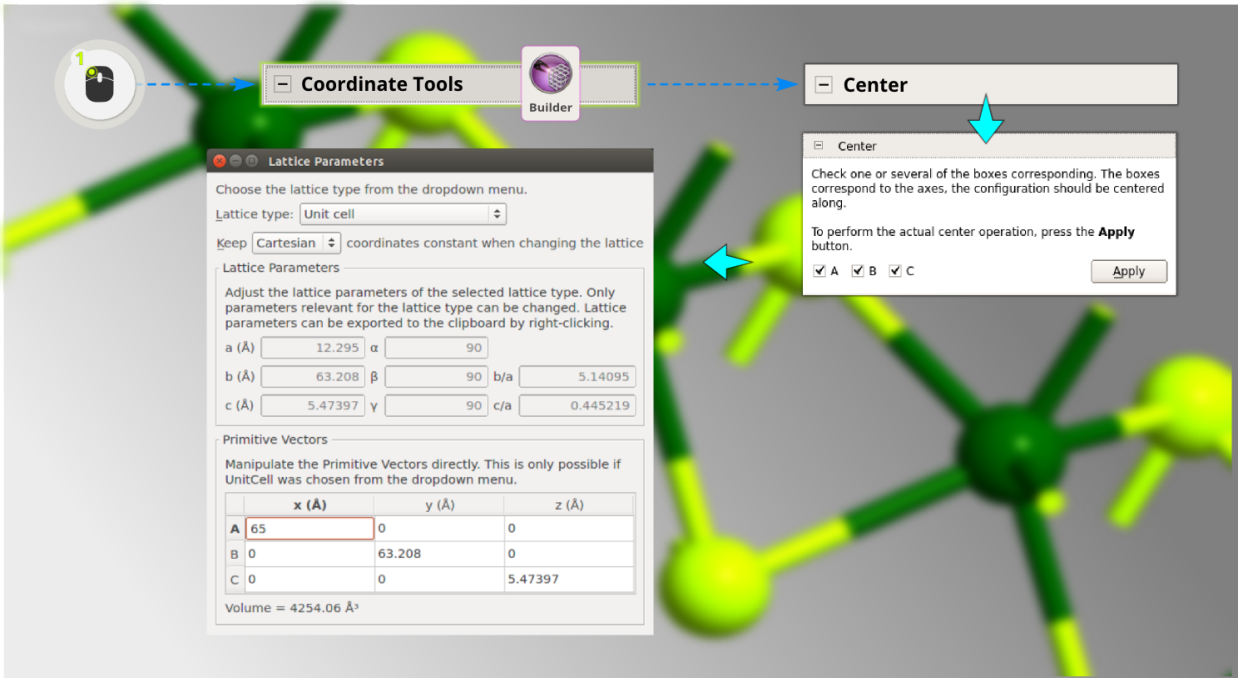
Note: **If you repeated in A**, use *Bulk Tools* → *Swap Axes* and click **A<->B** then **X<->Y** to reorient the system. If you repeated in B, skip this step.



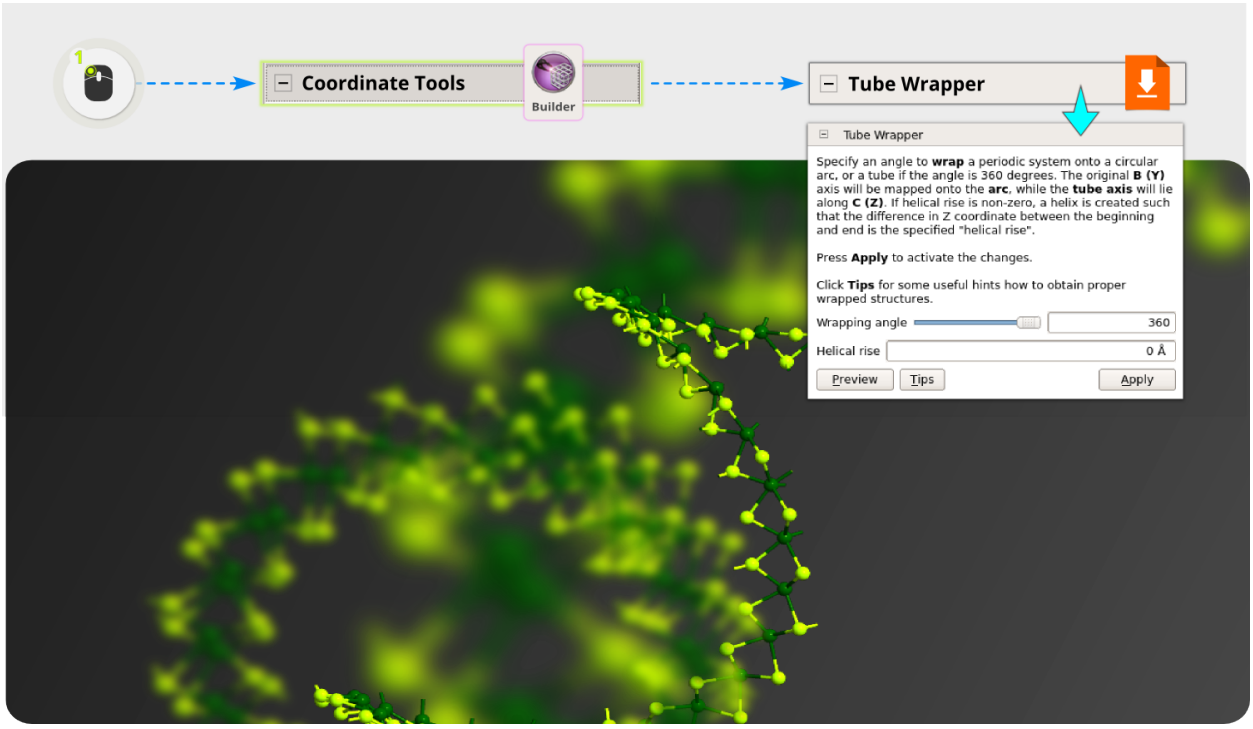
•**Step 4:** Using *Bulk Tools* → *Swap Axes*, click **C<->A** then **X<->Z** (do this regardless of whether you repeated in **A** or **B**):



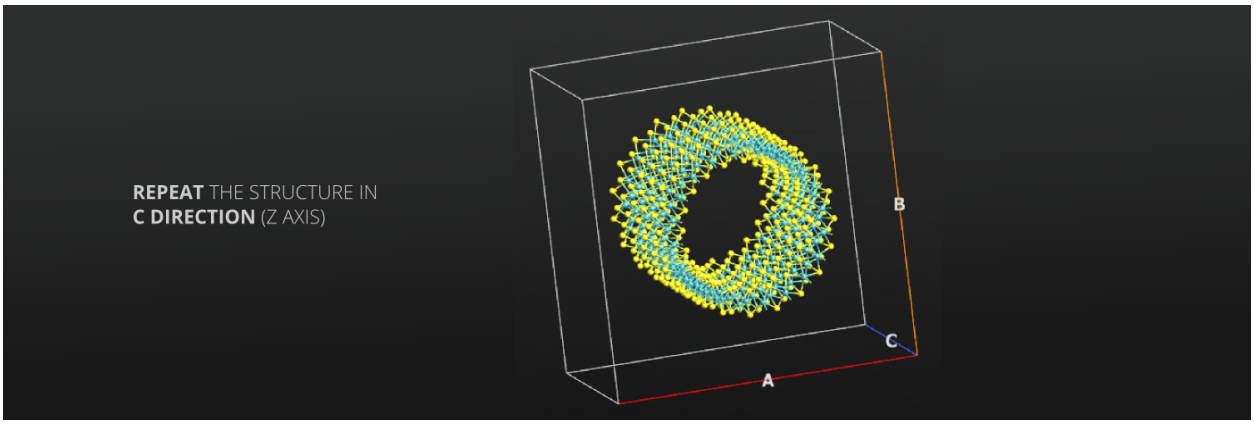
•**Step 5:** Open *Bulk Tools* → *Lattice Parameters* and select **Cartesian** coordinates. Then change the first cell vector **A** so that the size of the cell in X is at least as large as in Y. Open *Coordinate Tools* → *Center* and center the system.



•**Step 6:** Finally, open the plugin you just installed, *Coordinate Tools* → *Tube Wrapper* and wrap the tube. You can use 360 degrees directly to get a fully wrapped tube, or perhaps 180 degrees for some interesting novel work!



•**Step 7:** In the end, its a good idea to adjust the cell size (it was necessary to keep it large during the building procedure) and then center the system in **A** and **B** and afterwards repeat in z direction:



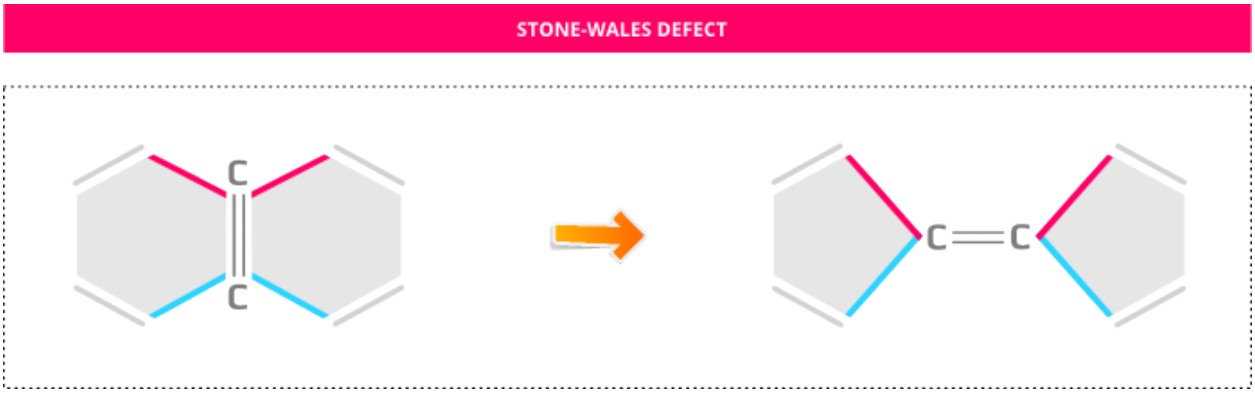
Tip: Whats next? Now you can perform calculations on MoS_2 nanotubes just as easily as CNTs. The DFTB model used in Ref.[Page 1821, 2] is also available in QuantumATK, and you can request the Mo/S parameters from , and run QuantumATK with those. How to install DFTB parameters is described in another tutorial: *The DFTB model in ATK-SE*.

You can of course also use the method outlined here to make carbon nanotubes, even though the dedicated plugin *Add → Add from Database → Nanotube* is much faster to use for a perfect, simple CNT. An interesting example where the Tube Wrapper plugin is anyway useful also for CNTs is for the creation of Stone–Wales defects, which are much easier to define in for a mololayer sheet than for the rolled-up tube. Or, you can make open or partially wrapped nanotubes.

References

3.12.18 Stone–Wales Defects in Nanotubes

A Stone–Wales defect changes the connectivity of two π-bonded carbon atoms by rotating them 90ř with respect to the midpoint of their bond, as illustrated below:



It is a crystallographic defect that occurs in e.g. nanotubes and graphene, and can have a strong influence on the electronic, chemical, and mechanical properties. It is named after Anthony Stone and David Wales of Cambridge University, who described it in a 1986 paper on fullerenes[1], but a similar defect was described much earlier by Peter Thrower in a paper on defects in graphite[2].

Note: You will create the Stone–Wales defect in graphene and then wrap it into a tube. You will therefore need the

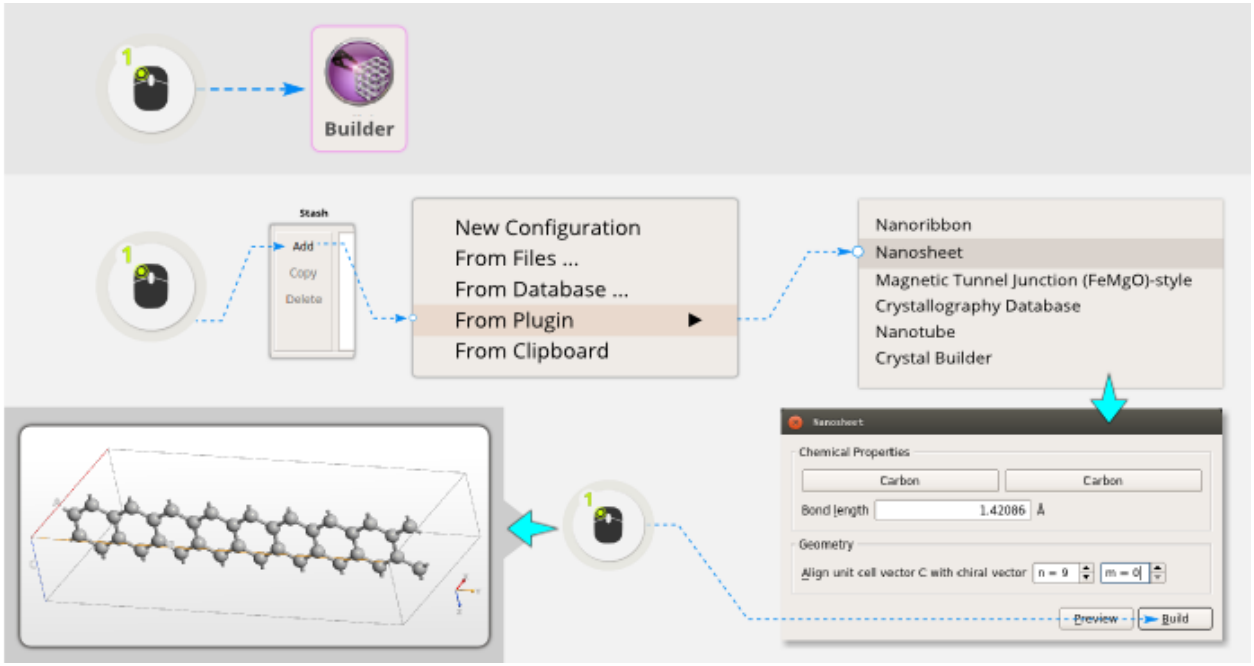
[1] A.J. Stone and D.J. Wales. Theoretical studies of icosahedral C60 and some related species . *Chemical Physics Letters*, 128(5-6):501–503, 1986. doi:10.1016/0009-2614(86)80661-3.

[2] P.ăThrower. The study of defects in graphite by transmission electron microscopy. *Chemistry and Physics of Carbon*, 5:217–320, 1969.

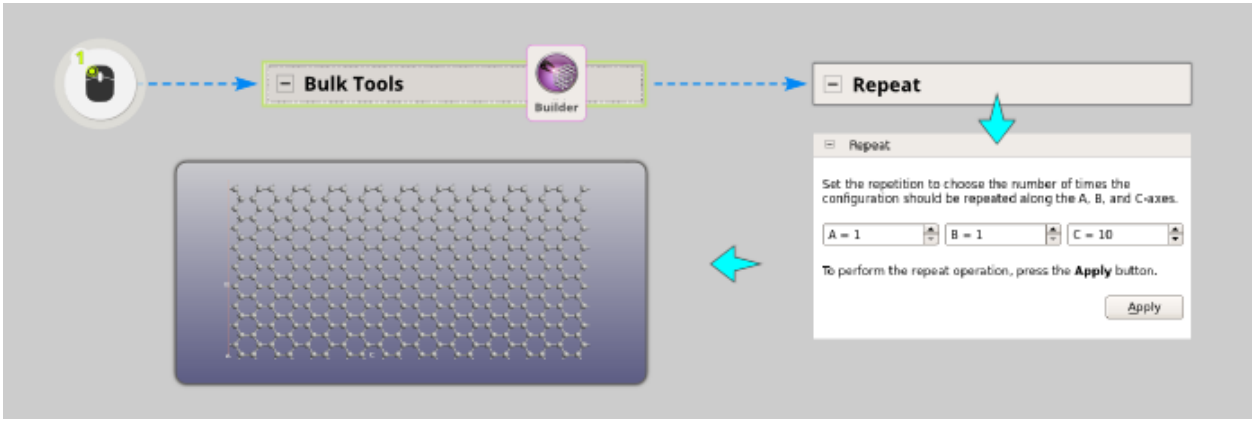
TubeWrapper addon. Download the `TubeWrapper.zip` file and install the addon following the instructions in the *AddOns* page.

Creating the defect and wrapping the tube

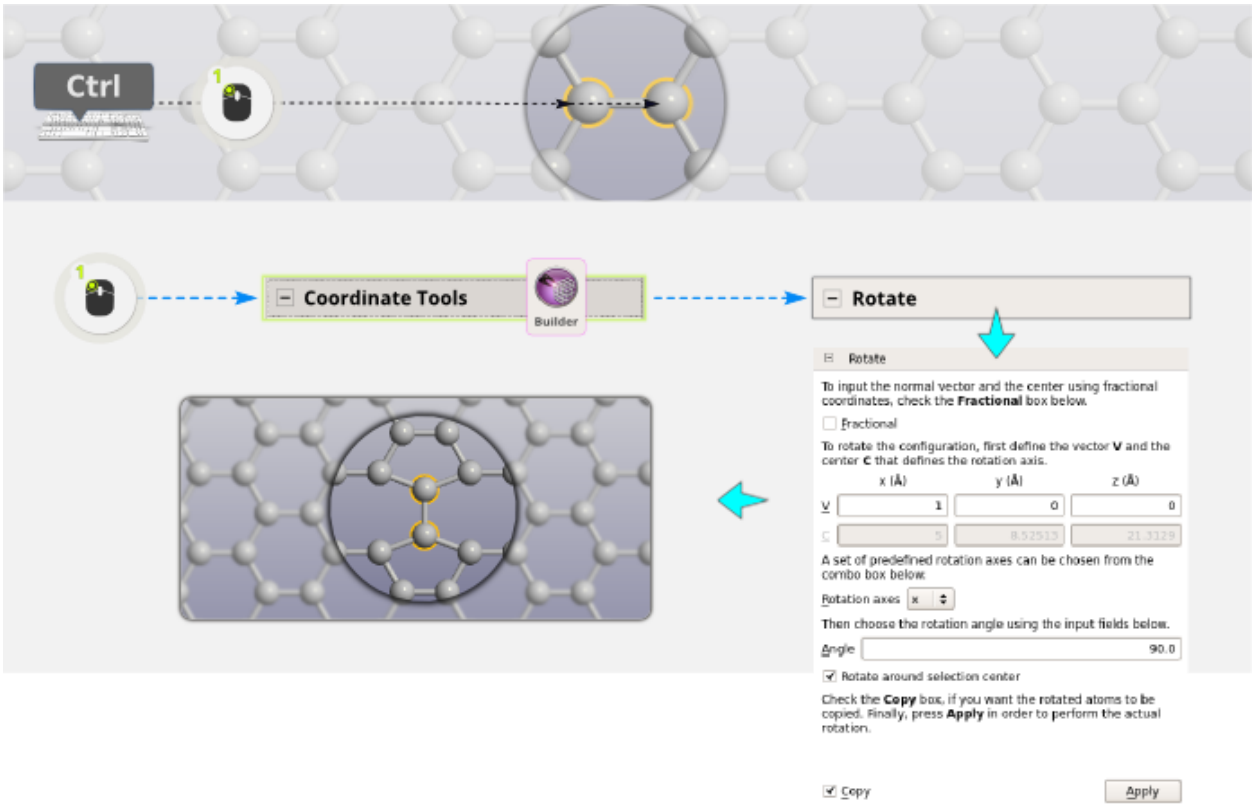
•**Step 1:** First create a graphene sheet by using the *Add* → *Add From Plugin* → *Nanosheet* plugin. Select **n=9** and **m=0** for the chiral indices, and click **Builder**.



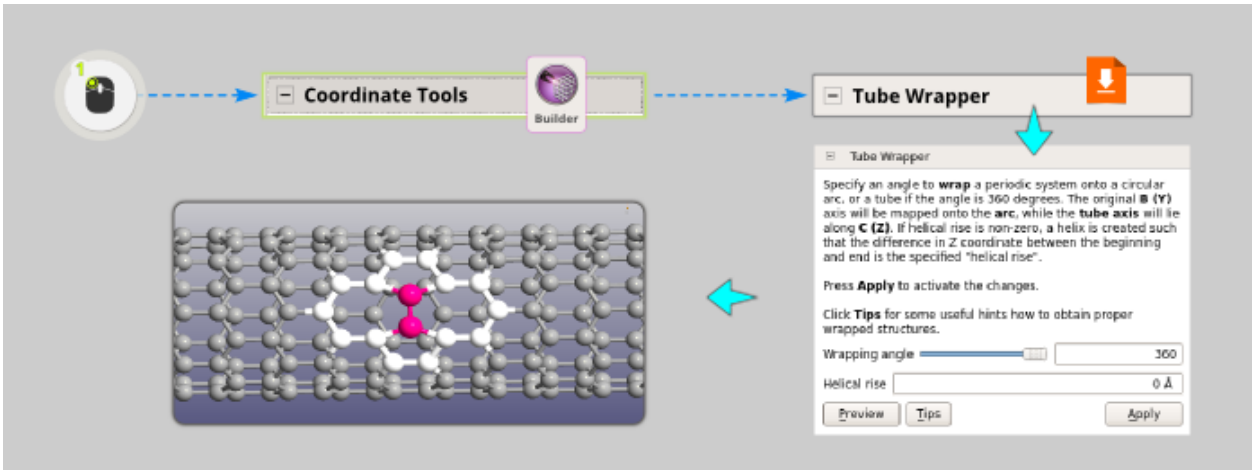
•**Step 2:** The purpose is to study an isolated defect, so it is necessary to make a large structure where a single carbon–carbon bond can be rotated. **Repeat** the configuration 10 times along the C direction using the *Bulk Tools* → *Repeat* tool, and press Ctrl+R to reset the view.



•**Step 3:** Next, **create the defect**: Select two atoms in the middle of the structure, and open the *Coordinate Tools* → *Rotate* tool. Select the rotation axis to be *X* (this is the default) and enter 90 degrees for the rotation angle. It is important that the checkbox *Rotate around selection center* is ticked. Then click **Apply**.



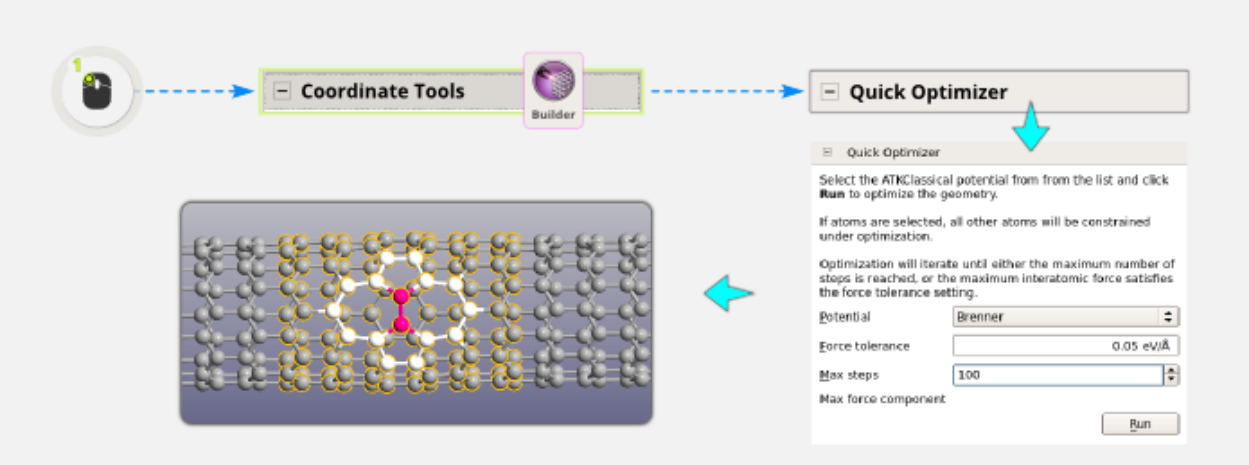
•**Step 4:** You can now **wrap** the graphene sheet into a tube. The sheet is periodic along the B and C directions. The tube axis should be along C, so the graphene sheet should be rolled up along B. Use the *Coordinate Tools* → *Tube Wrapper* tool to accomplish this; set the angle to 360 degrees and click **Apply**.



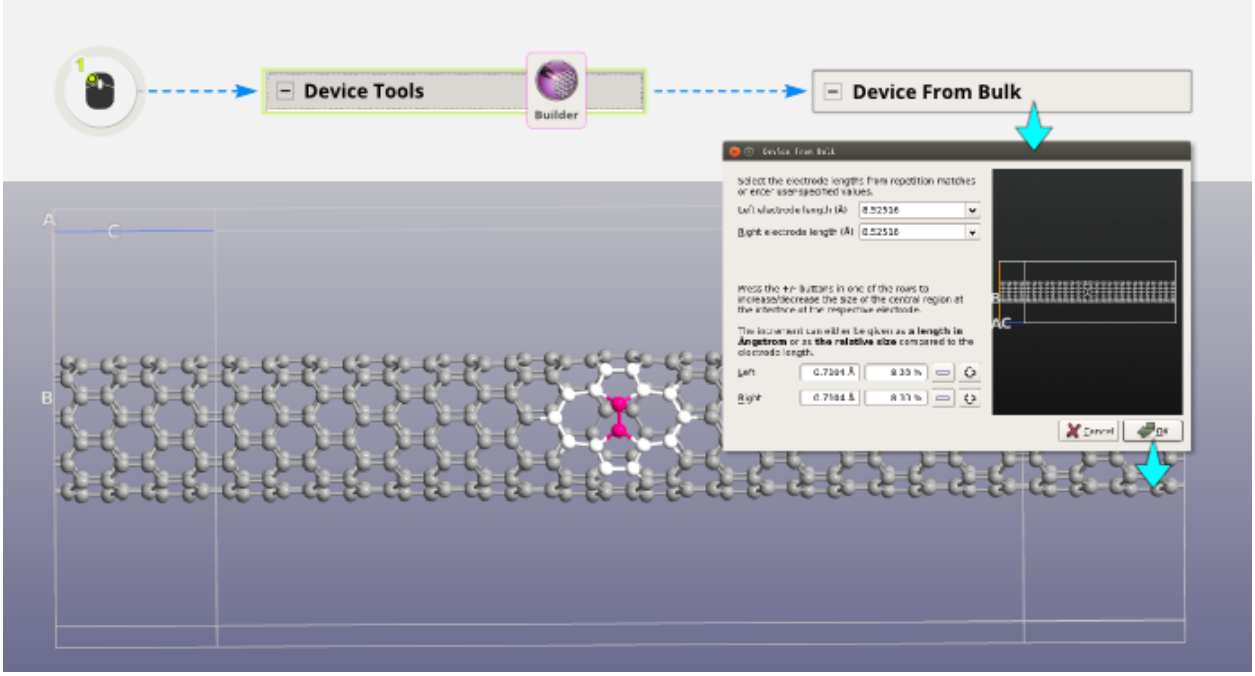
Optimizing the structure

The defect was created by a simple rotation of two carbon atoms, and is most likely not in its equilibrium shape. You should therefore geometry optimize the defect. The **ATK-ForceField** engine with the Brenner potential will provide a great starting point (conveniently available in *Coordinate Tools* → *Quick Optimizer*), but for a truly correct structure, you should run a full DFT optimization. In both cases, the ends of the tube should be constrained so they remain perfectly periodic, in order to use it for a device calculation later on.

Anyway, as a first approximation, select the defect atoms (white and pink in the figure below), and atoms immediately around the defect, to locally optimize the defect geometry. Use the **Quick Optimizer** with the Brenner potential (you will need to increase the number of steps to 100).



Then, convert the structure to a **device** using *Device Tools* → *Device From Bulk* (just click Create, the default settings are fine).



Save the device in a file (say) as **Device_stone.hdf5** in your project directory for other future calculations.

Transmission spectrum

Lets extract the transmission spectrum of the last device structure. This is a rather large device – the central region contains 360 atoms – but with the **ATK-SE** engine you can calculate the electron transmission spectrum in just a few minutes.

Use the Script Generator to create a Python script including a *Slater–Koster calculator* with the *Hancock.C ppPi* basis set and a *TransmissionSpectrum* analysis block. Then run the calculation using the Job Manager, and use the 2D Plot plugin to visualize the calculated transmission spectrum.

The resulting transmission spectrum is also available for download: `Device_stone.hdf5`.

E (eV)
Transmission spectrum
T(E)

The transmission spectrum is shown above. It was computed using the Hancock single-band tight-binding model with up to 3rd nearest neighbor interactions from Ref.[3]. A perfect (9,0) tube would have a step-like transmission spectrum around the Fermi level, but the defect introduces strong scattering and significantly modifies the electronic transmission. This will most certainly have a noticeable influence on the I-V curve.

Tip: You can easily calculate the corresponding I-V curve: Simply start a new Script Generator session and use **Analysis from File** and the **IVCurve** analysis object to create the script. Plot the results using the **IV-Plot** plugin.

You can also calculate the transmission spectrum and I-V curve for the defect free (9,0) nanotube and compare to the results found above.

CHAPTER

FOUR

MANUAL

4.1 General

4.1.1 Introduction

QuantumATK packages a powerful set of tools for calculating properties of nano-scale systems. These *atomic-scale calculators* are based on density functional theory, semi-empirical tight binding, and classical potentials. The non-equilibrium Greens function method is a unique feature of QuantumATK; it allows simulations on nano-scale devices and interfaces, including support for non-zero bias between the electrode leads and device components such as electrostatic gates and dielectrics. More information may be found at the QuantumATK website.

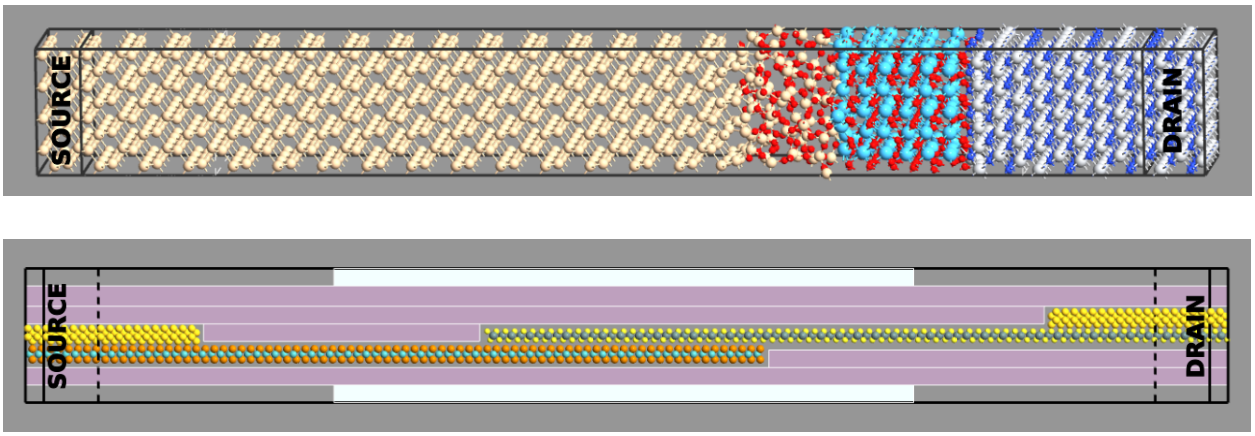

Fig. 4.1: Typical device systems; a high-k metal gate stack (top) and a field-effect transistor made of 2D materials (bottom), both with left and right semi-infinite electrode leads. One unique capability of QuantumATK is to simulate the electron transport through such two-probe systems. Gate electrodes may be included as non-current-carrying electrostatic gates (bright regions in the 2D-FET above), and regions of a particular dielectric constant may also be defined (pink regions in the 2D-FET above). One-probe systems with only a single electrode are also supported.

ATK is controlled using *ATK-Python*, which is an extension to the well-established Python scripting language. Setting up and executing QuantumATK calculations is therefore done in an ATK-Python script or directly from the command line in an interactive Python shell.

The main purpose of this manual is to document all QuantumATK functionality. The *QuantumATK Reference Manual* therefore gives a detailed summary of all input and output parameters, as well as notes on relevant theory and usage examples.

We also provide a thorough exposition of the theoretical background for the atomic-scale simulators implemented in QuantumATK (see *Atomic-Scale Calculators*), and a detailed introduction to Python scripting and using *ATK-Python* to control QuantumATK (see *Python in QuantumATK*).

For tutorials on how to use QuantumATK we refer to the Tutorials website.

New in QuantumATK X-2025.06

The X-2025.06 release of QuantumATK introduces a range of new features and performance improvements and an overview is given here: Release Overview. For a comprehensive list, see the full release notes, which can be found on the SolvNet portal.

Tip: For the full list of changes, see the release notes for the feature release, i.e. X-2025.06. The release notes for a service pack release will only list the changes relative to the feature release.

Installing and running the software

The QuantumATK binary installer is available for registered users at the SolvNet software portal. Access to a valid QuantumATK license is also needed. Detailed instructions are given in the Installation Guide. Note that a license is required and if your institution does not already have a license, you can request an evaluation license via the Synopsys Eval Portal.

When QuantumATK has been installed on your machine you can run it from the command line using the **atkpython** executable and a QuantumATK Python script. The executable should be in your `PATH` and is available here: `.../QuantumATK-VERSION/bin/atkpython`.

Parallel execution

ATK supports multi-level parallelism, using the Message Passing Interface (MPI) available on most supercomputing clusters for distributed memory parallelism, and OpenMP for shared memory parallelism. QuantumATK ships with Intel MPI, which you can find here: `.../QuantumATK-VERSION/mpi/bin/mpiexec.hydra`

How to read this manual

This manual is typeset using in-line references to QuantumATK Python objects and functions, and contains several script examples. The following style conventions are used:

- All QuantumATK objects and functions appear as links, e.g. *`MoleculeConfiguration`*. The link will take you to the relevant section of the *QuantumATK Reference Manual*, where a detailed description of the object MoleculeConfiguration is provided.
- References to particular chapters and sections are also links. For example, the links sect1.python.loops and sect1.python.tuples direct you to specific sections in the chapter *Python in QuantumATK*.
- Boldface letters are used to highlight specific words, e.g. **atkpython**, while in-line names of Python variables, functions, parameters, and methods are in general typeset using a monospace serif, e.g. `list_of_atoms` for a Python variable and `cartesianCoordinates()` for a method of the *`MoleculeConfiguration`* object.
- In-line names of files and directories are also typeset using a monospace serif, e.g. `file.txt` and `$HOME/QuantumATK/`.
- Python structures are visually enclosed in a box and typeset using a monospaced serif:

```
# This is a comment

for i in range(3):
    print(i)
```

Scripts can often be downloaded by following a link, e.g. `example_code.py`.

•Instructions for using the command line are indicated by the $ prefix:

```
$ atkpython script.py
```

while instructions for using an interactive Python session is indicated by the »> prefix:

```
>>> myList = [1, 2, 3, 4, 5]
>>> print(myList)
[1, 2, 3, 4, 5]
>>> print(len(myList))
5
```

4.2 Atomic-Scale Calculators

4.2.1 DFT: LCAO

Introduction

QuantumATK can model the electronic properties of closed and open quantum systems within the framework of **density functional theory (DFT)** using numerical LCAO basis sets (linear combination of atomic orbitals). For periodic systems, QuantumATK can also use the plane-wave basis set for DFT calculations, as discussed in *DFT: Plane Wave*.

The key parameter in the self-consistent calculation of the Kohn–Sham equations is the **density matrix**, which defines the electron density. For open systems, the density matrix is calculated using non-equilibrium Greens functions (NEGFs), see *NEGF: Device Calculators*, while for closed or periodic systems it is calculated by diagonalization of the Kohn–Sham Hamiltonian, as described in the present chapter. The electron density then sets up an effective potential, which is given by the Hartree, exchange-correlation, and external potentials. Knowing the effective potential allows us to obtain the Kohn–Sham Hamiltonian.

Information about provided pseudopotentials (SG15, PseudoDojo), pre-built LCAO basis sets sizes (medium, high, ultra) and their speed and accuracy against all-electron reference and DFT-PlaneWave calculations can be found in the QuantumATK reference paper by Smidstrup *et al.*[1]. The next section describes the mathematical formalism behind the DFT-LCAO model.

Background information

The *LCAOCalculator* provides a description of electronic structure using DFT and norm-conserving pseudopotentials. The method is based on an expansion of the single-particle wave functions in a basis of numerical atomic orbitals with compact support. In this section, we describe the mathematical formalism of the DFT-LCAO calculator, which closely follows the work of Soler *et al.*[2].

Kohn–Sham Hamiltonian

Within density functional theory, the many-body electronic structure of the system is described in terms of the one-electron Kohn–Sham Hamiltonian:

$$\hat{H}_{\mathrm{1el}} = -\frac{\hbar^2}{2m}\nabla^2 + V^{\mathrm{eff}}[n](\mathbf{r}).$$

In this equation, the first term is the kinetic energy of the electron, while the second term (the effective potential) is the potential energy of the electron moving in the mean field created by the other electrons as well as in any external potential field, e.g. the electrostatic potential of ions or any other external field. The electrons are described in terms of the total electron density, $n = n(\mathbf{r})$.

The electron density is discussed in detail in the section *Electron density*, and the effective potential in the section *Effective potential*.

Solving the Kohn–Sham equations by means of a basis set expansion

We calculate the one-electron eigenfunctions of the Kohn–Sham Hamiltonian, ψ_α, by solving the one-electron Schrödinger equation,

$$\hat{H}_{\mathrm{1el}}\psi_\alpha(\mathbf{r}) = \varepsilon_\alpha\psi_\alpha(\mathbf{r}).$$

This differential equation is called the Kohn–Sham equation within DFT. To solve it, we expand the eigenfunctions $\psi_\alpha(\mathbf{r})$ in a set of basis functions, ϕ_i:

$$\psi_\alpha(\mathbf{r}) = \sum_i c_{\alpha i}\phi_i(\mathbf{r}).$$

This allows us to represent the differential equation as a matrix equation for determining the expansion coefficients, $c_{\alpha i}$:

$$\sum_j H_{ij}c_{\alpha j} = \varepsilon_\alpha \sum_j S_{ij}c_{\alpha j},$$

where the Hamiltonian matrix, $H_{ij} = \langle\phi_i|\hat{H}_{\mathrm{1el}}|\phi_j\rangle$, and overlap matrix $S_{ij} = \langle\phi_i|\phi_j\rangle$ are given by the multiple integrals with respect to the electron coordinates.

Electron density

The electron density of the many-electron system is given by the occupied eigenstates of the Kohn–Sham Hamiltonian:

$$n(\mathbf{r}) = \sum_\alpha f_\alpha|\psi_\alpha(\mathbf{r})|^2,$$

where f_α is the occupation of the level denoted by α. For finite temperature calculation the occupations are determined by the Fermi-Dirac distribution $f_\alpha = \frac{1}{1+e^{(\epsilon_\alpha-\epsilon_F)/kT}}$ but other smooth distributions may be introduced in order to help speed convergence (see *Occupation Methods*).

The electron density can then be expressed in terms of the density matrix:

$$n(\mathbf{r}) = \sum_{ij} D_{ij}\phi_i(\mathbf{r})\phi_j(\mathbf{r}),$$

where the density matrix is given by the basis set expansion coefficients $c_{\alpha i}$:

$$D_{ij} = \sum_\alpha f_\alpha c^*_{\alpha i}c_{\alpha j}.$$

Note: For open systems (*DeviceConfiguration*), the density matrix is calculated using non-equilibrium Greens functions, see *NEGF: Device Calculators*.

Electron difference density

It is often convenient to compare the electron density of the many-body system to a superposition of individual atom-based electron densities, $n^{\mathrm{atom}}(\mathbf{r}-\mathbf{R}_\mu)$, where $\mathbf{R}_\mu$ is the position of atom μ in the many-body system:

$$\Delta n(\mathbf{r}) = n(\mathbf{r}) - \sum_\mu n^{\mathrm{atom}}(\mathbf{r}-\mathbf{R}_\mu).$$

Δn is called the electron difference density, and it is calculated using the *ElectronDifferenceDensity* analysis object.

Effective potential

The effective potential, $V^{\mathrm{eff}}[n]$, has three contributions:

$$V^{\mathrm{eff}}[n] = V^H[n] + V^{\mathrm{xc}}[n] + V^{\mathrm{ext}}.$$

The first two terms are due to electron–electron interactions, which depend on the electron density. The first term, $V^H[n]$, is the Hartree potential due to the mean-field electrostatic interaction between the electrons, while the second term, $V^{\mathrm{xc}}[n]$, is the exchange-correlation potential, which arises from the quantum mechanical nature of the electrons.

The potential V^{ext} represents any other electrostatic fields in the system. It can be separated into two contributions; the electrostatic potential of ions (given by norm-conserving pseudopotentials) and external electrostatic fields (given by one or more external sources).

External potential

The external potential is given by the pseudopotentials and an external electrostatic field. Such a field may arise from the inclusion of metallic gates:

$$V^{\mathrm{ext}} = \sum_\mu V_\mu^{\mathrm{pseudo}} + V^{\mathrm{gate}}.$$

The pseudopotential has two contributions:

$$V^{\mathrm{pseudo}} = V^{\mathrm{local}} + \sum_{n,n'} |\chi_n\rangle B_{n,n'} \langle\chi_{n'}|,$$

where the first and second terms correspond to the local and nonlocal part of the pseudopotential, respectively.

The term V^{gate} is the electrostatic potential due to external gates, calculated with zero electron density. This term will be returned by the Analysis object `ExternalPotential` and is calculated using the `MultigridSolver`, `DirectSolver` and `ParallelConjugateGradientSolver` Poisson solvers. The Analysis object `ElectrostaticDifferencePotential` also includes this term, among others.

Hartree potential

Using the electron density, we can calculate the classical electrostatic potential, the so-called Hartree potential. The actual calculation of the Hartree potential is described in detail in the section *Poisson solvers*.

Exchange-correlation potential

In the DFT method, the quantum mechanical part of the electron–electron interaction is approximated by the exchange-correlation term, and a large number of different approximate exchange-correlation density functionals exist. ATK supports many of these, see the section *Exchange-correlation energy*.

The exchange-correlation potential is defined as the functional derivative of the exchange-correlation energy with respect to the electron density, which corresponds to a mean-field quantum mechanical interaction potential between the electrons:

$$V^{\mathrm{xc}}[n](\mathbf{r}) = \frac{\delta E^{\mathrm{XC}}}{\delta n}(\mathbf{r}).$$

Total energy and forces

The DFT total energy of a many-electron system is a functional of the electron density, n:

$$E[n] = T[n] + E^{\mathrm{xc}}[n] + E^{H}[n] + E^{\mathrm{ext}}[n],$$

where $T[n]$ is the kinetic energy of a non-interacting electron gas with density n, $E^{\mathrm{xc}}[n]$ the exchange-correlation energy, $E^{H}[n]$ the Hartree potential energy, and $E^{\mathrm{ext}}[n]$ the interaction energy of the electrons in the electrostatic field created by ions and other external sources.

The electron kinetic energy may be defined as

$$T[n] = \sum_{\alpha} f_{\alpha} \langle \psi_{\alpha} | \frac{-\hbar^2}{2m} \nabla^2 | \psi_{\alpha} \rangle.$$

The total energy is calculated using *TotalEnergy*.

First-principles forces are calculated by differentiating the total energy with respect to the ionic coordinates of atom i at position $\mathbf{R}_i$:

$$\mathbf{F}_i = -\frac{dE[n]}{d\mathbf{R}_i}.$$

Pseudopotentials

QuantumATK uses norm-conserving pseudopotentials and PAW potentials, and is shipped with a database for the entire periodic table. See the full list here: *Pseudopotentials*. This database is reviewed and updated on a regular basis to provide increasingly accurate and general-purpose pseudopotentials and PAW potentials.

QuantumATK uses the unified pseudopotential format (`upf`) defined by the Quantum ESPRESSO consortium. From their website, one may download tools to convert several different pseudopotential formats into a `upf` file.

LCAO basis set

The eigenfunctions of the Kohn–Sham Hamiltonian can be expanded in a Linear Combination of Atomic Orbitals (LCAOs):

$$\phi_{nlm}(\mathbf{r}) = R_{nl}(r)Y_{lm}(\hat{\mathbf{r}}),$$

where Y_{lm} are spherical harmonics, and R_{nl} are radial functions with compact support, being exactly zero outside a confinement radius.

Note: The basis set functions have a finite range, but the interaction range of the Hamiltonian is larger than that of the basis set. Theoretically, the Hamiltonian interaction range may exceed twice the basis set range, but is usually smaller in practice.

The basis orbitals have a number of parameters that determine the shape of the orbitals. It is possible to assemble the basis orbitals into your own basis set through the use of the *BasisSet* keyword.

QuantumATK comes with a number of pre-built basis sets for each chemical element and for each type of pseudopotential. See the full list here: *LCAO basis sets*

Exchange-correlation energy

The QuantumATK package use the libxc library for providing a large suite of exchange-correlation functionals. For each functional it is possible to add a Hubbard correction, as described in the section *XC+U mean-field Hubbard term*.

The main families of exchange-correlation functionals supported in QuantumATK are the *Local-density approximation (LDA)*, the *Generalized-gradient approximation (GGA)*, and the *Meta-GGA*. Each functional comes in four spin variants:

- non-polarized,
- spin-polarized (collinear),
- noncollinear,
- noncollinear with spin-orbit coupling.

Important: The choice of spin variant for the exchange-correlation functional determines the spin type used in all of the DFT-LCAO calculation.

Furthermore, a Hubbard correction can be added to all exchange-correlation variants, regardless of spin type, see *XC+U mean-field Hubbard term*. Several standard GGA functionals can also be extended with the *DFT-D2* and *DFT-D3* dispersion corrections by Grimme and co-workers.

Initial spin

Both collinear and noncollinear calculations may have local minima of the total energy that correspond to different spin configurations. It is therefore important to prepare the system in the correct initial spin configuration, such that the DFT self-consistent calculation will end up in the lowest energy spin configuration. This is done through the use of the methods *InitialSpin* and *RandomSpin*. The initial spin direction on each atom is specified in physical spherical coordinates (r, θ, ϕ), where θ is the angle with the z-axis, and ϕ the polar angle in the x-y plane relative to the x-axis. The collinear case is $\theta = 0$ Radians or $\theta = \pi$ Radians.

Local-density approximation (LDA)

In the LDA approximation, the exchange-correlation energy is taken as a functional of the local electron density,

$$E^{\mathrm{LDA}}[n] = \int n(\mathbf{r})\varepsilon^{\mathrm{LDA}}(n(\mathbf{r}))d\mathbf{r},$$

where $\varepsilon^{\mathrm{LDA}}(n(\mathbf{r}))$ is the exchange-correlation energy density of a homogeneous electron gas with density $n(\mathbf{r})$.

It is possible to derive an exact, analytical expression for the exchange energy of the homogeneous electron gas, the so-called Dirac–Bloch exchange energy, which is used for all the LDA functionals. The correlation energy of the electron gas cannot be calculated exactly, so a number of different approximations have been proposed over the years. Most of them give almost identical results; the most commonly used variant is the parametrization by Perdew and Zunger, which is also the default LDA functional in *DFT: LCAO*.

For a list of the parametrizations for the LDA correlation functional implemented in QuantumATK, see the documentation of the *ExchangeCorrelation* class. In particular, the section *Abbreviations* explains how to select a particular exchange-correlation functional. See also Table 4.7, Table 4.10, and Table 4.11.

Generalized-gradient approximation (GGA)

The GGA functionals is a large family of semi-local approximations for the exchange-correlation energy, where the functional depends on both the local value and the local gradient of the electron density,

$$E^{\mathrm{GGA}}[n] = \int n(\mathbf{r})\varepsilon^{\mathrm{GGA}}(n(\mathbf{r}), \nabla n(\mathbf{r}))d\mathbf{r}.$$

For a list of the GGA exchange-correlation functionals available in QuantumATK, see the documentation of the *ExchangeCorrelation* class. In particular, the section *Abbreviations* explains how to select a particular exchange-correlation functional. See also Table 4.8, Table 4.10, and Table 4.11.

Meta-GGA

The meta-GGA (MGGA) family of functionals extend the GGA approximation by additionally depending on one or both of the following quantities: the Laplacian of the density

$$\nabla^2 n(\mathbf{r})$$

and the so-called kinetic energy density

$$\frac{1}{2}\sum_{\alpha} f_\alpha \left|\nabla\psi_\alpha(\mathbf{r})\right|^2.$$

For a list of the MGGA exchange-correlation functionals available in QuantumATK, see the documentation of the *ExchangeCorrelation* class. In particular, the section *Abbreviations* explains how to select a particular exchange-correlation functional. See also Table 4.9, Table 4.10, and Table 4.11.

Different formulations of the MGGA can produce functionals with different uses. The SCAN functional has been found to give improved energetics over the LDA and GGA in several cases; however, band gaps are similar.

Conversely, the TB09 functional can provide a much more accurate description of band gaps than ordinary LDA and GGA. In fact, the accuracy of semiconductor band gaps obtained with TB09 are often comparable to those from calculations using GW or hybrid functionals, which have a significantly higher computational cost. It is even possible to tune the TB09 method such that it works optimally on both sides of an interface (see *ExchangeCorrelation*). Alternatively, one can use the *Hubbard U model* within the LDA or GGA with the U parameters for the semiconductor elements fitted against TB09 results.

However, TB09 is not meant for energetics, and, hence, geometry optimizations are disabled with this functional. For this, the GGA or other MGGA functionals should be used.

XC+U mean-field Hubbard term

The local approximations to the exchange-correlation energy have a number of shortcomings. Two of these are of particular interest:

- **Self-interaction:** The electron is formally allowed to interact with itself. This can prevent electrons from localizing properly.
- **Excited states:** The LDA and GGA description of conduction-band energy levels is often poor, so band gaps are often too low.

The mean field Hubbard correction by Dudarev *et al.*[3] and Cococcioni *et al.*[4], often denoted XC+U, DFT+U, LDA+U, or GGA+U, is a semi-empirical correction which attempts to improve on these deficiencies of the local exchange-correlation functionals by adding an extra term to the exchange-correlation functional:

$$E_U = \frac{1}{2}\sum_{\mu} U_\mu (n_\mu - n_\mu^2).$$

In this equation, n_μ is the projection onto an atomic shell and U_μ is the **Hubbard U** for that shell. The E_U energy term is zero for a fully occupied or unoccupied shell, while positive for a fractionally occupied shell.

The energy is thereby lowered if states become fully occupied or empty. This may happen if the energy levels move away from the Fermi Level, increasing the band gap, or if the broadening of the states is decreased, the electrons are then more localized. Thus, the Hubbard U method improves on the deficiencies of the local exchange-correlation functionals listed above.

The value of U is often used as an empirical parameter, which is varied in order to improve the comparison between DFT and experimental data. However, it is also possible to calculate the U using either linear response theory with the function *calculateFiniteDifferenceLinearResponseHubbardU* or using the local screened Coulomb correction (LSCC) approximation with the function *calculateLocalScreenedCoulombCorrectionHubbardU* .

Some caution must be taken when using the XC+U correction, since for large U values the electron density may have several local minima where some of them are unphysical, and it is often necessary to select an anisotropic initial electron state to reach the correct local minimum.

XC+U implementations in QuantumATK

The XC+U implementation in QuantumATK comes in four main variants; a standard local-orbital formulation, so-called **Onsite** representation, and the **Dual** representation introduced by Han *et al.*[5]. The difference between the two implementations is in the definition of the local occupation matrix. The occupations may be summed over a single orbital or over an entire angular momentum shell, the latter corresponds to the **OnsiteShell** and **DualShell** representations.

Onsite representation

In the onsite representation, the local occupation matrix is given by

$$n^{\sigma}_{\mu,mm'} = D^{\sigma}_{\mu m,\mu m'},$$

where D is the density matrix, μ a basis orbital index, and σ a spin index.

OnsiteShell representation

In the onsite shell representation, the occupation is obtained by summing together all the basis functions in each angular momentum shell, l:

$$n^{\sigma}_{l,mm'} = \sum_{\mu \in l} n^{\sigma}_{\mu,mm'}.$$

Dual representation

In the dual representation, the local occupation matrix is given by

$$n^{\sigma}_{\mu,mm'} = \sum_{i,n} \left[S_{\mu m,in} D^{\sigma}_{in,\mu m'} + D^{\sigma}_{\mu m,in} S_{in,\mu m'} \right],$$

where S is the overlap matrix.

DualShell representation

Similar to the onsite shell representation, the dual shell occupation is obtained by summing up all dual occupations in each angular momentum shell, l:

$$n^{\sigma}_{l,mm'} = \sum_{\mu \in l} n^{\sigma}_{\mu,mm'}.$$

[5] M.ăJ. Han, T.ăOzaki, and J.ăYu. O(N) LDA+U electronic structure calculation method based on the nonorthogonal pseudoatomic orbital basis. *Phys. Rev. B*, 73:045110, Jan 2006. doi:10.1103/PhysRevB.73.045110.

Which model to use?

The onsite representation corresponds to projecting into a local orbital, and since the local orbitals are non-orthogonal, there are no sum rules for the occupation matrix and it is not guaranteed that a fully occupied shell has occupation 1.

In the dual representation, the occupation matrix has the form of a Mulliken population, and this form has the advantage that sum rules apply, i.e. the trace of the occupation matrix sums up to the total number of electrons.

The onsite shell and dual shell representations often give a better description with multiple-zeta basis sets compared to the onsite and dual representation, where the occupation is obtained by projecting into single basis functions.

Input format for XC+U

The Hubbard U approximation in the onsite representation may be selected through keywords of the types `LDAU.XCTYPE`, `LSDAU.XCTYPE`, `GGAU.XCTYP`, and `SGGAU.XCTYPE`.

The keyword `LSDAU.PZ` gives the default LSDA functional with the default Hubbard U method. The specification

```
exchange_correlation = LSDAU.PZ
```

is therefore identical to

```
exchange_correlation = ExchangeCorrelation(
    exchange=DiracBloch,
    correlation=PerdewZunger,
    hubbard_term=Onsite,
    number_of_spins=2,
    )
```

Use this form with the option `hubbard_term=Dual` to select the dual representation.

The value of the U term is specified through the basis set:

```
basis_set = [LDABasis.Nickel_SingleZeta(hubbard_u=[4.6, 0.0]*eV,
                                        filling_method=Anisotropic)]
```

which will give a single-zeta basis set for nickel, consisting of a 3d and a 4s orbital, where the 3d orbital has U=4.6 eV. The 3d orbitals are filled anisotropically, i.e, there is 1 electron in in orbitals with m=-2,-1,0,1, leaving m=2 empty. The alternative is `filling_method=SphericalSymmetric`, which puts 4/5 electron in each orbital.

DFT-1/2 method

The DFT-1/2 method (often also denoted LDA-1/2 or GGA-1/2) is a semi-empirical approach to correct the self-interaction error in local and semi-local exchange-correlation functionals for extended systems. As such, it can be viewed as an alternative to the *XC+U mean-field Hubbard term* with broadly the same aims: to improve the description of conduction-band energy levels and band gaps.

This method, introduced by Ferreira *et al.*[6], is based on the much older Slater half-occupation scheme for molecules[7] (also known as the transition state method). Slaters original method consists in carrying out a self-consistent calculation

[6] LuizăG. Ferreira, Marcelo Marques, and LaraăK. Teles. Approximation to density functional theory for the calculation of band gaps of semiconductors. *Phys. Rev. B*, 78:125116, Sep 2008. doi:10.1103/PhysRevB.78.125116.

[7] J.ăC. Slater and K.ăH. Johnson. Self-Consistent-Field $X\alpha \,$ Cluster Method for Polyatomic Molecules and Solids. *Phys. Rev. B*, 5:844–853, Feb 1972. doi:10.1103/PhysRevB.5.844.

with half an electron removed from the system, and taking the eigenvalue of the half-filled state as an estimate for the ionization energy. This approach was later formalized in the theorem by Janak[8]:

$$\frac{\partial E}{\partial f_\alpha} = \varepsilon_\alpha \left(f_\alpha \right),$$

where E is the total energy of the system, f_α is the occupation of state α (between 0 and 1), and ε_α is the eigenvalue of the state. The success of the half-occupation scheme is based on the fact that $\varepsilon_\alpha \left(f_\alpha \right)$ is known to be almost precisely linear for many cases, which makes the relationship with the ionization energy exact.

The DFT-1/2 method makes use of the theoretical insights from the half-occupation scheme and to tackle the fundamental problem of the self-interaction error for the case of extended systems with a band gap. The method attempts to correct for this by defining an atomic self-energy potential which cancels the electron-hole self-interaction energy. This potential is calculated for atomic sites in the system, and is defined as the difference between the potential of the neutral atom and that of a charged ion resulting from the removal of a fraction of its charge, between 0 and 1 electrons. The total self-energy potential is the sum of these atomic potentials.

The addition of the DFT-1/2 self-energy potential to the DFT Hamiltonian has been found to greatly improve band gaps for a wide range of semiconducting and insulating systems[9].

It is important to note that the method is not entirely free of empirical parameters. Much like the value of U for the Hubbard U method, there are two values which much be fixed for every species in the system: the fractional charge f_α removed from the neutral atom, and a cutoff radius r^{cut} beyond which to trim the atomic self-energy potential. The latter is needed to avoid excessive overlap of the potentials from different sites in the crystal.

The original authors of the method suggest to fix r^{cut} variationally, by choosing the value which maximizes the band gap[Page 1843, 69].

The choice of f_α is less well-defined: although a value of 0.5 is standard (hence the name of the method), this is known not to be the optimal choice for various materials (e.g., silicon). It may therefore be appropriate to treat it as an empirical parameter, to be varied by comparison with experiment.

It is also important to note that not all species in the system necessarily require the DFT-1/2 correction; it is generally advisable only to add this to the anionic species, and leave the cationic species as normal[Page 1843, 69].

Shell-DFT-1/2

Following the paper by Xue et al.[10] QuantumATK also supports calculations with the slightly modified shell-DFT-1/2 method. The difference between normal DFT-1/2 and shell-DFT-1/2 is that in the latter, the self-energy potential is added in a shell around the atom, and not in a sphere as in normal DFT-1/2. The shell is specified by an additional inner radius parameter in addition to the cutoff radius r^{cut}.

[10] Kan-Hao Xue, Jun-Hui Yuan, LeonardoăR.C. Fonseca, and Xiang-Shui Miao. Improved LDA-1/2 method for band structure calculations in covalent semiconductors. *Computational Materials Science*, 153:493–505, 2018. URL: https://www.sciencedirect.com/science/article/pii/S0927025618304166, doi:https://doi.org/10.1016/j.commatsci.2018.06.036.

Input format for DFT-1/2

The DFT-1/2 method may be selected by specifying one of the pre-defined exchange-correlation functionals: `LDAHalf`, `LSDAHalf`, `NCLDAHalf`, `SOLDAHalf`, `GGAHalf`, `SGGAHalf`, `NCGGAHalf`, `SOGGAHalf`.

The keyword `LDAHalf.PZ` gives the default LDA functional with the DFT-1/2 correction. The specification

```
exchange_correlation = LDAHalf.PZ
```

is therefore identical to

```
exchange_correlation = ExchangeCorrelation(
    exchange=DiracBloch,
    correlation=PerdewZunger,
    dft_half_enabled=True
    )
```

In general, the keyword `dft_half_enabled=True` can be specified for any user-defined exchange-correlation functional.

The value of the DFT-1/2 parameters are specified through the basis set:

```
dft_half_parameters = DFTHalfParameters(
    element=Arsenic,
    fractional_charge=[0.3, 0.0],
    cutoff_radius=4.0*Bohr,
    inner_radius=0.0*Bohr)

basis_set = [
    LDABasis.Arsenic_DoubleZetaPolarized(
        dft_half_parameters=dft_half_parameters),
    LDABasis.Gallium_DoubleZetaPolarized(
        dft_half_parameters=Disabled)
]
```

The above example shows a typical case for gallium arsenide, in which the anion (As) is given a DFT-1/2 self-energy potential calculated with $f_\alpha = 0.3$ and $r^{\mathrm{cut}} = 4\ a_0$, while the cation (Ga) has its DFT-1/2 correction turned off with the keyword `Disabled`.

If `dft_half_parameters` is not specified for a species, the default `Automatic` is used. This will set the *DFT-1/2 default parameters* from the table of optimized values given below.

Warning: When the DFT-1/2 method is enabled, the self-energy potential is included in the calculation of the total energy, forces and stress. However, the method is only intended as a scheme for calculating band structures, not for structural relaxations. We recommend that structural properties be calculated before applying the DFT-1/2 correction.

DFT-1/2 default parameters

The default DFT-1/2 parameters used by the `Automatic` keyword have been optimized against a wide range of materials, and should improve upon the standard DFT band gap in most cases. The complete list is given in the table below. As explained above, we only include elements which tend to have anionic character in compounds of interest.

Currently, only Ge (GGA) has an `inner_radius` different from zero, meaning that this is the only element using the shell-DFT-1/2 method as default.

Important: All elements not present in the table default to `Disabled`, i.e., no DFT-1/2 correction.

Important: For meta-GGA exchange-correlation functionals, **all** elements default to `Disabled`.

Table 4.1: Optimized DFT-1/2 parameters.

Spin-orbit coupling (SOC)

Background

The spin-orbit coupling can lead to energy level splits of bandstructures and molecular energy spectra. As a rule of thumb, the magnitude of SOC scales as Z^4/n^3l^2, where Z, n, and l are the atomic charge, principle, and angular quantum number of the considered energy level, respectively. The SOC is fundamentally a relativistic effect, and can be described by a second-order expansion of the relativistic Hamiltonian in terms of the fine structure constant α[11].

In *DFT: LCAO*, the SOC is taken into account via the *NormConservingPseudoPotential*. For example, the **SG15 pseudopotentials**, shipped with QuantumATK as of the 2016 release, come in two versions for each element; a standard

[11] L.ăFernandez-Seivane, M.ăA. Oliveira, S.ăSanvito, and J.ăFerrer. On-site approximation for spin–orbit coupling in linear combination of atomic orbitals density functional methods. *J. Phys.: Condensed Matter*, 18(34):7999, 2006. URL: http://stacks.iop.org/0953-8984/18/i=34/a=012.

scalar-relativistic pseudopotential (denoted SG15), and one that is generated by mapping the solution to the Dirac equation, which naturally includes the SOC, to a scalar-relativistic pseudopotential (denoted SG15-SO):

$$V_{ps} = V_L + V_{NL}^{+1/2} + V_{NL}^{-1/2},$$

with a local contribution V_L and non-local contributions from total angular momenta $j = l + 1/2$ and $j = l - 1/2$.

Each non-local term is expanded in spin-orbit projector functions $P_{\alpha\beta}^{l\pm1/2,\xi}$,

$$V_{NL}^{\pm1/2} = \sum_{l,\xi,\alpha,\beta} \nu_{l\pm1/2,\xi} P_{\alpha\beta}^{l\pm1/2,\xi},$$

where $\nu_{l\pm1/2,\xi}$ are normalization constants. The indices α, β denote the possible spin orientations (up, down). Each nonlocal pseudopotential term requires four projector functions per expansion order ξ.

Tip: Use SG15-SO or OpenMX pseudopotentials for *DFT: LCAO* calculations with spin-orbit.

Usage

The SOC terms are enabled by choosing a pseudopotential containing spin-orbit terms (SG15-SO or OpenMX), and appropriate settings for the *ExchangeCorrelation* keyword. For example, an QuantumATK Python script for silicon with SOC could contain the following specification for the calculator:

```
#------------------------------------------
# Basis Set
#------------------------------------------
basis_set = [
    BasisGGASG15SO.Silicon_Medium,
    ]
#------------------------------------------
# Exchange-Correlation
#------------------------------------------
exchange_correlation = SOGGA.PBE
#------------------------------------------
# Calculator
#------------------------------------------
k_point_sampling = MonkhorstPackGrid(na=9,nb=9,nc=9)
numerical_accuracy_parameters = NumericalAccuracyParameters(
    k_point_sampling=k_point_sampling,
    density_mesh_cutoff=100.0*Hartree,
    )
calculator = LCAOCalculator(
    basis_set=basis_set,
    exchange_correlation=exchange_correlation,
    numerical_accuracy_parameters=numerical_accuracy_parameters,
    )
```

Note the setting `exchange_correlation=SOGGA.PBE`, which switches on the SOC terms in the pseudopotential. Omitting this keyword or setting it to a non-SOC method, e.g. `NCGGA.PBE`, would still result in a calculation with the SG15-SO pseudopotential, but the SOC terms would be disregarded.

Hybrid functionals in the LCAO framework

Hybrid functionals are DFT functionals where part (or all) of the exchange in the exchange correlation functional is replaced by the exact exchange contribution. The exact exchange contribution in an LCAO basis set is defined as:

$$X_{ij} = \sum_{kl} V_{ik;jl} D_{kl} \ ,$$

in which D is the density matrix, and V are the 4-index coulomb integrals:

$$V_{ik;jl} = \int \int \frac{\phi_i^*(\mathbf{r})\phi_k(\mathbf{r})\phi_l^*(\mathbf{r}')\phi_j(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|} d\mathbf{r} d\mathbf{r}' \ .$$

In our LCAO implementation we use numerical orbitals, which makes the above integral very complicated to evaluate. To improve performance of the integral evaluations we introduce the resolution of identity (RI) approach[12] which writes a product of two orbitals as:

$$\phi_i^*(\mathbf{r})\phi_k(\mathbf{r}) = \sum_{\mu} C_{ik}^{\mu} P_{\mu}(\mathbf{r})$$

where we have defined the auxiliary basis functions P_μ and the auxiliary basis coefficients C_{ik}^{μ}. In the general RI approximation, the function P_μ in the above expansion can be located around any of the other atoms in the system. We will limit ourselves to the case where μ lies either on the atom I or K of the original orbitals. This approximation is called the PARI approximation[13], and is the reason for the linear computational scaling with system size.

The accuracy of the numerical evaluation of the integrals can be set by the user using the parameter class `ExactExchangeParameters`.

Dielectric dependent Hybrid functionals.

In HSE06 we mix 0.75 of screened PBE exchange with 0.25 of screened Fock exact exchange. The value of this optimal exchange fraction to use can be shown to be inversely proportionate to the dielectric constant, ϵ, in the material. This makes sense if we look at the two limiting cases. If we have a metal we have perfect screening and an infinite ϵ, so the exchange interaction is screened away fully and you dont want to use Fock exchange. In the vacuum, $\epsilon = 1$, there is no screening and the correct exchange fraction is 1. The factor of 0.25 was chosen to work well for semi-conductors such as Silicon or Germanium, but is not optimal for materials with comparatively large and small band gaps.

To improve on this, various dielectric dependent hybrid functionals (DDH) have been invented. We have chosen to follow the approach suggested in[14]. In this approach they suggest to calculate an estimator for the dielectric constant:

$$\bar{g} = \frac{1}{V} \int d\mathbf{r} \sqrt{\frac{\nabla\rho(\mathbf{r})}{\rho(\mathbf{r})}} \ .$$

It is then assumed that the exchange fraction depends on this property through a fourth order polynomial:

$$\alpha = a_0 + a_1\bar{g} + a_2\bar{g}^2 + a_3\bar{g}^3 + a_4\bar{g}^4 \ .$$

We have fitted these parameters so they give the best possible match to the experimental band gap for a number of semi-conducting and insulating materials. You can choose this functional by setting the exchange correlation:

Hybrid functionals for large periodic systems in an all-electron, numeric atom-centered basis framework. *Computer Physics Communications*, 192:60–69, 2015. URL: https://www.sciencedirect.com/science/article/pii/S001046551500079X, doi:https://doi.org/10.1016/j.cpc.2015.02.021.

[14] JonathanăH. Skone, Marco Govoni, and Giulia Galli. Nonempirical range-separated hybrid functionals for solids and molecules. *Phys. Rev. B*, 93:235106, Jun 2016. URL: https://link.aps.org/doi/10.1103/PhysRevB.93.235106, doi:10.1103/PhysRevB.93.235106.

```
exchange_correlation = HybridGGA.HSE06DDH
```

If you want to choose a custom parameterization, fitted to a specific set you are interested in, you can do that by manually assigning the fitting parameters:

```
hse06_ddh_parameters = (0.16957336, 0.0, 0.0, 0.0, 0.08940146)
exchange_correlation = HybridGGA.HSE06DDH(ddh_parameters=ddh_parameters)
```

This functional assumes that the whole system has the same exchange fraction, so it is meaningful only when used for homogeneous bulk systems.

For interface system consisting of two or more different materials with different properties, a different approach is needed. To this end the Local DDH functional has been invented[15]. In this approach a local estimator is defined:

$$\bar{g}(\mathbf{r},\sigma) = \frac{1}{(2\pi\sigma)^{\frac{3}{2}}} \int d\mathbf{r}' \sqrt{\frac{\nabla\rho(\mathbf{r}')}{\rho(\mathbf{r}')}} \exp\left(-\frac{|\mathbf{r}-\mathbf{r}'|^2}{2\sigma}\right) ,$$

from which an exchange fraction field is defined as:

$$a(\mathbf{r},\sigma) = a_0 + a_1\bar{g}(\mathbf{r},\sigma) + a_2\bar{g}(\mathbf{r},\sigma)^2 + a_3\bar{g}(\mathbf{r},\sigma)^3 + a_4\bar{g}(\mathbf{r},\sigma)^4.$$

This is then used to modify the 4-center coulomb integrals:

$$V_{ik;jl} = \int\int \alpha(\mathbf{r},\mathbf{r}';\sigma) \frac{\phi_i^*(\mathbf{r})\phi_k(\mathbf{r})\phi_l^*(\mathbf{r}')\phi_j(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|} d\mathbf{r}d\mathbf{r}' ,$$

with

$$\alpha(\mathbf{r},\mathbf{r}';\sigma) = \sqrt{a(\mathbf{r},\sigma)a(\mathbf{r}',\sigma)} .$$

Using this functional we can get the best results for the local density of states for interfaces, where in a $Si - SiO_2$ interface a 0.25 exchange fraction will be found for the Si part and a 0.35 for the SiO_2 part.

To use this functional you have to set the exchange correlation:

```
exchange_correlation = HybridGGA.HSE06LocalDDH
```

and once again you can set a custom parameterization by:

```
hse06_ddh_parameters = (0.16957336, 0.0, 0.0, 0.0, 0.08940146)
exchange_correlation = HybridGGA.HSE06LocalDDH(ddh_parameters=ddh_parameters)
```

A caveat for this method is that in the presence of vacuum the estimator blows up, and this has a negative influence on the convergence of the method. So we would recommend only using this functional for 3D systems.

The estimator also has difficulties with metallic systems, for which it should set the exchange fraction to zero. To improve on this we have implemented our own metallic estimator, which identifies metallic regions and sets the exchange fractions to zero in them. To use it just set the exchange correlation to:

```
exchange_correlation = HybridGGA.HSE06MetallicLocalDDH
```

When using this in a metal-semiconductor interface, it is as if you are using PBE for the metallic part and HSE06LocalDDH for the semi-conducting part.

[15] Pedro Borlido, Miguel A.ăL. Marques, and Silvana Botti. Local Hybrid Density Functional for Interfaces. *Journal of Chemical Theory and Computation*, 14(2):939–947, 2018. PMID: 29227686. URL: https://doi.org/10.1021/acs.jctc.7b00853, arXiv:https://doi.org/10.1021/acs.jctc.7b00853, doi:10.1021/acs.jctc.7b00853.

The Auxiliary Density Matrix Method (ADMM)

Using the PARI approximation, the calculation of the exchange matrix scales linearly with system size. There is one problem, however, and that is that the scaling with basis set size is polynomial with $\mathcal{O}(n^6)$. This means that if we need large basis sets to describe a system, the exchange calculation will become prohibitively expensive.

To overcome this issue the auxiliary density matrix method (ADMM) was developed[16], in which you run a DFT calculation with a large basis set, and use a smaller subset to compute the exchange properties.

The idea is simple, we project the density matrix of the system with the big basis set D down to a smaller basis set, and obtain the ADMM density matrix d. It is then postulated that a good approximation to the exchange matrix is:

$$X_{ij}(D) \approx x_{ij}(d) + \langle\phi_i|V_x(D)|\phi_j\rangle - \langle\phi_i|V_x(d)|\phi_j\rangle \ ,$$

in which the latter two terms are the exchange potentials generated by the full density and the ADMM density.

Up and down projections to and from the ADMM basis are done during the diagonalization procedure. This leads to some overhead in the diagonalization procedure. In return we get a significant speedup in the exchange matrix calculation.

The accuracy of the results depends on the ADMM basis set you choose. For the PseudoDojo basis sets we have constructed custom made ADMM basis sets, which are tuned to give accurate results for band gaps and structural properties (Δ-value) for a wide range of semi-conductors and insulators. In particular the PseudoDojo ADMM basis sets have been fitted to work best in combination with PseudoDojo Medium as main basis set, while for larger PseudoDojo basis sets we suggest to follow the hierarchy. For the FHI basis sets, you have a natural hierarchy you can choose from. For the other basis sets we dont recommend using ADMM.

To use it, you need to set:

```
exact_exchange_parameters = ExactExchangeParameters(
    use_admm=True,
    basis_set_admm=BasisGGAPseudoDojo.ADMM)

numerical_accuracy_parameters = NumericalAccuracyParameters(
    exact_exchange_parameters=exact_exchange_parameters
    )

lcao_calculator = LCAOCalculator(
    exchange_correlation=HybridGGA.HSE06,
    numerical_accuracy_parameters=numerical_accuracy_parameters,
    )
```

4.2.2 DFT: Plane Wave

Introduction

QuantumATK can model the electronic properties of periodic quantum systems within the framework of **density functional theory (DFT)** using a plane-wave (PW) basis set. For closed and open systems, QuantumATK can also use the DFT-LCAO calculator, as discussed in *DFT: LCAO*. The *DFT: Plane Wave* calculator is not suitable for open systems, because it assumes periodic boundary conditions when solving the Kohn–Sham equations.

[16] Manuel Guidon, Jürg Hutter, and Joost VandeVondele. Auxiliary Density Matrix Methods for Hartree-Fock Exchange Calculations. *Journal of Chemical Theory and Computation*, 6(8):2348–2364, 2010. PMID: 26613491. URL: https://doi.org/10.1021/ct1002225, arXiv:https://doi.org/10.1021/ct1002225, doi:10.1021/ct1002225.

The key parameter in the self-consistent DFT-PW calculation of the Kohn–Sham equations is the **electron density**. The electron density then sets up an effective potential, which is given by the Hartree, exchange-correlation, and external potential. Knowing the effective potential allows us to obtain the Kohn–Sham Hamiltonian.

The next section describes the similarities and differences of the *PlaneWaveCalculator* and *LCAOCalculator*.

Background information

The *PlaneWaveCalculator* provides a description of electronic structure using *DFT* in combination with norm-conserving *pseudopotentials* or PAW potentials[1]. This method is based on an expansion of the single-particle wave functions in a basis of plane-wave functions to *solve the Kohn–Sham equations*, instead of the *LCAO basis set*. The description for the mathematical formalism of the DFT-PW calculator and PAW potentials can be found in the QuantumATK reference paper by Smidstrup *et al.*[2] and the work by Blöchl[Page 1851, 1], respectively.

Similarly to the *DFT: LCAO* calculator, the *DFT: Plane Wave* calculator allows for calculating basic physical quantities:

- *Electron density*
- *Effective potential*
- *Hartree potential*
- *Exchange-correlation potentials*
- *Pseudopotentials*
- *Total energy, forces and stress*
- *Exchange-correlation energy*
- *Spin-orbit coupling (SOC)*

Unlike the *DFT: LCAO* calculator, the *DFT: Plane Wave* calculator does not support the *XC+U mean-field Hubbard term* and *DFT-1/2 method* yet, as well as some of QuantumATK analysis objects, which are available for the DFT-LCAO calculator.

In addition to norm-conserving *Pseudopotentials*, the *DFT: Plane Wave* calculator supports *PAW potentials*.

4.2.3 Semi Empirical

Introduction

SemiEmpirical (SE) calculator can model the electronic properties of molecules, crystals and devices using both self-consistent and non-self-consistent **tight-binding** models. In this chapter, the implemented tight-binding models based on the **Slater–Koster** model and the **extended Hückel** model are presented.

The **Slater–Koster tight-binding model** follows closely the DFTB formalism described in[1], and it is recommended that this paper, and[2], are cited in publications using the *SemiEmpiricalCalculator* and *DeviceSemiEmpiricalCalculator* with the *SlaterKosterHamiltonianParametrization* in QuantumATK.

[2] K.ăStokbro, D.ăE. Petersen, S.ăSmidstrup, A.ăBlom, M.ăIpsen, and K.ăKaasbjerg. Semiempirical model for nanoscale device simulations. *Phys. Rev. B*, 82:075420, Aug 2010. doi:10.1103/PhysRevB.82.075420.

The **extended Hückel model** in SE is described in[2], and it is recommended that this paper is cited in publications using the *SemiEmpiricalCalculator* and *DeviceSemiEmpiricalCalculator* with the *HuckelHamiltonianParametrization* in QuantumATK.

In SE, the non-self-consistent part of the tight-binding Hamiltonian is parametrized using a two-center approximation, i.e. the matrix elements only depend on the distance between two atoms and is independent of the position of the other atoms. In the extended Hückel model, the matrix elements are described in terms of overlaps between Slater orbitals on each site. In this way, the matrix elements can be defined by very few parameters. In the Slater–Koster model, the distance-dependence of the matrix elements is given as a numerical function; this gives higher flexibility but also makes the fitting procedure more difficult.

The self-consistent part of the calculation is identical for both SE models. The density matrix is calculated from the Hamiltonian using non-equilibrium Greens functions for device systems, while for molecules and crystals it is calculated by diagonalization. The density matrix defines the real-space electron density and consequently the Hartree potential can be obtained by solving the Poisson equation. The following describes the details of the mathematical formalism behind the implementation.

For a list of the built-in parameter sets in SE, see *Built-in semiempirical parameter sets in QuantumATK*. In addition to these, it is possible to directly use parameter sets downloaded from the DFTB website or define your own Slater–Koster table or extended Hückel basis set in the QuantumATK input scripts.

Background information

Non-self-consistent Hamiltonian

The Hamiltonian is expanded in a basis of local atomic orbitals (an LCAO expansion),

$$\phi_{nlm}(\mathbf{r}) = R_{nl}(r)Y_{lm}(\hat{\mathbf{r}}),$$

where Y_{lm} is a spherical harmonic and R_{nl} is a radial function. Typically, the atomic orbitals used in the LCAO expansion have a close resemblance to the atomic eigenfunctions.

Onsite terms

With this form of the basis set, the onsite elements are given by

$$S_{ij}^{\text{onsite}} = \delta_{ij},$$

$$H_{ij}^{\text{onsite}} = E_i\delta_{ij},$$

where E_i is an adjustable parameter that is often close to the atomic eigenenergy.

Offsite terms in the extended Hückel model

The central object in the extended Hückel model is the overlap matrix:

$$S_{ij} = \int_V \phi_i(\mathbf{r} - \mathbf{R}_i)\phi_j(\mathbf{r} - \mathbf{R}_j)\ \mathrm{d}\mathbf{r}.$$

To calculate this integral, the form of the basis functions must be specified. In the extended Hückel model, the basis functions are parametrized by Slater orbitals,

$$R_{nl}(r) = \frac{r^{n-1}}{\sqrt{(2n)!}}\left[C_1(2\eta_1)^{n+\frac{1}{2}}e^{-\eta_1 r} + C_2(2\eta_2)^{n+\frac{1}{2}}e^{-\eta_2 r}\right].$$

The LCAO basis is described by the adjustable parameters η_1, η_2, C_1, and C_2. These parameters must be defined for each angular shell of valence orbitals for each element.

The overlap matrix defines the Hamiltonian,

$$H_{ij} = \frac{1}{4}(\beta_i + \beta_j)(E_i + E_j)S_{ij},$$

where E_i is the onsite orbital energy and β_i is a Hückel fitting parameter (often chosen to be 1.75).

Weighting schemes

The are two variants of the weighting schemes for the orbital energies of the offsite Hamiltonian. The scheme used above,

$$\frac{1}{2}\beta(E_i + E_j)S_{ij},$$

where $\beta = \frac{1}{2}(\beta_i + \beta_j)$ is used by Wolfsberg[3], while Hoffmann ([4] and[5]) uses

$$\frac{1}{2}(\beta + \alpha^2 + (1-\beta)\alpha^4)(E_i + E_j),$$

where $\alpha = (E_i - E_j)/(E_i + E_j)$.

Both variants are available in *Semi Empirical* through the parameters `WolfsbergWeighting` and `HoffmannWeighting`, which can be given to the *HuckelHamiltonianParametrization* class.

Offsite Hamiltonian in the Slater–Koster model

The overlap matrix is given by pairwise integrals between the different basis functions. These integrals can be pre-calculated for all relevant distances and different orbital combinations, and stored in so-called Slater–Koster tables. The Slater–Koster table stores the distance-dependent parameters $s(d, Z_1, Z_2, l_1, l_2, m)$, where d is the distance, Z_1, Z_2 the element types, l_1, l_2 the angular momentum of the two orbitals, and the index $m \leq \min(l_1, l_2)$.

From the Slater–Koster tables, the overlap matrix elements are given by

$$S_{ij} = \sum_{m \leq \min(l_i, l_j)} \alpha_{l_i, m_i, l_j, m_j, m}(\hat{R}_{ij}) s(d_{ij}, Z_i, Z_j, l_i, l_j, m),$$

where α are the Slater–Koster expansion coefficients.

In the Slater–Koster, model it is assumed that also the Hamiltonian has a pairwise form and a Slater–Koster table is generated for the Hamiltonian matrix elements. This table may be generated by calculating Hamiltonian matrix elements for a set of dimer distances or by simply fitting matrix elements to the band structure for different lattice constants.

In *Semi Empirical*, the Slater–Koster table is constructed either by providing the path to a directory containing compatible Slater–Koster files (see *DFTBDirectory* and *HotbitDirectory*), or directly using the *SlaterKosterTable* class.

Note that the extended Hückel model is a Slater–Koster model too, but with a special fitting procedure for the Hamiltonian matrix elements.

Self-consistent Hamiltonian

In the self-consistent semi-empirical models in QuantumATK, the electron density is computed using the tight-binding model as described above. The density gives rise to a Hartree potential V_H. The calculation of the Hartree potential is described in detail in the section on *Poisson solvers*.

The Hartree potential is included through an additional term in the Hamiltonian:

$$H_{ij}^{\mathrm{SCF}} = \frac{1}{2}(V_H(\mathbf{R}_i) + V_H(\mathbf{R}_j))S_{ij}.$$

Electron density

The electron density is given by the occupied eigenfunctions,

$$n(\mathbf{r}) = \sum_{\alpha} f_\alpha |\psi_\alpha(\mathbf{r})|^2,$$

where f_α is the occupation of the level denoted by α. For finite temperature calculation the occupations are determined by the Fermi-Dirac distribution $f_\alpha = \frac{1}{1+e^{(\epsilon_\alpha - \epsilon_F)/kT}}$ with ϵ_α being the energy of the eigenstate ψ_α, ϵ_F the Fermi level and T the electron temperature. However, other smooth distributions may be introduced in order to help speed convergence (see *Occupation Methods*).

The eigenstates in the Slater orbital basis can be written as

$$\psi_\alpha = \sum_i c_{\alpha i}\phi_i,$$

where the total number of electrons, $N = \int_V n(\mathbf{r})\,\mathrm{d}\mathbf{r}$, is given by

$$N = \sum_{ij} D_{ij}S_{ij},$$

where $D_{ij} = \sum_\alpha f_\alpha c_{\alpha i}^* c_{\alpha j}$ is the density matrix.

An approximate atom-based electron density

In practice, a simple approximation is used for the electron density. To this end, we introduce the Mulliken population,

$$m_l = \sum_{i\in l}\sum_j D_{ij}S_{ij},$$

for shell l of atom number μ, and write the total number of electrons as a sum of atomic contributions, $N = \sum_\mu \sum_{l\in\mu} m_l$. The radial dependence of each atomic-like density is represented by a Gaussian function, and the total induced charge in the system is approximated by

$$\delta n(\mathbf{r}) = \sum_\mu \sum_{l\in\mu} \delta m_l \left(\frac{\alpha_l}{\pi}\right)^{\frac{3}{2}} e^{-\alpha_l|\mathbf{r}-\mathbf{R}_\mu|^2},$$

where $\delta m_l = m_l - Z_\mu$ is the total charge for shell l of atom μ, i.e. the sum of the valence electron charge m_l and the ionic charge $-Z_\mu$.

To see the significance of the width α_l of the Gaussian orbital, consider the electrostatic potential from a single Gaussian density at position $\mathbf{R}_\mu$:

$$V_H(\mathbf{r}) = (m_l - Z_\mu)\frac{\mathrm{erf}(\sqrt{\alpha_l}|\mathbf{r}-\mathbf{R}_\mu|)}{|\mathbf{r}-\mathbf{R}_\mu|}.$$

The onsite value of the Hartree potential is $V_H(\mathbf{R}_\mu) = (m_l - Z_\mu)U_l$, where $U_l = 2\sqrt{\frac{\alpha_l}{\pi}}$ is the onsite Hartree shift. In *Semi Empirical*, it is the specified value of U_l that is used to determine the width α_l of the Gaussian using the above relation.

Onsite Hartree shift parameters

The shell-dependent onsite Hartree shift U_l can be obtained from an atomic calculation. U_l is related to the linear shift of the eigenenergy ε_l of shell l as function of the shell occupation q_l:

$$U_l = \frac{d\varepsilon_l}{dq_l}.$$

Thus, U_l can be obtained by performing atomic calculations with different values of q_l.

In QuantumATK, it is recommended to use the same onsite Hartree shift parameter for the s- and p-shells of each atom.

QuantumATK provides a database for U_l calculated using DFT and the PBE functional (see *Generalized-gradient approximation (GGA)*). Access to the data is through the function *ATK_U*. Due to backwards compatibility, the `HoffmanHückelParameters` and `MullerHückelParameters` do not use the *ATK_U* database, but use special values of the electrostatic parameter U, see *Element data*.

Spin polarization

The inclusion of spin in the tight-binding Hamiltonian follows the scheme in[6]. The following spin dependent term is added to the Hamiltonian:

$$H_{ij}^{\sigma} = \pm\frac{1}{2}S_{ij}\left(dE_{l_i} + dE_{l_j}\right),$$

where the sign in the equation depends on the spin.

The spin splitting dE_l of shell l is calculated from the spin-dependent Mulliken populations μ_l of each shell at the local site:

$$dE_l = \sum_{l' \in \mu_l} W_{ll'}\,(m_{l'\uparrow} - m_{l'\downarrow}).$$

Onsite spin-split parameters

The shell-dependent spin splitting strength $W_{ll'}$ can be obtained from a spin-polarized atomic calculation[Page 1855, 6]:

$$W_{ll'} = \frac{1}{2}\left(\frac{d\varepsilon_{l\uparrow}}{dm_{l'\uparrow}} - \frac{d\varepsilon_{l\uparrow}}{dm_{l'\downarrow}}\right).$$

Since $W_{ll'}$ enters symmetrically in the Hamiltonian, it is convenient to symmetrize it:

$$\bar{W}_{ll'} = \frac{1}{2}(W_{ll'} + W_{l'l}).$$

QuantumATK provides a database for $\bar{W}_{ll'}$. Access to the data is through the function *ATK_W*.

[6] C.ăKohler, T.ăFrauenheim, B.ăHourahine, G.ăSeifert, and M.ăSternberg. Treatment of Collinear and Noncollinear Electron Spin within an Approximate Density Functional Based Method. *J. Phys. Chem. A*, 111(26):5622–5629, 2007. doi:10.1021/jp068802p.

Tight-binding total energy

The calculation of the total energy follows[7] and[Page 1851, 1]. The total energy has five terms:

$$E = E_{\mathrm{H}^0} + E_{\delta\mathrm{H}} + E_{\mathrm{ext}} + E_{\mathrm{spin}} + E_{\mathrm{pp}}.$$

•E_{H^0} is the one-electron energy of the non-self-consistent Hamiltonian, given by

$$E_{\mathrm{H}^0} = \sum_{ij} D_{ij} H^0_{ij}.$$

•$E_{\delta\mathrm{H}}$ is the electrostatic difference energy,

$$E_{\delta\mathrm{H}} = \frac{1}{2} \int V_0^H(\mathbf{r}) \delta n(\mathbf{r}) d\mathbf{r}.$$

•E_{ext} is the electrostatic interaction between the electrons and an external field,

$$E_{\mathrm{ext}} = \int V^{\mathrm{ext}}(\mathbf{r}) \delta n(\mathbf{r}) d\mathbf{r}.$$

•E_{spin} is the spin polarization energy[Page 1855, 6],

$$E_{\mathrm{spin}} = -\frac{1}{2} \sum_{\mu} \sum_{l \in \mu} \sum_{l' \in \mu} W(Z_\mu, l, l') m_l m_{l'}.$$

•E_{pp} is the repulsive energy from a pair-potential between each atom pair, $V^{\mathrm{pp}}(Z_\mu, Z_{\mu'}, R_{\mu,\mu'})$,

$$E_{\mathrm{pp}} = \sum_{\mu < \mu'} V^{\mathrm{pp}}(Z_\mu, Z_{\mu'}, R_{\mu,\mu'}).$$

It is optional to add this term to the tight-binding model; it does not affect the electronic structure. The tight-binding model will, however, not give sensible geometries without a repulsive pair-potential.

Important: In the current version of QuantumATK, only the DFTB and Hotbit parameter sets contain a repulsive pair potential term, and only these methods can be used for geometry optimizations.

Parameters

Parameters for the Slater–Koster method

The Slater–Koster parameters can be provided either through the *SlaterKosterTable* class or through various 3rd-party formats. The supported 3rd-party formats are the DFTB Slater–Koster files from the DFTB consortium, and the Hotbit Slater–Koster files from the Hotbit consortium.

To use parameters in the DFTB or Hotbit format, put the parameter files in a single directory, and setup the basis set and pair potentials using the functions *DFTBDirectory* or *HotbitDirectory*.

Tables showing which elements are covered by the parameters are given here: *Slater–Koster basis sets*.

[7] K.ăKaasbjerg and K.ăFlensberg. Strong Polarization-Induced Reduction of Addition Energies in Single-Molecule Nanojunctions. *Nano Letters*, 8(11):3809–3814, 2008. doi:10.1021/nl8021708.

Shipped DFTB and Hotbit parameters

The current version of SE is shipped with a number of DFTB style parameters from the CP2K and Hotbit consortia. We recommended that these resources are cited if the parameters are used in publications. It is most easy to setup these basis sets using the QuantumATK interface.

Shipped Slater–Koster Table parameters

A number of orthogonal tight-binding parameters are provided. The parameters are from Vogl *et al.*[8] and Jancu *et al.*[9], and it is recommended that these papers are cited if the parameters are used for publications. These basis sets can easily be set up using QuantumATK.

Parameters for the extended Hückel method

The parameters η_1, η_2, C_1, C_2, and E must be defined for each valence orbital, while β and U only depend on the element type. Different parameter sets are provided with *Semi Empirical*, but it is also possible to provide user-defined parameters in the input file using the *HuckelBasisParameters* class.

The tables below provide a mapping between the symbols in the equations and the corresponding keywords.

Table 4.2: HuckelBasisParameters.

Symbol	*HuckelBasisParameters*
E_i	`ionization_potential`
β	`wolfsberg_helmholtz_constant`
U	`onsite_hartree_shift`
W	`onsite_spin_split`
E^{VAC}	`vacuum_level`

Table 4.3: SlaterOrbital parameters.

Symbol	*SlaterOrbital* parameters
n	`principal_quantum_number`
l	`angular_momentum`
η	`slater_coefficients`
C	`weights`

The current version of QuantumATK comes with built-in Hoffmann and Müller parameter sets, which are appropriate for organic molecules. For crystalline structures, both metals and organic materials like graphene, parameters from J. Cerda are provided. When using these parameters,[10] should be referenced. Tables with the available parameter sets can be found here: *Extended Hückel basis sets*.

To combine parameters from different sources, it is important to make sure they use the same energy zero level, in order to obtain correct charge transfers. This can be obtained by ensuring that the crystals have the correct work function and molecules the correct ionisation energies. For this purpose, an additional parameter E^{VAC} is introduced, which shifts the energy of the vacuum level: If a calculation with $E^{\mathrm{VAC}} = 0$ eV has a work function of 6.5 eV, then by setting $E^{\mathrm{VAC}} = -1.5$ eV all bands shift rigidly upwards by 1.5 eV, and the work function becomes 5.0 eV.

Note: The Hückel parameters have been fitted for non-self-consistent calculations. To use the parameters in self-consistent calculations, the self-consistent onsite shifts must be compensated by a reverse shift of the `vacuum_levels`.

4.2.4 Force Field

Table of Contents

Introduction

The **ForceField** module provides calculators for empirical force fields[1]. It includes the following calculators:

•*TremoloXCalculator*

•*BrennerCalculator*

Note: For QuantumATK-version 2018, this module is present under the name **ATK-ForceField**.

TremoloX

The *TremoloXCalculator*, which provides most of the potential classes and parameters sets in the **ForceField** module, is developed by the Fraunhofer Institute for Algorithms and Scientific Computing (SCAI). For details about TremoloX, see also www.tremolo-x.com.

TremoloX uses highly efficient state of the art algorithms for the treatment of short- and long-range potentials. TremoloX provides a large database of pre-defined *TremoloX potential parameter sets*, for modeling of systems in material science and nanotechnology. It also allows the user to set up custom potentials by combining the available *TremoloX potential classes*.

How to choose the right pretrained neural network based force field

Selecting the best pretrained model for your system can be challenging. The optimal choice depends on the specific system, desired accuracy, and evaluation speed. It is recommended that users try several models and experiments to determine which suits their specific use case. Here are some guidelines to help you make an informed decision:

Prefer newer or updated models

Newer or updated models are typically more accurate than older ones. For example:

- Updated versions of the medium MACE models (`TorchX_MACE_MP_0b3_medium` and `TorchX_MACE_MPA_0_medium`) are expected to outperform the original medium MACE model (`TorchX_MACE_MP_0_L1_2023`).

Training dataset size

Models trained on larger datasets are typically more accurate than those trained on smaller datasets. For instance:

- `TorchX_MACE_MPA_0_medium` is trained on a larger dataset compared to `TorchX_MACE_MP_0b3_medium`, and is therefore expected to perform better.
- Similarly, MatterSim models are expected to be more accurate than M3GNet models because they are trained on larger datasets.

System type

The type of system you are working with can influence the choice of model. For example:

- For systems containing molecules, the Osaka versions of the MACE models are likely more suitable, as they are the only models trained on molecules.

Speed

Larger models may offer better accuracy but can be slower to evaluate. If speed is a concern, consider using smaller models or those optimized for faster evaluation.

- `TorchX_MACE_MP_0_L0_2023` is the fastest MACE model.
- MatterSim and M3GNet models are generally faster than any of the MACE models.

Pretrained moment tensor potential (MTP) parameter sets

Listed below are the defined pre-trained MTP parameter sets developed by Synopsys QuantumATK. These parameter sets require the *QuantumATK-ML-Elite* license.

QuantumATK_MTP_Ag_SiO2_2022 (O, Ag, Si)

Synopsys pretrained MTP parameters for c-Ag / SiO2 interfaces. Trained using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and 2000 MTP basis functions., Synopsys QuantumATK, T-2022.03

QuantumATK_MTP_CoSi_2022_12 (Co, Si)

Synopsys pretrained MTP parameters for cobalt silicide and Si / Co interfaces. Trained using DFT-LCAO PBE PseudoDojo-medium as reference calculator and 400 MTP basis functions. Supports MTP error prediction., Synopsys QuantumATK, U-2022.12

QuantumATK_MTP_CuH_2025_06 (Cu, H)

Synopsys pretrained MTP parameters for Hydrogen diffusion in Copper. Trained using DFT-LCAO PBES and PseudoDojo-high as reference calculator and 300 MTP basis functions., Synopsys QuantumATK, X-2025.06

QuantumATK_MTP_CuMnTaNSiO_2025_06 (Cu, Ta, Mn, N, O, Si)

Synopsys pretrained MTP parameters for Cu-Mn-Ta-N-Si-O alloy materials and interfaces for back-end-of-line (BEOL) applications. Trained using DFT-LCAO PBES and PseudoDojo-medium as reference calculator and 800 MTP basis functions. Supports MTP error prediction., Synopsys QuantumATK, X-2025.06

QuantumATK_MTP_FeCo_Alloy_2022 (Co, Fe)

Synopsys pretrained MTP parameters for bulk FexCo(1-x) alloy configuration, where x=0.5-1. Trained using DFT-LCAO PBE and spin polarization with PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis., Synopsys QuantumATK, U-2022.12

QuantumATK_MTP_FeCo_MgO_2022 (Co, O, Mg, Fe)

Synopsys pretrained MTP parameters for bulk Fe, FexCo(1-x) alloy, MgO and their interfaces, where x=0.5-1. Trained using DFT-LCAO PBE and spin polarization with PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis., Synopsys QuantumATK, U-2022.12

QuantumATK_MTP_FeCo_Ta_2022 (Ta, Co, Fe)

Synopsys pretrained MTP parameters for bulk Fe, FexCo(1-x) alloy, Ta and their interfaces, where x=0.5-1. Trained using DFT-LCAO PBE and spin polarization with PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis., Synopsys QuantumATK, U-2022.12

QuantumATK_MTP_FeCo_W_2022 (W, Co, Fe)

Synopsys pretrained MTP parameters for bulk Fe, FexCo(1-x) alloy, W and their interfaces, where x=0.5-1. Trained using DFT-LCAO PBE and spin polarization with PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis., Synopsys QuantumATK, U-2022.12

QuantumATK_MTP_Fe_MgO_2022 (Co, O, Mg, Fe)

Synopsys pretrained MTP parameters for bulk Fe, FexCo(1-x) alloy, MgO and their interfaces, where x=0.5-1. Trained using DFT-LCAO PBE and spin polarization with PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis., Synopsys QuantumATK, U-2022.12

QuantumATK_MTP_Fe_Ta_2022 (Ta, Co, Fe)

Synopsys pretrained MTP parameters for bulk Fe, FexCo(1-x) alloy, Ta and their interfaces, where x=0.5-1. Trained using DFT-LCAO PBE and spin polarization with PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis., Synopsys QuantumATK, U-2022.12

QuantumATK_MTP_Fe_W_2022 (W, Co, Fe)

Synopsys pretrained MTP parameters for bulk Fe, FexCo(1-x) alloy, W and their interfaces, where x=0.5-1. Trained using DFT-LCAO PBE and spin polarization with PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis., Synopsys QuantumATK, U-2022.12

QuantumATK_MTP_GST_2022_12 (Sb, Te, Ge)

Synopsys pretrained MTP parameters for bulk crystal and amorphous Ge2Sb2Te5 systems. Trained using DFT-LCAO PBE PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis. Supports MTP error prediction., Synopsys QuantumATK, U-2022.12

QuantumATK_MTP_HfO2_2022 (Hf, O)

Synopsys pretrained MTP parameters for bulk crystal and amorphous HfO2. Trained to monoclinic, orthorhombic, cubic, and low- and high-temperature am. HfO2, using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis., Synopsys QuantumATK, T-2022.03

QuantumATK_MTP_HfO2_2022_12 (Hf, O)

Synopsys pretrained MTP parameters for bulk crystal and amorphous HfO2. Trained to monoclinic, orthorhombic, cubic, and low- and high-temperature am. HfO2, using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis. Retrained version with improved accuracy. Supports MTP error prediction., Synopsys QuantumATK, U-2022.12

QuantumATK_MTP_HfO2_HfCl4_2022 (Hf, O, Cl)

Synopsys pretrained MTP parameters for HfCl4 deposition on HfO2 surfaces. Trained using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis., Synopsys QuantumATK, T-2022.03

QuantumATK_MTP_HfO2_Ru_2022 (Hf, O, Ru)

Synopsys pretrained MTP parameters for HfO2 / Ru interfaces. Trained using DFT-LCAO PBE PseudoDojo-medium as reference calculator and 5000 MTP basis functions., Synopsys QuantumATK, U-2022.12

QuantumATK_MTP_HfO2_Sc_2022 (Hf, O, Sc)

Synopsys pretrained MTP parameters for HfO2 / Sc interfaces. Trained using DFT-LCAO PBE PseudoDojo-medium as reference calculator and 5000 MTP basis functions., Synopsys QuantumATK, U-2022.12

QuantumATK_MTP_HfO2_SiO2_2022 (Hf, O, Si)

Synopsys pretrained MTP parameters for SiO2 / HfO2 interfaces. Trained using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis., Synopsys QuantumATK, T-2022.03

QuantumATK_MTP_HfO2_SiO2_2022_12 (Hf, O, Si)

Synopsys pretrained MTP parameters for SiO2 / HfO2 interfaces. Trained using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis. Retrained version with improved accuracy. Supports MTP error prediction., Synopsys QuantumATK, U-2022.12

QuantumATK_MTP_HfO2_TiN_2022 (Ti, Hf, O, N)

Synopsys pretrained MTP parameters for HfO2 / TiN interfaces. Trained using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis., Synopsys QuantumATK, T-2022.03

QuantumATK_MTP_HfO2_TiN_2022_12 (Ti, Hf, O, N)

Synopsys pretrained MTP parameters for HfO2 / TiN interfaces. Trained using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis. Retrained version with improved accuracy. Supports MTP error prediction., Synopsys QuantumATK, U-2022.12

QuantumATK_MTP_HfTiNAlO_2023_09 (Hf, Ti, N, O, Al)

Synopsys pretrained MTP parameters for bulk crystal and amorphous HfTiNAlO systems and interfaces. Trained using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and 800 MTP basis functions. Supports MTP error prediction., Synopsys QuantumATK., V-2023.09

QuantumATK_MTP_InGaZnOH_2023_09 (In, O, H, Ga, Zn)

Synopsys pretrained MTP parameters for crystal amorphous InGaZnO (IGZO) with Hydrogen. Trained using DFT-LCAO PBE PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis. Supports MTP error prediction., Synopsys QuantumATK, U-2023.09

QuantumATK_MTP_InGaZnO_2022_12 (Ga, O, In, Zn)

Synopsys pretrained MTP parameters for crystal amorphous InGaZnO (IGZO). Trained using DFT-LCAO PBE PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis. Supports MTP error prediction., Synopsys QuantumATK, U-2022.12

QuantumATK_MTP_MgO_FeCo_W_Ta_2022_12 (Ta, Mg, Fe, W, Co, O)

Synopsys pretrained MTP parameters for MgO / FeCo / W or MgO / FeCo / Ta interfaces in an MRAM stack. Trained using DFT-LCAO PBE PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis. Supports MTP error prediction., Synopsys QuantumATK, U-2022.12

QuantumATK_MTP_MoS2_Cl_Ar_2025_06 (Cl, Ar, S, Mo)

Synopsys pre-trained MTP parameters for MoS2 layers Cl and Ar. Trained using DFT-LCAO PBE PseudoDojo-high as reference calculator and 750 MTP basis functions. Supports MTP error prediction., Synopsys QuantumATK., X-2025.06

QuantumATK_MTP_Ru_2022 (Ru)

Synopsys pretrained MTP parameters for bulk crystal and amorphous Ru. Trained using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis., Synopsys QuantumATK, U-2022.12

QuantumATK_MTP_Sc_2022 (Sc)

Synopsys pretrained MTP parameters for bulk crystal and amorphous Sc. Trained using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis., Synopsys QuantumATK, U-2022.12

QuantumATK_MTP_SiC_Defects_2023 (C, Si)

Synopsys pre-trained MTP parameters for 4H and 6H bulk hexagonal SiC. Included defects are Si/C vacancies, Si/C anti-sites (native substitutionals), and various Si/C interstitials. DFT-LCAO PBE PseudoDojo-medium as reference calculator and 3000 MTP basis., Synopsys QuantumATK, V-2023.09

QuantumATK_MTP_SiO2_2022 (O, Si)

Synopsys pretrained MTP parameters for bulk crystal and amorphous SiO2. Trained to quartz, cristobalite, and low- and high-temperature am. SiO2, using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis., Synopsys QuantumATK, T-2022.03

QuantumATK_MTP_SiO2_2022_12 (O, Si)

Synopsys pretrained MTP parameters for bulk crystal and amorphous SiO2. Trained to quartz, cristobalite, and low- and high-temperature am. SiO2, using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis. Retrained version with improved accuracy. Supports MTP error prediction., Synopsys QuantumATK, U-2022.12

QuantumATK_MTP_Si_SiO2_2022 (O, Si)

Synopsys pretrained MTP parameters for Si / SiO2 interfaces. Trained using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis., Synopsys QuantumATK, T-2022.03

QuantumATK_MTP_Si_SiO2_2022_12 (O, Si)

Synopsys pretrained MTP parameters for Si / SiO2 interfaces. Trained using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis. Retrained version with improved accuracy. Supports MTP error prediction., Synopsys QuantumATK, T-2022.03

QuantumATK_MTP_Si_SiO2_HfO2_TiN_2022_12 (Hf, Ti, N, O, Si)

Synopsys pretrained MTP parameters for Si / SiO2 / HfO2 / TiN interfaces in an HKMG stack. Trained using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis. Supports MTP error prediction., Synopsys QuantumATK, U-2022.12

QuantumATK_MTP_Si_SiO2_HfO2_TiN_2025_06 (Hf, Ti, N, O, Si)

Synopsys pretrained MTP parameters for Si / SiO2 / HfO2 / TiN interfaces in an HKMG stack. Trained using DFT-LCAO PBE PseudoDojo-medium as reference calculator and 800 MTP basis functions. Retrained with improved accuracy. Supports MTP error prediction., Synopsys QuantumATK, X-2025.06

QuantumATK_MTP_Si_SiO2_HfO2_TiN_Al_2025_06 (Hf, Ti, N, O, Si, Al)

Synopsys pretrained MTP parameters for Si / SiO2 / HfO2 / TiN interfaces in an HKMG stack with Al doping. Trained using DFT-LCAO PBE PseudoDojo-medium as reference calculator and 800 MTP basis functions. Supports MTP error prediction., Synopsys QuantumATK, X-2025.06

QuantumATK_MTP_Si_Ti_TiSi_2022 (Ti, Si)

Synopsys pretrained MTP parameters for Si / Ti / TiSi interfaces. Trained to TiSi, C49- and C54-TiSi2, low- and high-temperature am. TiSi, a well as interfaces with crystalline Si and Ti, using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and 300 MTP basis functions., Synopsys QuantumATK, T-2022.03

QuantumATK_MTP_Si_Ti_TiSi_2023_09 (Ti, Si)

Synopsys pretrained MTP parameters for Si / Ti / TiSi interfaces. Trained to TiSi, C49- and C54-TiSi2, low- and high-temperature am. TiSi, a well as interfaces with crystalline Si and Ti, using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and 300 MTP basis functions. Supports MTP error prediction., Synopsys QuantumATK, V-2023.09

QuantumATK_MTP_TiNAlO_2022 (Ti, O, Al, N)

Synopsys pretrained MTP parameters for bulk crystal and amorphous TiNAlO systems and interfaces. Trained using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and 734 MTP basis functions., Synopsys QuantumATK, T-2022.03

QuantumATK_MTP_TiNAlO_2022_12 (Ti, O, Al, N)

Synopsys pretrained MTP parameters for bulk crystal and amorphous TiNAlO systems and interfaces. Trained using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and 734 MTP basis functions., Synopsys QuantumATK. Retrained version with improved accuracy., U-2022.12

QuantumATK_MTP_TiNAlO_2023_09 (Ti, O, Al, N)

Synopsys pretrained MTP parameters for bulk crystal and amorphous TiNAlO systems and interfaces. Trained using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and 800 MTP basis functions. Supports MTP error prediction., Synopsys QuantumATK. Retrained version with improved accuracy., V-2023.09

QuantumATK_MTP_TiN_2022 (Ti, N)

Synopsys pretrained MTP parameters for bulk crystal and amorphous TiN. Trained using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and PredefinedSmall MTP basis., Synopsys QuantumATK, T-2022.03

QuantumATK_MTP_TiN_2022_12 (Ti, N)

Synopsys pretrained MTP parameters for bulk crystal and amorphous TiN. Trained using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and 734 MTP basis functions. Retrained version with improved accuracy. Supports MTP error prediction., Synopsys QuantumATK, U-2022.12

QuantumATK_MTP_TiSi_2022 (Ti, Si)

Synopsys pretrained MTP parameters for bulk crystal and amorphous TiSi. Trained to TiSi, C49- and C54-TiSi2, low- and high-temperature am. TiSi, using DFT-LCAO PBE with PseudoDojo-medium as reference calculator and 300 MTP basis functions., Synopsys QuantumATK, T-2022.03

4.2.5 NEGF: Device Calculators

Introduction

This section describes the most important aspects of the formalism in QuantumATK for simulating device systems using the non-equilibrium Greens function (NEGF) method. For a more detailed description of the theory and application examples you may consult QuantumATK reference paper by Smidstrup *et al.*[1] and some of the many research papers on the subject[2],[3],[4],[5].

In QuantumATK, the NEGF formalism is implemented in combination with *DFT: LCAO* and *Semi Empirical* in the *DeviceLCAOCalculator* and the *DeviceSemiEmpiricalCalculator*, respectively.

Device configuration

A typical device configuration is illustrated in Fig. 4.2.

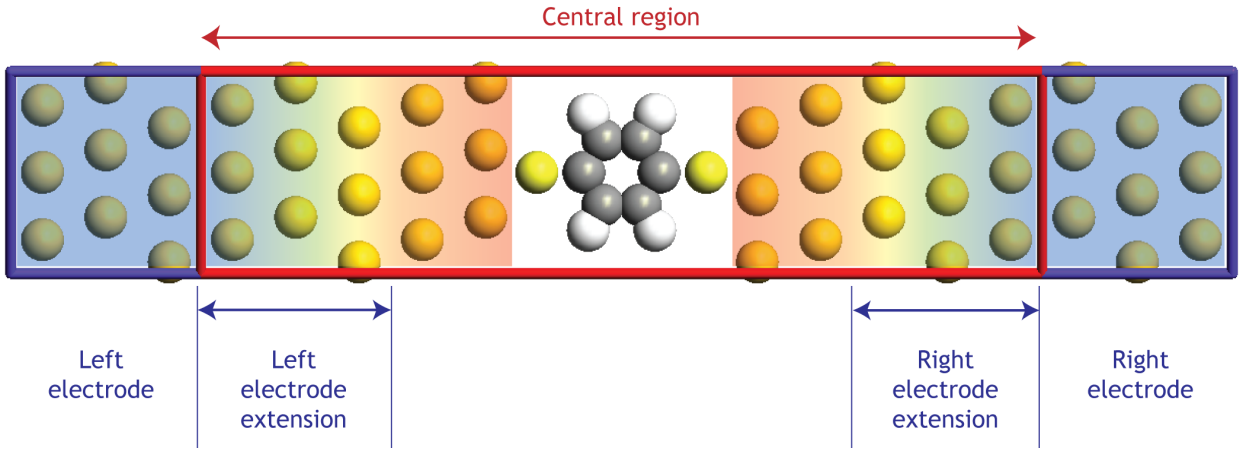

Fig. 4.2: Geometry of a device configuration with two electrodes (two-probe configuration). In the left and right electrode regions the system is periodic in the transport direction (the *C* direction). The central region seamlessly connects the left and right electrode regions, and the part of the central region where the atom positions follow the periodic arrangement of the electrodes is called the left and right electrode extension. The background color symbolizes the perturbation of the electrode effective potential relative to the electrode self-consistent value. A sufficient fraction of the electrodes must be included in the central region to screen out the perturbation of the scattering region, such that the outermost part of the central region attains an effective potential similar to the bulk potential of the electrodes. The matching between these potentials forms the boundary condition for the electrostatic problem.

The system can be divided into three regions: left, central, right. The implementation relies on the so-called screening approximation, which assumes that the properties of the left and right regions, the electrodes, can be described by solving a bulk problem for the fully periodic electrode cell. The screening approximation will formally be fulfilled

when the current through the system is sufficiently small that the electrode regions can be described by an equilibrium electron distribution.

Fig. 4.2 illustrates how the electrode regions must be extended into the central region, in order to screen out the perturbations from the scatterer (in this case the benzene molecule) inside the device. For metallic electrodes it is usually sufficient to extend the electrodes 5-10 Å into the central region.

Non-equilibrium electron distribution

The left and right regions are equilibrium systems with periodic boundary conditions, and the properties of these systems are obtained using a conventional electronic structure calculation. The challenge in calculating the properties of a device system lies in the calculation of the non-equilibrium electron distribution in the central region.

The assumption is that the system is in a steady state such that the electron density of the central region is constant in time. The electron density is given by the occupied eigenstates of the system. Since the chemical potential is different in the two electrodes, the contribution from each electrode to the total electron density in the central region must be calculated independently:

$$n(\mathbf{r}) = n^L(\mathbf{r}) + n^R(\mathbf{r}).$$

The contribution from the left (n^L) and right (n^R) electrodes can be obtained by calculating the scattering states, which are the eigenstates of the system when scattering boundary conditions are used. Fig. 4.3 illustrates a left moving scattering state with origin in the right electrode.

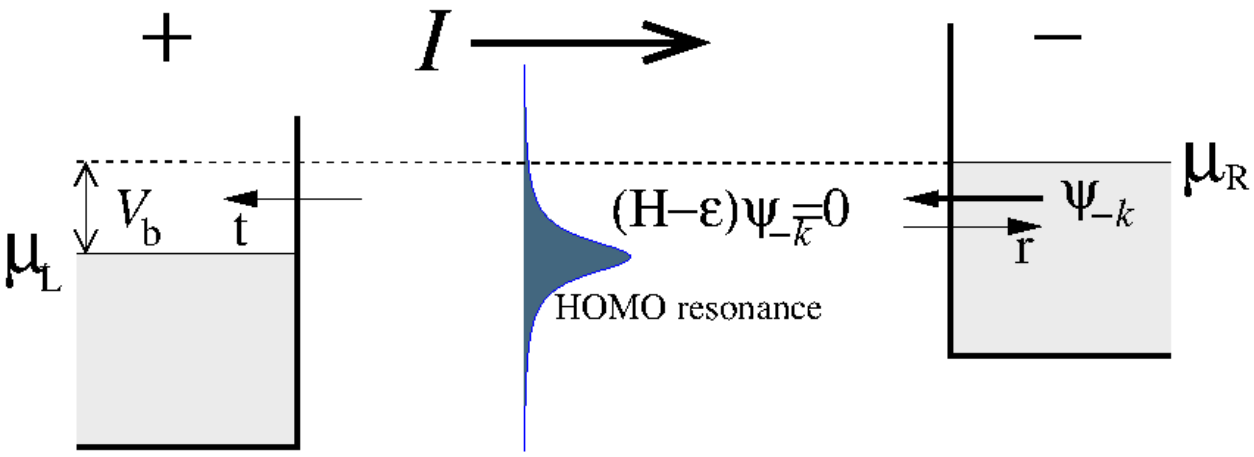

Fig. 4.3: The electron distribution in a device configuration. The left and right regions have an equilibrium electron distribution with chemical potentials μ_L and μ_R, related through the applied sample bias, $\mu_R - \mu_L = eV_b$. The electrons with energies in the bias window $\mu_L \leq \varepsilon \leq \mu_R$, give rise to a steady state electrical current. The figure illustrates a left moving scattering state with origin in the right electrode.

The left and right density are now calculated by summing up the occupied scattering states,

$$n^L(\mathbf{r}) = \sum_\alpha |\psi_\alpha(\mathbf{r})|^2 f\left(\frac{\varepsilon_\alpha - \mu_L}{kT}\right),$$

$$n^R(\mathbf{r}) = \sum_\alpha |\psi_\alpha(\mathbf{r})|^2 f\left(\frac{\varepsilon_\alpha - \mu_R}{kT}\right).$$

The scattering states of the system are calculated by first calculating the Bloch states in the electrodes and subsequently solving the Schrödinger equation of the central region using the Bloch states as matching boundary conditions.

The non-equilibrium Greens function (NEGF) method

Instead of using the scattering states to calculate the non-equilibrium electron density, QuantumATK uses the non-equilibrium Greens function (NEGF) method; the two approaches are formally equivalent and give identical results[Page 1935, 2].

The electron density is given in terms of the electron density matrix, as described in section *Electron density*. We divide the density matrix into left and right contributions,

$$D = D^L + D^R.$$

The left density matrix contribution is calculated using the NEGF method as[Page 1935, 2]

$$D^L = \int \rho^L(\varepsilon) f\left(\frac{\varepsilon - \mu_L}{k_B T_L}\right) d\varepsilon,$$

where

$$\rho^L(\varepsilon) \equiv \frac{1}{2\pi} G(\varepsilon)\Gamma^L(\varepsilon)G^\dagger(\varepsilon)$$

is the spectral density matrix. Note that while there is a non-equilibrium electron distribution in the central region, the electron distribution in the electrode is described by a Fermi function f with an electron temperature T_L .

In this equation, G is the retarded Greens function, and

$$\Gamma^L = \frac{1}{i}(\Sigma^L - (\Sigma^L)^\dagger)$$

is the broadening function of the left electrode, given in terms of the left electrode self energy, Σ^L . A similar equation exists for the right density matrix contribution.

The following section describes the calculation of G and Σ in more detail.

Retarded Greens function

The key quantity to calculate is the retarded Greens function matrix,

$$G(\varepsilon) = \frac{1}{(\varepsilon + i\,\delta_+)S - H},$$

where δ_+ is an infinitesimal positive number. S and H are the overlap and Hamiltonian matrices, respectively, of the entire system.

The Greens function is only required for the central region and can be calculated from the Hamiltonian of the central region by adding the electrode self energies:

$$G(\varepsilon) = [(\varepsilon + i\delta_+)S - H - \Sigma^L(\varepsilon) - \Sigma^R(\varepsilon)]^{-1}.$$

Therefore, the calculation of the Greens function of the central region at a specific energy requires the inversion of the Hamiltonian matrix of the central region. In QuantumATK this matrix is stored in a sparse format, and the inversion is done using an $\mathcal{O}(N)$ algorithm[6].

Self energy

The self energy describe the effect of the electrode states on the electronic structure of the central region. The self energy can be calculated from the electrode Hamiltonian. QuantumATK provides 4 different methods for calculating the self energy:

- *DirectSelfEnergy* uses an exact diagonalization of the Hamiltonian for calculating the self energy[7].
- *RecursionSelfEnergy* uses an iterative scheme for calculating the self energy[8], which gives essentially the same results as the direct method but is faster for some systems.
- *SparseRecursionSelfEnergy* uses the same iterative scheme as *RecursionSelfEnergy*, but exploits inherent sparsity. This provides a smaller memory footprint, as well as increased performance for all but the smallest systems.
- *KrylovSelfEnergy* is an approximate method which is an order of magnitude faster that the other methods, but may in rare cases give inaccurate results[9],[10] .

Complex contour integration

The energy integral needed to obtain the density matrix within the NEGF framework is evaluated through a complex contour integration. It is divided into two parts; an integral over equilibrium states and an integral over non-equilibrium states.

The integral over the **equilibrium states** can be done using two different methods:

- *SemiCircleContour*: Defines a semi-circular complex contour that gives high computational efficiency[Page 1935, 2].
- *OzakiContour*: Evaluation of the complex contour integral is based on the residue theorem and a continued-fraction representation of the Fermi–Dirac districation[11][12]. This is a highly stable method, but is also less efficient than *SemiCircleContour*.

The integral over the **non-equilibrium states** must be performed along the real axis, and uses the *RealAxisContour* method. Note that for large biases, this is often the most demanding part of the calculation.

Lastly, one of two different **contour methods** must be chosen (usually just left at the default value):

- *SingleContour* uses a single contour for the calculation. This is appropriate for small biases, and is the fastest method.
- *DoubleContour* uses a double contour for the calculation. This gives best stability and must be used for high biases. The method can also handle if there are bound states inside the bias window.

See also *ContourParameters*.

Spill-in terms

In terms of the density matrix, D , the electron density of the central region is given by

$$n(\mathbf{r}) = \sum_{ij} D_{ij}\phi_i(\mathbf{r})\phi_j(\mathbf{r}).$$

The Greens function of the central region gives the density matrix of the central region, D_{CC} , however, to calculate the density correctly close to the central cell boundaries the terms involving, $D_{LL}, D_{LC}, D_{CR}, D_{RR}$ are also needed. These terms are denoted spill-in terms[13].

ATK includes all the spill-in terms, both for calculating the electron density $n(\mathbf{r})$ and the Hamiltonian integral. This gives additional stability and well-behaved convergence in the device algorithm[Page 1939, 13].

Effective potential

Once the non-equilibrium density is obtained the next step in the self-consistent calculation is the calculation of the effective potential as the sum of the exchange-correlation and electrostatic Hartree potentials. The calculation of the exchange-correlation potential is straightforward since it is a local or semi-local function of the density. However, the calculation of the electrostatic Hartree potential requires some additional consideration for a device system. The following describes the calculation of the Hartree potential in more detail.

The starting point is the calculation of the self-consistent Hartree potential in the left and right electrodes. The Hartree potential of a bulk system is defined up to an arbitrary constant. However, in a device setup the Hartree potentials of the two electrodes are aligned through their chemical potentials (i.e. their Fermi levels), since these are related by the applied bias:

$$\mu_R - \mu_L = eV_b.$$

The Hartree potential of the central region is obtained by solving the Poisson equation, using the bulk-like Hartree potentials of the electrodes as boundary conditions at the interfaces between the electrodes and the central region. An overview of the available Poisson solvers and how boundary conditions are applied for NEGF calculations is given in *Boundary conditions*.

Total energy and forces

A device system is an open system where charge can flow in and out of the central region from the left and right reservoirs. Since the particle number is not conserved it is necessary to use a grand canonical potential to describe the energetics of the system[14]:

$$\Omega[n] = \varepsilon[n] - e\,N_L\,\mu_L - e\,N_R\,\mu_R,$$

where $N_{L/R}$ is the number of electrons contributed to the central region from the left/right electrode.

Due to the screening approximation, the central region will be charge neutral, and therefore $N_L + N_R = N$, where N is the ionic charge in the central region. Thus, at no applied bias, we ahve $\mu_L = \mu_R$ and the particle terms in Ω will be constant when atoms are moved in the central region. However, at finite bias, $\mu_L \neq \mu_R$, and the particle terms in Ω will be important.

The forces are given by

$$\mathbf{F}_i = -\frac{\partial\Omega[n]}{\partial\mathbf{R_i}}.$$

[13] D.ăStradi, U.ăMartinez, A.ăBlom, M.ăBrandbyge, and K.ăStokbro. General atomistic approach for modeling metal-semiconductor interfaces using density functional theory and nonequilibrium Greens function. *Phys. Rev. B*, 93:155302, Apr 2016. doi:10.1103/PhysRevB.93.155302.

[14] T.ăN. Todorov. Local heating in ballistic atomic-scale contacts. *Philosophical Magazine Part B*, 77(4):965–973, 1998. doi:10.1080/13642819808206398.

It can be shown that the calculation of this force is identical to the calculation of the equilibrium force, as described in *Total energy and forces*. In the non-equilibrium case it is however required that the density and energy density matrix is calculated with the NEGF framework[Page 1935, 2], [Page 1939, 14], [15].

See also *TotalEnergy*.

Transmission coefficient

When the self-consistent non-equilibrium density matrix has been obtained, it is possible to calculate various transport properties of the system. One of the most notable is the *TransmissionSpectrum* from which you can obtain the current and differential conductance.

By the transmission amplitude t_k we define the fraction of a scattering state k which propagates through a device. The transmission coefficient at energy ε is obtained by summing up the transmission amplitude from all the states at this energy,

$$T(\varepsilon) = \sum_k t_k^\dagger t_k \delta(\varepsilon - \varepsilon_k).$$

The transmission coefficient may also be obtained from *the retarded Greens function* using

$$T(\varepsilon) = G(\varepsilon)\Gamma^L(\varepsilon)G^\dagger(\varepsilon)\Gamma^R(\varepsilon),$$

and this is how it is calculated in QuantumATK. The transmission amplitude of individual scattering states may be obtained through the *TransmissionEigenvalues*.

Electrical current

To calculate the current you must first calculate a *TransmissionSpectrum*, and then from this extract the electrical current using the `current()` method on the object. This approach has the advantage that once the *TransmissionSpectrum* is calculated, it is fast to calculate the current for different electrode temperatures[Page 1939, 13].

See *TransmissionSpectrum* for more details.

All calculations in QuantumATK are controlled via *ATK-Python*, which is an extension to the well-known Python scripting language. All QuantumATK Python scripts are executed using the **atkpython executable**, which is installed with QuantumATK.

If you have no prior knowledge about the Python Programming Language you might want to check out our quick introduction in sect1.python.basics.

If you have an QuantumATK Python script named `script.py`, it is easy to run it from command line:

```
$ atkpython script.py
```

You can also simply execute `atkpython` without an argument to invoke an **interactive session** that allows you to execute ATK-Python commands one after another (hit Enter to execute a line):

```
$ atkpython

Input lines 1–4 in the example above are standard Python commands. However, input line 5 creates the primitive silicon bulk using the *BulkConfiguration* class from ATK-Python, while input line 6 uses the *nlprint* functionality to print the main contents of the parameters defining the silicon bulk.

All the standard functionality of Python is available when you invoke QuantumATK. However, the main purpose of this chapter is to introduce the ATK-Python module. If you have no prior experience with Python, we encourage you to first go through the section sect1.python.basics.

4.3.1 ATK-Python

ATK-Python extends the standard Python environment with concepts and objects relevant for computational nano-scale physics and chemistry. This enables a simple, flexible, and intuitive way to operate QuantumATK: Use Python scripting to define nano-structures, atomic-scale simulators, and post-SCF analyses to be performed. Simply write the QuantumATK Python script and execute it.

For example, ATK-Python contains a periodic table of the elements, units such as Rydberg and Angstrom, methods for calculating the one-electron spectrum of a molecule, band structure of solids, and transmission spectra of nano-scale devices, as well of constructors for creating molecules, Bravais lattices, and devices.

The *DFT: LCAO* calculator may be largely implemented in highly efficient C++ routines, but setting up and executing DFT calculations is done using Python and ATK-Python commands. The same applies to setting up and executing analysis tools, as well as reading and writing of computational data. Moreover, the graphical user interface NanoLab uses ATK-Python to read data produced by QuantumATK. ATK-Python is therefore the scripting language that binds all QuantumATK products together, and is a platform on which other developers and companies can build applications and extend the functionality of QuantumATK products.

Important: All QuantumATK functionality available through ATK-Python is documented in the *QuantumATK Reference Manual*.

Python packages in QuantumATK

The QuantumATK distribution comes with all the standard Python modules, plus some additional packages which are useful for scientific computing, such as NumPy and SciPy. The list is long and can change with every release, the best way to get the full list for your local installation of QuantumATK is to run this command on Linux:

```
sh$ /quantumatk_installation_directory/atkpython/bin/python -m pip list
```

or this command on Windows:

```
PS> C:\quantumatk_installation_directory\atkpython\Scripts\python -m pip list
```

Using NumPy with QuantumATK

NumPy is the fundamental package for **scientific computing** with Python, since it can be used to perform advanced mathematical operations much faster than using ordinary Python lists. The NumPy module is therefore used throughout ATK-Python to store and manipulate values from analysis functions. NumPy objects resemble ordinary lists, but contain a lot more functionality, and QuantumATK ships with built-in NumPy support to easily facilitate its usage.

A few major differences between ordinary lists and NumPy arrays can be seen from this short example:

```
>>> from numpy import array
>>> a = array([1,2]) # a NumPy array
>>> a = a+[3,4]
>>> print(a)
[4, 6]
>>> b = [1,2]  # an ordinary Python list
>>> b = b+[3,4]
>>> print(b)
[1, 2, 3, 4]
```

As seen in the example above, NumPy arrays can in many ways be regarded as matrices. The following example underlines this:

```
>>> a = array([1,2],[3,4]])
>>> a = a *[3,4]
>>> print(a)
[[ 3  8]
[ 9 16]]
>>> print(a.trace())
19
>>> a.transpose()
>>> print(a)
[[ 3  9]
 [ 8 16]]
>>> print(a.trace())
19
```

Note in the above that the values 8 and 9 changed place in the matrix after applying the `transpose()` operation. However, as expected, the *trace* of the matrix remains the same.

NumPy arrays may also be converted into lists:

```
>>> a = array([1,2],[3,4]])
>>> print(a.tolist())
[[1, 2], [3, 4]]
```

There are many more possibilities using arrays from the NumPy module, and it is usually faster than iterating through for-loops or using ordinary lists!

More information can be found at the NumPy website, or by using the `dir()` command on a NumPy `array` object. Details on how NumPy can be used for improved performance can be found at the online resource Python Performance Tips.

Cloning of QuantumATK Python objects

It is possible to get a **copy** of an QuantumATK object using a method called *cloning*. This is done by adding a closed parenthesis after the object:

```
parameter_object = IterationControlParameters(tolerance=1.e-5)
parameter_object_clone = parameter_object()
```

Very importantly, it is possible to **modify the parameters** of the clone by specifying the new parameters during cloning:

```
parameter_object = IterationControlParameters(tolerance=1.e-5)
parameter_object_clone = parameter_object(max_steps=50, damping_factor=0.2)
```

Plotting using pylab

The following script uses the NumPy and matplotlib modules for creating a 2D plot:

```
import pylab
x = numpy.linspace(-1,5,10)
y = numpy.exp(x)
pylab.figure()
pylab.plot(x,y)
pylab.show()
```

Note that the NumPy package is automatically loaded with the ATK-Python module, so the `import numpy` statement is not really needed when running **atkpython**.

Note that QuantumATK also has an advanced plotting module for plotting publication quality 2D plots. The Plot module is automatically included in the ATK-Python module, and plots can be created, modified and shown both from scripts and through the NanoLab GUI. Read more in the *NanoLab Plot Reference Manual*.

4.3.2 Physical quantities and units

Units are a key concept in QuantumATK. All parameters that correspond to physical quantities, such as lengths, energies, voltages, etc., should be specified with an explicit unit. Similarly, all physical results returned from QuantumATK calculations also contain an explicit unit. PhysicalQuantity objects are created by multiplying the scalar, list, or array, containing the quantitys value(s), with the desired unit:

```
>>> a = [[1.0, 2.0], [3.0, 4.0]]*Angstrom
>>> t = 0.5*femtoSecond**-1
```

See below sections for physical units available in *QuantumATK*.

All PhysicalQuantity objects have two query methods:

- `inUnitsOf(Unit)`: Returns the numerical value in the specified unit as a numpy-array, respectively numpy-float object for scalar values.
- `convertTo(Unit)`: Returns the value of the PhysicalQuantity as a new PhysicalQuantity object in the specified unit.

Moreover, since the PhysicalQuantity class derives from numpy.array, PhysicalQuantity objects can be used, in most respects, as a numpy array. This means that many class methods of numpy arrays, such as sum(), max(), or reshape() can be used with PhysicalQuantity objects.

Element-wise operations between two PhysicalQuantity objects work as in numpy, e.g.:

```
>>> a = [[1.0, 2.0], [3.0, 4.0]]*Ang
>>> b = [[2.0, 2.0], [4.0, 4.0]]*nanoMeter
>>> c = a + b
>>> print(c)
[[ 21.  22.]
 [ 43.  44.]] Ang
```

Note, that addition and multiplication require compatible units for all operands.

Most numpy universal functions, as well as the two numpy functions numpy.dot and numpy.cross, work for PhysicalQuantity objects, in the same way as for numpy arrays.

Note, however, that most other numpy and python functions, e.g. numpy.arange, are not supported for PhysicalQuantity. In order to use them, the units have to be removed, via `inUnitsOf()` before the function is invoked:

```
>>> a = 5.0*Ang
>>> b = 1.0*nanoMeter
>>> delta = 0.5*Ang
>>> distances = numpy.arange(a.inUnitsOf(Ang), b.inUnitsOf(Ang), delta.inUnitsOf(Ang))
```

If the result of a PhysicalQuantity-operation is unitless, e.g:

```
>>> a = [[1.0, 2.0], [3.0, 4.0]]*Ang
>>> b = [[2.0, 2.0], [4.0, 4.0]]*Ang**-1
>>> c = a*b
>>> print(c)
[[ 21.  22.]
 [ 43.  44.]]
```

the result is directly returned as a numpy array, respectively as numpy float for scalar values.

Usage Examples

Getting a float value:

```
>>> a = 5*Angstrom
>>> print(a.inUnitsOf(nanoMeter))
0.5
```

Getting a PhysicalQuantity object:

```
>>> print(a.convertTo(nanoMeter))
0.5 nm
```

Physical quantities can be transformed with an exponent:

```
>>> a = 2. * Meter * Second**-2
>>> v = (2 * a * (1*Meter))**0.5
>>> print(v)
2.0 m/s
```

Inverse units are specified by using the exponent operator **:

```
>>> f = 2.2/Second
>>> print(f.inUnitsOf(Second**-1))
2.2
```

Units are attached to values by multiplication. Thus, to specify a length of 5 Bohr:

```
>>> a = 5*Bohr
```

By printing the value of the variable `a`, the unit will automatically be displayed:

```
>>> print(a)
5.0 Bohr
```

Units can also be composite. The unit for force is Newton, which is Joule per Meter. This is a rather awkward unit for nano-scale calculations, where something like electron volt per nm makes more sense. Any energy divided by a length is, however, a valid force unit, so to specify a force, write:

```
>>> F = 5*eV/Bohr
```

Next, multiply this by a length again and the result will be an energy:

```
>>> b = F*5*Bohr
>>> print(b)
25*eV
```

Some unit abbreviations are only available with the `Units` prefix:

```
>>> b = 5.1*Units.Ry
>>> print(b)
5.1 Rydberg
```

Units that by default are specified without a prefix, can also be given with a prefix:

```
>>> b = 5.1*Rydberg
>>> c = 5.1*Units.Rydberg
```

Units available in QuantumATK

The following units are made available when importing *QuantumATK*:

Table 4.4: Units available in QuantumATK. More units are available using the `Units` prefix.

Unit type	Name
Length units	nm
	nanoMeter
	Ang
	Angstrom
	Bohr
	Meter
Energy units	Rydberg
	eV
	meV

4.3.3 Read and Write Support

Read and write functionality in *QuantumATK* is provided by two functions: *nlread* and *nlsave*. Storage of several objects per file is supported. Each object in native ATK files is associated with a unique identifier – the `object_id`. If a new entry is saved without specifying an `object_id`, the entry is appended to the file with an auto-generated `object_id`. If an `object_id` is specified which already is present in the file, the old entry is automatically deleted.

ATK natively supports the HDF5 file format (from QuantumATK version $\geq$ 2017). It is platform independent, i.e. the files can, for instance, be written on a Linux platform and later be read on a Windows platform. The internal data structure is performance-optimized.

HDF5 (Default File Format)

specification	HDF5 format
`object_id` (default)	classname_x with x being an increasing integer

HDF5 is the default file format for QuantumATK version $\geq$ 2017. The file format supports *Metatext*, and deleting objects – see *nldelete*. Due to the performance-optimized storage, the file size is not automatically reduced if objects have been deleted / overwritten. The free space can be reclaimed with *nlrepack*. The stored data can easily be accessed by hdf-view or by any program based on libhdf5.

4.3.4 Metatext

Most of the objects available in *QuantumATK* have support for Metatext. This feature allows the user to store additional text on an object. All *Configuration* and *Analysis* objects support this feature. The information is automatically written to / read from *HDF5* files. Access to the Metatext of an object `obj` is provided by two functions:

obj.setMetatext(metatext)	Sets the `metatext` on `obj`. `metatext` has to be of type str.
obj.metatext()	Returns the metatext of `obj`.

Moreover, with the utility functions *readMetatext* one can access the Metatext of an object stored in a file.

4.3.5 Spin

Spin is a flag. As such it cannot be constructed; `Spin()` is an invalid command. Instead, Spin provides derived classes (flags) to represent spin components and projections:

Spin.Up	The up component of a spinor (up-up component of a spin matrix).
Spin.Down	The down component of a spinor (down-down component of a spin matrix).
Spin.RealUpDown	The real part of the up-down component of a spinor (spin matrix.)
Spin.ImagUpDown	The imaginary part of the up-down component of a spinor (spin matrix).
Spin.All	All spin components.
Spin.Sum	The sum Spin.Up + Spin.Down
Spin.X	The spin projection along x (Spin.X = 2*Spin.RealUpDown).
Spin.Y	The spin projection along y (Spin.Y = -2*Spin.ImagUpDown).
Spin.Z	The spin projection along z (Spin.Z = Spin.Up - Spin.Down).
Spin.Unknown	Unknown spin.

Usage Example

Calculate the electron density for all spin and evaluate some components:

```
# Calculate the electron density for a given configuration.
ed_up = ElectronDensity(configuration, spin=Spin.All)

# Take some spin projections.
x = ed.spinProjection(spin=Spin.X)
y = ed.spinProjection(spin=Spin.Y)
z = ed.spinProjection(spin=Spin.Z)
s = ed.spinProjection(spin=Spin.Sum)
r = ed.spinProjection(spin=Spin.RealUpDown)
i = ed.spinProjection(spin=Spin.ImagUpDown)
u = ed.spinProjection(spin=Spin.Up)
d = ed.spinProjection(spin=Spin.Down)

# Evaluate for Spin.X at the origin.
data = ed.evaluate(0.0*Bohr, 0.0*Bohr, 0.0*Bohr, spin=Spin.X)
```

Note about Spin.All

Precisely which spin components are returned when calling an objects query method with `spin = Spin.All` depends on the queried object. E.g. `ElectronDensity.evaluate(x, y, z, spin=Spin.All)` returns a list of four electron density values at the grid point (x, y, z) corresponding to `Spin.Sum`, `Spin.X`, `Spin.Y`, and `Spin.Z`. In other cases (e.g. ExchangeCorrelationPotential), the returned array contains the values corresponding to the spinor components `Spin.Up`, `Spin.Down`, `Spin.RealUpDown`, and `Spin.ImagUpDown`. Refer to the objects documentation for details.

Note on Spin in low level interface functions

In all low level interface functions such as calculateHamiltonianAndOverlap, calculateDensityMatrix, calculateSelfEnergy etc., the following rules for the spin parameter apply:

- **UNPOLARIZED**: Valid spin parameters are Spin.Up and Spin.All, which both yield the same result in this case, as there is no designated spin direction in UNPOLARIZED calculations.
- **POLARIZED**: Valid spin parameters are Spin.All, Spin.Up, and Spin.Down. The default is Spin.All, in which case the function returns a pair of matrices, one for the Spin.Up and one for the Spin.Down component. For Spin.Up or Spin.Down, only the respective spin component is returned.
- **NONCOLLINEAR / SPINORBIT**: In noncollinear calculations, only Spin.All is an accepted parameter. The returned matrix contains the spin components Spin.Up, Spin.Down, Spin.UpDown, and Spin.DownUp in an interleaved fashion, see below for an example.

Examples

```
# Calculate the density matrix for a polarized system.
D = calculateDensityMatrix(polarized_configuration, spin=Spin.All)
# Extract the Spin.Up component.
D_uu = D[0]
# Extract the Spin.Down component.
D_dd = D[1]

# Calculate the density matrix for a noncollinear system.
```

(continues on next page)

(continued from previous page)

```
D = calculateDensityMatrix(noncollinear_configuration, spin=Spin.All)
# Get all up-up entries:
D_ud = D[::2,::2]
# Get all down-down entries:
D_du = D[1::2,1::2]
# Get all up-down entries:
D_ud = D[1::2,::2]
# Get all down-up entries:
D_du = D[::2,1::2]
```

4.3.6 Command Line Usage with QATK Shell Environments

Introduction

One of the most notable features of QuantumATK is the powerful graphical user interface, which makes it easy to develop complex workflows and analyze their results. Nevertheless, the command line (CLI) usage is common and sometimes necessary, for example in high performance computing (HPC) systems or when you want to experiment with new Python packages.

We present here two useful tools for these purposes:

- **QATK Shell Environment**: a convenient way to have all QuantumATK utilities at your fingertips when working in a CLI environment.
- **Python Virtual Environments**: the best way to experiment with additional Python packages in combination with QuantumATK modules.

In the following section you will find several examples of commands, the commands come after the command prompt which is here shortened to `sh$` for Bash on Linux and `PS>` for PowerShell on Windows.

Use QuantumATK effectively from CLI: Shell Environments

Starting from the W-2024.09 release, you can find an additional file in your QuantumATK installation, `atkpython/bin/activate_env` on Linux and `atkpython/Scripts/activate_env.ps1` on Windows. The first one is a Bash script and the second one a PowerShell script. These scripts make it easier to use ATKPython and other QuantumATK tools from a command line prompt, and the next two section will explain how.

Bash on Linux

From an open Bash shell you activate the environment by dot sourcing the script:

```
sh$ source <quantumatk_installation>/atkpython/bin/activate_env
```

You will notice a change in the command prompt written in the terminal, for example the common prompt `username@hostname$` will become `(qatk) username@hostname$`, the `(qatk)` prefix in the prompt text will help you remember you are inside the QATK Shell Environment.

Note: This can remind you of Python virtual environments, but it is not the same, because there is no virtualized environment, you are directly using the QuantumATK installation. The implications of this are explained in this section: *Customize the environment: Python venvs*.

Once the QATK Shell Environment is active, you have all the main QuantumATK binaries available in the shell, for example you can execute `atkpython` or execute the built-in `python` executable with access to all QuantumATK modules:

```
(qatk) sh$ atkpython -c 'print((5*Angstrom).convertTo(Bohr))'
9.44863062283 Bohr
(qatk) sh$ python -c 'from QuantumATK import Units; print((5*Units.Angstrom).
↪convertTo(Units.Bohr))'
9.44863062283 Bohr
```

The environment also gives access to a large class of executables, including those included with the pre-installed Python modules and the default Intel MPI installation. This means you can easily run an ATKPython script in parallel from inside this environment:

```
(qatk) sh$ mpiexec -n 4 atkpython /path/to/script.py
```

If you prefer to use a system installation of MPI instead of the Intel MPI setup included with QuantumATK, you can just add a flag when sourcing the activation script:

```
sh$ source <quantumatk_installation>/atkpython/bin/activate_env --use-system-mpi
```

In order to deactivate the environment and go back to the previous state of the shell:

```
(qatk) sh$ deactivate_qatk
```

The `(qatk)` prefix will disappear from the prompt, which means that the QATK Shell Environment is no longer active. If you do not want this prefix to be shown in the command prompt, you can assign any value to the `QATK_ENV_DISABLE_PROMPT` environment variable before activating the environment.

Advanced options for `activate_env`

Sourcing the `activate_env` script without additional options will set up the `LD_LIBRARY_PATH` and `PATH` environment variables to point to all the necessary bundled libraries and executables used for QuantumATK. This ensures that the QuantumATK tools can work in most environments.

By default, the `activate_env` script will add the following to the environment:

1.Prepend to `LD_LIBRARY_PATH`:

1.The C++ standard library `libstdc++`

2.A software rendering implementation of OpenGL `libGL`

3.The Intel MPI libraries

4.Many other 3rd party libraries located in `<quantumatk_installation>/atkpython/lib` (e.g. `libQt5Core`).

5.The python library used for QuantumATK

2.Append to `LD_LIBRARY_PATH`:

1.The CUDA libraries

3.Prepend to `PATH`:

1.The Intel MPI executables

The `activate_env` script comes with several options to change this behavior. You can see the full list of options by running:

```
sh$ <quantumatk_installation>/atkpython/bin/activate_env --help
```

Note: All libraries bundled with QuantumATK are using `DT_RUNPATH` to find their dependencies, so that QuantumATK can also run with an empty `LD_LIBRARY_PATH`. Since `LD_LIBRARY_PATH` has higher priority than `DT_RUNPATH` and could potentially be set to a conflicting value, we set `LD_LIBRARY_PATH` to the QuantumATK libraries by default. However, options to change this behavior are available.

Common cases where you might want to use these options are:

1. Systems with hardware accelerated OpenGL

   Use the system OpenGL libraries instead of the bundled software rendering implementation to get the best QuantumATK Nanolab performance:

   ```
   sh$ source <quantumatk_installation>/atkpython/bin/activate_env --use-system-gl
   ```

2. Systems with well integrated MPI libraries and executables (e.g. on HPC clusters)

   Try to use the system MPI installation, in case you encounter issues with the bundled Intel MPI:

   ```
   sh$ source <quantumatk_installation>/atkpython/bin/activate_env --use-system-mpi
   ```

3. Systems with a `libstdc++` newer than `libstdc++.so.6.0.31`

   Use the system `libstdc++` instead of the bundled one, as it will allow for the use of system tools in the QuantumATK environment:

   ```
   sh$ source <quantumatk_installation>/atkpython/bin/activate_env --use-system-stdcpp
   ```

4. Conflicts between the 3rd party libraries in `<quantumatk_installation>/atkpython/lib` and system tools you want to use in the QuantumATK environment

   In these cases you can try omitting the `lib` folder from the `LD_LIRBARY_PATH`:

   ```
   sh$ source <quantumatk_installation>/atkpython/bin/activate_env --prefer-system-libs
   ```

PowerShell on Windows

From an open Windows PowerShell shell you activate the environment with:

```
PS> & "<quantumatk_installation>\atkpython\Scripts\activate_env.ps1"
```

Just as in the case of Bash on Linux, the prompt text will show the prefix `(qatk)` when the environment is active, and it gives access to the already named executables and modules. As in the Linux case, you can assign any value to `$QATK_ENV_DISABLE_PROMPT` if you do not want this prefix to be displayed.

Note: The above command might fail because of restrictions in executing scripts inside PowerShell, if this happens the solution might be to modify the execution policy:

```
PS> Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope CurrentUser
```

The Intel MPI setup is included by default in the environment, but if you want to use a separate system installation of MPI you can add a flag as argument to the script:

```
PS> & "<quantumatk_installation>\atkpython\Scripts\activate_env.ps1" -UseSystemMPI
```

You can easily deactivate the environment and go back to the original shell state:

```
(qatk) PS> deactivate_qatk
```

Note: The above applies to all flavours of PowerShell, it is tested on Windows PowerShell which is shipped with Windows 10/11, but it is compatible with the newer PowerShell Core and PowerShell 7.

Customize the environment: Python venvs

In this section we will go through some of the reasons why it is a good idea to use virtual environments with Python, with a special focus on ATKPython.

The problems

With the scripts shown in the previous section you can now use all the powerful tools shipped with QuantumATK, including all the pre-installed Python modules. In fact ATKPython includes NumPy, SciPy, Pandas and many other Python packages which are useful for scientific computing.

But what if you need to install an additional package?

We suppose that you need a package named `final-destination`. You could find instructions online suggesting to run:

```
python -m pip install final-destination
```

But this is usually not a good idea because it installs the package in the *system site-packages directory* which, in the case of the Python executable shipped with QuantumATK, resides inside the QuantumATK installation directory. Therefore, if you run the above command and you have permissions to write to the QuantumATK installation directory, you are going to overwrite the pre-installed files. This can cause two issues. First, if the `final-destination` package depends on, for example, a very recent version of NumPy, this will be installed on top of the pre-installed NumPy package. But this new version of NumPy has not been reviewed by the QuantumATK team, and parts of QuantumATK or pre-installed Python packages might not be compatible with it. The result could be that you are no longer able to start QuantumATK and you would then need to reinstall the software from scratch. Second, if the package installation goes fine and `final-destination` is now installed and works, it will still *pollute* the QuantumATK environment, adding possible sources of problems that the QuantumATK team could not consider when preparing the QuantumATK release. If there is any issue after installing a package this way, the first suggestion would again be to reinstall the software from scratch.

A slightly better alternative is:

```
python -m pip install --user final-destination
```

This command will install the `final-destination` package and all its dependencies to the QuantumATK user folder (`$HOME/.quantumatk` on Linux, `%USERPROFILE%\.quantumatk` on Windows). Unfortunately the problem outlined above still apply, the only positive difference is that you can remove the QuantumATK user folder instead of removing the entire installation. But the QuantumATK user folder also contains the project folders, the license configuration, and many other files you would probably prefer to keep.

The solution

All of the above problems can be solved by using Python Virtual Environments (venv), which allow you to create isolated and self-contained environments you can safely play around with, without any risk for the QuantumATK installation or user folder.

Assuming you are already inside an active QATK Shell Environment and you want to name the virtual environment `final-destination-venv`, you can create a Python venv and activate it with:

```
(qatk) sh$ python -m venv --system-site-packages final-destination-venv
(qatk) sh$ source final-destination-venv/bin/activate
```

The prompt will now show the prefix `(final-destination-venv) (qatk)` to represent the two active environments. Note that the order matters in this case, since the first in the prompt is the last one that has been activated and is therefore the one that has priority. Of course this prefix is a bit long, so we suggest using shorter names for your venvs or specifying a shorter prompt with the `--prompt` flag.

The commands above are almost identical in Windows PowerShell:

```
(qatk) PS> python -m venv --system-site-packages final-destination-venv
(qatk) PS> & "final-destination-venv\Scripts\Activate.ps1"
```

Now that you are inside a virtual environment you can feel free to install your needed package:

```
python -m pip install final-destination
```

This will be installed inside the virtual environment and will not affect anything outside of it. After you are done working with the virtual environment you can go back to the original shell by deactivating the active environments, starting by the last one that has been activated:

```
(final-destination-venv) (qatk) sh$ deactivate
(qatk) sh$ deactivate_qatk
```

You will see the prefixes disappear which means that the environments have been deactivated and your `final-destination` package will not get in your way until you activate the `final-destination-venv` environment again.

If you do not need to have direct access to the additional executables contained in the QuantumATK installation folder, and you do not need to run anything under MPI, then you can skip the QATK Shell Environment activation above:

```
sh$ <quantumatk_installation>/atkpython/bin/python -m pip --system-site-packages final-
↪destination-venv
```

This will create a virtual environment which still has access to the Python modules shipped with QuantumATK, and will work in most cases. If you encounter any issue with this approach while using the Python modules shipped with QuantumATK, just revert to the two steps procedure explained above.

The virtual environment folder will always be available on the system until you manually delete it, and the venv can be activated again at any time by *dot sourcing* the `activate` (`Activate.ps1`) script on Linux (Windows) as explained above. There is no need to create the venv every time with the `python -m venv` command.

You can have several venvs, each in its dedicated folder, and activate them when they are needed. This allows for experimentation and can help organizing your work, when developing several projects in parallel.

Note: It is not guaranteed that QuantumATK modules can be imported and used in a virtual environment created with a different version of QuantumATK.

Step by step examples

We include some examples which summarize in a few commands what we explained above.

Bash on Linux, QATK Shell Environment + Python venv:

```
sh$ QATK_DIR="/path/to/your/QuantumATK/installation"
sh$ VENV_DIR="/path/to/your/custom/venv"
sh$ source "${QATK_DIR}/atkpython/bin/activate_env"
(qatk) sh$ python -m venv --system-site-packages --upgrade-deps "$VENV_DIR"
(qatk) sh$ source "${VENV_DIR}/bin/activate"
(venv) (qatk) sh$ python -m pip install emoji
[...]
(venv) (qatk) sh$ python -m pip show emoji
[...]
Location: /path/to/your/custom/venv/lib/python3.11/site-packages
[...]
(venv) (qatk) sh$ mpiexec -n 4 python -c "import emoji; print(emoji.emojize('This is an␣
↪ambulance: :ambulance:'))"
This is an ambulance:
This is an ambulance:
This is an ambulance:
This is an ambulance:
(venv) (qatk) sh$ atkpython -c "import emoji; length=3.5*Units.m; print(emoji.emojize(f
↪'The :ambulance: is {length.convertTo(Bohr)} long.'))"
The  is 66140414359.8 Bohr long.
(venv) (qatk) sh$ deactivate
(qatk) sh$ deactivate_qatk
sh$
```

In the above example you can see that we have access to `atkpython` and `mpiexec` because we are inside the QATK Shell Environment, but we can also install a new package (emoji) which ends up inside the Python venv folder (notice the Location line in the output) without disturbing our QuantumATK installation. We have also added the `--upgrade-deps` flag which makes sure that `pip` is updated to the latest version inside the virtual environment.

PowerShell on Windows, only Python venv:

```
PS> $QATK_DIR="C:\path\to\your\QuantumATK\installation"
PS> $VENV_DIR="C:\path\to\your\custom\venv"
PS> "$QATK_DIR\atkpython\python.exe" -m venv --system-site-packages --upgrade-deps "
↪$VENV_DIR"
PS> & "${VENV_DIR}\Scripts\Activate.ps1"
(venv) PS> python -m pip install pyjokes emoji
[...]
(venv) PS> pyjoke
What is Benoit B. Mandelbrot's middle name? Benoit B. Mandelbrot.
(venv) PS> python -c "from ATKVersion import Version; import emoji; print(emoji.emojize(f
↪'The QATK version is {Version.version()}. :atom_symbol:'))"
The QATK version is W-2024.09.
(venv) PS> deactivate
PS>
```

In this case we are using the `python` executable shipped with QuantumATK to create a Python venv, so we can access QuantumATK modules (if we import them) and we can peacefully install new packages inside the virtual environment.

4.4.12 Plot

Main reference: *NanoLab Plot Reference Manual*.

NanoLab Plot Reference Manual

The Plot module is built with the aim of making it easy to create publication quality scientific plots.

All plots can be saved using *Plot.save* and loaded using *nlread*. Specific plot items can be found using the *Plot.Plot* find method. An interactive plot window can be launched with the *Plot.show* function.

The NanoLab Plot framework helps you to edit, show and save plots created by the Analyzers in NanoLab. The Plot framework also makes it straight-forward to construct simple or complex plots from scratch, and to mix and match those plots with the plots created in NanoLab.

Note: All parts of the Plot framework are contained within the Plot module, meaning that all relevant classes and functions must be called with the Plot prefix.

Modifying Plots

Any plot constructed through the NanoLab GUI can be saved to an HDF5 file in the save dialog. The plots will show up in the NanoLab and can be opened again by the PlotViewer Plugin.

In a script the saved plot can be loaded by using the standard *nlread* function:

```
>>> plot = nlread('saved_plot.hdf5')[0]
```

The plot can then be shown using the special *Plot.show* function:

```
>>> Plot.show(plot, size=(600, 400))
```

This will show the plot in an interactive plot window with the full editing capability of NanoLab. The modified plot can then again be saved in the plot window; or it can be saved through scripting by using the special *Plot.save* function.

The plot can also be modified in a script. The easiest way to find the relevant plot items is through the *Plot.Plot*.find method:

```
>>> oxygen_lines = plot.find(types=Plot.Line, label='Oxygen')
```

Building Plots

All plots are constructed from a *Plot.PlotModel*.

```
>>> model = Plot.PlotModel()
```

The plots are then built from plot items, such as *Plot.Line*, *Plot.Scatter*, *Plot.HorizontalFill*, *Plot.Arrow*, *Plot.Measure*, etc.:

```
>>> model.addItem(
>>>     Line([0, 1, 2, 3, 4], [1, 2.2, 3.4, 6.7, 8.9])
>>>)
```

Multiple PlotModels can then be embedded in a *Plot.GridLayout* or *Plot.OverlayLayout* in order to build complex plots.

When a plot has been constructed it can be shown using the *Plot.show* function and saved using the *Plot.save* function.

Let us try to sketch a complete example that shows how to plot a dashed red *Plot.Line* with star markers on a log-plot. We also add a *Plot.CurveFit* to the line data.

```
# PlotModel with custom units.
model = Plot.PlotModel(x_unit=Angstrom, y_unit=eV)

# Change title
model.framing().setTitle('My plot')

# Set axis label and scale
```

(continues on next page)

(continued from previous page)

```
model.xAxis().setLabel('Length')
model.yAxis().setLabel('Energy')
model.yAxis().setScale(Plot.SCALES.LOG)

# Show legend.
model.legend().setVisible(True)

#Line.
line = Plot.Line([1, 2, 3, 4, 4] * nm, [1, 2.2, 3, 2.2, 1] * eV)
line.setLabel('My red line')
line.setColor('red')
line.setLineStyle(Plot.LINE_STYLES.DASHED)
line.setMarkerStyle(Plot.MARKER_STYLES.STAR)
line.setMarkerSize(8)

# Add fit.
fit = Plot.CurveFit('a * (x - x0)**2 + b')
line.addItem(fit)

# Add line.
model.addItem(line)

# Auto-adjust axis limits.
model.setLimits()

# Show plot and save afterwards to file and as raster.
Plot.show(model)
Plot.save(model, 'my_plot.hdf5')
Plot.save(model, 'my_plot.png')
```

Later, the plot can be loaded, and the line color can be changed to e.g. blue before it is saved again.

Framework

These are the core parts of the framework.

- *Plot.PlotModel*
- *Plot.show*
- *Plot.save*
- *Plot.Plot*

Plot Items

These are all the different items that can be added to or edited in a PlotModel.

- *Plot.Arrow*
- *Plot.AttributesLabel*
- *Plot.Average*
- *Plot.Axis*
- *Plot.Contour*
- *Plot.CurveFit*
- *Plot.Density*
- *Plot.Framing*
- *Plot.Group*
- *Plot.HorizontalBar*
- *Plot.HorizontalFill*
- *Plot.HorizontalLine*
- *Plot.HorizontalStackedFill*
- *Plot.Label*
- *Plot.Line*
- *Plot.LineGroup*
- *Plot.Measure*
- *Plot.PolynomialFit*
- *Plot.RollingAverage*
- *Plot.Scatter*
- *Plot.TransformedLine*
- *Plot.VerticalBar*
- *Plot.VerticalFill*
- *Plot.VerticalLine*
- *Plot.VerticalStackedFill*
- *Plot.WeightedLine*

Plot Layouts

These are the classes used for laying out plots in complex layouts.

- *Plot.GridLayout*
- *Plot.OverlayLayout*
- *Plot.PlotFrame*

Plot Constants

Some of the plot options must be supplied as special constants. All constants enumerations are uppercase, and their options are accessed using the usual dot notation, e.g. `Plot.COLOR_MODES.COLOR` or `Plot.SCALES.LOG`.

Enum	Constants
Plot.ALIGNMENTS	•TOP •CENTER •BOTTOM •LEFT •RIGHT
Plot.ARROW_STYLES	•FILLED •UNFILLED •NONE
Plot.BOUNDARY_CONDITIONS	•EXCLUDE •PERIODIC •MIRROR •REFLECT
Plot.COLOR_MODES	•COLOR •COLORS •MANY_COLORS •COLOR_MAP
Plot.DETAIL_LEVELS	•BASIC •MEDIUM •FULL
Plot.EDGES	•LEFT •RIGHT •TOP •BOTTOM •CENTER
Plot.KERNELS	•AVERAGE •GAUSSIAN
Plot.LAYOUT_MODES	•NORMAL •SHARE_X •SHARE_Y •SHARE_BOTH
Plot.LEGEND_LOCATIONS	•BEST •UPPER_LEFT •UPPER_CENTER •UPPER_RIGHT •CENTER_LEFT •CENTER •CENTER_RIGHT •LOWER_LEFT •LOWER_CENTER •LOWER_RIGHT •RIGHT
Plot.LINE_STYLES	•SOLID •DASHED

Full Plot module

All the plot classes and functions in alphabetical order:

Plot

Classes

Plot.Arrow

class Arrow(*tail_x*, *tail_y*, *head_x*, *head_y*)
An arrow pointing from tail to head and with custom color, line width and arrow head size.

Parameters

- **tail_x** (*PhysicalQuantity*) – The tail x coordinate.
- **tail_y** (*PhysicalQuantity*) – The tail y coordinate.
- **head_x** (*PhysicalQuantity*) – The head x coordinate.
- **head_y** (*PhysicalQuantity*) – The head x coordinate.

addItem(*item*, *emit=True*)
Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)
Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)
Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

applyStyle(*style_scheme=None*, *style_properties=None*)
Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.
- **style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

arrowScale()

Returns
The arrow scale.

Return type
float

color()

Returns
The label color.

Return type
str

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

headStyle()

Returns
The arrow head style.

Return type
ARROW_STYLES eum

hoverDetails()

Returns
The current hover details.

Return type
dict | None

isHoverable()

Returns
True, if hoverable.

Return type
bool

isHovered()

Returns
True, if the item is hovered.

Return type
bool

`isMovable`()

Returns
True, if the label is movable.

Return type
bool

`isSelectable`()

Returns
True, if the item is selectable.

Return type
bool

`isSelected`()

Returns
True, if the item is selected.

Return type
bool

`isVisible`()

Returns
True, if the item is visible.

Return type
bool

`items`(*selected=None*, *tag=None*)

Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **selected** (*None | bool*) – True, if only selected items should be returned.
- **tag** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

`lineStyle`()

Returns
The arrow line style.

Return type
LINE_STYLES enum

`lineWidth()`

Returns
The arrow line width.

Return type
float

`model()`

Returns
The model that this item belongs to.

Return type
PlotModel | None

`order()`

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

`owner()`

Returns
The owner type.

Return type
int | enum

`parent()`

Returns
The parent.

Return type
PlotItem based | None

`positions()`

Returns
The postions of the arrow ends in the format (x1, y1, x2, y2).

Return type
None | 4-tuple of PhysicalQuantity

`removeItem(item, emit=True)`
Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

`removeSubscriber(subscriber)`
Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

selectionDetails()

Returns
The current selection details.

Return type
dict | None

setArrowScale(*arrow_scale*)

Set the arrow scale.

Parameters
arrow_scale (*float*) – The arrow scale.

setColor(*color*)

Set the color.

Parameters
color (*str*) – A matplotlib formatted color.

setHeadPosition(*x*, *y*, *emit=True*)

Set the position.

Parameters

- **x** (*PhysicalQuantity*) – The x position.
- **y** (*PhysicalQuantity*) – The y position.
- **emit** (*bool*) – True, if signal should be emitted.

setHeadStyle(*head_style*)

Set the style of the arrow head.

Parameters
head_style (*ARROW_STYLES enum*) – The head style.

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setLineStyle(*line_style*)

Set the line style.

Parameters
line_style (*LINE_STYLES enum*) – The line style.

setLineWidth(*line_width*)

Set the line width.

Parameters
line_width (*float*) – The arorw line width.

setMovable(*movable*)

Set the movable property.

Parameters
movable (*bool*) – True, if the label should be movable.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setTailPosition(*x*, *y*, *emit=True*)

The tail position.

Parameters

- **x** (*PhysicalQuantity*) – The tail x position.
- **y** (*PhysicalQuantity*) – The tail y position.
- **emit** (*bool*) – True, if signal should be emitted.

setTailStyle(*tail_style*)

Set the style of the arrow tail.

Parameters
tail_style (*ARROW_STYLES enum*) – The tail style.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

`tags()`

Returns
The set of tags.

Return type
set

`tailStyle()`

Returns
The arrow tail style.

Return type
ARROW_STYLES enum

Plot.AttributesLabel

`class AttributesLabel(x, y)`

A Label that displays the attributes of a parent object in the plot.

Parameters

- **x** (*PhysicalQuantity*) – The x-coordinate of the label.
- **y** (*PhysicalQuantity*) – The y-coordinate of the label.

`addItem(item, emit=True)`

Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

`addSubscriber(subscriber)`

Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

`addTag(*args)`

Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

`alignment()`

Returns
The vertical and horizontal alignment.

Return type
2-tuple of str

applyStyle(*style_scheme=None*, *style_properties=None*)

Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.
- **style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

color()

Returns
The label color in hex format.

Return type
str

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

detailLevel()

Returns
The detail level of the attributes.

Return type
enum

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

fontSize()

Returns
The font size in points.

Return type
float

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

hoverDetails()

Returns
The current hover details.

Return type
dict | None

isBoxOn()

Returns
True, if the label has a box.

Return type
bool

isHoverable()

Returns
True, if hoverable.

Return type
bool

isHovered()

Returns
True, if the item is hovered.

Return type
bool

isMovable()

Returns
True, if the label is movable.

Return type
bool

isSelectable()

Returns
True, if the item is selectable.

Return type
bool

isSelected()

Returns
True, if the item is selected.

Return type
bool

classmethod isValidParent(*item*)

Check if an item is a valid parent.

Parameters
item (*PlotItem based*) – The item to check.

Returns
True, if the item can be derived.

Return type
bool

`isVisible()`

Returns
True, if the item is visible.

Return type
bool

`items(`*selected=None*, *tag=None*`)`

Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **selected** (*None | bool*) – True, if only selected items should be returned.
- **tag** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

`model()`

Returns
The model that this item belongs to.

Return type
PlotModel | None

`order()`

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

`owner()`

Returns
The owner type.

Return type
int | enum

`parent()`

Returns
The parent.

Return type
PlotItem based | None

`position()`

Returns
The label postion.

Return type
None | 2-tuple of *PhysicalQuantity*

`removeItem(item, emit=True)`

Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

`removeSubscriber(subscriber)`

Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

`selectionDetails()`

Returns
The current selection details.

Return type
dict | None

`setAlignment(vertical, horizontal)`

Set the label alignment with respect to the position.

Parameters

- **vertical** (*str*) – The vertical alignment (top, center, bottom).
- **horizontal** (*str*) – The horizontal alignment (left, center, right).

`setBoxOn(box_on)`

Set whether a box should be drawn around the label text.

Parameters
box_on (*bool*) – True, if the label should have a box.

`setColor(color)`

Set the color.

Parameters
color (*str*) – The label color in hex format.

`setDetailLevel(level)`

Set the detail level.

Parameters
level (*enum*) – A level from the DETAIL_LEVELS enum.

setFontSize(*fontsize*)

Set the font size.

Parameters
fontsize (*float*) – The font size in points.

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setMovable(*movable*)

Set whether the label should be movable.

Parameters
movable (*bool*) – True, if the label should be movable.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setPosition(*x*, *y*)

Set the label position.

Parameters

- **x** (*PhysicalQuantity*) – The x-position.
- **y** (*PhysicalQuantity*) – The y-position.

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setText(*text*)

Set the text.

Parameters
text (*str*) – The label text.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

style()

Returns
All the current style properties.

Return type
dict

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

tags()

Returns
The set of tags.

Return type
set

text()

Returns
The label text.

Return type
str

update(*data=None*)

Internal method.

Plot.Average

class Average

An Average can be added to a Line or a Scatter, and will then calculate the average value of its parent data.

addItem(*item*, *emit=True*)

Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)

Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)

Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

alpha()

Returns
The opacity for the line.

Return type
float

applyStyle(*style_scheme=None*, *style_properties=None*)

Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.
- **style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

attributes(*latex=False*, *detail_level='full'*)

The current line attributes.

Parameters

- **latex** (*bool*) – If True, return the attributes in Latex format.
- **detail_level** (*DETAIL_LEVELS enum*) – The level of detail of the attributes (unused).

Returns
The current line attributes.

Return type
dict

bounds()

Returns
The bounds.

Return type
tuple of physicalQuantity

color()

Returns
The line color.

Return type
str

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

evaluate(*x_data*)

Evaluate the average for the given x_data.

Parameters
x_data (*PhysicalQuantity*) – The x-data.

Returns
The evaluated x data and y data.

Return type
2-tuple of PhysicalQuantity

extent(*axis_name*, *padding=0.0*)

Get the data limits.

Parameters

- **axis_name** (*str*) – x or y.
- **padding** (*float*) – Padding around the data. **Default:** 0.0.

Returns
The min/max data values for the requested axis.

Return type
Sequence | PhysicalQuantity

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

hoverDetails()

Returns
The current hover details.

Return type
dict | None

isAxisSpanned()

Returns
True if the fit line should span the x-axis range of the plot.

Return type
bool

isBoundsVisible()

Returns
True, if fit bounds are shown in the plot.

Return type
bool

isHoverable()

Returns
True, if hoverable.

Return type
bool

isHovered()

Returns
True, if the item is hovered.

Return type
bool

isInteractive()

Returns
Whether the user can interact with this line.

Return type
bool

isSelectable()

Returns
True, if the item is selectable.

Return type
bool

isSelected()

Returns
True, if the item is selected.

Return type
bool

classmethod isValidParent(*item*)

Check if an item is derivable.

Parameters
item (*PlotItem based*) – The item to check.

Returns
True, if the item can be derived.

Return type
bool

`isVisible()`

Returns
True, if the item is visible.

Return type
bool

`items(`*selected=None*, *tag=None*`)`

Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **selected** (*None | bool*) – True, if only selected items should be returned.
- **tag** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

`label()`

Returns
The line label.

Return type
str

`lineStyle()`

Returns
The line style.

Return type
str | None

`lineWidth()`

Returns
The line width.

Return type
float

`markerEdgeColor()`

Returns
The edge color of the marker in hex format.

Return type
str

`markerEvery()`

Returns
The number of points between every marker.

Return type
int

`markerFaceColor()`

Returns
The face color of the marker in hex format.

Return type
str

`markerSize()`

Returns
The marker size.

Return type
float

`markerStyle()`

. :returns: The marker style. :rtype: str | None

`model()`

Returns
The model that this item belongs to.

Return type
PlotModel | None

`order()`

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

`owner()`

Returns
The owner type.

Return type
int | enum

`parent()`

Returns
The parent.

Return type
PlotItem based | None

removeItem(*item*, *emit=True*)

Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

removeSubscriber(*subscriber*)

Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

selectionDetails()

Returns
The current selection details.

Return type
dict | None

setAlpha(*alpha*)

Set the opacity for the line.

Parameters
alpha (*float*) – The opacity.

setBounds(*lower*, *upper*, *update=True*)

Set the derived line bounds.

Parameters

- **lower** (*float | PhysicalQuantity*) – The lower bound.
- **upper** (*float | PhysicalQuantity*) – The upper bound.
- **update** (*bool*) – True, if we should call update.

setBoundsVisible(*visible*)

Set whether to indicate the fit bounds in the plot.

Parameters
visible (*bool*) – If True, fit bounds will be shown in the plot.

setColor(*color*)

Set the line color.

Parameters
color (*str*) – The line color in hex format.

setData(*x=None*, *y=None*)

Overload since derived lines should not expose data setting.

Parameters

- **x** (*iterable*) – The x values.
- **y** (*iterable*) – They values.

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setInteractive(*interactive*)

Set whether the user can interact with this line.

Parameters
interactive (*bool*) – The desired state.

setLabel(*label*)

Set the label.

Parameters
label (*str*) – The line label.

setLineStyle(*line_style*)

Set the line style.

Parameters
line_style (*str | None*) – The line style.

setLineWidth(*line_width*)

Set the line width.

Parameters
line_width (*float*) – The line width.

setMarkerColor(*color*)

Set color of the marker. Remember to also set a valid marker style.

Parameters
color (*valid color*) – The color to set.

setMarkerEdgeColor(*color*)

Set the marker edge color. Remember to also set a valid marker style.

Parameters
color (*str*) – The edge color of the marker.

setMarkerEvery(*every*)

Set the number of points between each marker. Remember to also set a valid marker style.

Parameters
every (*int*) – The number of points between every marker.

setMarkerFaceColor(*color*)

Set the marker face-color. Remember to also set a valid marker style.

Parameters
color (*str*) – The face color of the marker.

setMarkerSize(*size*)

Set the marker size. Remember to also set a valid marker style.

Parameters
size (*float*) – The marker size.

setMarkerStyle(*marker*)

Set the marker style.

Parameters
marker (*str | None*) – The marker style.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setSpanAxis(*span_axis*)

Set whether the fit line should span the x-axis range of the plot.

Parameters
span_axis (*bool*) – If True, the fit line should span the x-axis range of the plot.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

sourceData()

Checks if the source data is valid, and if yes, return the valid source data on the form: (xs, ys, x_min, x_max, x_unit, y_unit) Else returns None

Returns
The validated and clipped source data.

Return type
tuple | None

style()

Returns
All the current style properties.

Return type
dict

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

tags()

Returns
The set of tags.

Return type
set

update(*data=None*)

Perform the update.

Parameters
data (*tuple | NoneType*) – The source data to use.

validSourceCoordinates(*xs*, *ys*)

True if the provided data coordinates are valid.

Parameters

- **xs** (ndarray) – The source x coordinates.
- **ys** (ndarray) – The source y coordinates.

Returns
True, if the coordinates are valid.

Return type
bool

xData()

Returns
The x-data.

Return type
PhysicalQuantity

yData()

Returns
The y-data.

Return type
PhysicalQuantity

Plot.Axis

class Axis(*unit=<Unit at 140734618035408 >*)

An Axis defines the x- or y-axis in a plot. The axis specifies limits, scale, label, fonts, ticks and grids.

Parameters
unit (Unit) – The unit of the axis.

addItem(*item*, *emit=True*)

Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)

Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)

Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

applyStyle(*style_scheme=None*, *style_properties=None*)

Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.
- **style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

autoscalePadding()

. :returns: The padding used when autoscaling. :rtype: 2-tuple of float

checkAutoScaleIncludeZero()

Utility to check if including zero is possible and if the option is selected.

Returns
True, if we can and should include zero.

Return type
bool

color()

The color of the axis and the axis label.

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

hoverDetails()

Returns
The current hover details.

Return type
dict | None

isAutoScaleZeroIncluded()

Returns
True, if the value zero should be explicitly included/shown on this axis.

Return type
bool

isHoverable()

Returns
True, if hoverable.

Return type
bool

isHovered()

Returns
True, if the item is hovered.

Return type
bool

isLocked()

Returns
True if the axis scroll is locked.

Return type
bool

`isMajorGridOn`()

Returns
True if major grid is shown.

Return type
bool

`isMinorGridOn`()

Returns
True if the minor grid is shown.

Return type
bool

`isMirrored`()

Returns
True, if ticks and label are mirrored.

Return type
bool

`isSelectable`()

Returns
True, if the item is selectable.

Return type
bool

`isSelected`()

Returns
True, if the item is selected.

Return type
bool

`isVisible`()

Returns
True, if the item is visible.

Return type
bool

`isZeroLineOn`()

Returns
True if zero line is shown.

Return type
bool

`items`(*selected=None*, *tag=None*)

Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items

•None : All items.

Parameters

•**selected** (*None | bool*) – True, if only selected items should be returned.

•**tag** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

label()

Returns
The label of the axis.

Return type
str

labelFontSize()

Returns
The axis font size in points.

Return type
float

limits()

Returns
The limits of the axis.

Return type
2-tuple of float

majorDivisions()

Returns
The number of major ticks.

Return type
Automatic | int

model()

Returns
The model that this item belongs to.

Return type
PlotModel | None

order()

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

owner()

Returns
The owner type.

Return type
int | enum

parent()

Returns
The parent.

Return type
PlotItem based | None

removeItem(*item*, *emit=True*)

Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

removeSubscriber(*subscriber*)

Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

scale()

Returns
Axis scale (linear | log).

Return type
str

selectionDetails()

Returns
The current selection details.

Return type
dict | None

setAutoScaleIncludeZero(*include_zero*)

Parameters
include_zero (*bool*) – True, if the value zero should be explicitly included/shown on this axis.

setAutoscalePadding(*padding_lower*, *padding_upper*)

Set autoscale padding. Do not emit changes.

Parameters

- **padding_lower** (*float*) – The lower padding.
- **padding_upper** (*float*) – The upper padding.

setColor(*color*)

Set the color of the axis and the axis label.

Parameters
color (*str*) – The color to set in hex format.

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setLabel(*label*, *font_size=None*)

Set the label.

Parameters

- **label** (*str*) – The label.
- **font_size** (*float*) – The absolute font size in points.

setLabelFontSize(*font_size*)

Parameters
font_size (*float*) – The label font size in points.

setLimits(*lower_limit=None*, *upper_limit=None*)

Set axis limits.

Parameters

- **lower_limit** (*float*) – The lower limit.
- **upper_limit** (*float*) – The upper limit.

setLocked(*state*)

Set the locked state of the axis.

Parameters
state (*bool*) – True if the axis should be locked.

setMajorDivisions(*major_divisions*)

Set the number of major divisions of the axis.

Parameters
major_divisions (*Automatic | int*) – The number of divisions.

setMajorGridOn(*grid_on*)

Parameters
grid_on (*bool*) – Set major grid lines on/off.

setMinorGridOn(*grid_on*)

Parameters
grid_on (*bool*) – Set minor grid lines on/off.

setMirrored(*mirrored*)

Set ticks and labels mirrored..

Parameters
mirrored (*bool*) – True, if ticks should show up on the opposite site.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setScale(*scale*)

Set scale. When setting to log scale, this may also change the limits.

Parameters
scale (*str*) – The scale (linear, log or symlog).

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setTickFontSize(*font_size*)

Set the tick font size.

Parameters
font_size (*float*) – The absolute font size in points.

setTicks(*positions=None*, *labels=None*, *font_size=None*, *major_divisions=<class 'NL.ComputerScienceUtilities.NLFlag._NLFlag.Automatic'>*, *length=None*, *direction=None*)

Set tick positions and labels for the axis.

Setting positions=None resets the ticks to use default locators and formatters.

Parameters

- **positions** (*list*) – List of tick float positions.
- **labels** (*list*) – List of tick label strings.
- **font_size** (*float*) – The absolute font size in points.
- **major_divisions** (*[type]*) – [description].
- **length** (*float*) – The length of ticks in points.
- **direction** (*enum*) – The direction of ticks.

setUnit(*unit*)

Set the axis unit.

Parameters
unit (Unit) – The unit.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

setZeroLineOn(*line_on*)

Parameters
line_on (*bool*) – True, if zero-line should be shown.

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

tags()

Returns
The set of tags.

Return type
set

tickDirection()

Returns
The direction of ticks.

Return type
enum

tickFontSize()

Returns
The tick font size in points.

Return type
float

tickLabels()

Returns
The list of tick labels.

Return type
list

tickLength()

Returns
The length of ticks in points.

Return type
float

ticks()

Returns
The a list of the tick positions as floats.

Return type
list

unit()

Returns
The unit of the axis.

Return type
Unit

Plot.Colors

class Colors

classmethod applyToItems(*items*, *offset=0*)
Color each plot item in a list with a distinct color.

Parameters

- **items** (*list of PlotItems*) – The items to color.
- **offset** (*int*) – The offset to start from.

classmethod list(*number=None*, *offset=0*)
Get colors in a list.

Parameters

- **number** (*int*) – The number of colors to get.
- **offset** (*int*) – The (optional) offset to start at.

Returns
List of colors.

Return type
list of str | str

Plot.Contour

class Contour(*x_data*, *y_data*, *z_data*)

A Contour displays three-dimensional data in a number of discrete levels, colored accordingly, and with an additional color bar.

The x, y data are 1D arrays spanning the regular z mesh. The z data is a 2D array mesh with values of the (x, y) points.

Parameters

- **x_data** (*PhysicalQuantity* | ndarray) – The one-dimensional x data.
- **y_data** (*PhysicalQuantity* | ndarray) – The one-dimensional y data.
- **z_data** (*PhysicalQuantity* | ndarray) – The two-dimensional z data.

addItem(*item*, *emit=True*)

Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)

Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)

Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

alpha()

Returns
The opacity for the contour.

Return type
float

applyStyle(*style_scheme=None*, *style_properties=None*)

Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.
- **style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

color()

Returns
The contour face color in HEX format.

Return type
str

colorMap()

Returns
The contour color map.

Return type
str | None

colorMode()

Returns
The current color mode.

Return type
str

colors()

Returns
The currnetly set list colors.

Return type
List of colors | None

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

extent(*axis_name*, *padding=0.0*)

Get the x-data or y-data limits.

Parameters

- **axis_name** (*str*) – x or y.
- **padding** (*float*) – Padding around the data. **Default:** 0.0.

Returns
The min/max data values for the requested axis.

Return type
2-tuple of PhysicalQuantity

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

`hoverDetails()`

Returns
The current hover details.

Return type
dict | None

`isColorBarVisible()`

Returns
True, if colorbar is visible.

Return type
bool

`isFilled()`

Returns
True, if contour should be filled.

Return type
bool

`isHoverable()`

Returns
True, if hoverable.

Return type
bool

`isHovered()`

Returns
True, if the item is hovered.

Return type
bool

`isLabelsVisible()`

Returns
True, if contour labels should be visible.

Return type
bool

`isSelectable()`

Returns
True, if the item is selectable.

Return type
bool

`isSelected()`

Returns
True, if the item is selected.

Return type
bool

`isVisible()`

Returns
True, if the item is visible.

Return type
bool

`items(`*selected=None*, *tag=None*`)`

Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **selected** (*None | bool*) – True, if only selected items should be returned.
- **tag** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

`label()`

Returns
The label of the z-axis.

Return type
str

`labelFontSize()`

Returns
The label font size.

Return type
int

`labelsFontSize()`

Returns
The contour labels font size.

Return type
int

`levels()`

Returns
The number of contour levels.

Return type
int

limits()

Returns
The limits of the z-axis.

Return type
List of *PhysicalQuantity*

model()

Returns
The model that this item belongs to.

Return type
PlotModel | None

order()

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

owner()

Returns
The owner type.

Return type
int | enum

parent()

Returns
The parent.

Return type
PlotItem based | None

removeItem(*item*, *emit=True*)

Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

removeSubscriber(*subscriber*)

Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

scale()

Returns
The z-axis scale (linear | log).

Return type
str

`selectionDetails()`

Returns
The current selection details.

Return type
dict | None

`setAlpha(alpha)`

Set the contour opacity as a float between zero and one.

Parameters
alpha (*float*) – The opacity.

`setColor(color)`

Set the uniform color of entire contour.

Note that this color is only used if the color mode has been set to color.

Parameters
color (*Any matplotlib supported color definition*) – The contour face color.

`setColorBarVisible(visible)`

Set colobar visibility.

Parameters
visible (*bool.*) – True, if colorbar should be shown.

`setColorMap(color_map)`

Set the contour color map.

Note that this color map is only used if the color mode has been set to color_map.

Parameters
color_map (*str*) – The color map.

`setColorMode(mode)`

Set the color mode.

Parameters
mode (*COLOR_MODES enum | str*) – The mode to set (color, colors, color_map).

`setColors(colors)`

Set the color sof the different contour levels.

Note that these colors are only used if the color mode has been set to colors.

Parameters
colors (*List of colors | None*) – The colors to set.

`setData(x_data, y_data, z_data)`

Set the data used in the contour.

Parameters

- **x_data** (*PhysicalQuantity* | ndarray) – The one-dimensional x data.
- **y_data** (*PhysicalQuantity* | ndarray) – The one-dimensional y data.
- **z_data** (*PhysicalQuantity* | ndarray) – The two-dimensional z data.

setFilled(*filled*)

Set whether the contour should be filled with colors.

Parameters
filled (*bool*) – True, if contour should be filled.

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setLabel(*label*)

Set the z-axis label.

Parameters
label (*str*) – Set z-axis label.

setLabelFontSize(*font_size*)

Set label font size.

Parameters
font_size (*int*) – The label font size.

setLabelsFontSize(*font_size*)

Set contour labels font size.

Parameters
font_size (*int*) – The font size.

setLabelsVisible(*visible*)

True, if contour labels should be visible.

Only applies to unfilled contours.

Parameters
visible (*bool*) – True, if visible.

setLevels(*levels*)

Set number of contour levels.

Parameters
levels (*int*) – The number of different contour levels.

setLimits(*lower_limit=None*, *upper_limit=None*)

Set the z-axis limits.

Parameters

- **lower_limit** (*float*) – The lower z-axis limit.
- **upper_limit** (*float*) – The upper z-axis limit.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setScale(*scale*)

Set the z-axis scale to either linear or log.

Parameters
scale (*str*) – The z-axis scale (linear | log).

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setTickFontSize(*font_size*)

Set the color bar tick font size.

Parameters
font_size (*int*) – The font size.

setUnit(*unit*)

Set the unit of the z-scale.

Parameters
unit (Unit) – The z-axis unit.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

setZData(*z_data*)

Set z data.

Parameters
z_data (*PhysicalQuantity* | ndarray) – The two-dimensional z data.

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

tags()

Returns
The set of tags.

Return type
set

tickFontSize()

Returns
The color bar tick font size.

Return type
int

unit()

Returns
The unit of the z-axis.

Return type
Unit

xData()

Returns
The one-dimensional x data.

Return type
PhysicalQuantity

yData()

Returns
The one-dimensional y data.

Return type
PhysicalQuantity

zData()

Returns
The two-dimensional z data.

Return type
PhysicalQuantity

Plot.CurveFit

class CurveFit(*expression=None*)
A CurveFit can be added to a Line or Scatter, and will then fit the supplied expression to the parent data.

Parameters
expression (*str*) – The expression for the fit function.

addItem(*item*, *emit=True*)
Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.

- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)

Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)

Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

alpha()

Returns
The opacity for the line.

Return type
float

applyStyle(*style_scheme=None*, *style_properties=None*)

Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.
- **style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

attributes(*latex=False*, *detail_level='full'*)

A description of the fit attributes.

Parameters

- **latex** (*bool*) – If True, return the attributes in Latex format.
- **detail_level** (*DETAIL_LEVELS enum*) – The level of detail of the attributes.

Returns
A description of the fit attributes.

Return type
collections.OrderedDict

bounds()

Returns
The bounds.

Return type
tuple of physicalQuantity

color()

Returns
The line color.

Return type
str

conditions()

Returns
The fit conditions.

Return type
collections.OrderedDict

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

determination()

Returns
The fit coefficient of determination.

Return type
float | NoneType

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

evaluate(*x_data*)

Evaluate the curve fit for the given x_data.

Parameters
x_data (*PhysicalQuantity*) – The x-data.

Returns
The evaluated x data and y data.

Return type
2-tuple of PhysicalQuantity

expression()

Returns
The fit expression.

Return type
str

extent(*axis_name*, *padding=0.0*)

Get the data limits.

Parameters

- **axis_name** (*str*) – x or y.
- **padding** (*float*) – Padding around the data. **Default:** 0.0.

Returns
The min/max data values for the requested axis.

Return type
Sequence | PhysicalQuantity

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

hoverDetails()

Returns
The current hover details.

Return type
dict | None

isAxisSpanned()

Returns
True if the fit line should span the x-axis range of the plot.

Return type
bool

isBoundsVisible()

Returns
True, if fit bounds are shown in the plot.

Return type
bool

isHoverable()

Returns
True, if hoverable.

Return type
bool

isHovered()

Returns
True, if the item is hovered.

Return type
bool

isInteractive()

Returns
Whether the user can interact with this line.

Return type
bool

isSelectable()

Returns
True, if the item is selectable.

Return type
bool

isSelected()

Returns
True, if the item is selected.

Return type
bool

classmethod isValidParent(*item*)

Check if an item is derivable.

Parameters
item (*PlotItem based*) – The item to check.

Returns
True, if the item can be derived.

Return type
bool

isVisible()

Returns
True, if the item is visible.

Return type
bool

items(*selected=None*, *tag=None*)

Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **selected** (*None | bool*) – True, if only selected items should be returned.
- **tag** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

label()

Returns
The line label.

Return type
str

`lineStyle()`

Returns
The line style.

Return type
str | None

`lineWidth()`

Returns
The line width.

Return type
float

`markerEdgeColor()`

Returns
The edge color of the marker in hex format.

Return type
str

`markerEvery()`

Returns
The number of points between every marker.

Return type
int

`markerFaceColor()`

Returns
The face color of the marker in hex format.

Return type
str

`markerSize()`

Returns
The marker size.

Return type
float

`markerStyle()`

. :returns: The marker style. :rtype: str | None

`model()`

Returns
The model that this item belongs to.

Return type
PlotModel | None

order()

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

owner()

Returns
The owner type.

Return type
int | enum

parameters()

Returns
The polynomial coefficients.

Return type
numpy.ndarray

parent()

Returns
The parent.

Return type
PlotItem based | None

removeItem(*item*, *emit=True*)

Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

removeSubscriber(*subscriber*)

Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

safeSetExpression(*expression*, *update=True*)

Safe setting of expression. Fails silently without changing anything.

Parameters

- **expression** (*str*) – The expression.
- **update** (*bool*) – True if the fit should be updated.

selectionDetails()

Returns
The current selection details.

Return type
dict | None

setAlpha(*alpha*)

Set the opacity for the line.

Parameters
alpha (*float*) – The opacity.

setBounds(*lower*, *upper*, *update=True*)

Set the derived line bounds.

Parameters

- **lower** (*float | PhysicalQuantity*) – The lower bound.
- **upper** (*float | PhysicalQuantity*) – The upper bound.
- **update** (*bool*) – True, if we should call update.

setBoundsVisible(*visible*)

Set whether to indicate the fit bounds in the plot.

Parameters
visible (*bool*) – If True, fit bounds will be shown in the plot.

setColor(*color*)

Set the line color.

Parameters
color (*str*) – The line color in hex format.

setConditions(*conditions*, *update=True*)

Set conditions.

Parameters

- **conditions** (*dict or list of floats*) – The conditions to set.
- **update** (*bool*) – True, if the fit should be updated.

setData(*x=None*, *y=None*)

Overload since derived lines should not expose data setting.

Parameters

- **x** (*iterable*) – The x values.
- **y** (*iterable*) – They values.

setExpression(*expression*, *update=True*)

Set the fit expression.

Parameters

- **expression** (*str*) – The fit expression to set.
- **update** (*bool*) – True, if the fit should be updated.

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setInteractive(*interactive*)

Set whether the user can interact with this line.

Parameters
interactive (*bool*) – The desired state.

setLabel(*label*)

Set the label.

Parameters
label (*str*) – The line label.

setLineStyle(*line_style*)

Set the line style.

Parameters
line_style (*str | None*) – The line style.

setLineWidth(*line_width*)

Set the line width.

Parameters
line_width (*float*) – The line width.

setMarkerColor(*color*)

Set color of the marker. Remember to also set a valid marker style.

Parameters
color (*valid color*) – The color to set.

setMarkerEdgeColor(*color*)

Set the marker edge color. Remember to also set a valid marker style.

Parameters
color (*str*) – The edge color of the marker.

setMarkerEvery(*every*)

Set the number of points between each marker. Remember to also set a valid marker style.

Parameters
every (*int*) – The number of points between every marker.

setMarkerFaceColor(*color*)

Set the marker face-color. Remember to also set a valid marker style.

Parameters
color (*str*) – The face color of the marker.

setMarkerSize(*size*)

Set the marker size. Remember to also set a valid marker style.

Parameters
size (*float*) – The marker size.

setMarkerStyle(*marker*)

Set the marker style.

Parameters
marker (*str | None*) – The marker style.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setSpanAxis(*span_axis*)

Set whether the fit line should span the x-axis range of the plot.

Parameters
span_axis (*bool*) – If True, the fit line should span the x-axis range of the plot.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

sourceData()

Checks if the source data is valid, and if yes, return the valid source data on the form: (xs, ys, x_min, x_max, x_unit, y_unit) Else returns None

Returns
The validated and clipped source data.

Return type
tuple | None

style()

Returns
All the current style properties.

Return type
dict

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

tags()

Returns
The set of tags.

Return type
set

update(*data=None*)

Perform the update.

Parameters
data (*tuple | NoneType*) – The source data to use.

validSourceCoordinates(*xs*, *ys*)

Check valid source coordinates.

Parameters

- **xs** (*numpy.ndarray*) – The x data values.
- **ys** (*numpy.ndarray*) – The y data values.

Returns
True, if the source coordinates are valid input for the fit algorithm.

Return type
bool

xData()

Returns
The x-data.

Return type
PhysicalQuantity

yData()

Returns
The y-data.

Return type
PhysicalQuantity

Usage Examples

Let us first construct a line object containing the data that we wish to fit.:

```
line = Plot.Line([0, 1, 2, 3, 4, 5], [1.3, 2.3, 4.2, 4.6, 2.6, 1.1])
```

Fitting to a parabola, can e.g. be done like this:

```
fit = Plot.CurveFit('curvature * (x - x0)**2 + offset')
line.addItem(fit)
print(fit.parameters())
print('R2=', fit.determination())
```

This will output the following values for `curvature`, `x0` and `offset`:

```
{
    'curvature': -0.5017857159048791,
    'x0': 2.50854092811564,
    'offset': 4.14691159949586
}
R2=0.8912692142744284
```

Of course something similar could have been achieved using a *Plot.PolynomialFit*. However, CurveFit can also fit to e.g. a gaussian curve:

```
fit = Plot.CurveFit('a * gaussian(x - b, c)')
line.addItem(fit)
print(fit.parameters())
print('R2=', fit.determination())
```

And in this case it produces a slightly better fit as evidenced by the `R2` value:

```
{
    'a': 16.505234582600096,
    'b': 2.5597234857461135,
    'c': 1.6884506777324249
}
R2= 0.9739999352271602
```

Notes

CurveFit can fit to any expression `y = f(x)`. The expression can be composed of all valid python algebraic components like numbers, operators `+, -, /, *`, the power operator `**`, the imaginary unit `1j` and many more.

In addition a number of special functions can be used.

Table 4.5: Special functions available in NanoLab expressions.

Function	Notes
`abs`	Absolute value
`real`	Real part
`imag`	Imaginary part
`sin`	Sine (radians)

continues on next page

Table 4.5 – continued from previous page

Function	Notes
cos	Cosine (radians)
tan	Tangent (radians)
asin	Inverse sine
acos	Inverse cosine
atan	Inverse tangent
atan2(a, b)	Inverse tangent of a/b in correct quadrant.
exp	Exponential
expm1	exp(a) - 1
sinh	Hyperbolic sine
cosh	Hyperbolic cosine
tanh	Hyperbolic tangent
asinh	Inverse sinh
acosh	Inverse cosh
atanh	Inverse tanh
log	Natural logarithm
log10	Logarithm base 10
log2	Logarithm base 2
sqrt	Square root
erf	Error function
erfc	1 - erf
gamma	Euler gamma function
ceil	Ceiling function
floor	Floor function
theta	Heaviside theta function, theta(a) = 0 for a < 0 and 1 for a > 0.
step	Heaviside theta function
sign	Sign function
sum	Sum
cumsum	Cumulative sum
cumtrapz	Cumulative trapezoidal sum |
gradient	1D gradient
wofz	Faddeeva function
lorentzian(x, g)	Lorentzian function, where g is the full width at half maximum (FWHM).
gaussian(x, a)	Gaussian function, wheere a is the full width at half maximum (FWHM).
voigt(x, a, g)	Voigt profile. Convolution of gaussian and lorentzian function. Here, a is the gaussian FWHM, and g is the lorentzian FWHM.
arange(a, b, step=1)	Range of values from a to b with custom step.

Plot.Density

class Density(*x=None*, *y=None*, *weights=None*)

A density plot item to effeciently show the density of (very many) points.

Parameters

- **x** (PhysicalQauntity | ndarray) – The x coordinates.
- **y** (PhysicalQauntity | ndarray) – The y coordinates.
- **weights** (PhysicalQauntity | ndarray) – The optional weights.

addItem(*item*, *emit=True*)

Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)

Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)

Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

alpha()

Returns
The opacity.

Return type
float

applyStyle(*style_scheme=None*, *style_properties=None*)

Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.
- **style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

broadening()

Returns
The broadening.

Return type
float

color()

Returns
The color in hex format.

Return type
str

colorMap()

The color map to use..

Returns
The color map.

Return type
str

colorMode()

The current color mode.

When set to COLOR_MODES.COLOR, the density is colored using the current color. When set to COLOR_MODES.COLOR_MAP colors the density using the current color_map.

Returns
The color mode (colormap or color)

Return type
COLOR_MODES enum

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

dpi()

Returns
The resolution in dots per inch.

Return type
int

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

extent(*axis_name*, *padding=0.0*)

Get the data limits.

Parameters

- **axis_name** (*str*) – x or y.
- **padding** (*float*) – Padding around the data. **Default:** 0.0.

Returns
The min/max data values for the requested axis.

Return type
2-tuple of PhysicalQauntity

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

hoverDetails()

Returns
The current hover details.

Return type
dict | None

isHoverable()

Returns
True, if hoverable.

Return type
bool

isHovered()

Returns
True, if the item is hovered.

Return type
bool

isSelectable()

Returns
True, if the item is selectable.

Return type
bool

isSelected()

Returns
True, if the item is selected.

Return type
bool

isVisible()

Returns
True, if the item is visible.

Return type
bool

items(*selected=None*, *tag=None*)

Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **selected** (*None | bool*) – True, if only selected items should be returned.
- **tag** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

`label()`

Returns
The density label.

Return type
str

`limits()`

Returns
The limits of the color axis.

Return type
2-tuple of float

`model()`

Returns
The model that this item belongs to.

Return type
PlotModel | None

`order()`

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

`owner()`

Returns
The owner type.

Return type
int | enum

`parent()`

Returns
The parent.

Return type
PlotItem based | None

`removeItem(item, emit=True)`

Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

removeSubscriber(*subscriber*)

Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

resampler()

Returns
The resampler.

Return type
PlotStorable with resample method | NoneType

selectionDetails()

Returns
The current selection details.

Return type
dict | None

setAlpha(*alpha*)

Set the opacity.

Parameters
alpha (*float*) – The opacity.

setBroadening(*broadening*)

Set the broadening.

Parameters
broadening (*float*) – The broadening.

setColor(*color*)

Set the color.

Parameters
color (str | QColor) – The color to set.

setColorMap(*color_map*)

Set the color map.

Parameters
color_map (*str*) – The color map.

setColorMode(*mode*)

Set the color mode.

Parameters
mode (*COLOR_MODES enum*) – The mode to set.

setData(*x_data*, *y_data*, *weights=None*)

Set data.

Parameters

- **x_data** (PhysicalQauntity | ndarray) – The one-dimensional x data.
- **y_data** (PhysicalQauntity | ndarray) – The one-dimensional y data.
- **weights** (ndarray | None) – The optional weights.

setDpi(*dpi*)

Set the resolution in dots per inch.

Parameters
dpi (*int*) – The resolution in dots per inch.

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setLabel(*label*)

Set the density label.

Parameters
label (*str*) – The label.

setLimits(*lower_limit*, *upper_limit*)

Set the color axis limit.

Parameters

- **lower_limit** (*float | NoneType*) – The lower limit.
- **upper_limit** (*float | NoneType*) – The upper limit.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setResampler(*resampler*)

Set the resampler used to dynamically upsample or downsample the data.

Parameters
resampler (*Any PlotStorable with a resample method | None*) – The resampler.

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

setWeights(*weights*)

Set the weights.

Parameters
weights (PhysicalQauntity | ndarray) – The weights.

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

tags()

Returns
The set of tags.

Return type
set

weights()

Returns
The weights if any.

Return type
ndarray | None

xData()

The 1D x-data.

Returns
The x data.

Return type
PhysicalQauntity | ndarray

yData()

The 1D y-data.

Returns
The y data.

Return type
PhysicalQauntity | ndarray

Plot.Framing

class Framing(*title=''*, *font_size=16.0*, *show_title=True*)

The Framing specifies properties of the visual frame of the plot model (not to be confused with Plot.PlotFrame). This includes properties such as the plot title, the border line width and the background color.

Parameters

- **title** (*str*) – The title text.
- **font_size** (*float*) – The title font size.
- **show_title** (*bool*) – If True, the title is visible.

addItem(*item*, *emit=True*)

Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)

Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)

Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

applyStyle(*style_scheme=None*, *style_properties=None*)

Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.
- **style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

backgroundColor()

Returns
The background color of the plot in hex format.

Return type
str

borderLineWidth()

Returns
The border line width in points.

Return type
float

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

fontSize()

Returns
The font size.

Return type
float

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

hoverDetails()

Returns
The current hover details.

Return type
dict | None

isBottomBorderVisible()

Returns
Whether or not the border is visible.

Return type
bool

isHoverable()

Returns
True, if hoverable.

Return type
bool

isHovered()

Returns
True, if the item is hovered.

Return type
bool

`isLeftBorderVisible`()

Returns
Whether or not the border is visible.

Return type
bool

`isRightBorderVisible`()

Returns
Whether or not the border is visible.

Return type
bool

`isSelectable`()

Returns
True, if the item is selectable.

Return type
bool

`isSelected`()

Returns
True, if the item is selected.

Return type
bool

`isTitleVisible`()

Returns
Whether or not the title is visible.

Return type
bool

`isTopBorderVisible`()

Returns
Whether or not the border is visible.

Return type
bool

`isVisible`()

Not implemented for Framing.

`items`(*selected=None*, *tag=None*)

Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **selected** (*None | bool*) – True, if only selected items should be returned.
- **tag** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

model()

Returns
The model that this item belongs to.

Return type
PlotModel | None

order()

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

owner()

Returns
The owner type.

Return type
int | enum

parent()

Returns
The parent.

Return type
PlotItem based | None

removeItem(*item*, *emit=True*)

Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

removeSubscriber(*subscriber*)

Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

selectionDetails()

Returns
The current selection details.

Return type
dict | None

setBackgroundColor(*color*)

Set the background color of the plot.

Parameters
color (*str*) – The color to set in hex format.

setBorders(*line_width=None*, *show_left_border=None*, *show_right_border=None*, *show_top_border=None*, *show_bottom_border=None*)

Set border properties.

Parameters

- **line_width** (*int*) – The border line width.
- **show_left_border** (*bool*) – If True, the left(polar) border is visible for rectilinear(polar) projections.
- **show_right_border** (*bool*) – If True, the right(inner) border is visible for rectilinear(polar) projections.
- **show_top_border** (*bool*) – If True, the top border(end) is visible for rectilinear(polar) projections.
- **show_bottom_border** (*bool*) – If True, the bottom(start) border is visible for rectilinear(polar) projections.

setFontSize(*font_size*)

Set the font size for the plot title.

Parameters
font_size (*float*) – The absolute font size in points.

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setText(*title*)

Set the title text.

Parameters
text (*str*) – The title text.

setTitle(*title*)

Set the title text.

Parameters
text (*str*) – The title text.

setTitleVisible(*visible*)

Set the title visibility.

Parameters
visible (*bool*) – If True, the title is visible.

setVisible()

Not implemented for Framing.

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

tags()

Returns
The set of tags.

Return type
set

text()

Returns
The title text.

Return type
str

title()

Returns
The title text.

Return type
str

Plot.GridLayout

class GridLayout(*rows=1*, *columns=1*)

Grid layout that sets up a grid where frames can be placed.

Items are placed at a row, column position and has a size, that is a multiple of rows or columns.

The grid can optionally sync the x- or y-axis of all immediately contained frames.

Parameters

- **rows** (*int*) – The number of rows.
- **columns** (*int*) – The number of columns.

addItem(*item*, *row=None*, *column=None*, *height=1*, *width=1*)

Add item to grid layout.

Parameters

- **item** (*LayoutItem based*) – The item to add.
- **row** (*int*) – The row to insert at.
- **column** (*int*) – The column to insert at.
- **height** (*int*) – The height (row span).
- **width** (*int*) – The width (column span).

addModel(*model*, *row=None*, *column=None*)

Convenience method for easily adding a plot model to the layout.

Parameters

- **model** (PlotModel) – The plot model to add.
- **row** (*int*) – The row where to add it.
- **column** (*int*) – The column where to add it.

Returns
The added plot frame.

Return type
PlotFrame

copy()

Returns
A copy of the layout.

Return type
BaseLayout

dimensions()

Returns
The dimensions (rows, columns).

Return type
2-tuple of int

find(*, *types=None*, *function=None*, ***kwargs*)

Find plot items within this layout filtered on types and properties.

Find all lines with e.g. the label Result, by writing:

```
layout.find(types=Line, label='Result')
```

Or find all Scatter plots with an outline:

```
layout.find(types=Scatter, outline=True).
```

Or all lines which has a label that starts with the characters band,:

```
def labelStartWithBand(item):
    return item.label().lower().startswith('band')

layout.find(
    types=Line,
    function=labelStartsWithBand
).
```

Parameters

- **types** (*None | PlotItem type*) – An optional type or multiple types, e.g. Line or Scatter.
- **function** (*None | function*) – An optional filter function taking the plot item as the only input.
- ****kwargs** (*dict*) – Optional properties which should be matched exactly for the items.

Returns
A list of the items matching the query.

Return type
list of PlotItem

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

isCompatible(*item*)

Check compatibility of item.

Parameters
item (*LayoutItem based*) – The item.

Returns
True, if compatible.

Return type
bool

itemAt(*row*, *column*)

Return the frame at the provided position.

Parameters

- **row** (*int*) – The row where the frame is.
- **column** (*int*) – The column where the frame is.

items()

Returns
The items in the layout.

Return type
list of LayoutItems.

mode()

Returns
The layout mode.

Return type
enumerator | int

models(*plotter=None*)

Get all models in the layout for a given plotter.

Parameters
plotter (*Plotter based | NoneType*) – The plotter or None for all plotters.

Returns
The models.

Return type
list

plotters()

Returns
The plotters in the layout.

Return type
set of Plotters

removeItem(*item*)

Remove item from layout.

Parameters
item (PlotFrame | *BaseLayout*) – The item to remove from the layout.

Returns
True, if removal succeeded. Otherwise False.

Return type
bool

replaceItem(*old_item*, *new_item*)

Replace an existing item.

Parameters

- **old_item** (*LayoutItem based*) – The old item to replace.

•**new_item** (*LayoutItem based*) – The new item the replaces the old item.

setDimensions(*rows*, *columns*)

Set layout dimensions.

Parameters

•**rows** (*int*) – Number of rows.

•**columns** (*int*) – Number of columns.

setMode(*mode*)

Set the layouts mode, i.e. if axes should be shared.

Parameters
mode (*enumerator | int*) – The layout type.

setSpacing(*spacing*)

Set spacing between layout items. This is given as a fraction of the average axis width and height.

Parameters
spacing (*float*) – The spacing.

spacing()

Returns
The spacing between layout items as a fraction sof the average axis width or height.

Return type
float

Usage Examples

A GridLayout arranges *Plot.PlotFrame* in a grid. A GridLayout can be constructed in the NanoLab GUI by dropping one plot next to another. See *Merge plots* for further details.

Below we show how to achieve the same functionality in a script. As an example we construct two *PlotModels*, the first showing density as a function of distance, the other showing energy as a function of distance. We build a GridLayout showing one model above the other and with their x-axises shared.

```
# Model showing the density as a function of distance.
density_model = Plot.PlotModel(Angstrom, Angstrom**-3)
density_model.addItem(Plot.Line([0, 1,  2] * Angstrom, [0.1, 0.2, 0.3] * Angstrom**-3))

# Frame the model.
density_frame = PlotFrame()
density_frame.addModel(density_model)

# Model showing an energy potential as a function of distance.
potential_model = Plot.PlotModel(Angstrom, eV)
potential_model.addItem(Plot.Line([0, 1, 2] * Angstrom, [2, 3, 4] * eV))

# Frame the model. Position y-axis to the right.
potential_frame = PlotFrame()
potential_frame.addModel(density_model)
potential_frame.title().setVisible(False)
```

(continues on next page)

(continued from previous page)

```
# Construct the GridLayout and add the two models such that they share the x-axis.
# Here we make sure that the bottom frame is twice as high as the first.
layout = Plot.GridLayout(rows=3, columns=1)
layout.setMode(Plot.LAYOUT_MODES.SHARE_X)
layout.addItem(density_frame, row=0, column=0, width=1, height=1)
layout.addItem(potential_frame, row=1, column=0, width=1, height=2)

# Show the plot.
Plot.show(layout)
```

Plot.Group

class Group(*label=None*)

A Group can contain any number of plot items.

Parameters
label (*str*) – The group label.

addItem(*item*, *emit=True*)

Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)

Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)

Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

applyStyle(*style_scheme=None*, *style_properties=None*)

Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.
- **style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

extent(*axis_name*, *padding=0*)

Propagate the limits of all children.

Parameters

- **axis_name** (*str*) – The axis name (x or y).
- **padding** (*float*) – The padding.

Returns
The limits.

Return type
NoneType | tuple of *PhysicalQuantity*

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

hoverDetails()

Returns
The current hover details.

Return type
dict | None

isHoverable()

Returns
True, if hoverable.

Return type
bool

isHovered()

Returns
True, if the item is hovered.

Return type
bool

isSelectable()

Returns
True, if the item is selectable.

Return type
bool

isSelected()

Returns
True, if the item is selected.

Return type
bool

isVisible()

Returns
True, if the item is visible.

Return type
bool

items(*selected=None*, *tag=None*)

Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **selected** (*None | bool*) – True, if only selected items should be returned.
- **tag** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

label()

Returns
The group label.

Return type
str

model()

Returns
The model that this item belongs to.

Return type
PlotModel | None

order()

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

owner()

Returns
The owner type.

Return type
int | enum

parent()

Returns
The parent.

Return type
PlotItem based | None

removeItem(*item*, *emit=True*)

Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

removeSubscriber(*subscriber*)

Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

selectionDetails()

Returns
The current selection details.

Return type
dict | None

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setLabel(*label*)

Set the group label.

Parameters
label (*str*) – The label.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

tags()

Returns
The set of tags.

Return type
set

Plot.HorizontalBar

class HorizontalBar(*bins*, *data*)

A bar plot showing data as horizontal filled bins.

The shape of the bins is determined in the following way: - If the number of bins equals the number of data values, the bins parameter is interpreted as the bin centers and bin widths are uniformly set to the match minimum distance between the bin centers. - If the number of bins is one larger than the number of data values, the bins parameter is interpreted as the edges of the bins. - If the number of bins is double the number of data values, the bins are instead interpreted as the left and right edge of each of the bins.

Parameters

- **bins** (Sequence of *PhysicalQuantity*) – The bins.

•**data** (Sequence of *PhysicalQuantity*) – The data values.

addItem(*item*, *emit=True*)

Add item as child of this item.

Parameters

•**item** (*PlotItem based*) – The item.

•**emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)

Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)

Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

alpha()

Returns
The opacity of the bar plot.

Return type
int

applyStyle(*style_scheme=None*, *style_properties=None*)

Apply style properties from a style scheme.

Parameters

•**style_scheme** (*dict*) – The style scheme.

•**style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

binCenters()

Returns
The center of each bin.

Return type
Sequence of *PhysicalQuantity*

binEdges()

. :returns: The left edges of each bin. :rtype: *PhysicalQuantity*

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

edgeColor()

Returns
The edge color of the bar plot.

Return type
str

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

extent(*axis_name*, *padding=0.0*)

The limits around the bar plot.

Parameters

- **axis_name** (*str*) – x or y.
- **padding** (*float*) – Optional padding.

Returns
The min/max data values for the requested axis.

Return type
2-tuple of *PhysicalQuantity*

faceColor()

Returns
The face color of the bar plot.

Return type
str

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

histogram()

Returns
The bin counts for each bin.

Return type
Sequence of *PhysicalQuantity*

hoverDetails()

Returns
The current hover details.

Return type
dict | None

`isHoverable`()

Returns
True, if hoverable.

Return type
bool

`isHovered`()

Returns
True, if the item is hovered.

Return type
bool

`isSelectable`()

Returns
True, if the item is selectable.

Return type
bool

`isSelected`()

Returns
True, if the item is selected.

Return type
bool

`isVisible`()

Returns
True, if the item is visible.

Return type
bool

`items`(*selected=None*, *tag=None*)
Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **`selected`** (*None | bool*) – True, if only selected items should be returned.
- **`tag`** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

label()

Returns
The label.

Return type
str

model()

Returns
The model that this item belongs to.

Return type
PlotModel | None

order()

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

owner()

Returns
The owner type.

Return type
int | enum

parent()

Returns
The parent.

Return type
PlotItem based | None

removeItem(*item*, *emit=True*)
Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

removeSubscriber(*subscriber*)
Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

selectionDetails()

Returns
The current selection details.

Return type
dict | None

setAlpha(*alpha*)

. :param alpha: The opacity of the bar plot. :type alpha: float

setColor(*color*)

Set the same color for both the bar face and the bar edge.

Parameters
color (*str*) – The color to set in hex format.

setData(*bins*, *data*, *emit=True*)

Set bins and histogram data.

The shape of the bins is determined in the following way: - If the number of bins equals the number of data values, the bins parameter is interpreted as the bin centers and bin widths are uniformly set to the match minimum distance between the bin centers. - If the number of bins is one larger than the number of data values, the bins parameter is interpreted as the edges of the bins. - If the number of bins is double the number of data values, the bins are instead interpreted as the left and right edge of each of the bins.

Parameters

- **bins** (Sequence of *PhysicalQuantity*) – The bins.
- **data** (Sequence of *PhysicalQuantity*) – The data values.
- **emit** (*bool*) – True, if the data should be emitted.

setEdgeColor(*color*)

Set the bar plot edge color.

Parameters
color (*str*) – The edge color of the bar plot.

setFaceColor(*color*)

. :param color: The face color of the bar plot. :type color: str

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setLabel(*label*)

Set the label.

Parameters
label (*str*) – The label of the bar plot.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

tags()

Returns
The set of tags.

Return type
set

xData()

Returns
The bin counts for each bin.

Return type
Sequence of *PhysicalQuantity*

yData()

Returns
The center of each bin.

Return type
Sequence of *PhysicalQuantity*

Plot.HorizontalFill

class HorizontalFill(*x*, *y_lower*, *y_upper*)
A HorizontalFill for filling an area between two lines

Parameters

- **x** (Sequence of *PhysicalQuantity*) – The x-values of the data.
- **y_lower** (Sequence of *PhysicalQuantity*) – The lower y-values in the fill.
- **y_upper** (Sequence of *PhysicalQuantity*) – The upper y-values in the fill.

addItem(*item*, *emit=True*)
Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)
Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)
Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

alpha()

Returns
The opacity of the fill.

Return type
float

applyStyle(*style_scheme=None*, *style_properties=None*)
Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.
- **style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

copy()
Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

edgeColor()

Returns
The edge color of the fill in hex format.

Return type
str

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

extent(*axis_name*, *padding=0.0*)

The data extent.

Parameters

- **axis_name** (*str*) – x or y.
- **padding** (*float*) – Padding around the data.

Returns
The minimum and maximum data values for the requested axis.

Return type
2-tuple of *PhysicalQuantity*

faceColor()

Returns
The edge color of the fill in hex format.

Return type
str

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

hoverDetails()

Returns
The current hover details.

Return type
dict | None

isHoverable()

Returns
True, if hoverable.

Return type
bool

`isHovered`()

Returns
True, if the item is hovered.

Return type
bool

`isSelectable`()

Returns
True, if the item is selectable.

Return type
bool

`isSelected`()

Returns
True, if the item is selected.

Return type
bool

`isVisible`()

Returns
True, if the item is visible.

Return type
bool

`items`(*selected=None*, *tag=None*)

Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **selected** (*None | bool*) – True, if only selected items should be returned.
- **tag** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

`label`()

Returns
The current label.

Return type
str

lower()

Returns
The lower values in the fill.

Return type
float

model()

Returns
The model that this item belongs to.

Return type
PlotModel | None

order()

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

owner()

Returns
The owner type.

Return type
int | enum

parent()

Returns
The parent.

Return type
PlotItem based | None

removeItem(*item*, *emit=True*)
Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

removeSubscriber(*subscriber*)
Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

selectionDetails()

Returns
The current selection details.

Return type
dict | None

setAlpha(*alpha*)

Set the opacity.

Parameters
alpha (*float*) – The opacity of the fill.

setColor(*color*)

Set the same color for both the face and the edge.

Parameters
color (*str*) – Set the color of the fill in hex format.

setEdgeColor(*color*)

Set the edge color of the fill.

Parameters
color (*str*) – The edge color of the fill in hex-format.

setFaceColor(*color*)

Set the face color of the fill.

Parameters
color (*str*) – The face color of the fill.in hex format.

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setLabel(*label*)

Set the label.

Parameters
label (*str*) – The label of the line.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

tags()

Returns
The set of tags.

Return type
set

upper()

Returns
The upper values in the fill.

Return type
float

values()

Returns
The values in the fill.

Return type
float

Plot.HorizontalLine

class HorizontalLine(*y*)

A HorizontalLine shows a straight horizontal line.

Parameters
y (*PhysicalQuantity | float*) – The y-value of the line.

addItem(*item*, *emit=True*)

Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)

Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)

Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

alpha()

Returns
The opacity for the line.

Return type
float

applyStyle(*style_scheme=None*, *style_properties=None*)

Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.
- **style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

color()

Returns
The line color.

Return type
str

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

`hoverDetails()`

Returns
The current hover details.

Return type
dict | None

`isHoverable()`

Returns
True, if hoverable.

Return type
bool

`isHovered()`

Returns
True, if the item is hovered.

Return type
bool

`isSelectable()`

Returns
True, if the item is selectable.

Return type
bool

`isSelected()`

Returns
True, if the item is selected.

Return type
bool

`isVisible()`

Returns
True, if the item is visible.

Return type
bool

`items(`*selected=None*, *tag=None*`)`

Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **selected** (*None | bool*) – True, if only selected items should be returned.
- **tag** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

`label()`

Returns
The line label.

Return type
str

`lineStyle()`

Returns
The line style.

Return type
str | None

`lineWidth()`

Returns
The line width.

Return type
float

`markerEdgeColor()`

Returns
The edge color of the marker in hex format.

Return type
str

`markerEvery()`

Returns
The number of points between every marker.

Return type
int

`markerFaceColor()`

Returns
The face color of the marker in hex format.

Return type
str

`markerSize()`

Returns
The marker size.

Return type
float

`markerStyle()`

. :returns: The marker style. :rtype: str | None

`model()`

Returns
The model that this item belongs to.

Return type
PlotModel | None

`order()`

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

`owner()`

Returns
The owner type.

Return type
int | enum

`parent()`

Returns
The parent.

Return type
PlotItem based | None

`removeItem(item, emit=True)`

Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

`removeSubscriber(subscriber)`

Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

`selectionDetails()`

Returns
The current selection details.

Return type
dict | None

setAlpha(*alpha*)

Set the opacity for the line.

Parameters
alpha (*float*) – The opacity.

setColor(*color*)

Set the line color.

Parameters
color (*str*) – The line color in hex format.

setData(*y*)

Set y-data.

Parameters
y (*PhysicalQuantity*) – The y-data.

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setLabel(*label*)

Set the label.

Parameters
label (*str*) – The line label.

setLineStyle(*line_style*)

Set the line style.

Parameters
line_style (*str | None*) – The line style.

setLineWidth(*line_width*)

Set the line width.

Parameters
line_width (*float*) – The line width.

setMarkerColor(*color*)

Set color of the marker. Remember to also set a valid marker style.

Parameters
color (*valid color*) – The color to set.

setMarkerEdgeColor(*color*)

Set the marker edge color. Remember to also set a valid marker style.

Parameters
color (*str*) – The edge color of the marker.

setMarkerEvery(*every*)

Set the number of points between each marker. Remember to also set a valid marker style.

Parameters
every (*int*) – The number of points between every marker.

setMarkerFaceColor(*color*)

Set the marker face-color. Remember to also set a valid marker style.

Parameters
color (*str*) – The face color of the marker.

setMarkerSize(*size*)

Set the marker size. Remember to also set a valid marker style.

Parameters
size (*float*) – The marker size.

setMarkerStyle(*marker*)

Set the marker style.

Parameters
marker (*str | None*) – The marker style.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

style()

Returns
All the current style properties.

Return type
dict

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

tags()

Returns
The set of tags.

Return type
set

xData()

Returns
The x-data.

Return type
PhysicalQuantity

yData()

Returns
The y-data.

Return type
PhysicalQuantity

Plot.HorizontalStackedFill

class HorizontalStackedFill(*y_values*, *values*)

A HorizontalStackedFill shows multiple fills laid out next to each other.

Parameters

- **y_values** (Sequence of *PhysicalQuantity*) – The y-values of the data.
- **values** (2D *PhysicalQuantity*) – The values to plot in the stack.

addItem(*item*, *emit=True*)

Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)

Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)

Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

alphas()

Returns
The opacities of the fills.

Return type
list

applyStyle(*style_scheme=None*, *style_properties=None*)

Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.
- **style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

edgeColors()

Returns
The edge colors of the fills.

Return type
list

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

faceColors()

Returns
The face colors of the fills.

Return type
list

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

`hoverDetails()`

Returns
The current hover details.

Return type
dict | None

`isHoverable()`

Returns
True, if hoverable.

Return type
bool

`isHovered()`

Returns
True, if the item is hovered.

Return type
bool

`isSelectable()`

Returns
True, if the item is selectable.

Return type
bool

`isSelected()`

Returns
True, if the item is selected.

Return type
bool

`isVisible()`

Returns
True, if the item is visible.

Return type
bool

`items(`*selected=None*, *tag=None*`)`

Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **selected** (*None | bool*) – True, if only selected items should be returned.
- **tag** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

labels()

Returns
The labels of the fills.

Return type
list

model()

Returns
The model that this item belongs to.

Return type
PlotModel | None

order()

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

owner()

Returns
The owner type.

Return type
int | enum

parent()

Returns
The parent.

Return type
PlotItem based | None

removeItem(*item*, *emit=True*)

Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

removeSubscriber(*subscriber*)

Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

selectionDetails()

Returns
The current selection details.

Return type
dict | None

setAlphas(*alphas*)

Set the alphas for all fills in the stack.

Parameters
alphas (*list*) – The opacities of the fills.

setColors(*colors*)

Set the same color for both the face and the edge for all filss in the stack.

Parameters
colors (*list*) – The colors of the fills.

setEdgeColors(*colors*)

Set the edge colors for all fills in the stack.

Parameters
colors (*list*) – The edge colors of the fills.

setFaceColors(*colors*)

Set the face colors for all fills in the stack.

Parameters
colors (*list*) – The face colors of the fills.

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setLabels(*labels*)

Set the labels for all fills in the stack.

Parameters
labels (*list*) – The labels of the fills.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

tags()

Returns
The set of tags.

Return type
set

values()

Returns
The values of the data.

Return type
2D *PhysicalQuantity*

Plot.Label

class Label(*x*, *y*, *text=''*)

A Label displays text in a plot.

Parameters

- **x** (*PhysicalQuantity*) – The x-coordinate of the label.
- **y** (*PhysicalQuantity*) – The y-coordinate of the label.
- **text** (*str*) – The label text.

addItem(*item*, *emit=True*)

Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)

Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)

Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

alignment()

Returns
The vertical and horizontal alignment.

Return type
2-tuple of str

applyStyle(*style_scheme=None*, *style_properties=None*)

Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.
- **style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

color()

Returns
The label color in hex format.

Return type
str

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

`fontSize()`

Returns
The font size in points.

Return type
float

`classmethod fromProperties(`*properties*`)`

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

`hoverDetails()`

Returns
The current hover details.

Return type
dict | None

`isBoxOn()`

Returns
True, if the label has a box.

Return type
bool

`isHoverable()`

Returns
True, if hoverable.

Return type
bool

`isHovered()`

Returns
True, if the item is hovered.

Return type
bool

`isMovable()`

Returns
True, if the label is movable.

Return type
bool

`isSelectable`()

Returns
True, if the item is selectable.

Return type
bool

`isSelected`()

Returns
True, if the item is selected.

Return type
bool

`isVisible`()

Returns
True, if the item is visible.

Return type
bool

`items`(*selected=None*, *tag=None*)

Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **selected** (*None | bool*) – True, if only selected items should be returned.
- **tag** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

`model`()

Returns
The model that this item belongs to.

Return type
PlotModel | None

`order`()

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

owner()

Returns
The owner type.

Return type
int | enum

parent()

Returns
The parent.

Return type
PlotItem based | None

position()

Returns
The label postion.

Return type
None | 2-tuple of *PhysicalQuantity*

removeItem(*item*, *emit=True*)

Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

removeSubscriber(*subscriber*)

Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

selectionDetails()

Returns
The current selection details.

Return type
dict | None

setAlignment(*vertical*, *horizontal*)

Set the label alignment with respect to the position.

Parameters

- **vertical** (*str*) – The vertical alignment (top, center, bottom).
- **horizontal** (*str*) – The horizontal alignment (left, center, right).

setBoxOn(*box_on*)

Set whether a box should be drawn around the label text.

Parameters
box_on (*bool*) – True, if the label should have a box.

setColor(*color*)

Set the color.

Parameters
color (*str*) – The label color in hex format.

setFontSize(*fontsize*)

Set the font size.

Parameters
fontsize (*float*) – The font size in points.

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setMovable(*movable*)

Set whether the label should be movable.

Parameters
movable (*bool*) – True, if the label should be movable.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setPosition(*x*, *y*)

Set the label position.

Parameters

- **x** (*PhysicalQuantity*) – The x-position.
- **y** (*PhysicalQuantity*) – The y-position.

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setText(*text*)

Set the text.

Parameters
text (*str*) – The label text.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

style()

Returns
All the current style properties.

Return type
dict

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

tags()

Returns
The set of tags.

Return type
set

text()

Returns
The label text.

Return type
str

Plot.Line

class Line(*x*, *y*, *tooltips=None*, *selectable=True*)

A line display a line in a plot.

Parameters

- **x** (Sequence | *PhysicalQuantity* | ndarray) – The x-data of the line.
- **y** (Sequence | *PhysicalQuantity* | ndarray) – The y-data of the line.
- **tooltips** (*list | list of str*) – The line tooltips.
- **selectable** (*bool*) – True, if the line is selectable.

addItem(*item*, *emit=True*)

Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)

Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)

Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

alpha()

Returns
The opacity for the line.

Return type
float

applyStyle(*style_scheme=None*, *style_properties=None*)

Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.
- **style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

color()

Returns
The line color.

Return type
str

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

extent(*axis_name*, *padding=0.0*)

Get the data extent.

Parameters

- **axis_name** (*str*) – x or y.
- **padding** (*float*) – Padding around the data. **Default:** 0.0.

Returns
The min/max data values for the requested axis.

Return type
PhysicalQuantity

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

hoverDetails()

Returns
The current hover details.

Return type
dict | None

isHoverable()

Returns
True, if hoverable.

Return type
bool

isHovered()

Returns
True, if the item is hovered.

Return type
bool

isSelectable()

Returns
True, if the item is selectable.

Return type
bool

`isSelected`()

Returns
True, if the item is selected.

Return type
bool

`isVisible`()

Returns
True, if the item is visible.

Return type
bool

`items`(*selected=None*, *tag=None*)

Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **selected** (*None | bool*) – True, if only selected items should be returned.
- **tag** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

`label`()

Returns
The line label.

Return type
str

`lineStyle`()

Returns
The line style.

Return type
str | None

`lineWidth`()

Returns
The line width.

Return type
float

markerEdgeColor()

Returns
The edge color of the marker in hex format.

Return type
str

markerEvery()

Returns
The number of points between every marker.

Return type
int

markerFaceColor()

Returns
The face color of the marker in hex format.

Return type
str

markerSize()

Returns
The marker size.

Return type
float

markerStyle()

. :returns: The marker style. :rtype: str | None

model()

Returns
The model that this item belongs to.

Return type
PlotModel | None

order()

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

owner()

Returns
The owner type.

Return type
int | enum

parent()

Returns
The parent.

Return type
PlotItem based | None

removeItem(*item*, *emit=True*)

Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

removeSubscriber(*subscriber*)

Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

selectionDetails()

Returns
The current selection details.

Return type
dict | None

setAlpha(*alpha*)

Set the opacity for the line.

Parameters
alpha (*float*) – The opacity.

setColor(*color*)

Set the line color.

Parameters
color (*str*) – The line color in hex format.

setData(*x=None*, *y=None*, *tooltips=None*)

Set data.

Parameters

- **x** (Sequence | *PhysicalQuantity* | ndarray) – The x values.
- **y** (Sequence | *PhysicalQuantity* | ndarray) – The y values.
- **tooltips** (*list of str | str*) – Tooltips for each entry.

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setLabel(*label*)

Set the label.

Parameters
label (*str*) – The line label.

setLineStyle(*line_style*)

Set the line style.

Parameters
line_style (*str | None*) – The line style.

setLineWidth(*line_width*)

Set the line width.

Parameters
line_width (*float*) – The line width.

setMarkerColor(*color*)

Set color of the marker. Remember to also set a valid marker style.

Parameters
color (*valid color*) – The color to set.

setMarkerEdgeColor(*color*)

Set the marker edge color. Remember to also set a valid marker style.

Parameters
color (*str*) – The edge color of the marker.

setMarkerEvery(*every*)

Set the number of points between each marker. Remember to also set a valid marker style.

Parameters
every (*int*) – The number of points between every marker.

setMarkerFaceColor(*color*)

Set the marker face-color. Remember to also set a valid marker style.

Parameters
color (*str*) – The face color of the marker.

setMarkerSize(*size*)

Set the marker size. Remember to also set a valid marker style.

Parameters
size (*float*) – The marker size.

setMarkerStyle(*marker*)

Set the marker style.

Parameters
marker (*str | None*) – The marker style.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

style()

Returns
All the current style properties.

Return type
dict

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

tags()

Returns
The set of tags.

Return type
set

tooltips()

Returns
The tooltips.

Return type
list of str | NoneType

xData()

Returns
The x-data.

Return type
PhysicalQuantity

yData()

Returns
The y-data.

Return type
PhysicalQuantity

Plot.LineGroup

class LineGroup(*items=None*)

Group containing multiple lines.

The group makes it easy to handle many lines.

It also has better performance when drawing lines, but unfortunately only supports a subset of the normal line properties. This means that e.g. markers cannot be drawn, and that visibility is only controlled for all line in the line group.

The line group also shows up in the legend as a single item.

Parameters
items (*list*) – List of Line instances.

addItem(*item*, *emit=True*)

Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)

Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)

Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

alpha()

Returns
The opacity for the group.

Return type
float | None

applyStyle(*style_scheme=None*, *style_properties=None*)

Override PlotItem.applyStyle.

Apply the style of the LineGroup to the lines.

Parameters

- **style_scheme** (*dict*) – The style scheme.

•**style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style.

colors()

Returns
The colors.

Return type
list

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

•**key** (*str*) – The key to emit.

•**value** (*object*) – The value to emit.

extent(*axis_name*, *padding=0.0*)

Set extent.

Parameters

•**axis_name** (*str*) – The axss name (x or y).

•**padding** (*float*) – The extra padding.

Returns
The extent.

Return type
Sequence of PhysicalQuantity

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

hoverDetails()

Returns
The current hover details.

Return type
dict | None

`isHoverable`()

Returns
True, if hoverable.

Return type
bool

`isHovered`()

Returns
True, if the item is hovered.

Return type
bool

`isSelectable`()

Returns
True, if the item is selectable.

Return type
bool

`isSelected`()

Returns
True, if the item is selected.

Return type
bool

`isVisible`()

Returns
True, if the item is visible.

Return type
bool

`items`(*selected=None*, *tag=None*)
Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **selected** (*None | bool*) – True, if only selected items should be returned.
- **tag** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

label()

Returns
The current label.

Return type
str

lineStyles()

Returns
A list of line style for each item.

Return type
list

lineWidths()

Returns
A list of line widths for each item.

Return type
list

model()

Returns
The model that this item belongs to.

Return type
PlotModel | None

order()

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

owner()

Returns
The owner type.

Return type
int | enum

parent()

Returns
The parent.

Return type
PlotItem based | None

removeItem(*item*, *emit=True*)

Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

removeSubscriber(*subscriber*)

Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

selectionDetails()

Returns
The current selection details.

Return type
dict | None

setAlpha(*alpha*)

Set the alpha/opacity, for all items.

Parameters
alpha (*float*) – The opacity.

setColor(*color*)

Set the line color for all items.

Parameters
color (*Any matplotlib supported color definition*) – The color.

setColors(*colors*)

Set the line color for all items.

Parameters
color (*Any matplotlib supported color definition*) – The color.

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setItems(*items*)

Set items.

Parameters
items (*items.*) – The items to set.

setLabel(*label*)

Set the label.

Parameters
label (*str*) – The label of the linegroup.

setLineStyle(*line_style*)

Set the line style, for all items.

Parameters
line_style (*str | None*) – The line style.

setLineStyles(*line_styles*)

Set the line style, for all items.

Parameters
line_style (*list*) – The line style list.

setLineWidth(*line_width*)

Set the line width, for all items.

Parameters
line_width (*float*) – The line width.

setLineWidths(*line_widths*)

Set the line width, for all items. return list(self._properties[items])

Parameters
line_width (*list*) – The line width list.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *information=None*)

Set the selected property. Overloads the base class method.

Parameters

- **selected** (*bool*) – True, if item given by index should be selected.
- **information** (*dict*) – information of the pick event.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

style()

Returns
All the current style properties.

Return type
dict

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

tags()

Returns
The set of tags.

Return type
set

Plot.Measure

class Measure(*tail_x*, *tail_y*, *head_x*, *head_y*)

A Measure shows the distance between its tail-point and head-point along the x- and y-axis.

A Measure can be interactively moved with the mouse and can snap to nearby points on e.g. a Line.

Parameters

- **tail_x** (scalar *PhysicalQuantity*) – The tail x coordinate.
- **tail_y** (scalar *PhysicalQuantity*) – The tail y coordinate.
- **head_x** (scalar *PhysicalQuantity*) – The head x coordinate.
- **head_y** (scalar *PhysicalQuantity*) – The head x coordinate.

addItem(*item*, *emit=True*)

Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)

Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)

Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

applyStyle(*style_scheme=None*, *style_properties=None*)

Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.

•**style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

color()

Returns
The measure color.

Return type
str

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

•**key** (*str*) – The key to emit.

•**value** (*object*) – The value to emit.

fontSize()

Returns
The measure label font size.

Return type
float

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

hoverDetails()

Returns
The current hover details.

Return type
dict | None

isHoverable()

Returns
True, if hoverable.

Return type
bool

isHovered()

Returns
True, if the item is hovered.

Return type
bool

isMovable()

Returns
True, if the label is movable.

Return type
bool

isSelectable()

Returns
True, if the item is selectable.

Return type
bool

isSelected()

Returns
True, if the item is selected.

Return type
bool

isSnapping()

Returns
True, if snapping is active.

Return type
bool

isVerticalLabelFlipped()

Returns
True, if the label displaying measurement along the vertical axis is flipped.

Return type
bool

isVisible()

Returns
True, if the item is visible.

Return type
bool

isXShown()

Returns
True, if the x-measurement is shown.

Return type
bool

isYShown()

[summary].

Returns
True, if the y-measurement should be shown.

Return type
bool

items(*selected=None*, *tag=None*)

Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **selected** (*None | bool*) – True, if only selected items should be returned.
- **tag** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

labelPosition()

Returns
The label position in terms of whether they are inside or outside of the arrows.

Return type
enum

lineWidth()

Returns
The measure line width.

Return type
float

model()

Returns
The model that this item belongs to.

Return type
PlotModel | None

order()

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

owner()

Returns
The owner type.

Return type
int | enum

parent()

Returns
The parent.

Return type
PlotItem based | None

positions()

Returns
The postions of the arrow ends in the format (x1, y1, x2, y2).

Return type
None | 4-tuple of PhysicalQuantity

precision()

Returns
The number of significant digits shown the in measurement labels.

Return type
int

removeItem(*item*, *emit=True*)

Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

removeSubscriber(*subscriber*)

Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

selectionDetails()

Returns
The current selection details.

Return type
dict | None

setColor(*color*)

Set the color of the measure.

Parameters
color (*str*) – A matplotlib compatible color.

setFontSize(*fontsize*)

Set the font size of the measure labels.

Parameters
fontsize (*float*) – The font size.

setHeadPosition(*x*, *y*, *emit=True*)

Set the position.

Parameters

- **x** (*PhysicalQuantity*) – The x position.
- **y** (*PhysicalQuantity*) – The y position.
- **emit** (*bool*) – True, if signal should be emitted.

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setLabelPosition(*position*)

Set the label position to be either inside or outside of the arrows.

Parameters
position (*enum*) – The position choice.

setLineWidth(*line_width*)

Set the line width.

Parameters
line_width (*float*) – The measure line width.

setMovable(*movable*)

Set the movable property.

Parameters
movable (*bool*) – True, if the label should be movable.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setPrecision(*digits*)

Set the number of significant digits to show in the measurement labels.

Parameters
digits (*int*) – The number of significant digits.

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setSnapping(*snap*)

Set whether the measurement should snap to points on *Line*, *Scatter* or *LineGroup*.

Parameters
snap (*bool*) – True, if the measurement should snap.

setTailPosition(*x*, *y*, *emit=True*)

The tail position.

Parameters

- **x** (*PhysicalQuantity*) – The tail x position.
- **y** (*PhysicalQuantity*) – The tail y position.
- **emit** (*bool*) – True, if signal should be emitted.

setVerticalLabelFlipped(*flipped*)

Set whether the label displaying measurement along the vertical axis is rotated 90 degrees.

Parameters
flipped (*bool*) – True, if the label displaying measurement along the vertical axis is flipped.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

setXShown(*x_measure_shown*)

Set whether to show the x-meaurement.

Parameters
x_measure_shown (*bool*) – True, if x-measurement should be shown.

setYShown(*y_measure_shown*)

Set whether to show the y-meaurement.

Parameters
y_measure_shown – if y-measurement should be shown.

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

`tags()`

Returns
The set of tags.

Return type
set

Plot.MultiLineResampler

`class MultiLineResampler(sampling=None)`

A resampler for resampling data in a `Plot-Density` item. Works really well for data representing multiple intersecting lines.

This resampler is essential if the size of the saved plot should not explode.

Provide 1D x-data and an array of multiple line data e.g. 2D y-data, and perhaps some extra weights data in the same shape as the y-data.

The resampler then upsamples the data using sampling number of linear spaced points in the x-data.

Parameters
sampling (*int | NoneType*) – The number of sampling points to use.

`copy()`

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

`classmethod fromProperties(properties)`

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

`resample(x_data, y_data, weights=None)`

Resample the data.

Parameters

- **x_data** (PhysicalQauntity | ndarray) – The 1D x-data.
- **y_data** (PhysicalQauntity | ndarray) – The 1D or 2D y-data.
- **weights** (ndarray) – Optional weirhts

Returns
The upsampled data.

Return type
2 or 3-tuple of ndarrays

sampling()

Returns
The sampling.

Return type
int

setSampling(*sampling*)

Set the sampling.

Parameters
sampling (*int*) – The sampling.

Plot.OverlayLayout

class OverlayLayout

An overlaying plot layout that can contain exactly two frames, shown as an overlay on the same plot.

The two frames can share either the x-axis or the y-axis. The actual mode can take values of either SHARE_X or SHARE_Y.

addItem(*item*)

Add a frame to the layout.

Raise an error if more than two frames are added.

Parameters
item (PlotFrame) – The frame.

copy()

Returns
A copy of the layout.

Return type
BaseLayout

find(*, *types=None*, *function=None*, ***kwargs*)

Find plot items within this layout filtered on types and properties.

Find all lines with e.g. the label Result, by writing:

```
layout.find(types=Line, label='Result')
```

Or find all Scatter plots with an outline:

```
layout.find(types=Scatter, outline=True).
```

Or all lines which has a label that starts with the characters band,:

```
def labelStartWithBand(item):
    return item.label().lower().startswith('band')

layout.find(
```

(continues on next page)

(continued from previous page)

```
    types=Line,
    function=labelStartsWithBand
).
```

Parameters

- **types** (*None | PlotItem type*) – An optional type or multiple types, e.g. Line or Scatter.
- **function** (*None | function*) – An optional filter function taking the plot item as the only input.
- ****kwargs** (*dict*) – Optional properties which should be matched exactly for the items.

Returns
A list of the items matching the query.

Return type
list of PlotItem

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

items()

Returns
The items in the layout.

Return type
list of LayoutItems.

mode()

Returns
The overlay mode.

Return type
enumerator | int

models(*plotter=None*)

Get all models in the layout for a given plotter.

Parameters
plotter (*Plotter based | NoneType*) – The plotter or None for all plotters.

Returns
The models.

Return type
list

plotters()

Returns
The plotters in the layout.

Return type
set of Plotters

removeItem(*item*)

Remove a frame from the layout.

Parameters
item (PlotFrame) – The frame to remove.

replaceItem(*old_item*, *new_item*)

Replace an existing item.

Parameters

- **old_item** (*LayoutItem based*) – The old item to replace.
- **new_item** (*LayoutItem based*) – The new item the replaces the old item.

setMode(*mode*)

Set the overlay mode.

Note that this layout does not have a LAYOUT_MODES.NORMAL layout mode, but only supports LAYOUT_MODES.SHARE_X or LAYOUT_MODES.SHARE_Y.

Parameters
mode (*enumerator | int*) – The overlay layout mode.

Usage Examples

An OverlayLayout lays two *Plot.PlotFrame* over one another. Each PlotFrame has its own axises. The most common usage is to show two PlotFrames together which only share a single axis.

An OverlayLayout can be constructed in the NanoLab GUI by dropping one plot on top of another. See the *Merge plots* part of the Plotting guide for further details.

Below we show how to achieve the same functionality in a script. As an example we construct two *PlotModels*, the first showing density as a function of distance, the other showing energy as a function of distance. They are overlaid on top of each other with a shared x-axis.

```
# Model showing the density as a function of distance.
density_model = Plot.PlotModel(Angstrom, Angstrom**-3)
density_model.addItem(Plot.Line([0, 1,  2] * Angstrom, [0.1, 0.2, 0.3] * Angstrom**-3))

# Frame the model.
density_frame = PlotFrame()
density_frame.addModel(density_model)

# Model showing an energy potential as a function of distance.
potential_model = Plot.PlotModel(Angstrom, eV)
potential_model.addItem(Plot.Line([0, 1, 2] * Angstrom, [2, 3, 4] * eV))

# Frame the model. Position y-axis to the right.
potential_frame = PlotFrame()
```

(continues on next page)

(continued from previous page)

```
potential_frame.addModel(density_model)
potential_frame.yAxis().setMirrored(True)
potential_frame.title().setVisible(False)

# Construct the OverlayLayout and add the two models such that they share the x-axis.
overlay = Plot.OverlayLayout()
overlay.setMode(Plot.LAYOUT_MODES.SHARE_X)
overlay.addItem(density_frame)
overlay.addItem(potential_frame)

# Show the plot.
Plot.show(overlay)
```

Plot.Plot

class Plot(*layout*, *size*)

A Plot wraps a plot layout such that it can be saved to and loaded from an HDF5 file.

Parameters

- **layout** (*BaseLayout based*) – The plot layout to wrap.
- **size** (*2-tuple of floats*) – The pixel size of the layout.

find(*, *types=None*, *function=None*, ***kwargs*)

Find plot items within this plot filtered on type and properties.

Find all lines with e.g. the label Result, by writing:

```
layout.find(types=Line, label='Result')
```

Or find all Scatter plots with an outline:

```
layout.find(types=Scatter, outline=True).
```

Or all lines which has a label that starts with the characters band,:

```
def labelStartWithBand(item):
    return item.label().lower().startswith('band')

layout.find(
    types=Line,
    function=labelStartsWithBand
).
```

Parameters

- **types** (*None | PlotItem type*) – An optional type or types, e.g. Line or Scatter.
- **function** (*None | function*) – An optional filter function taking the plot item as the only input.
- ****kwargs** (*dict*) – Optional properties which should be matched exactly for the items.

Returns

A list of the items matching the query.

Return type
list of PlotItem

`layout()`

Returns
The wrapped plot layout.

Return type
BaseLayout based

`metatext()`

Returns
The metatext of the object or None if no metatext is present.

Return type
str | None

`setMetatext(metatext)`

Set a given metatext string on the object.

Parameters
metatext (*str | None*) – The metatext string that should be set. A value of None can be given to remove the current metatext.

`size()`

Returns
The layout pixel size.

Return type
2-tuple of floats

`uniqueString()`

Return a unique string representing the state of the object.

Plot.PlotFrame

`class PlotFrame(use_frame_model=True)`

A plot frame lives inside a layout, and contains one or more plot models.

In the matplotlib front end, a frame is plotted as exactly one main matplotlib Axes object. However, the frame may control multiple auxiliary axes like e.g. colorbars.

The plot frame plots all the items contained in the plot models. Special care must be taken with the title, legend, axiss and user annotations. Each model contains their own instances of these items, and it can be unclear how, for example, the x-axis of one plot model should be reconciled with another.

Instead, the frame uses only a single x-axis, y-axis etc. There are two implementations:

1. The frame uses a frame model, and ignores all the model titles, legends etc. This is the implementation for plots that are saved. This also means that plugin developers should not rely on changing axis, title or legends as part of their controls, since these features can easily be lost when the plot has been saved and loaded anew.

2. The frame instead uses the first model. This is the default solution for embedded plot views where frames are added using the GridLayout.addModel() method. It ensures maximum control for embedded PlotViews, but you should not rely too heavily on the freedom it allows, as all the saved plots use a private view model (see 1.).

Parameters
use_frame_model (*bool*) – True, if the frame should use a separate view model..

addModel(*model*, *flipped=False*)

Add a model to the plot frame.

Note that the frame will explicitly *not* listen to model changes.

Syncronization between frame and model must happen in the view implementation.

Parameters

- **model** (PlotModel) – The model to add.
- **flipped** (*bool*) – True, if the model axes are flipped.

autoscaleLimits()

Update the autoscaled axis limits.

axis(*name*)

The axis with a given name.

Parameters
name (*str*) – The name (x or y).

Returns
The axis.

Return type
class:*~.Plot.Axis*

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

flip()

Flip the x- and y-axis.

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

isFlipped()

Returns
The frame model.

Return type
Plot Model

isModelFlipped(*model*)

Check if a given model is flipped in this frame.

Parameters
model (PlotModel) – The model to check.

Returns
True, if the model is flipped.

Return type
bool

model()

Returns
The frame model.

Return type
PlotModel

models(*plotter=None*)

Return all models, perhaps filtered by a plotter.

Parameters
plotter (*None | Plotter based*) – The plotter to filter on.

Returns
The added models.

Return type
list of class:~.*Plot.PlotModel*

plotters()

Returns
The plotter referenced in the frame.

Return type
list of Plotter based

projection()

Returns
The projection.

Return type
str | NoneType

setFlipped(*flipped*)

Set flipped property.

Parameters
flipped (*bool*) – True, if the frame is flipped.

setProjection(*projection*)

Set the projection.

Parameters
projection (*str*) – The projection.

usesFrameModel()

. :returns: True, if the frame has a separate frame model. :rtype: bool

Usage Examples

A PlotFrame makes it possible to embed a *Plot.PlotModel* into a layout – just like a beautiful painting must be framed before it can be hung on the wall togehter with other paintings.

However, the PlotFrame is much more versatile than a standard picture frame. The PlotFrame can contain multiple PlotModels:

```
>>> frame = Plot.PlotFrame()
>>> frame.addModel(Plot.PlotModel())
```

And the frame can easily exchange the x- and y-axises:

```
>>> frame.flip()
```

Note: The PlotFrame must contain contain at least one PlotModel before it can be embedded in e.g. a *Plot.GridLayout* or a *Plot.OverlayLayout*.

Multiple PlotModels can also be embedded in a common PlotFrame, and complex plots can be built by combining multiple PlotFrames in a layout like the *Plot.GridLayout* or the *Plot.OverlayLayout*. A more complex usage example is given below.

```
# Build one plot model.
frame1.addModel(model1)
frame1.addModel(model2, flipped=True)

# Add the second model to its own frame.
frame2 = Plot.PlotFrame()
frame2.addmodel(model1)

# Add frames to grid layout.
layout = Plot.GridLayout(2, 1)
layout.addItem(frame1)
layout.addItem(frame2)

# Show the plot.
Plot.show(layout)
```

Plot.PlotModel

class PlotModel(*x_unit=<Unit at 140734618035408 >*, *y_unit=<Unit at 140734618035408 >*, *projection='rectilinear'*)

A plot model contains plot items.

The items contain data objects like lines, bars etc. and can be named for easy retrieval.:

```
>>> model = PlotModel(x_unit, y_unit)
>>> model.setItem('line', Line([0, 1], [1, 2]))

>>> line = model.item('line').
```

The plot model also contains the special items: xAxis, yAxis, legend and title. These items are special in the sense that they are only applied when the frame containing the model is reset. So for most purposes they only serve as initial values.

Parameters

- **x_unit** (Unit) – The unit of the x axis of the plot model data.
- **y_unit** (Unit) – The unit of the y axis of the plot model data.
- **projection** (*str*) – The projection.

addItem(*item*)

Add a plot item to the model.

Parameters
item (*PlotItem based*) – The item to add.

addItems(*items*)

Add multiple items to the model.

Parameters
items (*list of PlotItem*) – The items.

axis(*name*)

Parameters
name (*str*) – The name of the axis to get, x or y.

Returns
The x- or y-axis for the sub-plot.

Return type
Axis

clearItems(*plot_item_type=None*)

Clear all items from the model.

Parameters
plot_item_type (*tuple of class*) – Optional tuple of item types to clear.

copy(*items=True*)

Create a copy of the model (sometimes without items).

Parameters
items (*bool*) – True, if items should be copied.

Returns
The copied model.

Return type
PlotModel

deleteKey(*key*, *emit=True*)

Delete the item stored at specific key.

Parameters

- **key** (*str*) – The key to delete.
- **emit** (*bool*) – True, if the change should be emitted.

findItems(*types=None*, *function=None*, ***kwargs*)

Find all (possibly nested) items by querying the item properties. Mutliple arguments can be supplied and applies in an exclusive way,:

```
model.findItems(
    types=Line,
    function=lambda item: 'line' in item.label(),
    line_width=2
)
```

It is always faster and safer to find the item directly by traversing the object hierarchy, e.g.:

```
item = model.item('my_key')
```

or for nested items:

```
item = model.item('my_key').items()[1]
```

If searching for top level items only, the items method can be very useful.

Parameters

- **types** (*NoneType | PlotItem class*) – An optional type filter specifying the plot items to find e.g. Line or Scatter.
- **function** (*NoneType | function*) – An optional filter function taking the plot item as its only input.
- ****kwargs** (*dict*) – Optional query properties.

Returns
The items matching the query.

Return type
dict

framing()

Returns
The model framing.

Return type
Framing

classmethod fromProperties(*properties*)

Convert properties into plot model.

Parameters
properties (*dict*) – The properties.

Returns
The created PlotModel.

Return type
PlotModel

item(*key*)

Get the item stored on a specific key in the model. Simply returns None if if no item exist at the given key.

Parameters
key (*str*) – The key to get.

Returns
The item

Return type
object

`itemKey`(*item*)

Get the key for the given item.

Parameters
`item` (*PlotItem*) – The given item.

Returns
The key.

Return type
str

`itemKeys`()

All currently set item keys.

Returns
All item keys.

Return type
iterable of str

`items`(*tag=None*, *plot_item_type=None*)

Get plot items of specific type.

Parameters

- `tag` (*str*) – Filter items on an optional tag.
- `plot_item_type` (*class | tuple of class*) – Filter items on an optional item type.

Returns
Returns the items of either plot item type.

Return type
view | list

`legend`()

Returns
The model legend.

Return type
Legend

`limits`(*name*)

Get limits for one axis.

Parameters
`name` (*str*) – The axis name.

Returns
Limits.

Return type
tuple of float

`plotter`()

Returns
The plotter this model belongs to.

Return type
Plotter | None

projection()

Returns
The model projection (rectilinear or polar).

Return type
str

removeItem(*item*)

Remove an item from the model.

Parameters
item (*PlotItem based*) – The item to remove.

selectedItems()

Returns
The selected plot items.

Return type
list of PlotItems

setItem(*key*, *item*, *overwrite=True*, *emit=True*)

Add a plot item to the model and assign it to a specific.

Parameters

- **key** (*str*) – The key to set.
- **item** (*PlotItem based*) – The item to add.
- **overwrite** (*bool*) – True, if any existing item at that key should be silently overwritten.
- **emit** (*bool*) – True, if the addition should be emitted.

setLimits(*name=None*, *lower_limit=None*, *upper_limit=None*, *item_filter=None*)

Set model data limits. Passing no limits will autoscale the current plot limits.

Parameters

- **name** (*str*) – The name of the axis (x or y).
- **lower_limit** (*None | float*) – The lower limit.
- **upper_limit** (*None | float*) – The upper limit.
- **item_filter** (*function*) – An additional item filter used when automatically setting limits.

setProjection(*projection*)

Set the model projection.

Parameters
projection (*str*) – The projection (rectilinear or polar).

title()

Returns
The model framing, which contains the title.

Return type
Framing

static transferUniformProperties(*templates*, *items*, *exclude_data=True*)

Determine which properties that are the same for all of the provided templates, and transfer those properties to the provided items.

Parameters

- **templates** (*list of PlotItem*) – The list of plot items to use as templates.
- **items** (*list of PlotItem*) – The items to transfer properties to.
- **exclude_data** (*bool*) – True, if we do not wish to transfer the item data.

Returns
True, if the transfer succeeded.

Return type
bool

xAxis()

Returns
The x-axis for the-plot.

Return type
Axis

yAxis()

Returns
The y-axis for the-plot.

Return type
Axis

Usage Examples

The PlotModel is a container for PlotItems like `Line`, `Scatter`, `Label` etc. The most basic PlotModel is constructed without units on the axises:

```
>>> model = Plot.PlotModel()
>>> model.addItem(Plot.Line([0, 1, 2, 3, 4], [1, 2, 3, 4, 5]))
```

Set up a PlotModel with Angstrom on the x-axis and eV on the y-axis.

```
>>> model = PlotModel(x_unit=Angstrom, y_unit=eV)
>>> model.addItem(Line([0, 1, 2, 3, 4] * nm, [1, 2, 3, 4, 5] * eV))
```

PlotModels can be shown and saved using the *Plot.show* and *Plot.save* functions.

```
>>> Plot.show(model)
>>> Plot.save(model, 'export.hdf5')
```

Notes

Multiple PlotModels can also be embedded in a common *Plot.PlotFrame*, and complex plots can be built by combining multiple PlotFrames in a layout like the *Plot.GridLayout* or the *Plot.OverlayLayout*.

Plot.PolynomialFit

class PolynomialFit(*order=1*)

A PolynomialFit can be added to a `Line` or `Scatter`. A PolynomialFit then fits a polynomial of the given order to the parent data. The fit will update every time the parent data changes.

Parameters
order (*int*) – The polynomial order.

addItem(*item*, *emit=True*)

Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)

Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)

Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

alpha()

Returns
The opacity for the line.

Return type
float

applyStyle(*style_scheme=None*, *style_properties=None*)

Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.
- **style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

attributes(*latex=False*, *detail_level='full'*)

A description of the fit properties.

Parameters

- **latex** (*bool*) – If True, return the attributes in Latex format.
- **detail_level** (*DETAIL_LEVELS enum*) – The level of detail of the attributes.

Returns
A description of the fit properties.

Return type
dict

bounds()

Returns
The bounds.

Return type
tuple of physicalQuantity

coefficients()

Returns
The polynomal coefficients.

Return type
numpy.ndarray

color()

Returns
The line color.

Return type
str

copy()
Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

determination()

Returns
The fit coefficient of determination.

Return type
float | NoneType

emit(*key*, *value=None*)
Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

evaluate(*x_data*)
Evaluate the polynomial between minimum and maximum bounds.

Parameters
x_data (*PhysicalQuantity*) – The x-data.

Returns
The evaluated x data and y data.

Return type
2-tuple of PhysicalQuantity

extent(*axis_name*, *padding=0.0*)

Get the data limits.

Parameters

- **axis_name** (*str*) – x or y.
- **padding** (*float*) – Padding around the data. **Default:** 0.0.

Returns
The min/max data values for the requested axis.

Return type
Sequence | PhysicalQuantity

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

hoverDetails()

Returns
The current hover details.

Return type
dict | None

isAxisSpanned()

Returns
True if the fit line should span the x-axis range of the plot.

Return type
bool

isBoundsVisible()

Returns
True, if fit bounds are shown in the plot.

Return type
bool

isHoverable()

Returns
True, if hoverable.

Return type
bool

isHovered()

Returns
True, if the item is hovered.

Return type
bool

isInteractive()

Returns
Whether the user can interact with this line.

Return type
bool

isSelectable()

Returns
True, if the item is selectable.

Return type
bool

isSelected()

Returns
True, if the item is selected.

Return type
bool

classmethod isValidParent(*item*)

Check if an item is derivable.

Parameters
item (*PlotItem based*) – The item to check.

Returns
True, if the item can be derived.

Return type
bool

isVisible()

Returns
True, if the item is visible.

Return type
bool

items(*selected=None*, *tag=None*)

Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **selected** (*None | bool*) – True, if only selected items should be returned.
- **tag** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

label()

Returns
The line label.

Return type
str

lineStyle()

Returns
The line style.

Return type
str | None

lineWidth()

Returns
The line width.

Return type
float

markerEdgeColor()

Returns
The edge color of the marker in hex format.

Return type
str

markerEvery()

Returns
The number of points between every marker.

Return type
int

markerFaceColor()

Returns
The face color of the marker in hex format.

Return type
str

markerSize()

Returns
The marker size.

Return type
float

markerStyle()

. :returns: The marker style. :rtype: str | None

model()

Returns
The model that this item belongs to.

Return type
PlotModel | None

order()

Returns
The order of the fitted polynomial.

Return type
int

owner()

Returns
The owner type.

Return type
int | enum

parent()

Returns
The parent.

Return type
PlotItem based | None

removeItem(*item*, *emit=True*)

Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

removeSubscriber(*subscriber*)

Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

selectionDetails()

Returns
The current selection details.

Return type
dict | None

setAlpha(*alpha*)

Set the opacity for the line.

Parameters
alpha (*float*) – The opacity.

setBounds(*lower*, *upper*, *update=True*)

Set the derived line bounds.

Parameters

- **lower** (*float | PhysicalQuantity*) – The lower bound.
- **upper** (*float | PhysicalQuantity*) – The upper bound.
- **update** (*bool*) – True, if we should call update.

setBoundsVisible(*visible*)

Set whether to indicate the fit bounds in the plot.

Parameters
visible (*bool*) – If True, fit bounds will be shown in the plot.

setColor(*color*)

Set the line color.

Parameters
color (*str*) – The line color in hex format.

setData(*x=None*, *y=None*)

Overload since derived lines should not expose data setting.

Parameters

- **x** (*iterable*) – The x values.
- **y** (*iterable*) – They values.

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setInteractive(*interactive*)

Set whether the user can interact with this line.

Parameters
interactive (*bool*) – The desired state.

setLabel(*label*)

Set the label.

Parameters
label (*str*) – The line label.

setLineStyle(*line_style*)

Set the line style.

Parameters
line_style (*str | None*) – The line style.

setLineWidth(*line_width*)

Set the line width.

Parameters
line_width (*float*) – The line width.

setMarkerColor(*color*)

Set color of the marker. Remember to also set a valid marker style.

Parameters
color (*valid color*) – The color to set.

setMarkerEdgeColor(*color*)

Set the marker edge color. Remember to also set a valid marker style.

Parameters
color (*str*) – The edge color of the marker.

setMarkerEvery(*every*)

Set the number of points between each marker. Remember to also set a valid marker style.

Parameters
every (*int*) – The number of points between every marker.

setMarkerFaceColor(*color*)

Set the marker face-color. Remember to also set a valid marker style.

Parameters
color (*str*) – The face color of the marker.

setMarkerSize(*size*)

Set the marker size. Remember to also set a valid marker style.

Parameters
size (*float*) – The marker size.

setMarkerStyle(*marker*)

Set the marker style.

Parameters
marker (*str | None*) – The marker style.

setOrder(*order*, *update=True*)

Set the order of the fitted polynomial.

Parameters

- **order** (*int*) – The polynomial order.
- **update** (*bool*) – True if the fit should be updated.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setSpanAxis(*span_axis*)

Set whether the fit line should span the x-axis range of the plot.

Parameters
span_axis (*bool*) – If True, the fit line should span the x-axis range of the plot.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

sourceData()

Checks if the source data is valid, and if yes, return the valid source data on the form: (xs, ys, x_min, x_max, x_unit, y_unit) Else returns None

Returns
The validated and clipped source data.

Return type
tuple | None

style()

Returns
All the current style properties.

Return type
dict

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

tags()

Returns
The set of tags.

Return type
set

update(*data=None*)

Perform the update.

Parameters
data (*tuple | NoneType*) – The source data to use.

validSourceCoordinates(*xs*, *ys*)

True if the data coordinates are valid.

Parameters

- **xs** (ndarray) – The source x-coordinates.
- **ys** (ndarray) – The source y-coordinates.

Returns
True, if the coordinates are valid.

Return type
bool

xData()

Returns
The x-data.

Return type
PhysicalQuantity

yData()

Returns
The y-data.

Return type
PhysicalQuantity

Plot.RollingAverage

class RollingAverage(*window=5*)

A RollingAverage can be added to a Line or Scatter, and will then calculate the rolling average using the supplied window size.

Parameters
window (*int*) – The number of close points to average over.

addItem(*item*, *emit=True*)

Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)

Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)

Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

alpha()

Returns
The opacity for the line.

Return type
float

applyStyle(*style_scheme=None*, *style_properties=None*)

Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.
- **style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

attributes(*latex=False*, *detail_level=None*)

A description of the fit properties.

Parameters

- **latex** (*bool*) – If True, return the attributes in Latex format.
- **detail_level** (*DETAIL_LEVELS enum*) – The level of detail of the attributes (unused).

Returns
A description of the fit properties.

Return type
dict

boundaryCondition()

Returns
The current boundary condition.

Return type
BOUNDARY_CONDICTIONS enum

bounds()

Returns
The bounds.

Return type
tuple of physicalQuantity

color()

Returns
The line color.

Return type
str

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

extent(*axis_name*, *padding=0.0*)

Get the data limits.

Parameters

- **axis_name** (*str*) – x or y.
- **padding** (*float*) – Padding around the data. **Default:** 0.0.

Returns
The min/max data values for the requested axis.

Return type
Sequence | PhysicalQuantity

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

hoverDetails()

Returns
The current hover details.

Return type
dict | None

isHoverable()

Returns
True, if hoverable.

Return type
bool

`isHovered`()

Returns
True, if the item is hovered.

Return type
bool

`isInteractive`()

Returns
Whether the user can interact with this line.

Return type
bool

`isSelectable`()

Returns
True, if the item is selectable.

Return type
bool

`isSelected`()

Returns
True, if the item is selected.

Return type
bool

`classmethod isValidParent`(*item*)

Check if an item is derivable.

Parameters
item (*PlotItem based*) – The item to check.

Returns
True, if the item can be derived.

Return type
bool

`isVisible`()

Returns
True, if the item is visible.

Return type
bool

`items`(*selected=None*, *tag=None*)

Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items

•None : All items.

Parameters

•**selected** (*None | bool*) – True, if only selected items should be returned.

•**tag** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

kernel()

Returns
The current averaging kernelS.

Return type
KERNELS enum

label()

Returns
The line label.

Return type
str

lineStyle()

Returns
The line style.

Return type
str | None

lineWidth()

Returns
The line width.

Return type
float

markerEdgeColor()

Returns
The edge color of the marker in hex format.

Return type
str

markerEvery()

Returns
The number of points between every marker.

Return type
int

markerFaceColor()

Returns
The face color of the marker in hex format.

Return type
str

markerSize()

Returns
The marker size.

Return type
float

markerStyle()

. :returns: The marker style. :rtype: str | None

model()

Returns
The model that this item belongs to.

Return type
PlotModel | None

order()

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

owner()

Returns
The owner type.

Return type
int | enum

parent()

Returns
The parent.

Return type
PlotItem based | None

removeItem(*item*, *emit=True*)

Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

removeSubscriber(*subscriber*)

Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

selectionDetails()

Returns
The current selection details.

Return type
dict | None

setAlpha(*alpha*)

Set the opacity for the line.

Parameters
alpha (*float*) – The opacity.

setBoundaryCondition(*boundary_condition*, *update=True*)

Set the boundary condition.

Parameters

- **boundary_condition** (*BOUNDARY_CONDICTIONS enum*) – The boundary condition
- **update** (*bool*) – True, if the average should be updated.

setBounds(*lower*, *upper*, *update=True*)

Set the derived line bounds.

Parameters

- **lower** (*float | PhysicalQuantity*) – The lower bound.
- **upper** (*float | PhysicalQuantity*) – The upper bound.
- **update** (*bool*) – True, if we should call update.

setColor(*color*)

Set the line color.

Parameters
color (*str*) – The line color in hex format.

setData(*x=None*, *y=None*)

Overload since derived lines should not expose data setting.

Parameters

- **x** (*iterable*) – The x values.
- **y** (*iterable*) – They values.

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.

- **details** (*dict | NoneType*) – The hover details.

setInteractive(*interactive*)

Set whether the user can interact with this line.

Parameters
interactive (*bool*) – The desired state.

setKernel(*kernel*, *update=True*)

Set the rolling average kernel.

The KERNELS.AVERAGE kernel is simply flat across the window length. A KERNELS.GAUSSIAN kernel is a gaussian with a variance given by the window length.

Parameters

- **kernel** (*KERNELS enum*) – The kernel to use.
- **update** (*bool*) – True, if the average should be updated.

setLabel(*label*)

Set the label.

Parameters
label (*str*) – The line label.

setLineStyle(*line_style*)

Set the line style.

Parameters
line_style (*str | None*) – The line style.

setLineWidth(*line_width*)

Set the line width.

Parameters
line_width (*float*) – The line width.

setMarkerColor(*color*)

Set color of the marker. Remember to also set a valid marker style.

Parameters
color (*valid color*) – The color to set.

setMarkerEdgeColor(*color*)

Set the marker edge color. Remember to also set a valid marker style.

Parameters
color (*str*) – The edge color of the marker.

setMarkerEvery(*every*)

Set the number of points between each marker. Remember to also set a valid marker style.

Parameters
every (*int*) – The number of points between every marker.

setMarkerFaceColor(*color*)

Set the marker face-color. Remember to also set a valid marker style.

Parameters
color (*str*) – The face color of the marker.

setMarkerSize(*size*)

Set the marker size. Remember to also set a valid marker style.

Parameters
size (*float*) – The marker size.

setMarkerStyle(*marker*)

Set the marker style.

Parameters
marker (*str | None*) – The marker style.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

setWindow(*window*, *update=True*)

Set the window size for the rolling average.

Parameters

- **window** (*int*) – The window size to set.
- **update** (*bool*) – True, if the fit should be updated.

sourceData()

Checks if the source data is valid, and if yes, return the valid source data on the form: (xs, ys, x_min, x_max, x_unit, y_unit) Else returns None

Returns
The validated and clipped source data.

Return type
tuple | None

style()

Returns
All the current style properties.

Return type
dict

`styleProperties`(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

`tags`()

Returns
The set of tags.

Return type
set

`update`(*data=None*)

Perform the update.

Parameters
data (*tuple | NoneType*) – The source data to use.

`validSourceCoordinates`(*xs*, *ys*)

True if the data coordinates are valid.

Parameters

- **xs** (*numpy.ndarray*) – The source x coordinates.
- **ys** (*numpy.ndarray*) – The source y coordinates.

Returns
True, if the coordinates are valid.

Return type
bool

`window`()

Returns
The window size to use for the rolling average.

Return type
int

`xData`()

Returns
The x-data.

Return type
PhysicalQuantity

`yData`()

Returns
The y-data.

Return type
PhysicalQuantity

Plot.Scatter

class Scatter(*x=None*, *y=None*, *values=None*)

A Scatter displays x- and y-data as a scatter plot.

Parameters

- **x** (Sequence | *PhysicalQuantity* | None) – The x-values of the data.
- **y** (Sequence | *PhysicalQuantity* | None) – The y-values of the data.
- **values** (*Sequence | None*) – The values of the data. Used for coloring or resizing the data points.

addItem(*item*, *emit=True*)

Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)

Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)

Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

alpha()

Returns
The opacity of the points.

Return type
float

applyStyle(*style_scheme=None*, *style_properties=None*)

Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.
- **style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

color()

Returns
The face color in hex format.

Return type
str

colorMap()

. :returns: The color map. :rtype: str

colorMode()

Returns
The color mode.

Return type
COLOR_MODES enum

colors()

Returns
The colors.

Return type
None | list of str

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

extent(*axis_name*, *padding=0.0*)

Get the data extent.

Parameters

- **axis_name** (*str*) – x or y.
- **padding** (*float*) – Padding around the data. **Default:** 0.0.

Returns
The min/max data values for the requested axis.

Return type
PhysicalQuantity

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

hoverDetails()

Returns
The current hover details.

Return type
dict | None

isHoverable()

Returns
True, if hoverable.

Return type
bool

isHovered()

Returns
True, if the item is hovered.

Return type
bool

isSelectable()

Returns
True, if the item is selectable.

Return type
bool

isSelected()

Returns
True, if the item is selected.

Return type
bool

isVisible()

Returns
True, if the item is visible.

Return type
bool

items(*selected=None*, *tag=None*)

Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **selected** (*None | bool*) – True, if only selected items should be returned.
- **tag** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

`label()`

Returns
The current scatter label.

Return type
str

`model()`

Returns
The model that this item belongs to.

Return type
PlotModel | None

`order()`

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

`outline()`

Returns
True, if the scatter circles should be outlined.

Return type
bool

`owner()`

Returns
The owner type.

Return type
int | enum

`parent()`

Returns
The parent.

Return type
PlotItem based | None

`removeItem`(*item*, *emit=True*)

Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

removeSubscriber(*subscriber*)

Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

scaling()

Returns
The scaling parameters.

Return type
tuple

selectionDetails()

Returns
The current selection details.

Return type
dict | None

setAlpha(*alpha*)

Parameters
alpha (*float*) – The opacity of the points.

setColor(*color*)

Set the uniform color.

Note that this color is only used when color mode is set to COLOR.

Parameters
color (*str*) – The face color.

setColorMap(*color_map*)

The color map.

Note that the color map is only used when the color mode is set to COLOR_MAP.

Parameters
color_map (*None | str*) – The color map to use.

setColorMode(*mode*)

Set the color mode. One of either COLOR_MODES.COLOR, COLOR_MODES.COLORS, COLOR_MODES.COLOR_MAP.

Parameters
mode (*COLOR_MODES enum*) – The mode to set.

setColors(*colors*)

Set the colors.

Note that the colors are only used when the color mode is set to COLORS

Parameters
colors (*None | list of str*) – The colors in hex format.

setData(*x=None*, *y=None*, *tooltips=None*)

Set the scatter data.

Parameters

- **x** (list | ndarray | *PhysicalQuantity*) – The x-data.
- **y** (list | ndarray | *PhysicalQuantity*) – The y-data.
- **tooltips** (*list | str | NoneType*) – The corresponding tool tips.

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setLabel(*label*)

Set the scatter label.

Parameters
label (*str*) – The label of the scatter.

setOutline(*outline*)

Set the outline property.

Parameters
outline (*bool*) – True, if the scatter circles should be outlined.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setScaling(*lower*, *upper*, *use_absolute_values=False*)

Scale points based on their values. Requires *values* to be specified to have any effect.

Parameters

- **lower** (*float*) – The size of the smallest value.
- **upper** (*float*) – The size of the largest value.
- **use_absolute_values** (*bool*) – Use absolute values when scaling the points.

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setValues(*values*)

Set the weights of the data.

Parameters
values (*Sequence | None*) – The values of the data. Used for coloring or resizing the data points.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

style()

Returns
The current scatter style properties.

Return type
dict

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

tags()

Returns
The set of tags.

Return type
set

tooltips()

Returns
The tool tips.

Return type
list of str | str | NoneType

values()

Returns
The weights of the data. Used for coloring or setting line widths.

Return type
Sequence | None

xData()

Returns
The x-data.

Return type
PhysicalQuantity

yData()

Returns
The y-data.

Return type
PhysicalQuantity

Plot.TransformedLine

class TransformedLine(*x_expression='x'*, *y_expression='y'*)

A TransformedLine can be added to a Line or Scatter, and will then calculate a transformed line using the supplied x- and y-expression.

Parameters

- **x_expression** (*str*) – The expression to apply to the source x-data.
- **y_expression** (*str*) – The expression to apply to the source y-data.

addItem(*item*, *emit=True*)

Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)

Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)

Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

alpha()

Returns
The opacity for the line.

Return type
float

applyStyle(*style_scheme=None*, *style_properties=None*)

Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.
- **style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

attributes(*latex=False*, *detail_level='full'*)

The attributes of the Transformed line.

Parameters

- **latex** (*bool*) – If True, return the attributes in Latex format.
- **detail_level** (*DETAIL_LEVELS enum*) – The level of detail of the attributes (unused).

Returns
Either an OK message, or an error message if any of the expressions did not evaluate properly.

Return type
collections.OrderedDict

bounds()

Returns
The bounds.

Return type
tuple of physicalQuantity

color()

Returns
The line color.

Return type
str

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

extent(*axis_name*, *padding=0.0*)

Get the data limits.

Parameters

- **axis_name** (*str*) – x or y.
- **padding** (*float*) – Padding around the data. **Default:** 0.0.

Returns
The min/max data values for the requested axis.

Return type
Sequence | PhysicalQuantity

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

hoverDetails()

Returns
The current hover details.

Return type
dict | None

isHoverable()

Returns
True, if hoverable.

Return type
bool

isHovered()

Returns
True, if the item is hovered.

Return type
bool

isInteractive()

Returns
Whether the user can interact with this line.

Return type
bool

isSelectable()

Returns
True, if the item is selectable.

Return type
bool

isSelected()

Returns
True, if the item is selected.

Return type
bool

classmethod isValidParent(*item*)

Check if an item is derivable.

Parameters
item (*PlotItem based*) – The item to check.

Returns
True, if the item can be derived.

Return type
bool

`isVisible`()

Returns
True, if the item is visible.

Return type
bool

`items`(*selected=None*, *tag=None*)

Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **`selected`** (*None | bool*) – True, if only selected items should be returned.
- **`tag`** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

`label`()

Returns
The line label.

Return type
str

`lineStyle`()

Returns
The line style.

Return type
str | None

`lineWidth`()

Returns
The line width.

Return type
float

markerEdgeColor()

Returns
The edge color of the marker in hex format.

Return type
str

markerEvery()

Returns
The number of points between every marker.

Return type
int

markerFaceColor()

Returns
The face color of the marker in hex format.

Return type
str

markerSize()

Returns
The marker size.

Return type
float

markerStyle()

. :returns: The marker style. :rtype: str | None

model()

Returns
The model that this item belongs to.

Return type
PlotModel | None

order()

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

owner()

Returns
The owner type.

Return type
int | enum

parent()

Returns
The parent.

Return type
PlotItem based | None

removeItem(*item*, *emit=True*)

Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

removeSubscriber(*subscriber*)

Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

safeSetXExpression(*expression*, *update=True*)

Safe setting of expression. Fails silently without changing anything.

Parameters

- **expression** (*str*) – The expression.
- **update** (*bool*) – True if the fit should be updated.

safeSetYExpression(*expression*, *update=True*)

Safe setting of expression. Fails silently without changing anything.

Parameters

- **expression** (*str*) – The expression.
- **update** (*bool*) – True if the fit should be updated.

selectionDetails()

Returns
The current selection details.

Return type
dict | None

setAlpha(*alpha*)

Set the opacity for the line.

Parameters
alpha (*float*) – The opacity.

setBounds(*lower*, *upper*, *update=True*)

Set the derived line bounds.

Parameters

- **lower** (*float | PhysicalQuantity*) – The lower bound.
- **upper** (*float | PhysicalQuantity*) – The upper bound.
- **update** (*bool*) – True, if we should call update.

setColor(*color*)

Set the line color.

Parameters
color (*str*) – The line color in hex format.

setData(*x=None*, *y=None*)
Overload since derived lines should not expose data setting.

Parameters

- **x** (*iterable*) – The x values.
- **y** (*iterable*) – They values.

setHoverable(*hoverable*)
Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)
Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setInteractive(*interactive*)
Set whether the user can interact with this line.

Parameters
interactive (*bool*) – The desired state.

setLabel(*label*)
Set the label.

Parameters
label (*str*) – The line label.

setLineStyle(*line_style*)
Set the line style.

Parameters
line_style (*str | None*) – The line style.

setLineWidth(*line_width*)
Set the line width.

Parameters
line_width (*float*) – The line width.

setMarkerColor(*color*)
Set color of the marker. Remember to also set a valid marker style.

Parameters
color (*valid color*) – The color to set.

setMarkerEdgeColor(*color*)
Set the marker edge color. Remember to also set a valid marker style.

Parameters
color (*str*) – The edge color of the marker.

setMarkerEvery(*every*)

Set the number of points between each marker. Remember to also set a valid marker style.

Parameters
every (*int*) – The number of points between every marker.

setMarkerFaceColor(*color*)

Set the marker face-color. Remember to also set a valid marker style.

Parameters
color (*str*) – The face color of the marker.

setMarkerSize(*size*)

Set the marker size. Remember to also set a valid marker style.

Parameters
size (*float*) – The marker size.

setMarkerStyle(*marker*)

Set the marker style.

Parameters
marker (*str | None*) – The marker style.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

setXExpression(*expression*, *update=True*)

Set the expression for x-data.

Parameters

- **expression** (*str*) – The x-expression to set.
- **update** (*bool*) – True, if the fit should be updated.

setYExpression(*expression*, *update=True*)

Set the expression for y-data.

Parameters

- **expression** (*str*) – The y-expression to set.
- **update** (*bool*) – True, if the fit should be updated.

sourceData()

Checks if the source data is valid, and if yes, return the valid source data on the form: (xs, ys, x_min, x_max, x_unit, y_unit) Else returns None

Returns
The validated and clipped source data.

Return type
tuple | None

style()

Returns
All the current style properties.

Return type
dict

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

tags()

Returns
The set of tags.

Return type
set

tooltip()

Returns
The tool tip.

Return type
str

update(*data=None*)

Perform the update.

Parameters
data (*tuple | NoneType*) – The source data to use.

validSourceCoordinates(*xs*, *ys*)

Re-implement for custom validation of the source. See e.g. PolynomialFit.

Parameters

- **xs** (*PhysicalQuantity*) – The source x data.
- **ys** (*PhysicalQuantity*) – The source y data.

Returns
True, if valid.

Return type
bool

xData()

Returns
The x-data.

Return type
PhysicalQuantity

xExpression()

Return the expression for x-data.

Returns
The expression.

Return type
str

yData()

Returns
The y-data.

Return type
PhysicalQuantity

yExpression()

Return the expression for y-data.

Returns
The expression.

Return type
str

Plot.VerticalBar

class VerticalBar(*bins*, *data*)

A bar plot showing data as vertical filled bins.

The shape of the bins is determined in the following way: - If the number of bins equals the number of data values, the bins parameter is interpreted as the bin centers and bin widths are uniformly set to the match minimum distance between the bin centers. - If the number of bins is one larger than the number of data values, the bins parameter is interpreted as the edges of the bins. - If the number of bins is double the number of data values, the bins are instead interpreted as the left and right edge of each of the bins.

Parameters

- **bins** (Sequence of *PhysicalQuantity*) – The bins.
- **data** (Sequence of *PhysicalQuantity*) – The data values.

addItem(*item*, *emit=True*)

Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)

Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)

Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

alpha()

Returns
The opacity of the bar plot.

Return type
int

applyStyle(*style_scheme=None*, *style_properties=None*)

Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.
- **style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

binCenters()

Returns
The center of each bin.

Return type
Sequence of *PhysicalQuantity*

binEdges()

. :returns: The left edges of each bin. :rtype: *PhysicalQuantity*

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

edgeColor()

Returns
The edge color of the bar plot.

Return type
str

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

extent(*axis_name*, *padding=0.0*)

The limits around the bar plot.

Parameters

- **axis_name** (*str*) – x or y.
- **padding** (*float*) – Optional padding.

Returns
The min/max data values for the requested axis.

Return type
2-tuple of *PhysicalQuantity*

faceColor()

Returns
The face color of the bar plot.

Return type
str

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

histogram()

Returns
The bin counts for each bin.

Return type
Sequence of *PhysicalQuantity*

hoverDetails()

Returns
The current hover details.

Return type
dict | None

`isHoverable`()

Returns
True, if hoverable.

Return type
bool

`isHovered`()

Returns
True, if the item is hovered.

Return type
bool

`isSelectable`()

Returns
True, if the item is selectable.

Return type
bool

`isSelected`()

Returns
True, if the item is selected.

Return type
bool

`isVisible`()

Returns
True, if the item is visible.

Return type
bool

`items`(*selected=None*, *tag=None*)
Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **`selected`** (*None | bool*) – True, if only selected items should be returned.
- **`tag`** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

label()

Returns
The label.

Return type
str

model()

Returns
The model that this item belongs to.

Return type
PlotModel | None

order()

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

owner()

Returns
The owner type.

Return type
int | enum

parent()

Returns
The parent.

Return type
PlotItem based | None

removeItem(*item*, *emit=True*)
Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

removeSubscriber(*subscriber*)
Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

selectionDetails()

Returns
The current selection details.

Return type
dict | None

setAlpha(*alpha*)

. :param alpha: The opacity of the bar plot. :type alpha: float

setColor(*color*)

Set the same color for both the bar face and the bar edge.

Parameters
color (*str*) – The color to set in hex format.

setData(*bins*, *data*, *emit=True*)

Set bins and histogram data.

The shape of the bins is determined in the following way: - If the number of bins equals the number of data values, the bins parameter is interpreted as the bin centers and bin widths are uniformly set to the match minimum distance between the bin centers. - If the number of bins is one larger than the number of data values, the bins parameter is interpreted as the edges of the bins. - If the number of bins is double the number of data values, the bins are instead interpreted as the left and right edge of each of the bins.

Parameters

- **bins** (Sequence of *PhysicalQuantity*) – The bins.
- **data** (Sequence of *PhysicalQuantity*) – The data values.
- **emit** (*bool*) – True, if the data should be emitted.

setEdgeColor(*color*)

Set the bar plot edge color.

Parameters
color (*str*) – The edge color of the bar plot.

setFaceColor(*color*)

. :param color: The face color of the bar plot. :type color: str

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setLabel(*label*)

Set the label.

Parameters
label (*str*) – The label of the bar plot.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

tags()

Returns
The set of tags.

Return type
set

xData()

Returns
The center of each bin.

Return type
Sequence of *PhysicalQuantity*

yData()

Returns
The bin counts for each bin.

Return type
Sequence of *PhysicalQuantity*

Plot.VerticalFill

class VerticalFill(*y*, *x_lower*, *x_upper*)
A VerticalFill display a filled area between two lines.

Parameters

- **y** (Sequence of *PhysicalQuantity*) – The y-values of the data.
- **x_lower** (SSequence of *PhysicalQuantity*) – The lower x-values in the fill.
- **x_upper** (Sequence of *PhysicalQuantity*) – The upper x-values in the fill.

addItem(*item*, *emit=True*)
Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)
Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)
Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

alpha()

Returns
The opacity of the fill.

Return type
float

applyStyle(*style_scheme=None*, *style_properties=None*)
Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.
- **style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

copy()
Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

edgeColor()

Returns
The edge color of the fill in hex format.

Return type
str

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

extent(*axis*, *padding=0.0*)

The data extent.

Parameters

- **axis** (*str*) – x or y.
- **padding** (*float*) – Padding around the data. **Default:** 0.0.

Returns
The min/max data values for the requested axis.

Return type
2-tuple *PhysicalQuantity*

faceColor()

Returns
The edge color of the fill in hex format.

Return type
str

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

hoverDetails()

Returns
The current hover details.

Return type
dict | None

isHoverable()

Returns
True, if hoverable.

Return type
bool

`isHovered`()

Returns
True, if the item is hovered.

Return type
bool

`isSelectable`()

Returns
True, if the item is selectable.

Return type
bool

`isSelected`()

Returns
True, if the item is selected.

Return type
bool

`isVisible`()

Returns
True, if the item is visible.

Return type
bool

`items`(*selected=None*, *tag=None*)
Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **selected** (*None | bool*) – True, if only selected items should be returned.
- **tag** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

`label`()

Returns
The current label.

Return type
str

lower()

Returns
The lower values in the fill.

Return type
float

model()

Returns
The model that this item belongs to.

Return type
PlotModel | None

order()

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

owner()

Returns
The owner type.

Return type
int | enum

parent()

Returns
The parent.

Return type
PlotItem based | None

removeItem(*item*, *emit=True*)
Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

removeSubscriber(*subscriber*)
Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

selectionDetails()

Returns
The current selection details.

Return type
dict | None

setAlpha(*alpha*)

Set the opacity.

Parameters
alpha (*float*) – The opacity of the fill.

setColor(*color*)

Set the same color for both the face and the edge.

Parameters
color (*str*) – Set the color of the fill in hex format.

setEdgeColor(*color*)

Set the edge color of the fill.

Parameters
color (*str*) – The edge color of the fill in hex-format.

setFaceColor(*color*)

Set the face color of the fill.

Parameters
color (*str*) – The face color of the fill.in hex format.

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- hovered (*bool*) – True, if the item was hovered.
- details (*dict | NoneType*) – The hover details.

setLabel(*label*)

Set the label.

Parameters
label (*str*) – The label of the line.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

tags()

Returns
The set of tags.

Return type
set

upper()

Returns
The upper values in the fill.

Return type
float

values()

Returns
The values in the fill.

Return type
float

Plot.VerticalLine

class VerticalLine(*x*)

A VerticalLine shows a straight vertical line.

Parameters
x (*PhysicalQuantity*) – The x-value of the line.

addItem(*item*, *emit=True*)

Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)

Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)

Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

alpha()

Returns
The opacity for the line.

Return type
float

applyStyle(*style_scheme=None*, *style_properties=None*)

Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.
- **style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

color()

Returns
The line color.

Return type
str

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

`hoverDetails()`

Returns
The current hover details.

Return type
dict | None

`isHoverable()`

Returns
True, if hoverable.

Return type
bool

`isHovered()`

Returns
True, if the item is hovered.

Return type
bool

`isSelectable()`

Returns
True, if the item is selectable.

Return type
bool

`isSelected()`

Returns
True, if the item is selected.

Return type
bool

`isVisible()`

Returns
True, if the item is visible.

Return type
bool

`items(`*selected=None*, *tag=None*`)`

Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **selected** (*None | bool*) – True, if only selected items should be returned.
- **tag** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

`label()`

Returns
The line label.

Return type
str

`lineStyle()`

Returns
The line style.

Return type
str | None

`lineWidth()`

Returns
The line width.

Return type
float

`markerEdgeColor()`

Returns
The edge color of the marker in hex format.

Return type
str

`markerEvery()`

Returns
The number of points between every marker.

Return type
int

`markerFaceColor()`

Returns
The face color of the marker in hex format.

Return type
str

`markerSize()`

Returns
The marker size.

Return type
float

markerStyle()

. :returns: The marker style. :rtype: str | None

model()

Returns
The model that this item belongs to.

Return type
PlotModel | None

order()

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

owner()

Returns
The owner type.

Return type
int | enum

parent()

Returns
The parent.

Return type
PlotItem based | None

removeItem(*item*, *emit=True*)

Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

removeSubscriber(*subscriber*)

Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

selectionDetails()

Returns
The current selection details.

Return type
dict | None

setAlpha(*alpha*)

Set the opacity for the line.

Parameters
alpha (*float*) – The opacity.

setColor(*color*)

Set the line color.

Parameters
color (*str*) – The line color in hex format.

setData(*x*)

Set x data.

Parameters
x (*PhysicalQuantity*) – The x-data.

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setLabel(*label*)

Set the label.

Parameters
label (*str*) – The line label.

setLineStyle(*line_style*)

Set the line style.

Parameters
line_style (*str | None*) – The line style.

setLineWidth(*line_width*)

Set the line width.

Parameters
line_width (*float*) – The line width.

setMarkerColor(*color*)

Set color of the marker. Remember to also set a valid marker style.

Parameters
color (*valid color*) – The color to set.

setMarkerEdgeColor(*color*)

Set the marker edge color. Remember to also set a valid marker style.

Parameters
color (*str*) – The edge color of the marker.

setMarkerEvery(*every*)

Set the number of points between each marker. Remember to also set a valid marker style.

Parameters
every (*int*) – The number of points between every marker.

setMarkerFaceColor(*color*)

Set the marker face-color. Remember to also set a valid marker style.

Parameters
color (*str*) – The face color of the marker.

setMarkerSize(*size*)

Set the marker size. Remember to also set a valid marker style.

Parameters
size (*float*) – The marker size.

setMarkerStyle(*marker*)

Set the marker style.

Parameters
marker (*str | None*) – The marker style.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

style()

Returns
All the current style properties.

Return type
dict

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

tags()

Returns
The set of tags.

Return type
set

xData()

Returns
The x-data.

Return type
PhysicalQuantity

yData()

Returns
The y-data.

Return type
PhysicalQuantity

Plot.VerticalStackedFill

class VerticalStackedFill(*x_values*, *values*)

A VerticalStackedFill shows multiple fills laid on top of each other.

Parameters

- **x_values** (Sequence of *PhysicalQuantity*) – The x-values of the data.
- **values** (2D *PhysicalQuantity*) – The values to plot in the stack.

addItem(*item*, *emit=True*)

Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)

Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)

Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

alphas()

Returns
The opacities of the fills.

Return type
list

applyStyle(*style_scheme=None*, *style_properties=None*)

Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.
- **style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

edgeColors()

Returns
The edge colors of the fills.

Return type
list

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

faceColors()

Returns
The face colors of the fills.

Return type
list

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

`hoverDetails()`

Returns
The current hover details.

Return type
dict | None

`isHoverable()`

Returns
True, if hoverable.

Return type
bool

`isHovered()`

Returns
True, if the item is hovered.

Return type
bool

`isSelectable()`

Returns
True, if the item is selectable.

Return type
bool

`isSelected()`

Returns
True, if the item is selected.

Return type
bool

`isVisible()`

Returns
True, if the item is visible.

Return type
bool

`items(`*selected=None*, *tag=None*`)`

Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **selected** (*None | bool*) – True, if only selected items should be returned.
- **tag** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

labels()

Returns
The labels of the fills.

Return type
list

model()

Returns
The model that this item belongs to.

Return type
PlotModel | None

order()

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

owner()

Returns
The owner type.

Return type
int | enum

parent()

Returns
The parent.

Return type
PlotItem based | None

removeItem(*item*, *emit=True*)

Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

removeSubscriber(*subscriber*)

Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

selectionDetails()

Returns
The current selection details.

Return type
dict | None

setAlphas(*alphas*)

Set the alphas for all fills in the stack.

Parameters
alphas (*list*) – The opacities of the fills.

setColors(*colors*)

Set the same color for both the face and the edge for all filss in the stack.

Parameters
colors (*list*) – The colors of the fills.

setEdgeColors(*colors*)

Set the edge colors for all fills in the stack.

Parameters
colors (*list*) – The edge colors of the fills.

setFaceColors(*colors*)

Set the face colors for all fills in the stack.

Parameters
colors (*list*) – The face colors of the fills.

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setLabels(*labels*)

Set the labels for all fills in the stack.

Parameters
labels (*list*) – The labels of the fills.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

`setSelectable`(*selectable*)

Set whether this item is selectable.

Parameters
`selectable` (*bool*) – True, if the item should be selectable.

`setSelected`(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- `selected` (*bool*) – True, if item should be selected.
- `details` (*dict | NoneType*) – The selection details.

`setVisible`(*visible*)

Set visible.

Parameters
`visible` (*bool*) – True, if the item should be visible.

`styleProperties`(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
`style_scheme` (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

`tags`()

Returns
The set of tags.

Return type
set

`values`()

Returns
The values of the data.

Return type
2D *PhysicalQuantity*

Plot.WeightedLine

`class WeightedLine`(*x=None*, *y=None*, *weights=None*)

A WeightedLine plots a line where the line width changes along the line.

Parameters

- `x` (Sequence | *PhysicalQuantity* | None) – The x-values of the data.
- `y` (Sequence | *PhysicalQuantity* | None) – The y-values of the data.
- `weights` (*Sequence | None*) – The weights of the data. Used for coloring or setting line widths.

addItem(*item*, *emit=True*)

Add item as child of this item.

Parameters

- **item** (*PlotItem based*) – The item.
- **emit** (*bool*) – True, if change should be emitted.

addSubscriber(*subscriber*)

Add a subscriber. Each subscriber is called once every time the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

addTag(**args*)

Add tag. Used for grouping plot items.

Parameters
***args** (*tuple of str*) – The tags to add.

alpha()

Returns
The opacity of the line.

Return type
float

applyStyle(*style_scheme=None*, *style_properties=None*)

Apply style properties from a style scheme.

Parameters

- **style_scheme** (*dict*) – The style scheme.
- **style_properties** (*dict | None*) – A specific set of style properties to apply. If None, the style properties are retrieved from the plot model using the given style scheme.

color()

Returns
The line color in hex format

Return type
str

colorMap()

Returns
The current color map.

Return type
str

colorMode()

The current color mode.

Returns
The color mode.

Return type
COLOR_MODES enum

copy()

Make a copy of the plot storable by using the serialize/deserialize functionality.

This creates a new instance with a new id, but all other properties copied.

emit(*key*, *value=None*)

Emit a single key and value change to all subscribers.

Parameters

- **key** (*str*) – The key to emit.
- **value** (*object*) – The value to emit.

extent(*axis_name*, *padding=0.0*)

Get the data extent.

Parameters

- **axis_name** (*str*) – x or y.
- **padding** (*float*) – Padding around the data. **Default:** 0.0.

Returns
The min/max data values for the requested axis.

Return type
Sequence | *PhysicalQuantity*

classmethod fromProperties(*properties*)

Create a plot storable from a dict of properties.

Used when deserializing a PlotStorable.

Parameters
properties (*dict*) – The properties which are used to populate the properties dict of the newly created plot storable.

Returns
The newly created PlotStorable.

Return type
PlotStorable

hoverDetails()

Returns
The current hover details.

Return type
dict | None

isHoverable()

Returns
True, if hoverable.

Return type
bool

isHovered()

Returns
True, if the item is hovered.

Return type
bool

isSelectable()

Returns
True, if the item is selectable.

Return type
bool

isSelected()

Returns
True, if the item is selected.

Return type
bool

isVisible()

Returns
True, if the item is visible.

Return type
bool

items(*selected=None*, *tag=None*)

Return the requested items.

The optional selected key word filter selected and deselected lines, with the options:

- True : Only selected items
- False : Only unselected items
- None : All items.

Parameters

- **selected** (*None | bool*) – True, if only selected items should be returned.
- **tag** (*str*) – The tag to filter on.

Returns
The child items with the selected filtering.

Return type
items

label()

Returns
The current label.

Return type
str

model()

Returns
The model that this item belongs to.

Return type
PlotModel | None

order()

Returns
A number describing the current order of the item within the PlotModel. Can be used for sorting.

Return type
int | None

owner()

Returns
The owner type.

Return type
int | enum

parent()

Returns
The parent.

Return type
PlotItem based | None

removeItem(*item*, *emit=True*)

Remove item from the child items.

Parameters

- **item** (*PlotItem based*) – The item to remove.
- **emit** (*bool*) – True, if removal should be emitted.

removeSubscriber(*subscriber*)

Remove a subscriber method from the plot item updates.

Parameters
subscriber (*bound method*) – The subscriber. Must be callable.

scaling()

Returns
The scaling of the weights.

Return type
float

selectionDetails()

Returns
The current selection details.

Return type
dict | None

setAlpha(*alpha*)

. :param alpha: The opacity of the line. :type alpha: float

setColor(*color*)

Set the line color.

Note that the color map is only used when the color mode is COLOR.

Parameters
color (*str*) – The color in hex format.

setColorMap(*color_map*)

Set a color map.

Note that the color map is only used when the color mode is COLOR_MAP.

Parameters
color_map (*str*) – A color map.

setColorMode(*mode*)

Set the color mode (whether to use color map or color for drawing).

Parameters
mode (*COLOR_MODES enum*) – The mode.

setData(*x=None*, *y=None*)

Set data.

Parameters

- **x** (list | ndarray | *PhysicalQuantity*) – The x-data.
- **y** (list | ndarray | *PhysicalQuantity*) – The y-data.

setHoverable(*hoverable*)

Enable or disable hover evetn. When enabled the line will be set to hovered, once the mouse hovers over the item.

Parameters
hoverable (*bool*) – True, if the item should be sensitive to hover events.

setHovered(*hovered*, *details=None*)

Set hovered with some details. This is called once the mouse hovers over the item. Should only be called once hoverable has been enabled.

Parameters

- **hovered** (*bool*) – True, if the item was hovered.
- **details** (*dict | NoneType*) – The hover details.

setLabel(*label*)

Set the label.

Parameters
label (*str*) – The label of the line.

setOwner(*owner*)

Set the owner of the item (either OWNERS.MODEL or OWNERS.VIEW).

Parameters
owner (*int | enum*) – The owner type.

setScaling(*scaling*)

Set the scaling.

Parameters
scaling (*float*) – The scaling of the weights. Requires *weights* to be specified to have any effect.

setSelectable(*selectable*)

Set whether this item is selectable.

Parameters
selectable (*bool*) – True, if the item should be selectable.

setSelected(*selected*, *details=None*)

Set the item as selected or unselected.

Parameters

- **selected** (*bool*) – True, if item should be selected.
- **details** (*dict | NoneType*) – The selection details.

setVisible(*visible*)

Set visible.

Parameters
visible (*bool*) – True, if the item should be visible.

setWeights(*weights*)

Set the weights of the data.

Parameters
weights (*Sequence | None*) – The weights of the data. Used for coloring and setting line widths.

styleProperties(*style_scheme*)

Check if the given style scheme has a style for this item.

Parameters
style_scheme (*dict*) – The style scheme.

Returns
The style, if any.

Return type
dict | None

tags()

Returns
The set of tags.

Return type
set

weights()

Returns
The weights of the data. Used for coloring and setting line widths.

Return type
Sequence | None

xData()

Returns
The x-data.

Return type
PhysicalQuantity

yData()

Returns
The y-data.

Return type
PhysicalQuantity

Functions

Plot.save

save(*plot*, *filename*, *size=None*, ***kwargs*)

Save a plot to a file.

Save can save the full, interactive plot. This is done by supplying a filename with the HDF5 file extension. The plot can then later be loaded by using the standard `nlread` function.

Save also supports rendering of the plot to SVG, PNG, JPEG or PDF. Simply pass in a filename with the appropriate file extension. Note that this requires full graphical support for the NanoLab GUI. This support can be lacking on clusters or computing nodes. When generating plots on a computing node, they must then be saved in HDF5 files. The plots can then be rendered to SVG, PNG, JPEG or PDF on a machine with the proper graphical support.

Parameters

- **plot** (*BaseLayout based | PlotModel*) – The plot to save.
- **filename** (*str*) – The filename.
- **size** (*NoneType | 2-tuple of ints*) – The plot size in pixels.
- ****kwargs** (*dict*) – Additional arguments passed on to matplotlib when saving a figure.

Plot.show

show(*plot*, *size=None*)

Show an interactive plot.

Note that this function requires full graphical support for the NanoLab GUI. This support can be lacking on clusters or computing nodes. When generating plots on a computing node, they must then be saved in HDF5 files. The plots can then be shown on a machine with the proper graphical support.

Parameters

- **plot** (*Plot | BaseLayout based | PlotModel*) – The plot to show.
- **size** (*NoneType | 2-tuple of ints*) – The plot size in pixels.

Returns
The final layout and size.

Return type
2-tuple of GridLayout and size tuple

The NanoLab Plot module makes it possible to create and manipulate publication quality plots. Read more in the dedicated *NanoLab Plot Reference Manual*.

4.4.13 Full QuantumATK package

QuantumATK

Modules

Classes

ARTnSaddleSearch

class ARTnSaddleSearch(*constraints=None*, *initial_direction_generator=None*, *index_selector=None*, *active_sphere=None*, *min_move_distance=None*, *adaptive_displacement=False*, *max_forces=None*, *max_steps=None*, *max_step_length=None*, *optimizer_method=None*, *lanczos_relative_error=None*, *lanczos_maximum_iterations=None*, *finite_difference=None*, *finite_difference_method=None*, *threshold_orthogonal_steps=None*, *inflection_threshold=None*, *reorthogonalize=None*)

Class for performing a saddle search using the ARTn algorithm.

Parameters

- **constraints** (*list of ints*) – The atoms that should be constrained during the process search. **Default:** []
- **initial_direction_generator** (*DirectionGenerator*) – The generator for the initial displacements. **Default:** RandomDirection
- **index_selector** (*callable*) – A callable to select the indices to displace. Takes as input the current configuration and returns the indices to displace.
- **active_sphere** – This argument is used to control the radius of an active sphere around the atoms selected by the index_selector argument. All atoms that are outside this sphere will be constrained.
- **min_move_distance** (*PhysicalQuantity* of type length) – The minimum distance that the selected indices must have moved between reactant and saddle. All saddle configurations that do not meet this criteria will be discarded.
- **adaptive_displacement** (*bool*) – When using adaptive displacement the initial atom displacement magnitude will be set dynamically. The chosen magnitude will be 0.8 multiplied with the average distance between reactant and saddle point. This will overewrite the value set in by the initial_direction_generator.
- **max_forces** (*PhysicalQuantity* of type force) – The maximum forces allowed in the orthogonal optimization. **Default:** 0.01*eV/Angstrom
- **max_steps** (*int*) – The maximum number of uphill steps and orthogonal steps. **Default:** 200
- **max_step_length** (*PhysicalQuantity* of type length) – The maximum step length for the uphill steps and orthogonal steps. **Default:** 0.1*Angstrom
- **optimizer_method** (list of OptimizerMethod) – The optimizer method to use. **Default:** LBFGS
- **lanczos_relative_error** (*float*) – The relative error for the Lanczos algorithm. **Default:** 0.0001
- **lanczos_maximum_iterations** (*int*) – The maximum number of iterations for the Lanczos algorithm. **Default:** 20
- **finite_difference** (*PhysicalQuantity* of type length) – The step size for the finite difference estimation of the second derivatives. **Default:** 0.01*Angstrom
- **finite_difference_method** (*Forward | Central*) – The type of finite difference used to estimate the second derivatives. **Default:** Central

- **threshold_orthogonal_steps** (*int*) – The maximum number of orthogonal steps below the inflection point. **Default:** 5
- **inflection_threshold** (*PhysicalQuantity* of type energy per length squared=) – The threshold for the inflection point of the energy after which the algorithm changes from following the initial direction to the minimum mode. Uses the current estimate of the lowest eigenvalue. A value of 0.0*eV/Angstrom**2 means that the actual inflection point is used. Values smaller than 0.0*eV/Angstrom**2 will cause the switching to be delayed. **Default:** 0.0*eV/Angstrom**2

reset()

Reset the direction generator.

run(*reactant_configuration*)

Run the saddle search algorithm.

Parameters
reactant_configuration (*AtomicConfiguration*) – The configuration to start the search from.

Returns
The data from the saddle search.

Return type
SaddleSearchData

setRandomSeed(*seed*)

Set the random seed for the initial direction generator.

Parameters
seed (*int*) – The random seed.

Notes

ARTnSaddleSearch is one of the three saddle search methods available for use in *AdaptiveKineticMonteCarlo*. It uses the original Activation Relaxation Technique nouveau (ARTn) as described in[1] and[2].

ARTnSaddleSearch requires an initial direction which is used to initiate the saddle search, controlled by the initial_direction_generator argument. The direction generator should be a callable that returns a vector. This callable will be used to generate a configuration from which the saddle search is started. Therefore, care must be taken so that it returns a vector of the correct dimensionality. There are two pre-made direction generators available. The RandomDirectionGenerator generates a random direction, while the *HypersphereDirection* generates a radial vector on a hypersphere of given radius. Each time a new saddle search is initiated, a new initial direction is generated.

Note that the magnitude argument of the initial direction generator is ignored when using *ARTnSaddleSearch*.

In addition to the initial direction, one can specify which atom(s) to displace. This is done using the index_selector argument. This argument can be either a list of indices or a (picklable) callable.

Acidity

class Acidity(*reactant_species*, *product_species*, *solvent_components*, *temperature=None*, *parameters=None*)

Calculate the pKa of a hydrogen transfer reaction taking into account solvation effects.

Parameters

- **reactant_species** (Sequence of *CosmoRealSpecies*) – The neutral reactants in the in the proton transfer reaction
- **product_species** (Sequence of *CosmoRealSpecies*) – The ionized products in the in the proton transfer reaction
- **solvent_components** (*CosmoRealSolvent* | *MoleculeConfiguration* | *CosmoRSMixture*) – The solvent in which the proton transfer occurs
- **temperature** (*PhysicalQuantity* of type temperature) – The solvent temperature. **Default:** `298 * Kelvin`
- **parameters** (*CosmoRSParameters*) – The COSMO-RS parameters

acidity()

Returns
The pKa of the reaction, defined as the negative base-10 logarithm of the equilibrium constant.

Return type
float

parameters()

Returns
The COSMO-RS parameters

Return type
CosmoRSParameters

productSpecies()

Returns
The ionized products in the proton transfer reaction.

Return type
Sequence of *CosmoRealSpecies*

reactantSpecies()

Returns
The neutral reactants in the in the proton transfer reaction.

Return type
Sequence of *CosmoRealSpecies*

solventComponents()

Returns
The components of the solvent.

Return type
CosmoRSMixture

temperature()

Returns
The solvent temperature.

Return type
PhysicalQuantity of type temperature

uniqueString()
Return a unique string representing the state of the object.

Usage Examples

Calculate the pK_a of acetic acid in water.

```
# Create the species for acetate
cosmo_rs = CosmoRS(
    configuration=optimized_configuration,
    solvation_energy=solvation_energy
)
acetate = cosmo_rs.evaluate()

# Calculate the pKa of acetic acid
acetic_acid_pka = Acidity(
    reactant_species=[acetic_acid, water],
    product_species=[acetate, hydronium],
    solvent_components=water,
    temperature=298*Kelvin,
    parameters=CosmoRSParameters()
)
pka = acetic_acid_pka.acidity()
nlprint(f'The calculated pKa of acetic acid is {pka}')
```

acetic_acid_example.py

Notes

The *Acidity* object calculates the pK_a of a compound. It does this by calculating the acid/base equilibrium of the form:

$$AH + B \rightleftarrows A^- + BH^+$$

Here A acts as an acid transferring its proton to molecule B which acts as a base, forming two charged species. The molecule B can either be a solvent molecule or some other. In cases where water is a component of the solvent, B will often be water, forming a hydronium ion on the right hand side of the equation.

In COSMO-RS, pK_a is calculated based on the solvated energies of each molecule as well as each molecules interaction with solvent. The pK_a can be simply given as:

$$pK_a = \frac{E_{COSMO}^{A^-+BH^+} - E_{COSMO}^{AH+B} + \mu_S^{A^-+BH^+} - \mu_S^{AH+B}}{\ln(10)RT}$$

Here E_{COSMO} represents the COSMO internal energy of each pair of molecules and μ_S represents the solvated chemical potential of each molecular species.

Due to systematic errors in calculating both the internal energy and the solvated chemical potential, it is possible to use a linear correction to estimate the observed pK_a[1]. Given the pK_a calculated by the COSMO-RS method as pK_a^{raw}, the

[1] Andreas Klamt, Frank Eckert, Michael Diedenhofen, and MichaelăE. Beck. First principles calculations of aqueous pKa values for organic and inorganic acids using COSMO-RS reveal an inconsistency in the slope of the pKa scale. *J. Phys. Chem. A.*, 107:9380–9386, 2003. doi:10.1021/jp034688o.

corrected pK_a can be given as:

$$pK_a = A \times pK_a^{raw} + B$$

Here A and B are simply the slope and the intercept of the linear correction. They are both parameters contained in the *CosmoRSParameters* object.

It should also be noted that, with the exception of hydronium, all molecules in the COSMO-RS molecule database are neutral molecules. For pK_a calculations it will then be necessary to perform a DFT calculation on the deprotonated molecule. In this case, since it is a charged molecule, *Multipole* boundary conditions should be used. While slower than used *Periodic FFT* boundary conditions, *Multipole* boundary conditions ensure that the molecule is treated as a single, charged molecule without periodicity.

AcousticDeformationPotentialSelfEnergy

class AcousticDeformationPotentialSelfEnergy(*coupling=None*)

A class which represents a deformation potential model for acoustic phonon modes.

Parameters
coupling (*PhysicalQuantity* of type energy) – The electron-phonon coupling strength of the acoustic modes. The coupling strength can be given as a single value, or a 1D array specifying the value for each atom (in units of energy).
Default: `0 * eV`

coupling()

Returns
The electron-phonon coupling strength of the acoustic modes.

Return type
PhysicalQuantity with unit `eV**2`

uniqueString()

Return a unique string representing the state of the object.

ActiveLearningSimulation

class ActiveLearningSimulation(*fitting_parameters*, *initial_training_data*, *mtp_study_filename*, *mtp_study_object_id*, *reference_calculator*, *correction_calculator=None*, *d3_dispersion_calculator=None*, *candidate_threshold=None*, *retrain_threshold=None*, *check_interval=None*, *limit_candidates=None*, *max_forces_check=None*, *use_stress=None*, *candidate_trajectory_filename=None*, *candidate_trajectory_object_id=None*, *max_iterations=None*, *processes_per_calculation=None*, *extrapolation_selection_parameters=None*, *use_linearized_coefficient_matrix=None*, *minimum_bond_length_percent=None*, *log_filename_prefix=None*, *restart_simulation=None*)

Set up an object that can be used to run active learning simulations using the Moment Tensor Potential.

Parameters

- **fitting_parameters** (*MomentTensorPotentialFittingParameters*) – The parameters for MTP fitting.

- **initial_training_data** (*TrainingSet* | *Trajectory* | *ConfigurationDataContainer* | *MDTrajectory* | *MomentTensorPotentialTraining* | sequence of [*TrainingSet* | *Trajectory* | *ConfigurationDataContainer* | *MDTrajectory* | *MomentTensorPotentialTraining*] | Table) – The initial training data. All configurations in the initial training data must have precalculated reference data (energy, forces, and possibly stress), otherwise the configuration is not included in the active learning training.
- **mtp_study_filename** (*str*) – The file name of file that contains the MTP study object used for training the moment tensor potential.
- **mtp_study_object_id** (*str*) – The object_id of the MTP study object used to train the moment tensor potential.
- **reference_calculator** (*Calculator*) – The reference calculator.
- **correction_calculator** (*Calculator*) – Calculator used to correct reference values. The MTP is fit to the reference calculator minus the contribution of the correction calculator.
- **d3_dispersion_calculator** (*TremoloXCalculator*) – A D3 dispersion calculator that, when added, is used in the MD simulation during the active learning cycle as a correction to the MTP output. **Default:** None
- **candidate_threshold** (*float*) – The threshold above which configurations will be added as candidates for the next training iteration. **Default:** 1
- **retrain_threshold** (*float*) – The extrapolation threshold at which the simulation is stopped and trained again. **Default:** 3
- **check_interval** (*int*) – The interval at which the extrapolation grade is calculated and checked in MD simulations. In active learning optimization the extrapolation grade is always checked at every step. **Default:** 10
- **limit_candidates** (*int*) – Upper limit for the number of candidates collected each iteration that trigger retraining. This can be used to limit the number of reference calculator calls when many configurations fall between the candidate and retrain thresholds. **Default:** No limit
- **max_forces_check** (*PhysicalQuantity* of type energy / length) – If the max. force on an atom exceeds this value the extrapolation grade is always checked. Only available with MD active learning; has no effect in other cases. **Default:** 10*eV / Angstrom
- **use_stress** (*bool*) – Whether or not stress is used in training the MTP potential. **Default:** True
- **candidate_trajectory_filename** (*str*) – The filename for the trajectory to store the candidate configurations that have been added to the training set.
- **candidate_trajectory_object_id** (*str*) – The object ID for the trajectory to store the candidate configurations that have been added to the training set.
- **max_iterations** (*int*) – The max number of retraining iterations. **Default:** 20
- **processes_per_calculation** (int | `None`) – The number of processes used for each calculation with the reference calculator. **Default:** All processes corresponding to `None`.
- **extrapolation_selection_parameters** (*ExtrapolationSelectionParameters*) – The parameters that specify the details of the extrapolation grade calculation and candidate selection.
- **use_linearized_coefficient_matrix** (*bool*) – **Deprecated:** Use `extrapolation_grad_algorithm=MaxvolLinearized` in *ExtrapolationSelectionParameters* instead.
- **minimum_bond_length_percent** (*float*) – The minimum percentage of bond length as fraction of the covalent radii that is allowed in a training configuration. If any bond is less than that value then the configuration will be discarded from the training data. **Default:** 0.35
- **log_filename_prefix** (*str | LogToStdOut | None*) – The prefix used in the log file names generated by the training data calculation and fitting parts of the simulation.
- **restart_simulation** (*bool*) – Restart the simulation with any configurations added during previous active learning. simulations **Default:** False

additionalTrainingData()

Returns
The training dataset that has been added during the active learning simulation.

Return type
Trajectory

additionalTrainingSet()

Returns
The training dataset that has been added during the active learning simulation or None if no training data has been added.

Return type
TrainingSet | None

candidateThreshold()

Returns
The candidate threshold.

Return type
float

candidateTrajectoryFilename()

Returns
The filename to which the candidate trajectory is written.

Return type
str

candidateTrajectoryObjectId()

Returns
The object ID to which the candidate trajectory is written.

Return type
str

checkInterval()

Returns
The check interval for the extrapolation grade.

Return type
int

committeeSize()

Returns
The number of committee members when the query-by-committee method is used for the extrapolation grade.

Return type
int

correctionCalculator()

Returns
The correction calculator, if defined.

Return type
Calculator

`extrapolationGradeAlgorithm()`

Returns
Which extrapolation grade algorithm should be used.

Return type
MaxvolStandard | MaxvolLinearized | MaxForce | QueryByCommitteeForces | QueryByCommitteeEnergy

`fittingParameters()`

Returns
The MTP fitting parameters.

Return type
MomentTensorPotentialFittingParameters

`forcesCap()`

Returns
The forces cap.

Return type
PhysicalQuantity of type energy / length.

`initialTrainingData()`

Returns
The initial training dataset.

Return type
Trajectory

`initialTrainingSet()`

Returns
The initial training dataset for this active learning simulation.

Return type
TrainingSet

`limitCandidates()`

Returns
Upper limit for the number of candidates that are collected each iteration before retraining.

Return type
int

`logFilenamePrefix()`

Returns
The prefix used in MTP training log files. The flag LogToStdOut causes log output to be written to standard out.

Return type
str

`maxForcesCheck()`

Returns
The max. forces value at which a check of the extrapolation grade is enforced.

Return type
PhysicalQuantity of type energy / length.

maxIterations()

Returns
The maximum number of retraining iterations.

Return type
int

minBondLengthPercent()

Returns
The minimum bond length as fraction of the covalent radii.

Return type
float

mtpParameters()

Returns
Gets the MTPParameters containing the Optimized MTP parameters

Return type
MTPParameters | None

processesPerCalculation()

Returns
The number of processes that is used for a configuration when calculating the reference data.

Return type
int

referenceCalculator()

Returns
The reference calculator

Return type
Calculator

restartSimulation()

Returns
Whether or not the simulation and training are restarted from a previous run.

Return type
bool

retrainThreshold()

Returns
The retrain threshold.

Return type
float

runMolecularDynamics(*configuration*, *constraints=None*, *trajectory_filename=None*, *steps=None*, *log_interval=None*, *method=None*, *xyz_filename=None*, *hook_functions=None*, *pre_step_hook=None*, *post_step_hook=None*, *write_velocities=None*, *write_forces=True*, *write_stresses=None*, *domain_decomposition_pattern=None*, *trajectory_interval=None*, *measurement_hook=None*, *trajectory_object_id=None*, *number_of_independent_runners=None*, *log_filename_prefix=None*)

Run an active learning MD simulation.

Parameters

- **configuration** (*BulkConfiguration* | sequence of type *BulkConfiguration*) – The initial configuration. When using multiple independent runners this can be given as a list with a different item for each runner.
- **constraints** (list of ints | list of BaseConstraint) – The list of atomic indices, denoting fixed atoms, or constraint objects, such as *RigidBody*. **Default:** [].
- **trajectory_filename** (*str | sequence of str | None*) – The filename of the file to be used for storing the trajectory, or None if no trajectory should be written. A trajectory filename should not be given if configuration is a trajectory. When using multiple independent runners this can be given as a list with a different item for each runner. **Default:** None.
- **steps** (*int*) – The number of time-steps to take in the simulation. **Default:** 50.
- **log_interval** (*int*) – The interval at which information, such as time, energy, temperature, etc. is written to the log output. **Default:** 1.
- **method** (BaseMDmethod) – The MD method used for the simulation. When using multiple independent runners this can be given as a list with a different item for each runner. **Default:** *NVEVelocityVerlet*.
- **xyz_filename** (*str*) – The name of the file to be used for storing the xyz trajectory, or None if no xyz-trajectory should be written. **Default:** None.
- **hook_functions** (*None*) – Currently not supported in active learning.
- **pre_step_hook** (*function | list of functions | None*) – An optional user-defined function or a list of functions which will be called just before the forces evaluation. The signature of the function requires the arguments (step, time, configuration). The return status is ignored. Unhandled exceptions will terminate the evaluation. If a list is given the functions will be called in the given order. **Default:** None.
- **post_step_hook** (*function | list of functions | None*) – An optional user-defined function or a list of functions which will be called just after the forces evaluation. The signature of the function requires the arguments (step, time, configuration). Optional arguments include, forces, local_forces (for distributed MD), stress, trajectory (the MD trajectory), temperature, pressure, potential_energy, and/or kinetic_energy. The return status is ignored. Unhandled exceptions will terminate the evaluation. If a list is given the functions will be called in the given order. **Default:** None.
- **write_velocities** (*bool*) – Write the velocities to the trajectory file every log_interval steps. If configuration is a trajectory (i.e. this is a restart calculation) this parameter will be the same value as it was in the previous trajectory. **Default:** True.
- **write_forces** (*bool*) – Write the forces to the trajectory file every log_interval steps. If configuration is a trajectory (i.e. this is a restart calculation) this parameter will be the same value as it was in the previous trajectory. **Default:** True.
- **write_stresses** (*bool*) – Write the stress to the trajectory file every log_interval steps. A value of None means that write_stresses is True by default for NPT methods and False otherwise. This is to avoid the additional work of calculating the stress when it is not needed. If configuration is a trajectory (i.e. this is a restart calculation) this parameter will be the same value as it was in the previous trajectory. **Default:** None.
- **domain_decomposition_pattern** (list of type int | Automatic | None) – The pattern how the domains should be arranged in a parallel simulations. E.g. [1, 2, 4] means 1 domain in A-, 2 in B-, and 4 in C-direction. If Automatic domain decomposition is used, then the simulation cell will be divided into domains whose edges are as close together in length as possible. If None is given then domain decomposition will be disabled. **Default:** Automatic.
- **trajectory_interval** (*int*) – The resolution used in saving steps to a trajectory file. A value of 1 results in all steps being saved; a value of 2 results in every second step being saved; etc. If configuration is a trajectory (i.e. this is a restart simulation) this parameter will use the same value as was used in the previous trajectory. **Default:** The same value as log_interval.

- **measurement_hook** (*function | list of functions | None*) – An optional user-defined function or a list of functions which will be called at the end of each step after all constraints have been applied. The signature of the function requires the arguments (step, time, configuration). Optional arguments include, forces, local_forces (for distributed MD), stress, trajectory (the MD trajectory), temperature, pressure, potential_energy, and/or kinetic_energy. The return value should be a dictionary that maps string keys to values. The values may be numbers, numpy arrays, or PhysicalQuantities. These values are stored on the MDTrajectory and may be accessed using the measurement method. Unhandled exceptions will terminate the evaluation. If a list is given the functions will be called in the given order. **Default:** None.

- **trajectory_object_id** (*str | None*) – The object id of the trajectory written to `trajectory_filename`. If a value of `None` is given, then an object id will be chosen automatically. **Default:** None.

- **number_of_independent_runners** (*int*) – The number of independent simulations that should be run. If greater than 1, each runner will run in an independent process group and at the end of each iteration, the candidates of all runners will be gathered, selected, and added to the training data. The simulation completes if all runners complete without exceeding the retraining threshold. **Default:** Length of `configuration`.

- **log_filename_prefix** (*str | None*) – The prefix used in log files containing details of the molecular dynamics simulation.

Returns
The final trajectory or, in case of multiple runners, a list containing the trajectories of all runners. In case the active learning simulation does not complete within the max. number of iterations, None is returned.

Return type
MDTrajectory | list | None

runOptimizeGeometry(*configuration*, *max_forces=None*, *max_stress=None*, *max_steps=None*, *max_step_length=None*, *constraints=None*, *trajectory_filename=None*, *trajectory_object_id=None*, *optimize_cell=None*, *disable_stress=None*, *optimizer_method=None*, *target_stress=None*, *constrain_bravais_lattice=None*, *trajectory_interval=None*, *remove_drift=None*, *enable_optimization_stop_file=None*, *restart_strategy=<class 'NL.ComputerScienceUtilities.NLFlag._NLFlag.NoRestart'>*, *number_of_independent_runners=None*, *log_filename_prefix=None*, *continue_on_non_convergence=None*)

Run an active learning geometry optimization.

Parameters

- **configuration** (*BulkConfiguration* | sequence of type *BulkConfiguration*) – The configuration to be optimized. When using multiple independent runners this can be given as a list with a different item for each runner.

- **max_forces** (*PhysicalQuantity* of type force) – The convergence criterion for the atomic forces. **Default:** 0.05*eV/Angstrom.

- **max_stress** (*PhysicalQuantity* of type pressure) – The convergence criterion for the maximum difference between the internal stress and the target stress. **Default:** 0.1*GPa.

- **max_steps** (*int*) – The maximum number of optimization steps. **Default:** 200.

- **max_step_length** (*PhysicalQuantity* of type length) – The maximum step length the optimizer may take. **Default:** 0.2*Ang.

- **constraints** (*list of integers and Constraints objects*) – A list of indices of the atom with fixed positions and Constraints objects. **Default:** [].

- **trajectory_filename** (*str | sequence of str | None*) – The filename used to store the trajectory. If the value is None then no trajectory file will be written. When using multiple independent runners this can be given as a list with a different item for each runner. **Default:** None.

•**trajectory_object_id** (*str | None*) – The object id of the trajectory written to `trajectory_filename`. If a value of `None` is given, then an object id will be chosen automatically. **Default:** None.

•**optimize_cell** (*bool*) – The lattice vectors for bulk configuration will change during the optimization. Enabling the stress calculation for bulk configurations. **Default:** True for BulkConfigurations otherwise False.

•**disable_stress** (*bool*) – **Deprecated:** from v2022.03, use `optimize_cell` parameter instead.

•**optimizer_method** (*FIRE* | *LBFGS*) – The optimization algorithm to use. **Default:** *LBFGS*.

•**target_stress** (*PhysicalQuantity* of type pressure|PHYSICALQUANTITY| of type pressure) – The target internal stress (tensor) of the system. Can be given as a single value in case of isotropic pressure, or as an internal stress vector in Voigt notation or as a 3x3-matrix. **Default:** 0*GPa.

•**constrain_bravais_lattice** (*bool*) – Enable preserving the Bravais lattice symmetry of the configuration. **Default:** True if the `target_stress` is commensurate with the lattice symmetries.

•**trajectory_interval** (int | *PhysicalQuantity* of type time) – The resolution used in saving steps to a trajectory file. This can either be given as an integer (a value of 1 results in all steps being saved; a value of 2 results in every second step being saved; etc.) or as a time interval. **Default:** 1.

•**remove_drift** (*bool*) – In ab-initio calculations, the sum of the forces along each Cartesian direction does not necessarily sum to zero due to numerical inaccuracies. This option controls if the drift in the forces should be removed by subtracting the average force along each Cartesian direction from all atoms. **Default:** True.

•**enable_optimization_stop_file** (*bool*) – Determines whether to enable a file for stopping the geometry optimization. If `True`, creation of the stop file will stop the optimization at the next step. The name of the stop file will be shown in the log output; it will be `stop-geometry-optimization-uniqueID`, where `uniqueID` is a randomly generated identifier for this optimization. The file must be created in the current working directory. **Default:** True.

•**restart_strategy** (`NoRestart`) – The restart mechanism has to be set to `NoRestart` for ActiveLearningSimulation **Default:** `NoRestart`.

•**number_of_independent_runners** (*int*) – The number of independent geometry optimizations that should be run. If greater than 1, each runner will run in an independent process group and at the end of each iteration, the candidates of all runners will be gathered, selected, and added to the training data. The simulation completes if all runners complete without exceeding the retraining threshold. **Default:** Length of `configuration`.

•**log_filename_prefix** (*str | None*) – The prefix used in log files containing details of the geometry optimization.

•**continue_on_non_convergence** (*bool*) – Continue with the converged configurations when using multiple runners and only some optimizations converge in the given number of active learning cycles. If `False` is given the calculation will raise an exception if any optimization does not converge. **Default:** False

runOptimizeNudgedElasticBand(*neb*, *max_forces=None*, *max_stress=None*, *max_steps=None*, *max_step_length=None*, *constraints=None*, *trajectory_filename=None*, *spring_constant=None*, *climbing_image=None*, *preoptimization=None*, *optimizer_method=None*, *log_filename_prefix=<class 'NL.ComputerScienceUtilities.NLFlag._NLFlag.Automatic'>*, *optimize_cell=None*, *target_stress=None*, *trajectory_interval=None*, *restart_strategy=<class 'NL.ComputerScienceUtilities.NLFlag._NLFlag.NoRestart'>*)

Run an active learning nudged elastic band optimization.

Parameters

•**neb** (*NudgedElasticBand*) – The nudged elastic band configuration to optimize.

•**max_forces** (*PhysicalQuantity* of type force) – The convergence criterion for the atomic forces. **Default:** 0.05*eV/Angstrom.

- **max_stress** (*PhysicalQuantity* of type pressure) – The convergence criterion for the maximum difference between the internal stress and the target stress. **Default:** 0.1*GPa.
- **max_steps** (*int*) – The maximum number of optimization steps. **Default:** 200.
- **max_step_length** (*PhysicalQuantity* of type length) – The maximum step length the optimizer may take. **Default:** 0.2*Ang.
- **constraints** (*list of ints*) – List of atom indices that are kept fixed during optimization. **Default:** [].
- **trajectory_filename** (*str | sequence of str | None*) – The filename used to store the trajectory. If the value is None then no trajectory file will be written. **Default:** None.
- **spring_constant** (*PhysicalQuantity* of type eV/Ang**2) – The spring constant used for the NEB relaxation. **Default:** 5.0*(eV/Ang**2).
- **climbing_image** (*bool*) – Flag indicating if the climbing image algorithm should be used to find a transition state. **Default:** False.
- **preoptimization** (*bool*) – Flag indicating if the endpoints should be optimized before the NEB optimization. **Default:** False.
- **optimizer_method** (*FIRE* | *LBFGS*) – The optimizer to use for optimizing the structure. **Default:** *LBFGS*.
- **log_filename_prefix** (`Automatic` | str | None) – The logging output from each image will be written to filenames starting with this value. If it is set to Automatic then the prefix will be the name of the calling python script. If it is set to None, then all output will be written to stdout. **Default:** `Automatic`.
- **optimize_cell** (*bool*) – If it is *None*, it will be set automatically according to the NEB configuration. If the NEB configuration is composed of configurations of the type *BulkConfiguration* and the lattice vectors of the configurations are different, it is set to True; otherwise it is False. **Default:** None.
- **target_stress** (*PhysicalQuantity* of type pressure) – The target internal stress (tensor) of the system. Can be given as a single value in case of isotropic pressure, or as an internal stress vector in Voigt notation or as a 3x3-matrix. **Default:** 0*GPa.
- **trajectory_interval** (int | *PhysicalQuantity* of type time) – The resolution used in saving steps to a trajectory file. This can either be given as an integer (a value of 1 results in all steps being saved; a value of 2 results in every second step being saved; etc.) or as a time interval. **Default:** 1.
- **restart_strategy** (`NoRestart`) – The restart mechanism has to be set to `NoRestart` for ActiveLearningSimulation **Default:** `NoRestart`.

Returns
The optimized NEB. In case the active learning MD simulation does not complete within the max. number of iterations, None is returned.

Return type
NudgedElasticBand | None

runTimeStampedForceBiasMonteCarlo(*configuration*, *constraints=None*, *trajectory_filename=None*, *steps=None*, *log_interval=None*, *method=None*, *hook_functions=None*, *pre_step_hook=None*, *post_step_hook=None*, *write_velocities=None*, *write_forces=None*, *write_stresses=None*, *trajectory_interval=None*, *trajectory_object_id=None*, *number_of_independent_runners=None*, *log_filename_prefix=None*)

Run an active learning TFMC simulation.

Parameters

- **configuration** (*BulkConfiguration* | sequence of type *BulkConfiguration*) – The initial configuration. When using multiple independent runners this can be given as a list with a different item for each runner.

•**constraints** (list of ints | list of BaseConstraint) – The list of atomic indices, denoting fixed atoms, or constraint objects, such as *RigidBody*. **Default:** [].

•**trajectory_filename** (*str | sequence of str | None*) – The filename of the file to be used for storing the trajectory, or None if no trajectory should be written. A trajectory filename should not be given if configuration is a trajectory. When using multiple independent runners this can be given as a list with a different item for each runner. **Default:** None.

•**steps** (*int*) – The number of time-steps to take in the simulation. **Default:** 50.

•**log_interval** (*int*) – The interval at which information, such as time, energy, temperature, etc. is written to the log output. **Default:** 1.

•**method** (ForceBiasMontCarlo | *ForceBiasMonteCarloNPTBerendsen*) – The Monte Carlo method used for the simulation. When using multiple independent runners this can be given as a list with a different item for each runner. **Default:** *ForceBiasMonteCarlo*

•**hook_functions** (*None*) – Currently not supported in active learning.

•**pre_step_hook** (*function | list of functions | None*) – An optional user-defined function or a list of functions which will be called just before the forces evaluation. The signature of the function requires the arguments (step, time, configuration). The return status is ignored. Unhandled exceptions will terminate the evaluation. If a list is given the functions will be called in the given order. **Default:** None.

•**post_step_hook** (*function | list of functions | None*) – An optional user-defined function or a list of functions which will be called just after the forces evaluation. The signature of the function requires the arguments (step, time, configuration, forces, stress). The return status is ignored. Unhandled exceptions will terminate the simulation. If a list is given the functions will be called in the given order. **Default:** None

•**write_velocities** (*bool*) – Write the velocities to the trajectory file every log_interval steps. Since, the time-stamped force-bias Monte Carlo algorithm does not use velocities explicitly, zero velocities will be written. If configuration is a trajectory (i.e. this is a restart calculation) this parameter will be the same value as it was in the previous trajectory. **Default:** False

•**write_forces** (*bool*) – Write the forces to the trajectory file every log_interval steps. **Default:** True

•**write_stresses** (*bool*) – Write the stress to the trajectory file every log_interval steps. **Default:** False

•**trajectory_interval** (*int*) – The resolution used in saving steps to a trajectory file. A value of 1 results in all steps being saved; a value of 2 results in every second step being saved; etc. If configuration is a trajectory (i.e. this is a restart MD simulation) this parameter will use the same value as was used in the previous trajectory. **Default:** The same value as log_interval.

•**trajectory_object_id** (*str | None*) – The object id of the trajectory written to trajectory_filename. If a value of None is given, then an object id will be chosen automatically. **Default:** None.

•**number_of_independent_runners** (*int*) – The number of independent simulations that should be run. If greater than 1, each runner will run in an independent process group and at the end of each iteration, the candidates of all runners will be gathered, selected, and added to the training data. The simulation completes if all runners complete without exceeding the retraining threshold. **Default:** Length of configuration.

•**log_filename_prefix** (*str | None*) – The prefix used in log files containing details of the molecular dynamics simulation.

Returns
The final trajectory or, in case of multiple runners, a list containing the trajectories of all runners. In case the active learning simulation does not complete within the max. number of iterations, None is returned.

Return type
MDTrajectory | list | None

static supportedConfigurationTypes()

Returns
Supported configuration types for initial training data.

Return type
tupleColuz

trainingSetTable()

Returns
A table containing the initial and additional training data for this active learning simulation.

Return type
Table

uniqueString()

Return a unique string representing the state of the object.

useLinearizedCoefficientMatrix()

Returns
Whether the matrix used to calculate the extrapolation grade should include only the linear coefficients or additionally the linearized version of the non-linear coefficients.

Return type
bool

static validatorType()

Returns
The validator type.

Return type
Validator

writeAtomicErrorEstimates()

Returns
True if the per-atom error estimates should be written to the trajectory.

Return type
bool

Usage Examples

Run a molecular dynamics ActiveLearningSimulation for amorphous HfO2 using an initial training data set that is read from file. The method `runMolecularDynamics` takes the same arguments as the normal *MolecularDynamics* function. The extrapolation process is done by *query-by-committee* method.

```
# Load the training data. This can be one or several TrainingSet,␣
↪MomentTensorPotentialTraining or
# Trajectory objects, which contain energy, forces, stress calculated with the reference
# calculator.
initial_training_data = [nlread('HfO2_crystal_training.hdf5', TrainingSet)[0]]

# Use the predefined small MTP basis.
mtp_basis = PredefinedBasisSmall
```

(continues on next page)

(continued from previous page)

```
# Optimize the non-linear coefficients on the energy only.
nl_parameters = NonLinearCoefficientsParameters(
    perform_optimization=True,
    energy_only=True,
)

fitting_parameters = MomentTensorPotentialFittingParameters(
    basis_size=mtp_basis,
    outer_cutoff_radii=4.5*Ang,
    mtp_filename='HfO2_active_learning.mtp',
    non_linear_coefficients_parameters=nl_parameters,
    use_element_specific_coefficients=True,
)

active_learning = ActiveLearningSimulation(
    fitting_parameters=fitting_parameters,
    initial_training_data=initial_training_data,
    mtp_study_filename='HfO2_mtp_study',
    mtp_study_object_id='HfO2',
    reference_calculator=reference_calculator,
    candidate_threshold=1.0,
    retrain_threshold=3.0,
    check_interval=20,
    max_forces_check=10.0*eV/Ang,
    use_stress=True,
    candidate_trajectory_filename='HfO2_am_active_learning_candidates.hdf5',
    restart_simulation=True,

Notes

MTP Active Learning

The *ActiveLearningSimulation* class can be used to continuously extend the training data for a machine-learned Moment Tensor Potential (MTP) during a molecular dynamics simulation, as described in[1] and[2].

A typical active learning simulation is started from an initial training data set, which can be generated using the *MomentTensorPotentialTraining* framework. By calling a method such as `runMolecularDynamics` or `runOptimizeGeometry`, an active learning simulation is initiated. From the initial training data set a starting MTP is trained which is used to run the MD simulation. During the simulation the extrapolation grade is calculated at regular intervals for the current configuration, as described in[Page 2202, 1] and[2]. A value above zero means that the current configuration extrapolates the potential, i.e. is outside the space of configurations covered by the training data. If the extrapolation grade exceeds the first threshold `candidate_threshold`, a copy of the configuration is stored as a candidate to add to the extended training data set. If the extrapolation grade exceeds the `retrain_threshold`, the simulation is stopped. The most relevant configurations are selected from the collected candidates using the *maxvol* criterion[1]. Energy, forces, and stress are calculated for these configurations using the reference calculator, and added to the training data set. A new MTP is trained on this extended data set and the simulation is started from the beginning with the new MTP.

This cycle is repeated until the simulation completes without extrapolating significantly, i.e. without exceeding the retrain threshold, or the maximum number of iterations as specified by `max_iterations` is reached.

All additional configurations, which are added to the original training data set during an active learning simulation, are stored with their calculated reference energy, forces, and stress to a *ConfigurationDataContainer* object which is saved to `candidate_trajectory_filename`. The additional training data can also be be accessed via the method `additionalTrainingData()`. The method `additionalTrainingSet()` returns the additional training data as *TrainingSet* object. Furthermore, *ActiveLearningSimulation* provides a method `trainingSetTable()`, which returns a Table that contains both the initial training set as well as the additional training set. This table can directly be used as input to a *MomentTensorPotentialTraining* object to perform a final MTP fitting run and optimize the MTP hyperparameters.

A D3 dispersion calculator can be added in order to account for dispersion during the MD simulations of the active learning cycle. This is achieved by creating the *ActiveLearningSimulation* object with a D3 dispersion calculator attached via the `d3_dispersion_calculator` keyword. This calculator is required to be a *TremoloXCalculator* calculator wrapped around a given D3 dispersion potential. For creating the calculator a D3 dispersion potential, e.g. `DispersionD3Z(xc='PBE')`, has to used for creating a *TremoloXCalculator* object - yielding the overall input `TremoloXCalculator(DispersionD3Z(xc='PBE'))`. The type of D3 dispersion potential and the xc functional included in the *TremoloXCalculator* object should be explicitly specified according to the specific modeling needs.

Query-by-committee

Query-by-committee is an alternative to the *maxvol* algorithm to calculate the extrapolation grade for multi-element systems. In this case, an ensemble of different MTP models is trained on the same training data (default is 6 different models), each with different initial guesses. The ensemble standard deviation of the forces prediction is used as a measure of extrapolation, which can be interpreted as a prediction of the forces error in the configuration[3]. The query-by-committee algorithm typically provides a numerically more stable way to calculate the extrapolation grade and does not require reduced MTP accuracy settings. In particular it can be used with any MTP basis size and it is therefore the recommended algorithm.

The query-by-committee method can be activated by setting `extrapolation_grade_algorithm=QueryByCommitteeForces` in *ExtrapolationSelectionParameters*. Unlike maxvol, query-by-committee does not provide a native algorithm for selecting the most different candidate configurations out of all extrapolating candidates. Instead, a dedicated separate selection algorithms is used (MTP-structural-descriptor). The parameters for this method can be selected through the `extrapolation_selection_parameters`, which takes an *ExtrapolationSelectionParameters* object.

Multiple runners

Using multiple runners in active learning MD or optimization is an extension to the standard way of running active learning to increase the exploration of different new configurations. Here, the simulation is split up and run on multiple different initial configurations simultaneously, collecting candidates from all simulations. When all simulations have stopped due to exceeding the retraining threshold, all the candidates are gathered, selected, and collectively included in the training before the next iteration is started. This allows to include, e.g. various stoichiometric compositions, or interface representations in the same active learning simulation, instead of running multiple simulations sequentially.

Multiple runners can be set up by passing a list of initial configurations as `configuration` parameter in `runMolecularDynamics()` or `runOptimizeGeometry()`. For running this type of simulation efficiently, one should ideally allocate at least as many MPI processes as number of initial configurations.

Practical guide

Although it can also be used in production simulations, the *ActiveLearningSimulation* class is primarily designed to efficiently extend existing training data via MD simulations without having to run computationally expensive ab-initio MD simulations for amorphous or high-temperature systems. Apart from the automatically added training data in the candidate trajectory file, it can also be useful to take snapshots from the final MD trajectory, recalculate energy, forces, and stress with the reference calculators (e.g. by passing it as *TrainingSet* to *MomentTensorPotentialTraining*) to obtain additional training configurations that can be added to a larger training data set.

For consistency with the input of *MomentTensorPotentialTraining* it is recommended to use a list or Table of *TrainingSet* objects to pass the initial training data.

When using the default maxvol algorithm, it is recommended to reduce the MTP accuracy settings, e.g. MTP basis, outer cutoff radius, and to include only the most relevant training data in the initial training data set to be run in a robust and efficient way. One can occasionally encounter the error message No new candidates found in active learning, often accompanied by very large extrapolation grade values. This is typically caused by an MTP basis set being too large for the given training data, which leads to numerical inaccuracies when calculating the extrapolation grade and selecting the candidates to add to the next training iteration. In this case it often helps to reduce the MTP basis size in the *MomentTensorPotentialFittingParameters* until the problem disappears. Alternatively, one can try to include more diverse configurations to the initial training data, for example by running DFT-MD.

Choosing the query-by-committee algorithm instead, can often avoid this problem from the start and provide a more stable simulation.

[3] Christoph Schran, Krystof Brezina, and Ondrej Marsalek. Committee neural network potentials control generalization errors and enable active learning. *The Journal of Chemical Physics*, 153(10):104105, 2020.

When starting an active learning simulation from scratch it is recommended to scan over randomly generated initial non-linear coefficients and select the best fit for further training, as shown in the example section. If an active learning simulation is continued, then it is best to use the non-linear coefficients from the previous run to keep he training consistent. This can be done by passing the MTP filename from the previous run as `initial_coefficients` parameter in the *NonLinearCoefficientsParameters*.

In order to run an active learning MD simulation more efficiently one can increase the `check_interval` parameter, to reduce the frequency at which the extrapolation grade is calculated. As a fallback the extrapolation grade is always checked, whenever the largest force on an atom exceeds the value `max_forces_check`, which is typically a sign of extrapolation. This is only supported for MD, whereas in optimization simulations the extrapolation grade is always checked at every step.

Note, that the initial training data must have pre-calculated reference data (e.g. DFT energy, forces, stress). That means e.g. `TrainingSet` objects must be set up with `recalculate_training_data=False` ActiveLearningSimulation does not support calculating the reference data for the initial training data that is given.

RJL This sentence seems to be cut off. The training data generated during an active learning run can be accessed via

Active Learning MD

A typical workflow for training via active learning MD could be to use displaced bulk crystal or interface configurations generated via *RandomDisplacementsParameters* or *CrystalInterfaceTrainingParameters* respectively, as initial training data. Simulating the crystal at high temperature using active learning MD to melt it can then be used to include liquid and amorphous configurations to the training data. Typical values for candidate and retrain threshold are 1.0 and 3.0, respectively. The larger these values are, the more extrapolation is allowed.

MD with active learning can be combined with hook functions. This can be used to include non-equilibrium simulations in the training.

Active Learning geometry optimization

This type of optimization can supplement molecular dynamics simulations by bridging e.g. amorphous and crystalline phases. Since optimization trajectories tend to be shorter than MD trajectories, and configurations can change more significantly between optimization steps, it is recommended to set the `check_interval` parameter to 1 and lower the candidate- and retrain thresholds to add sufficiently many new structures to the training set. Note that `restart_strategy` and hook functions available in *OptimizeGeometry* are not supported in *ActiveLearningSimulation*. This method is used when crystal structure prediction is run with an *ActiveLearningSimulation* object (see also the *CrystalStructurePrediction* reference manual).

Active Learning nudged elastic band optimization

This type of active learning optimization can be used to train potentials for reaction paths and transition states. Similarly to *OptimizeGeometry*, hook functions and `restart_strategy` arguments are not available when running *OptimizeNudgedElasticBand* through active learning. Every image in the *NudgedElasticBand* is checked individually for its extrapolation grade, potentially adding multiple candidate structures each optimization iteration. However, it is still recommended to set the `check_interval` parameter to 1. A preoptimization of the endpoints can be performed. In that case the initial MTP should be able to perform the optimization without unphysical results, as they are not part of the learning process. Note that multiple independent runners are not supported.

AdaptiveGrid

class AdaptiveGrid(*kA_range=None*, *kB_range=None*, *tolerance=None*, *error_measure=None*, *number_of_initial_levels=None*, *maximum_number_of_levels=None*, *kpoints=None*, *intervals=None*, *triangles=None*, *function_values=None*, *integral_value=None*)

Parameters

- **kA_range** (*list(2) of float | float*) – Interval for k-points in the kA-direction given in fractional coordinates. If a single number is given there will be no k-points in this direction. **Default:** `[-0.5, 0.5]`
- **kB_range** (*list(2) of float | float*) – Interval for k-points in the kA-direction given in fractional coordinates. If a single number is given there will be no k-points in this direction. **Default:** `[-0.5, 0.5]`
- **tolerance** (*Positive float*) – Tolerance for integration. **Default:** `1e-3`
- **error_measure** (Absolute | `Relative`) – Method to calculate error. Either `Absolute` (absolute error) or `Relative` (relative error). **Default:** `Absolute`
- **number_of_initial_levels** (*Non-negative int*) – Minimum number of refinement steps in the adaptive grid. **Default:** `3`
- **maximum_number_of_levels** (*Non-negative int*) – Maximum number of refinement steps in the adaptive grid. **Default:** `20`
- **kpoints** – List of initial k-point, e.g. `[[0.0, 0.0], [0.1, 0.0]]`. Mutually exclusive with kA_range and kB_range. Can be used for restarting from a previous calculation. **Default:** `None`
- **intervals** (*list(n_intervals) of list(2) of int*) – List of intervals represented two integers, e.g. `[(0, 1), (1, 2), (2, 3)]`. The integers correspond to the indices of the k-points that are the end points of each interval. Mutually exclusive with kA_range and kB_range. Can be used for restarting from a previous calculation. **Default:** `None`
- **triangles** (*list(n_triangles) of list(3) of int*) – List of triangles represented three integers, e.g. `[(0, 1, 2), (0, 2, 3)]`. The integers correspond to the indices of the k-points that are the corner points of each triangle. Mutually exclusive with kA_range and kB_range. Can be used for restarting from a previous calculation. **Default:** `None`
- **function_values** (*list(n_kpoints) of float*) – List of function values corresponding to each k-point. Mutually exclusive with kA_range and kB_range. Can be used for restarting from a previous calculation. **Default:** `None`

dimension()

Returns
The dimension of the k-point integration. Can be either 1 or 2.

Return type
int

errorMeasure()

Returns
The `error_measure` used for this AdaptiveGrid.

Return type
`Absolute` or `Relative`

functionValues()

Returns
The values of the integrated function in all the k-points.

Return type
ndarray(n) where n is the number of k-points.

`initialIntervals()`

Returns
A list of the initial intervals.

Return type
list(n) of `Intervals` where n is the number of intervals.

`initialKpoints()`

Returns
The list of initial k-points.

Return type
ndarray(n, m) of floats where n is the number of k-points and m is the dimension.

`initialTriangles()`

Returns
A list of the initial triangles.

Return type
list(n) of `Triangles` where n is the number of triangles.

`integralValue()`

Returns
The value of the integrated function.

Return type
float

`intervals()`

Returns
A list of the intervals once the integration is finished.

Return type
list(n) of `Intervals` where n is the number of intervals.

`kARange()`

Returns
The range of k-points in the kA-direction.

Return type
list(2) of float.

`kBRange()`

Returns
The range of k-points in the kB-direction.

Return type
list(2) of float.

`kpoints()`

Returns
All of the k-points used in the integration.

Return type
list(n) of k-points where n is the number of k-points.

`kpointsWeights()`

Returns
The weight of all the k-points used in the integration.

Return type
list(n) of float where n is the number of k-points.

`maximumNumberOfLevels()`

Returns
The number of maximum levels allowed in the adaptive integration.

Return type
int

`nlinfo()`

Returns
The nlinfo.

Return type
dict

`numberOfInitialLevels()`

Returns
The number of initial levels used in the adaptive integration.

Return type
int

`tolerance()`

Returns
The tolerance at which the adaptive integration should stop.

Return type
float

`triangles()`

Returns
A list of the triangles once the integration is finished.

Return type
list(n) of `Triangles` where n is the number of triangles.

`uniqueString()`

Return a unique string representing the state of the object.

Usage Examples

Define an adaptive grid:

```
# Setup adaptive grid object.
adaptive_grid = AdaptiveGrid(
        kA_range=[-0.5, 0.5],
        kB_range=[-0.5, 0.5],
        tolerance=1e-2,
        error_measure=Absolute,
        number_of_initial_levels=2,
        maximum_number_of_levels=7)

# Use adaptive grid instead of kpoints in transmission spectrum.
transmission_spectrum = TransmissionSpectrum(device_configuration,
                                             kpoints=adaptive_grid)

# Use adaptive grid instead of kpoints in spin transfer torque.
spin_transfer_torque = SpinTransferTorque(device_configuration,
                                          contributions=Left,
                                          kpoints=adaptive_grid)
```

adaptive_grid.py

Notes

When using adaptive grids for integration, the integration domain is divided into triangles, as illustrated in Fig. 4.4. The integral over each triangle area is estimated as

$$I_0 = A_0(F_1 + F_2 + F_3)/3,$$

where A_0 is the area of the triangle, and F_1, F_2, F_3 are the function values at the triangle corner points. In order to estimate whether the integral, I_0, (left inset in Fig. 4.4) is converged or not, each triangle is divided into four smaller triangles with integral values I_1, I_2, I_3, I_4 (right inset in Fig. 4.4). The integral error, E_{I_0}, for triangle integral I_0 is computed as

$$E^{abs}_{I_0} = \frac{|I_0 - (I_1 + I_2 + I_3 + I_4)|}{A_0},$$

if the `error_measure` is `Absolute` and as

$$E^{rel}_{I_0} = \frac{|I_0 - (I_1 + I_2 + I_3 + I_4)|}{I_{tot}},$$

if the `error_measure` is `Relative`, where I_{tot} is the total integral over the entire integration domain at the present level of refinement.

It depends on the actual problem, if one should use the `error_measure=Absolute` or `error_measure=Relative` option. If one has some knowledge about the function values, e.g., the transmission spectrum, the use of `Absolute` may be more advantageous. On the other hand, if there is no information available on the function values, using `Relative` is a better option. This is also the case if `spin.Up` and `spin.Down` have rather different transmission spectra.

Fig. 4.5 illustrates schematically the data flow in the adaptive algorithm.

The AdaptiveGrid can be used as the kpoint keyword in the following analysis objects:

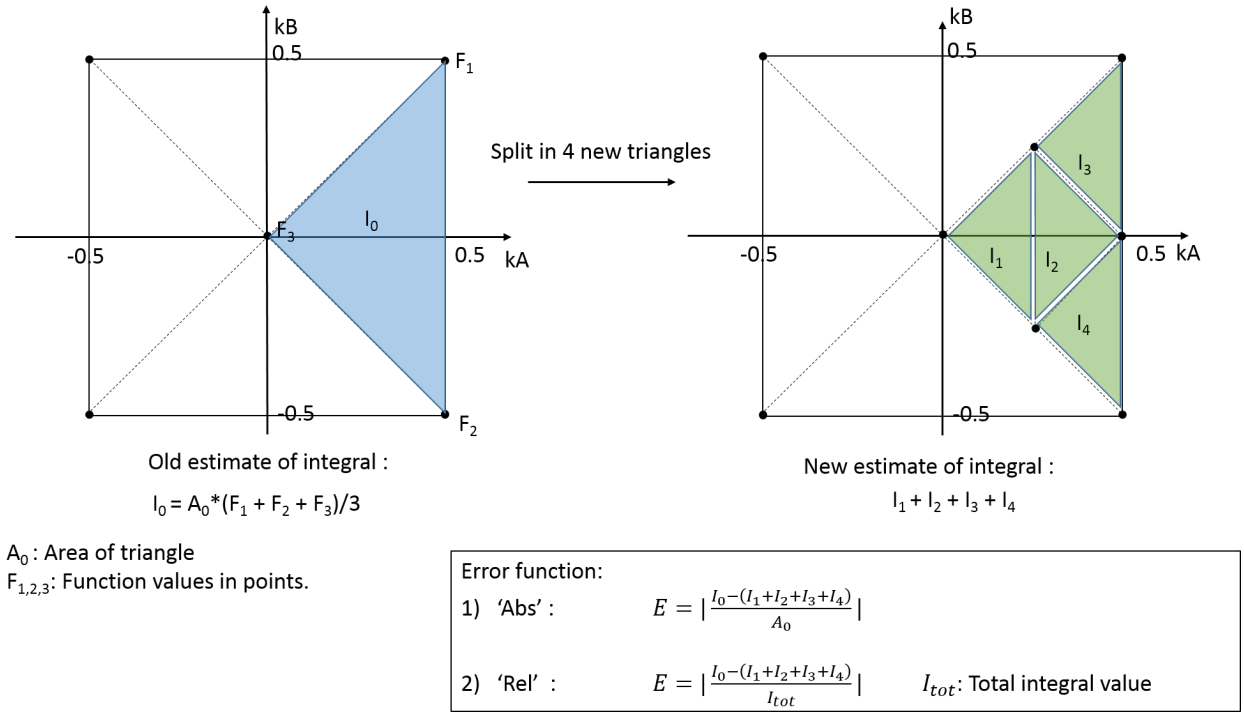

Fig. 4.4: The integration domain is divided into triangle areas. In order to estimate whether the integral, I_0, (left inset) is converged or not, each triangle is divided into four smaller triangles with integral values I_1, I_2, I_3, I_4 (right inset).

- *TransmissionSpectrum*
- *SpinTransferTorque*

AdaptiveHistoryRestart

class AdaptiveHistoryRestart(*effective_rank_fraction=None*, *rank_tolerance=None*)

Class for constructing an adaptive history restart option for the *PulayMixer*. A restart of the mixer history is triggered when the rank of the Gram matrix of the residual vectors is lower than a given fraction of the history size.

A restart can be beneficial to mitigate error stagnation, which can be sometimes been observed in the SCF convergence. The rank of the Gram matrix is used as decision criteria, since it can be seen as a measure of quality of the previous SCF history steps in determining the next guess.

Parameters

- **effective_rank_fraction** (*float of range [0; 1]*) – A tolerance level which determines when an SCF history should be reset/restarted. In the default case, if the effective rank is 50% less than the number of history steps then restart. A value of 0 implies higher chance of restart, and a value of 1 is equivalent to selecting no restart. **Default:** `0.5`
- **rank_tolerance** (*float*) – The tolerance used to determine whether two vectors are linearly dependent. It must be non-negative. **Default:** `1e-6`

effectiveRankFraction()

Returns
The effective rank fraction.

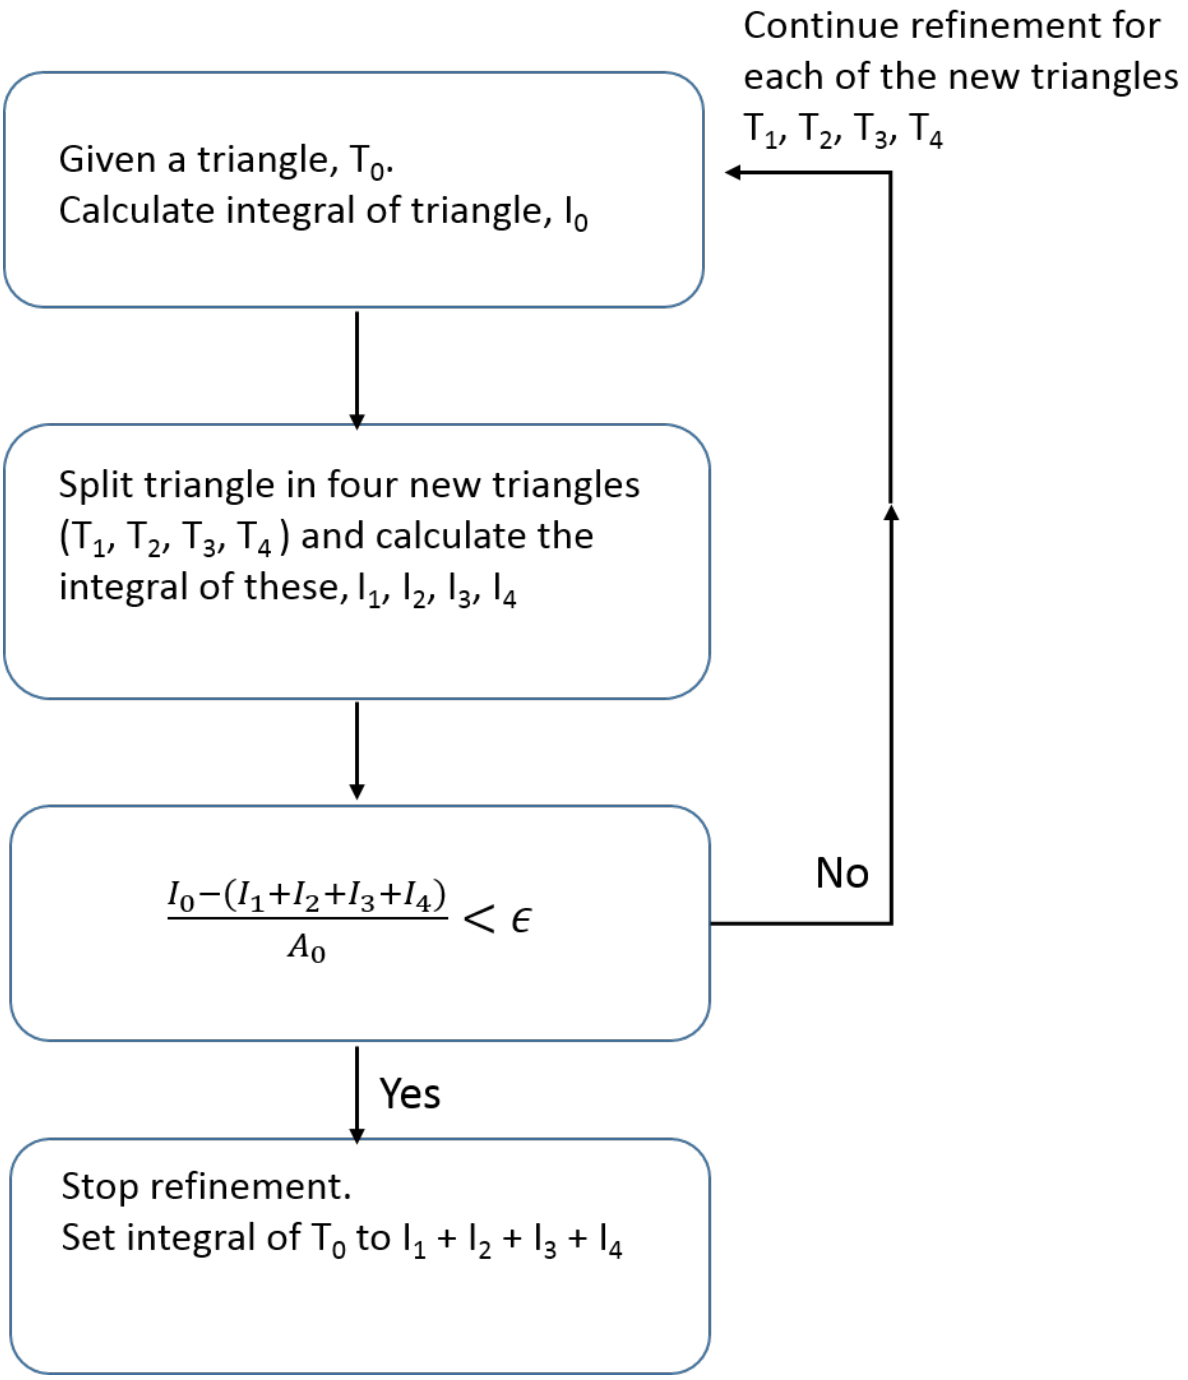

Fig. 4.5: Schematic drawing of the adaptive algorithm. If the error is larger than the tolerance, ϵ, the triangle is divided into four smaller triangles.

Return type
float

nlinfo()

Returns
The nlinfo.

Return type
dict

rankTolerance()

Returns
The rank tolerance.

Return type
float

uniqueString()

Return a unique string representing the state of the object.

AdaptiveKineticMonteCarlo

class AdaptiveKineticMonteCarlo(*markov_chain*, *kmc_temperature*, *calculator*, *kmc=None*, *superbasin_threshold=None*, *saddle_offset_magnitude=None*, *saddle_search_method=None*, *optimize_geometry_parameters=None*, *htst_parameters=None*, *confidence=None*, *filename_prefix=None*, *write_log=None*, *write_searches=None*, *write_markov_chain=None*, *write_kmc=None*)

Class for representing AdaptiveKineticMonteCarlo simulations.

Parameters

•**markov_chain** (*MarkovChain*) – The Markov chain.

•**kmc_temperature** (*PhysicalQuantity* of type temperature) – The temperature of the kinetic Monte Carlo simulation.

•**calculator** (*Calculator*) – The calculator object that should be attached to the configuration.

•**kmc** (*KineticMonteCarlo*) – Optional, existing kinetic Monte Carlo simulation, useful for resuming a calculation. **Default:** None.

•**superbasin_threshold** (*int*) – The number of steps between two states before they are merged together and treated with the coarse graining algorithm. A value of *None* disables coarse graining. **Default:** None.

•**saddle_offset_magnitude** (*SaddleSearchParameters*) – The parameters for the saddle search.

•**saddle_search_method** (*LanczosSaddleSearch* | ARTnSaddleSearch | MDSaddleSearch) –

•**optimize_geometry_parameters** (*OptimizeGeometryParameters*) –

•**htst_parameters** (*HTSTParameters*) – The parameters used when calculating the reaction rate based on harmonic transition-state-theory (HTST). By default, the prefactors will be approximated by only including atoms that move more than 0.05 Angstrom and the force constants will be calculated using a central finite difference scheme. A fixed prefactor can instead be assumed for all reactions: HTSTParameters(assumed_prefactor=1e12/Second) **Default:** None.

•**confidence** (*float*) – The confidence in the kinetic Monte Carlo rate table for each state in the simulation. This confidence is the probability that the correct kinetic Monte Carlo step was taken. The confidence should be in the range (0, 1). **Default:** 0.99.

- **filename_prefix** (*str*) – The filename prefix for saved files. **Default:** akmc.
- **write_log** (*bool*) – Whether the log that records the outcome for each search should be written. **Default:** True.
- **write_searches** (*bool*) – Whether the objects for each search (e.g. saddle point, NEB, or MD) should be written. **Default:** True.
- **write_markov_chain** (*bool*) – Whether the *MarkovChain* object should be written. **Default:** True.
- **write_kmc** (*bool*) – Whether the *KineticMonteCarlo* object should be written. **Default:** True.

kmc()

Returns
The KineticMonteCarlo object.

Return type
KineticMonteCarlo

log()

Returns
The AKMC log object.

Return type
AKMCLog

markovChain()

Returns
The Markov chain object

Return type
MarkovChain

run(*max_searches*, *max_kmc_steps=None*)

Run the adaptive kinetic Monte Carlo simulation.

Parameters

- **max_searches** (*int*) – The AKMC simulation will terminate after this many saddle searches.
- **max_kmc_steps** (*int*) – The AKMC simulation will terminate after this many kinetic Monte Carlo steps. **Default:** 10000

state()

Returns
The current state id.

Return type
int

Usage Examples

Below are two examples of modelling diffusion using AKMC. The first example models the diffusion of Hydrogen in a Copper lattice using the Lanczos saddle search method to locate new states. In the second example, two platinum atoms are diffusing on a platinum surface This example uses the MD saddle search method to locate new states.

```
# Set up the direction generator for the saddle search.
direction_generator = HypersphereDirection(
    order=Furthest,
    magnitude=(0.5*Angstrom, 1.0*Angstrom),
)

# Set up the LanczosSaddleSearch object. We are interested in the hydrogen atom, so we␣
↪set the
# index_selector to the index of the hydrogen atom.
hydrogen_index = copper.indicesFromTags(['hydrogen'])
saddle_search = LanczosSaddleSearch(
    initial_direction_generator=direction_generator,
    constraints=optimized_configuration.indicesFromTags(['constrain']),
    index_selector=hydrogen_index,
)

akmc = AdaptiveKineticMonteCarlo(
    markov_chain=markov_chain,
    kmc_temperature=300.0 * Kelvin,
    calculator=optimized_configuration.calculator(),
    kmc=kmc,
    saddle_search_method=saddle_search
)

akmc.run(max_searches=10, max_kmc_steps=1000)
```

hydrogen_diffusion_example.py

```
saddle_search = MDSaddleSearch(
    temperature=1000.0*Kelvin,
    constraints=constraints,
)

akmc = AdaptiveKineticMonteCarlo(
    markov_chain=markov_chain,
    kmc_temperature=300.0*Kelvin,
    calculator=bulk_configuration.calculator(),
    kmc=kmc,
    confidence=0.99,
    htst_parameters=htst_parameters,
    filename_prefix='akmc',
    saddle_search_method=saddle_search
)

akmc.run(max_searches=50, max_kmc_steps=10000)
```

akmc.py

Notes

In solid state systems, atoms reside near their equilibrium positions and reactions are rare events. MD simulations are typically limited to nanosecond timescale while room temperature solid-state reactions of interest may occur on the millisecond timescale or longer.

Adaptive kinetic Monte Carlo (AKMC) is a tool for simulating the dynamics of solid-state systems.[1][2] The goal to is automatically construct a kinetic Monte Carlo (KMC) simulation without prior knowledge of the reaction rates. Unlike lattice KMC, the atomic positions are not limited to lattice sites. Instead the geometries are the stable minima of the potential energy surface obtained from geometry optimization.

The reaction rates are calculated using harmonic transition state theory (HTST). See the *HTSTEvent notes* for more details. HTST calculates the reaction rate between stable states (minima) if the saddle point between them is known. Thus in AKMC the main goal (and computational expense) is to locate new stable states and the saddle points between then.

Algorithm Details

There are three different saddle search methods available. The `LanczosSaddleSearch` and `ARTnSaddleSearch` methods are based on the Lanczos and ARTn algorithms respectively. The `MDSaddleSearch` method is based on molecular dynamics simulations. The saddle search methods are used to locate saddle points on the potential energy surface (PES) between two given geometries. If no saddle point is found, a number of different exceptions can be raised, depending on why the search failed.

We recommend using the `LanczosSaddleSearch` method for most systems (which is also the default). As an alternative, the `ARTnSaddleSearch` method can be used.

Once a saddle point has been found a check is made to ensure that the saddle point is *connected* to the initial state. It is possible that the saddle point that was found does not describe a reaction for the initial minima. Two geometry optimization starting from the saddle point (displaced in the position and negative directions of the unstable direction) are performed. If one of the minima is the initial state then the saddle is *connected*. If neither minima is the starting minima then the saddle is *disconnected* and the saddle search ends.

Once a connected saddle point is located for the first time, the HTST prefactor must be calculated for the forward and reverse reactions. The prefactor can either be set to a fixed value for all reactions or it can be estimated. The prefactor calculation is controlled by the `htst_parameters` argument.

The prefactor involves calculating the dynamical matrix at both minima and the saddle point. This is a computationally expensive calculation and for many systems it is unnecessary, because there is a typical value for the prefactor that does not vary much between reactions. This value can be determined by calculating the prefactor for some reactions in the system.

When numerically calculating the prefactor, not all atoms need to be included in the dynamical matrix to get a good result. Instead, only the atoms that move significantly along the reaction pathway (and their nearest neighbors) need to be considered. The `minimium_displacement` parameter stored in the `HTSTParameters` object allows you to specify how much an atom needs to move by to be included in the dynamical matrix.

Note that there is a slight difference in the meaning of the `max_searches` argument depending on which saddle search method used. When using `MDSaddleSearch`, saddle searches are performed each KMC step until either the specified confidence has been reached, or the maximum number of searches has been performed. When using the other two saddle search methods the saddle searches are terminated when `max_searches` have been performed, since in this case there is no concept of confidence.

Parallel Saddle Searches

AKMC simulations are highly parallelizable since each saddle search is an independent calculation. Thus, many saddle searches can be run in parallel. When multiple MPI processes are used to run an AKMC calculation, QuantumATK automatically determines how many saddle searches can be run in parallel. It is important to note that one process is always used as a master that coordinates the work of the parallel saddle searches. This makes calculating the total number of MPI processes to use a little trickier than normal.

The number of saddle searches that will be run simultaneously is given by:

$$\frac{N_\mathrm{p} - 1}{N_\mathrm{s}}$$

where N_p is the total number of MPI Processes and N_s is the number of processes to use per saddle search (this is defined by the *ParallelParameters* object attached to the calculator that is being used).

Resuming Previous Calculations

The Python script that is generated by the QuantumATK Scripter supports resuming the AKMC simulation. The typical way to run the calculation would be to set the `max_searches` parameter to a value small enough that the script will finishing running in a reasonable period of time (perhaps a day or so for DFT calculators) and then re-running the script as needed to model the dynamics of interest.

When each saddle search is completed all of the files on disk are updated impenitently. This means that it is possible to monitor the progress of the simulation as it progresses.

AKMC With MDSaddleSearch and Active Learning

When running AKMC calculation with the MDSaddleSearch method, one can also utilize active learning (see *ActiveLearningSimulation*) to simulate the dynamics of solid-state systems while training MTPs. While AKMC with active learning can be utilized for different purposes, the main purpose is to populate a training set for an *ActiveLearningSimulation* object with diverse configurations encountered during AKMC molecular dynamics or optimization steps. AKMC with active learning can also be used for production runs but, for this use case, the quality of the results depends on the system at hand as well as the variance and degree of coverage of the initial active learning training set in respect to the actual system (as described by the reference calculator).

As with normal AKMC usage, the initial configuration needs to be preoptimized and have its *TotalEnergy* evaluated before starting the AKMC state searches. When passing an *ActiveLearningSimulation* object to the AKMC object, the AKMC simulation will automatically use the active learning objects methods for MD and optimization. Hence, the *calculator* input is **ignored** and will not be used during the AKMC simulation. Configurations and their associated energies are therefore evaluated via the MTP calculator as defined from the current active learning object/training set state. Here it should be noted that the AKMC simulation does **not** restart in the event that new configurations are added to the training data as is the default for other active learning applications. Instead, the AKMC simulation continues from the latest transition state search but with an updated MTP calculator.

Since the fitted MTP can change over the course of the AKMC simulation, certain pitfalls should be noted - especially if used for production runs. If the approach is mainly used for diversifying MTP training data, the implications on the quality of the AKMC output are not as severe. States found at previous cycles in the AKMC simulation and their corresponding energies might no longer be accurate according to the newer MTP version. Assuming a simulation is started with an *ActiveLearningSimulation* object that was created from a small *TrainingSet* or a training set that does not represent the initially encountered solid state dynamics well, the credibility of the early AKMC results for energies and states is limited. Nevertheless, as the simulation carries on, more and more structures will be added to the training set from other phase-space regions of the solid assuming that the given reference calculator can describe the structures with sufficient precision and level of detail. If the conditions for a such scenario is met in a production run,

it should be considered to either use a larger and more diverse initial training set, or starting a new, separate AKMC simulation using the updated MTP from the beginning. Another significant caveat is that the saddle searches cannot utilize the parallelization scheme described above. In order to ensure consistency between subsequent state transition searches, the AKMC simulation is only allowed to run saddle searches in serial mode when using active learning. In spite of these caveats, AKMC with active learning is a promising approach for speeding up simulations of solid state dynamics in complex systems.

A usage example showing how the method could be utilized is sketched in the following code snippet, where a silicon carbide supercell with an interstitial magnesium atom is modelled. A training set for the active learning object has been created beforehand. The code snippet shows how the setup deviates from a normal AKMC simulation in order to have the initial configuration have a calculator and total energy based on the MTP created from the *ActiveLearningSimulation* object.

```
# First AKMC simulation: Initial configuration setup for an AKMC simulation
# with active learning that should be started from scratch

# Set up configuration
configuration_0 = BulkConfiguration(
    bravais_lattice=lattice,
    elements=elements,
    fractional_coordinates=fractional_coordinates
    )

# Add tags - constraints needed for AKMC
configuration_0.addTags('fixed', [36, 37])

configuration_name_0 = "optimized_configuration_sic_mginterstitial"

configuration_table = Table()
configuration_table.addInstanceColumn(key='configuration', types=BulkConfiguration)
configuration_table.append(configuration_0)

configuration_names_table = Table()
configuration_names_table.addStringColumn(key='configuration_name')
configuration_names_table.append(configuration_name_0)

# %% ActiveLearningOptimizeGeometry

optimized_configuration_table = runActiveLearningOptimizeGeometry(
    active_learning_simulation=active_learning_simulation,
    configurations=configuration_table,
    max_forces=0.01 * eV / Angstrom,
    constraints=[BravaisLatticeConstraint()],
    trajectory_filename='AKMC-AL_SiC_Mg-interstitial.hdf5',
    trajectory_object_id='alopt',
    log_filename_prefix='AKMC-AL_pre-optimize_geometry',
)

nlsave(
    'AKMC-AL_SiC_Mg-interstitial.hdf5', optimized_configuration_table, object_id='alopt_1
↪'
)
```

(continues on next page)

(continued from previous page)

```
training_set_table = active_learning_simulation.trainingSetTable()

# Custom block for extraction the configuration from the table

def custom(table):
    # This custom script supports atkpython syntax
    # and can perform almost any procedure.

    configuration = table[0, 0]
    configuration.update()
    return configuration

configuration = custom(optimized_configuration_table)

nlsave('AKMC-AL_SiC_Mg-interstitial.hdf5', configuration)

# %% TotalEnergy

total_energy = TotalEnergy(configuration=configuration)
nlsave('AKMC-AL_SiC_Mg-interstitial.hdf5', total_energy)
```

After the initial setup, the AKMC simulation is scripted as usual but with an extra parameter for the active learning simulation object.

```
saddle_search_method = MDSaddleSearch(
    temperature=2900.0 * Kelvin,
    saddle_search_parameters=saddle_search_parameters,
    active_learning=active_learning_simulation,
    constraints=configuration.indicesFromTags(['fixed']),
)

akmc = AdaptiveKineticMonteCarlo(
    markov_chain=markov_chain,
    kmc_temperature=300.0 * Kelvin,
    calculator=configuration.calculator(),
    kmc=kmc,
    filename_prefix='akmc-al',
    saddle_search_method=saddle_search_method,
)

akmc.run(max_searches=50, max_kmc_steps=50)
```

The full script is available for download: `AKMC-AL_example.py`

The restarting with AKMC-AL needs to be handled with more care than for regular AKMC where a static calculator is used. Due to the (potential) updates of the MTP, there is no guarantee that one AKMC simulation script run is going to produce results that are consistent with the next run. For production runs, if many new candidates are added during a script run, it may be favorable to use the most recent *ActiveLearningSimulation* object to create a new AKMC simulation (with new Markov Chain and Kinetic Monte Carlo filenames). If the MTP on the other hand is already so

mature that it is rarely updated or if training set updates do not alter predictions significantly, the AKMC simulation can be resumed by loading the saved initial configuration and total energy objects and use them as AKMC inputs instead of preoptimizing the initial configuration and evaluating its total energy again. The restarting syntax is also outlined in the script, but is commented out and should remain so until the first submission of the script has finished running.

AdsorbedSurfaceGenerator

class AdsorbedSurfaceGenerator(*substrate=None*, *search_depth=None*, *distance=None*, *grouping_precision=None*)

A data structure for keeping track of the input needed to create an adsorbed surface.

Parameters

- **substrate** (*BulkConfiguration* | *SurfaceConfiguration*) – Optionally provide a substrate.
- **search_depth** (*PhysicalQuantity* of type length) – The depth below the surface (defined from the highest atom in the configuration) at which atoms are included in defining adsorption sites.
- **distance** (*PhysicalQuantity* of type length) – The distance above the surface at which to place the adsorption sites.
- **grouping_precision** (*float*) – The precision of grouping unique adsorption sites. Higher values result in more adsorption sites. The allowed range is [0, 2].

addAnchorAtom(*molecule_key*, *atom_index*, *site_type=None*, *site_index=<class 'NL.ComputerScienceUtilities.NLFlag._NLFlag.Random'>*)

Add an anchor atom to the molecule type referenced by molecule_key.

Parameters

- **molecule_key** (*str*) – A unique key specifying a molecule type.
- **atom_index** (*int*) – The atom index of the anchor atom.
- **site_type** (*str*) – The site type that the anchor atom should occupy.
- **site_index** (*Random | int*) – A site_index from the given site type that this anchor atom should occupy.

addMolecule(*molecule_key*, *molecule*, *site_type=None*, *distribution=<class 'NL.ComputerScienceUtilities.NLFlag._NLFlag.Random'>*, *count=0*, *occupancy=0.0*, *height=PhysicalQuantity(2.0, Ang)*, *orientation=0*, *anchor_atom_index=0*, *gridcell_repetitions=(1, 1)*, *gridcell_center=False*)

Add a molecule type to the surface.

Parameters

- **molecule_key** (*str*) – A unique key specifying a molecule type.
- **molecule** (*MoleculeConfiguration*) – A molecule to be added to the surface.
- **site_type** (*str*) – The site type that the molecules main anchor atom should occupy.
- **distribution** (*int | Random | Quasirandom | SurfaceGrid*) – The distribution for the molecule, which is also the distribution of the main anchor atom. Should be a site index for the given site_type or a flag.
- **count** (*int*) – The number of molecules of this type.
- **occupancy** (*float*) – The occupancy of this molecule type on the main_anchor_atom_site_type. The allowed range is from 0.0 (a clean surface) to 1.0 (maximum site occupation).
- **height** (*PhysicalQuantity* of type length) – The height of the molecules of this type.
- **orientation** (*ORIENTATION | ORIENTATIONS*) – The orientation for this molecule type.

•**anchor_atom_index** (*int*) – The atom index for the main anchor atom.

•**gridcell_repetitions** (*tuple of two integers*) – If distributing to SurfaceGrid, the repetitions of the grid.

•**gridcell_center** (*bool*) – If distributing to SurfaceGrid, whether to use the center of grid cells.

adsorptionSiteParameters()

Returns
The parameters used to find the current adsorption sites as a tuple of the search_depth, distance and grouping_precision, in that order.

Return type
tuple

adsorptionSiteTypes()

Returns
The names of all available adsorption site types.

Return type
tuple

changeAnchorAtom(*molecule_key*, *index*, *atom_index=None*, *site_type=None*, *site_index=None*)

Change an anchor atom in the molecule type referenced by molecule_key.

Parameters

•**molecule_key** (*str*) – A unique key specifying a molecule type.

•**index** (*int*) – The index of the anchor atom to change.

•**atom_index** (*int*) – The atom index of the anchor atom.

•**site_type** (*str*) – The site type that the anchor atom should occupy.

•**site_index** (*Random | SurfaceGrid | Quasirandom | int*) – A distribution flag or a site_index from the given site type that this anchor atom should occupy.

changeMolecule(*molecule_key*, *new_molecule_key=None*, *molecule=None*, *site_type=None*, *distribution=None*, *count=None*, *occupancy=None*, *height=None*, *orientation=None*, *anchor_atom_index=None*, *gridcell_repetitions=None*, *gridcell_center=None*)

Change a molecule type.

Parameters
molecule_key (*str*) – A unique key specifying a molecule type.

:param new_molecule_key:A new molecule key. :type new_molecule_key:str

Parameters

•**molecule** (*MoleculeConfiguration*) – The molecule being changed.

•**site_type** (*str*) – The site type that the molecules main anchor atom should occupy.

•**distribution** (*int | Random | Quasirandom | SurfaceGrid*) – The distribution for the molecule, which is also the distribution of the main anchor atom. This should be a site index for the given site_type or a flag.

•**count** (*int*) – The number of molecules of this type.

•**occupancy** (*float*) – The occupancy of this molecule type on the main_anchor_atom_site_type. Range: [0.0, 1.0].

•**height** (*PhysicalQuantity* of type length) – The height of the molecules of this type.

•**orientation** (*ORIENTATION | ORIENTATIONS*) – The orientation for this molecule type.

•**anchor_atom_index** (*int*) – The atom index for the main anchor atom.

•**gridcell_repetitions** (*tuple of two integers*) – If distributing to SurfaceGrid, the repetitions of the grid.

•**gridcell_center** (*bool*) – If distributing to SurfaceGrid, whether to use the center of grid cells.

copyMoleculeTypes(*other*, *molecule_key=None*)

Copy molecule types from another instance of AdsorbedSurfaceGenerator into this instance. If molecule_key is given, a copy of a single molecule type corresponding to the molecule_key is made, else all molecule types are copied. Note that this does not copy the site_type and distribution for any anchor atoms, as they may not match the adsorption sites in this instance, and should be set explicitly after copying.

Parameters

•**other** (AdsorbedSurfaceGenerator) – The AdsorbedSurfaceGenerator to copy from.

•**molecule_key** (*str*) – A specific molecule_key.

findAdsorptionSites(*search_depth=PhysicalQuantity(0.9, Ang)*, *distance=PhysicalQuantity(2.0, Ang)*, *grouping_precision=1.0*)

Find adsorption sites by defining a volume with the dimensions cell vector A, cell vector B and search_depth. All atoms within this volume are assumed to constitute the substrate surface and will be used to generate adsorption sites. These sites are then placed at the distance from the substrate surface specified by the distance argument.

Parameters

•**search_depth** (*PhysicalQuantity* of type length) – The depth below the surface (defined from the highest atom in the configuration) at which atoms are included in defining adsorption sites.

•**distance** (*PhysicalQuantity* of type length) – The distance above the surface at which to place the adsorption sites.

•**grouping_precision** (*float*) – The precision of grouping unique adsorption sites. Higher values result in more adsorption sites. The allowed range is [0, 2].

Returns
The adsorption sites.

Return type
dict

generateAdsorbedSurface()

Create a configuration consisting of a substrate with adsorbed molecules.

Returns
A configuration consisting of the substrate with adsorbed molecules.

Return type
BulkConfiguration

moleculeKeys()

Returns
The keys of all molecule types added.

Return type
tuple

numberOfAnchorAtoms(*molecule_key*)

Get the number of anchor atoms on the molecule type referenced by molecule_key.

Parameters
molecule_key (*str*) – The key of the molecule of interest.

Returns
The number of anchor atoms.

Return type
int

`static overlappingMolecules`(*configuration*, *tolerance=PhysicalQuantity(1.0, Ang)*)

Find overlapping molecules. The premise of this method is as follows:

1.Find all pairs of overlapping atoms. These pairs are unique and do not contain mirrored copies, i.e., only one of [0, 1] and [1, 0] will be in the list.

2.Collect molecule tags for relevant overlaps by extracting the tags for each pair of overlapping atoms.

a.Ignore any that involve the substrate.

b.Ignore tags that are were not added by AdsorbedSurfaceGenerator by using the prefix adsmol.

c.Intramolecular overlaps are false positives, so we ignore these as well. These will have the same molecular tag on both atoms.

3.By default, only take the second molecule tag in a pair of overlapping molecules, since only one of them needs to be moved to fix the overlap. If take_both=True, then both tags are taken (This is useful if we need to check if a particular molecule is overlapping any other).

Parameters

•**configuration** (BulkConfiguration) – The adsorbed surface configuration.

•**tolerance** (PhysicalQuantity of type distance) – The intermolecule distance tolerance. **Default:** 1 * Angstrom.

Returns
The set of unique tags for overlapping molecules.

Return type
list

`raiseDistributionError`(*message*)

Reset the site distribution and raise NLValueError.

Parameters
message (*str*) – The error message.

`redistributeOverlappingMolecules`(*configuration*, *tolerance=PhysicalQuantity(1.0, Ang)*)

Try to redistribute overlapping molecules to remove the overlaps.

Note! This only applies to molecules distributed with the Random distribution.

The premise of this method is as follows:

1. Find molecules that need to be moved due to atomic overlaps with other molecules. The substrate is ignored since there are better ways to avoid molecules cutting into the surface.

2. If any, then loop over the found molecules and for each of them: a. Loop over all free sites for the molecules site type b. Place the molecule and check if it overlaps anything. c. If yes, then check the next free site. d. If not, then accept the position and move on to the next molecule.

3. If all free sites were checked and none of them satisfied the distance criteria, the molecule remains at its original adsorption site. .

Parameters

•**configuration** (BulkConfiguration) – The adsorbed surface configuration.

•**tolerance** (PhysicalQuantity of type distance) – The intermolecule distance tolerance. **Default:** 1 * Angstrom.

Returns
The adjusted configuration.

Return type
BulkConfiguration

removeAnchorAtom(*molecule_key*, *index*)

Remove an anchor atom in the molecule given by molecule_key.

Parameters

•**molecule_key** (*str*) – A unique key specifying a molecule type.

•**index** (*int*) – The index of the anchor atom to remove.

removeMolecule(*molecule_key*, *redistribute=False*)

Remove a molecule type.

Parameters
molecule_key (*str*) – A unique key specifying a molecule type.

setSubstrate(*substrate*)

Set a substrate if the current substrate is None. SurfaceConfigurations will be converted into BulkConfiguration. If the given configuration has insufficient vacuum at its surface, vacuum will be added such that the total amount of vacuum becomes 10 Angstrom.

Parameters
substrate (*BulkConfiguration* | *SurfaceConfiguration*) – The substrate.

substrate()

Returns
The configuration used as the substrate, which is a surface slab with vacuum.

Return type
BulkConfiguration

Usage Examples

Example 1. Adsorb water molecules onto the ontop sites of a Pt(100) surface at 50% coverage, anchored by their oxygen atoms and oriented vertically.

```
from example_configurations import substrate, water

# ------------------------------------------------------------
# Create surface with adsorbed molecules.
# ------------------------------------------------------------
# Instantiate the AdsorbedSurfaceGenerator with the substrate and find adsorption sites.
generator = AdsorbedSurfaceGenerator(
    substrate=substrate,
    search_depth=0.9 * Angstrom,
    distance=1.0 * Angstrom,
    grouping_precision=1.0
)

# Add molecules.
```

(continues on next page)

(continued from previous page)

```
generator.addMolecule(
    molecule_key='Water',
    molecule=water,
    count=9,
    orientation=ORIENTATIONS.VERTICAL,
    anchor_atom_index=1,
    site_type='ontop_Platinum',
    distribution=Random
)

# Generate a configuration with the molecules adsorbed to the substrate surface.
configuration = generator.generateAdsorbedSurface()
```

adsorbed_surface_example1.py example_configurations.py

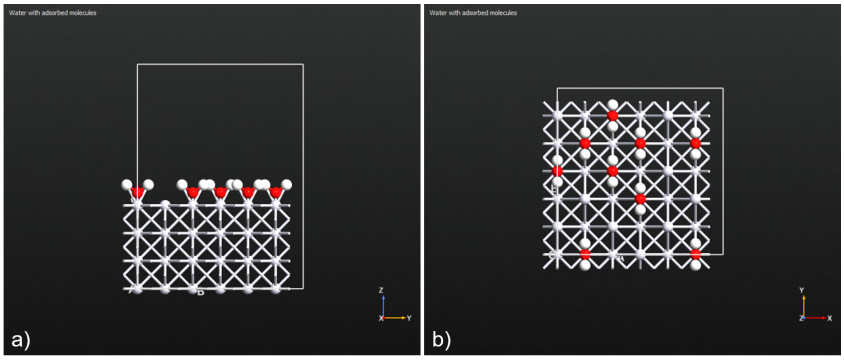

Fig. 4.6: Resulting configuration from Example 1. a) Side view. b) Top view.

Example 2. Adsorb water molecules onto the ontop sites of a Pt(100) surface at 50% coverage, anchored by both of their hydrogen atoms and oriented with the second anchor atom on bridge sites.

```

↪with the molecules␣
↪adsorbed to the␣
↪substrate surface.
configuration = generator.
↪generateAdsorbedSurface()
```

`adsorbed_surface_example2.py` `example_configurations.py`

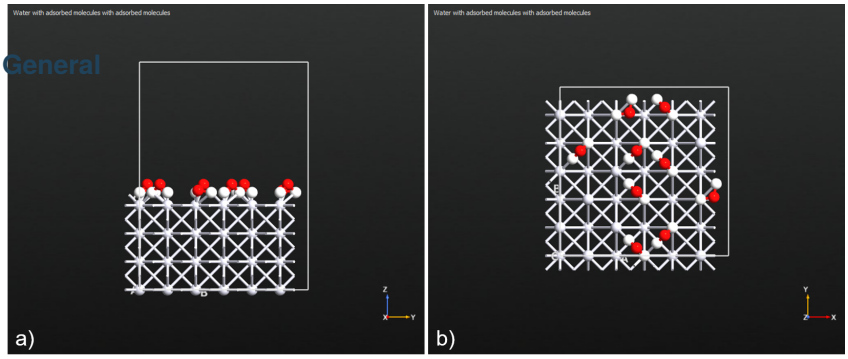

Fig. 4.7: Resulting configuration from Example 2. a) Side view. b) Top view.

The *AdsorbedSurfaceGenerator* class is designed to collect the necessary components for creating a surface with adsorbed molecules, as well as to modify these components and generate the final configuration. The basic steps of using the class are:

1. Add a substrate.
2. Calculate adsorption sites for the substrate.
3. Add molecule types and define how they should be distributed onto the substrate.
4. Optionally add additional anchor atoms.
5. Call `generateAdsorbedSurface` to create the final configuration.

The class can be instantiated with a substrate configuration and parameters for finding adsorption sites as optional input arguments. This allows for a quick start-up by setting the substrate and calculating the adsorption sites in one go.

Substrate and adsorption sites

The substrate can be set using the `setSubstrate` method. Note that each instance of *AdsorbedSurfaceGenerator* can only set a substrate once. This is to avoid a mismatch between the substrate and adsorption sites, as well as the substrate and anchor atom site types and distributions. If a new substrate should be used, a new instance of *AdsorbedSurfaceGenerator* needs to be created. If the same molecules are to be used on the new substrate, use the `copyMoleculeTypes` method to copy any molecule types from the old instance to the new instance, i.e.

```
new_instance.copyMoleculeTypes(old_instance)
```

to copy all molecule types or

```
new_instance.copyMoleculeTypes(old_instance, 'water')
```

to copy only the molecule type water.

Note that this method does not copy the site_type or distribution from any anchor atoms, so these must be set in the new instance after copying to ensure that they match the new substrate and its adsorption sites. Similarly, if the parameters used to calculate adsorption sites in the old instance can be used again in the new instance, these can be retrieved using the `adsorptionSiteParameters` method, i.e.

```
new_instance.findAdsorptionSites(*old_instance.adsorptionSiteParameters())
```

Adsorption sites can be found using the `findAdsorptionSites` method. A list of basic adsorption site types can be found in **Table 1**.

The volume defined by the search_depth parameter should not contain atoms that are repeated in multiple layers, i.e. atoms should not have the same in-plane coordinates in multiple layers. Otherwise, undesired adsorption sites may be generated inside the substrate. See the figure below for clarification. The option to set the search_depth to an arbitrary value within the substrate thickness is useful for more complex crystal structures where adsorption sites are not all at the same height above the surface. This is especially useful for amorphous substrates, in which the surface volume is arbitrarily defined.

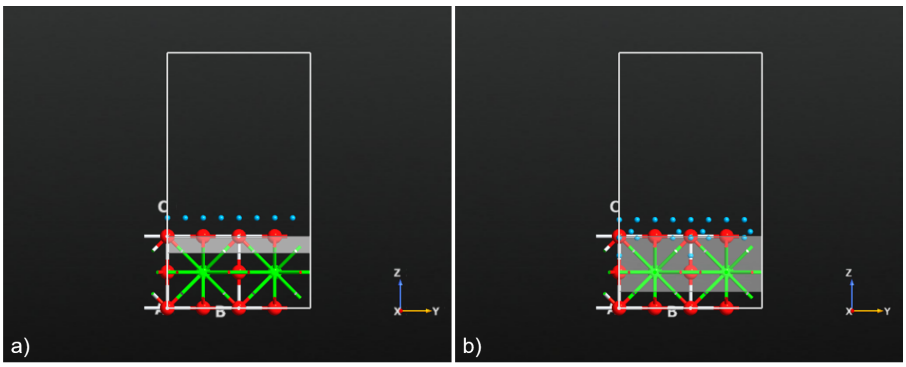

Fig. 4.8: Examples of the volume defined by surface_depth, a) with and b) without repeating atoms in multiple layers. In b), some of the red atoms are repeated in all three layers. Since the volume includes both the first and second layers, adsorption sites can be seen between these layers, inside the substrate.

The grouping_precision parameter can be used to further sort the basic adsorption site types by unique local environments. For instance, the short and long bridge sites on an elemental crystal FCC(110) surface can be sorted into bridge_0 and bridge_1. Similarly, for multi-element substrates, bridge sites between unique pairs of elements can also be sorted into bridge_0, bridge_1, etc.

Table 1. Basic adsorption site types. Additional sorting among each basic site type may be indicated by a trailing underscore and integer.

Site type	Description
on-top_el-ement	A surface site that is 1-fold coordinated. *element* is the name of the element that the site is on top of, e.g., ontop_Oxygen.
bridge	A surface site that is 2-fold coordinated.
hol-low_3fol	A surface site that is 3-fold coordinated.
hol-low_4fol	A surface site that is 4-fold coordinated. Requires at least two layers of atoms in the substrate, otherwise these are labeled as bridge sites.
hcp	A 3-fold coordinated site that corresponds to hexagonal-close-packed stacking. Requires at least three layers of atoms in the substrate to be identified, otherwise these are labeled as hollow_3fold sites.
fcc	A 3-fold coordinated site that corresponds to face-centered-cubic stacking. Requires at least three layers of atoms in the substrate to be identified, otherwise these are labeled as hollow_3fold sites.

Molecules and alignment

Molecule types can be added, modified and removed using the `addMolecule`, `changeMolecule` and `removeMolecule` methods, respectively.

Each molecule type will have one anchor atom by default, which cannot be removed. It is used to define how a molecule type should be distributed onto the substrate surface. Each anchor atom specifies the index of an atom in the molecule, the site type that that atom (equivalently, the molecule type) should occupy and how the molecule should be distributed on these sites.

- For a single molecule (i.e. `count=1`), the distribution may be `Random` or a specific site.
- For multiple molecules, the distribution options are `Random` or `Quasirandom`.
- The `Quasirandom` distribution will attempt to space out the molecules among the sites, and approaches a uniform distribution for sufficiently large numbers of molecules.

The number of molecules of each molecule type can be set either as a coverage or a count. The coverage is calculated in terms of the number of sites that should be occupied for the chosen site type. If both count and coverage are given, the coverage will be used.

The molecule orientation can be given as an option from `ORIENTATIONS`; the available options are summarize in **Table 2**. The orientation can also be given as a set of custom rotation angles, by using the named tuple for which descriptions of the different angles are given in **Table 3**. Example:

```
ORIENTATION(surface_rotation_angle, surface_tilt_angle, molecule_rotation_angle)
```

If `ORIENTATIONS.ANCHORED` is used, it is expected that more than one anchor atom has been added. Additional anchor atoms can be added, modified and removed using the `addAnchorAtom`, `changeAnchorAtom` and `removeAnchorAtom` methods, respectively. If, however, additional anchor atoms have not been given but the orientation is set to `ORIENTATIONS.ANCHORED`, the generator will use the `ORIENTATIONS.VERTICAL` orientation. For additional anchor atoms beyond the first, the site type and distribution of each anchor atom should be set.

- Similar to the first anchor atom, the distribution of additional anchor atoms can be set to a specific site of the chosen site type for a single molecule.
- For both single and multiple molecules, the distribution of additional anchor atoms can also be set to `Random`. In this case, this means the generator will find the site of the chosen site type that comes closest to the that anchor atom.

The same type of molecule can be added more than once. This can be useful when more precise control of the placement of each molecule of a single type is needed. To achieve this, add each molecule with a count of one and distribute it to a specific site type and site.

Table 2. Orientation options.

Orientation	Description
ORIENTATI(VERTICAL	Orient the molecule such that it appears to stand vertically on the substrate. This is the default orientation and corresponds to when all rotation angles are equal to zero. Often, this orientation also coincides with the ORIENTAITONS.ALIGN_I3 orientation.
ORIENTATI(FLAT	Orient the molecule such that it appears to lay flat on the substrate. This corresponds to setting the tilt angle to 90 degrees.
ORIENTATI(ALIGN_I1	Orient the molecule such that the first (smallest) principle moment axis of inertia is aligned to the substrate surface normal.
ORIENTATI(ALIGN_I2	Orient the molecule such that the second principle moment axis of inertia is aligned to the substrate surface normal.
ORIENTATI(ALIGN_I3	Orient the molecule such that the third (largest) principle moment axis of inertia is aligned to the substrate surface normal.
ORIENTATI(ANCHORED	Orient the molecule by designating multiple anchor atoms.

Table 3. Custom orientation angles. All angles are given in degrees.

Angle	Range	Description
surface_rotation_	0 - 360	The angle of the molecule around the substrate surface normal.
surface_tilt_angl	-90 - +90	The angle of the molecule towards the substrate surface, in the direction or the surface_rotation_angle.
molecule_rotation_	0 - 360	The angle of the molecule around the axis defined by the surface_rotation_angle and surface_tilt_angle.

AlgorithmParameters

class AlgorithmParameters(*density_predictor=None*, *density_matrix_method=None*, *store_grids=None*, *store_basis_on_grid=None*, *store_energy_density_matrix=None*, *scf_restart_step_length=None*, *use_symmetries=None*, *reciprocal_space_paw_quantities=None*)

Class for representing the parameters for setting solver parameters.

Some parameter defaults are specific for each calculator, see *HuckelCalculator*, *SlaterKosterCalculator*, *LCAOCalculator*, or *PlaneWaveCalculator*.

Parameters

- **density_predictor** (DensityPredictor | False) – The parameters for the density predictor to be used for the initial guess for density in a DFT calculation. This option is currently only used for LCAOCalculator. **Default:** False
- **density_matrix_method** (*DiagonalizationSolver* | *FeastSolver* | *ChebyshevExpansionSolver* | *PEXSISolver* | PlaneWaveResidualMinimizer | *GeneralizedDavidsonSolver* | *PPCGSolver*) – The method used for obtaining the density matrix. **Default:** *PPCGSolver* for *PlaneWaveCalculator*. *DiagonalizationSolver* for the other calculators.

- **store_grids** (*bool*) – Enable or disable the storage of grids that can be reused in the SCF process. True will increase the memory usage, but reduce the computation time. **Default:** `True`
- **store_basis_on_grid** (`Automatic` | `True` | `False`) – Control the storage of the basis functions on a real space grid. When enabled, increases the memory usage but reduces the computation time. **Default:** `Automatic`
- **store_energy_density_matrix** (bool | `Automatic`) – Enable or disable the computation and storage of the energy density matrix while the density matrix is calculated. When enabled, can slow down the SCF loop but speeds up subsequent evaluations of forces and/or stress. **Default:** Disabled unless forces and/or stress will be evaluated immediately after the self-consistent calculation (`Automatic`).
- **scf_restart_step_length** (*PhysicalQuantity* of type length) – The maximum distance by which an atom can move so that the calculation can be restarted from the previous initial state. **Default:** `0.1 * Ang`
- **use_symmetries** (`Automatic` | `True` | `False`) – Whether the symmetries of the configuration should be used to reduce the number of k-points. If set to `Automatic` the symmetries are disabled for a single k-point and enabled for multiple k-points. **Default:** `True`
- **reciprocal_space_paw_quantities** (*bool*) – If this flag is set to true, the paw quantities will be calculated in reciprocal space, this can only be done when we use periodic boundary conditions. **Default:** `True`

densityMatrixMethod()

Returns
The advanced solver.

Return type
DiagonalizationSolver | *FeastSolver* | *ChebyshevExpansionSolver* | *PEXSISolver* | PlaneWaveResidualMinimizer | *GeneralizedDavidsonSolver* | *PPCGSolver*

densityPredictor()

Returns
The density predictor.

Return type
DensityPredictor | False

nlinfo()

Returns
The nlinfo.

Return type
dict

static noSCFDensityMatrixMethod()

Returns
The solver to use for LCAO when no SCF iterations are done.

Return type
DiagonalizationSolver

scfRestartStepLength()

Returns
The SCF restart step length of this calculator.

Return type
PhysicalQuantity of type length

storeBasisOnGrid()

Returns
True if the storage of the basis functions on a real space grids is enabled

Return type
bool

storeEnergyDensityMatrix()

Returns
True if the simultaneous computation and storage of the energy density matrix during the calculation of the density matrix is enabled.

Return type
bool | Automatic

storeGrids()

Returns
True if the storage of grids is enabled

Return type
bool

uniqueString()

Return a unique string representing the state of the object.

useSymmetries()

Returns
Whether the symmetries of the configuration should be used to reduce the number of k-points.

Return type
bool

Usage Examples

Setup a calculation that uses the Diagonalization Solver.

```
density_matrix_method = DiagonalizationSolver()
algorithm_parameters = AlgorithmParameters(density_matrix_method)
calculator = LCAOCalculator(algorithm_parameters=algorithm_parameters)
```

Setup a calculation that uses the Feast Solver.

```
density_matrix_method = FeastSolver(lambda_min=-10*Hartree, lambda_max=10*Hartree,␣
↪number_of_eigenvalues=10)
algorithm_parameters = AlgorithmParameters(density_matrix_method)
calculator = LCAOCalculator(algorithm_parameters=algorithm_parameters)
```

AllElectronDensity

class AllElectronDensity(*configuration*, *grid_sampling=None*)

A class for calculating the all electron density for a configuration.

Parameters

- **configuration** (*BulkConfiguration*.) – The configuration for which the density should be calculated.
- **grid_sampling** (*PhysicalQuantity* of type energy | *GridSampling* | *OptimizedFFTGridSampling*) – The density grid sampling. The sampling must be a positive energy or a *GridSampling* object. **Default:** Specific for each calculator.

absolute()

Returns
A new grid containing the absolute values (or modulus) of the current field.

Return type
GridValues

axisProjection(*projection_type='sum'*, *axis='c'*, *spin=None*, *projection_point=None*, *coordinate_type=<class 'NL.ComputerScienceUtilities.NLFlag._NLFlag.Fractional'>*)

Get the values projected on one of the grid axes.

Parameters

- **projection_type** (*str*) –

The type of projection to perform. Should be either

– sum for the sum over the plane spanned by the two other axes.

– average or avg for the average value over the plane spanned by the two other axes.

– line for the value along a line parallel to the axis and through a point specified by the *projection_point* parameter.

Default: sum

- **axis** (*str*) – The axis to project the data onto. Should be either a, b or c. **Default:** c
- **spin** (Spin.Sum | Spin.Z | Spin.X | Spin.Y | Spin.Up | Spin.Down | Spin.RealUpDown | Spin.ImagUpDown) – Which spin component to project on. **Default:** Spin.All
- **projection_point** (sequence, PhysicalQuantity) – Axis coordinates of the point through which to take a line if projection_type is projection_point. Must be given as a sequence of three coordinates *[a, b, c]*. It the numbers have units of length, they are first divided by the length of the respective primitive vectors [A, B, C], and then interpreted as fractional coordinates. Unitless coordinates are immidiately interpreted as fractional.
- **coordinate_type** (Fractional | Cartesian) – Flag to toggle if the returned axis values should be given in units of Angstrom (NLFlag.Cartesian) or in units of the norm of the axis primitive vector (NLFlag.Fractional). **Default:** Fractional

Returns
A 2-tuple of 1D numpy.arrays containing the axis values and the projected data. For Cartesian coordinate type the grid offset is added to the axis values.

Return type
tuple.

classmethod defaultDensityMeshCutoff(*max_atomic_number*)

The default density mesh cutoff.

These cutoffs have been obtained by performing calculations on bulk systems like He, Li, Be, C, O, N, O, F, Ne, .. and integrating the all eletron density to give the integrated number of electrons.

The cutoff is the cutoff that gives an error in the integrated number of electron below 0.01

Parameters
max_atomic_number (*int*) – The maximum atomic number.

Returns
The default density mesh cutoff.

Return type
PhysicalQuantity of type energy

derivatives(*x*, *y*, *z*, *spin=None*)

Calculate the derivative in the point (x, y, z).

Parameters

- **x** (*PhysicalQuantity* with type length) – The Cartesian x coordinate.
- **y** (*PhysicalQuantity* with type length) – The Cartesian y coordinate.
- **z** (*PhysicalQuantity* with type length) – The Cartesian z coordinate.
- **spin** (`Spin.All` | `Spin.Sum` | `Spin.Up` | `Spin.Down` | `Spin.X` | `Spin.Y` | `Spin.Z`) – The spin component to project on. **Default:** `Spin.All`

Returns
The gradient at the specified point for the given spin. For `Spin.All`, a tuple with (`Spin.Sum`, `Spin.X`, `Spin.Y`, `Spin.Z`) components is returned.

Return type
PhysicalQuantity of type length^{-4}

downsample(*downsampling_a=None*, *downsampling_b=None*, *downsampling_c=None*)

Generate a new GridValues object where the grid is downsampled. Along periodic directions an FFT downsampling is performed. Along non-periodic directions antialiasing and downsampling is performed.

Parameters

- **downsampling_a** (*int*) – The new number of grid points along the A direction. **Default:** No downsampling.
- **downsampling_b** (*int*) – The new number of grid points along the B direction. **Default:** No downsampling.
- **downsampling_c** (*int*) – The new number of grid points along the C direction. **Default:** No downsampling.

evaluate(*x*, *y*, *z*, *spin=None*)

Evaluate in the point (x, y, z).

Parameters

- **x** (*PhysicalQuantity* with type length) – The Cartesian x coordinate.
- **y** (*PhysicalQuantity* with type length) – The Cartesian y coordinate.
- **z** (*PhysicalQuantity* with type length) – The Cartesian z coordinate.
- **spin** (`Spin.All` | `Spin.Sum` | `Spin.Up` | `Spin.Down` | `Spin.X` | `Spin.Y` | `Spin.Z`) – The spin component to project on. **Default:** `Spin.All`

Returns
The value at the specified point for the given spin. For `Spin.All`, a tuple with (`Spin.Sum`, `Spin.X`, `Spin.Y`, `Spin.Z`) components is returned.

Return type
PhysicalQuantity of type length^{-3}

`gridCoordinate`(*i*, *j*, *k*)

Return the coordinate for a given grid index.

Parameters

- **i** (*int*) – The grid index in the A direction.
- **j** (*int*) – The grid index in the B direction.
- **k** (*int*) – The grid index in the C direction.

Returns
The Cartesian coordinate of the given grid index.

Return type
PhysicalQuantity of type length.

`metatext`()

Returns
The metatext of the object or None if no metatext is present.

Return type
str | None

`nlprint`(*stream=None*)

Print a string containing an ASCII table useful for plotting the AnalysisSpin object.

Parameters
stream (*python stream*) – The stream the table should be written to. **Default:** `NLPrintLogger()`

`primitiveVectors`()

Returns
The primitive vectors of the grid.

Return type
PhysicalQuantity of type length.

`scale`(*scale*)

Scale the field with a float.

Parameters
scale (*float*) – The parameter to scale with.

`setMetatext`(*metatext*)

Set a given metatext string on the object.

Parameters
metatext (*str | None*) – The metatext string that should be set. A value of None can be given to remove the current metatext.

`shape`()

Returns
The number of grid points in each direction.

Return type
tuple of three int.

spin()

Returns
The spin the electron density is calculated for, always `Spin.All`.

Return type
`Spin.All`

spinProjection(*spin=None*)

Construct a new *GridValues* object with the values of this object projected on a given spin component.

Parameters
spin (`Spin.All` | `Spin.Sum` | `Spin.X` | `Spin.Y` | `Spin.Z`) – The spin component to project on. **Default:** `Spin.All`

Returns
A new *GridValues* object for the specified spin.

Return type
GridValues

classmethod supportedAtomicNumber(*atomic_number*)

Return true, if the atomic number is supported.

Atomic numbers larger than 20 is not supported because the accumulation of electron density near the atomic position can not easily be described with a cartesian grid.

Parameters
atomic_number (*int*) – The maximum atomic number.

Returns
True, then atomic number supported.

Return type
bool

toArray()

Returns
The values of the grid as a numpy array slicing off any units.

Return type
numpy.array

uniqueString()

Return a unique string representing the state of the object.

unit()

Returns
The unit of the data in the grid.

Return type
A physical unit.

unitCell()

Returns
The unit cell of the grid.

Return type
PhysicalQuantity of type length.

volumeElement()

Returns
The volume element of the grid represented by three vectors.

Return type
PhysicalQuantity of type length.

Usage Examples

Calculate the all-electron density and save it to a file:

```
# -*- coding: utf-8 -*-
# ------------------------------------------------------------
# Bulk Configuration
# ------------------------------------------------------------

# Set up lattice
lattice = FaceCenteredCubic(4.348*Angstrom)

# Define elements
elements = [Silicon, Carbon]

# Define coordinates
fractional_coordinates = [[ 0.  ,  0.  ,  0.  ],
                          [ 0.25,  0.25,  0.25]]

# Set up configuration
bulk_configuration = BulkConfiguration(
    bravais_lattice=lattice,
    elements=elements,
    fractional_coordinates=fractional_coordinates
    )

    number_of_history_steps=5,
    )

calculator = PlaneWaveCalculator(
    basis_set=basis_set,
    numerical_accuracy_parameters=numerical_accuracy_parameters,
    iteration_control_parameters=iteration_control_parameters,
    )

bulk_configuration.setCalculator(calculator)
nlprint(bulk_configuration)
bulk_configuration.update()
nlsave('SiC_all_electron_density.hdf5', bulk_configuration)

# ------------------------------------------------------------
# All Electron Density
# ------------------------------------------------------------
all_electron_density = AllElectronDensity(
    configuration=bulk_configuration,
    grid_sampling=5000*Hartree,
    )
nlsave('SiC_all_electron_density.hdf5', all_electron_density)
```

SiC_all_electron_density.py

Notes

•This class inherits from the *GridValues* class.

•Returns the all-electron density $n_{ae}(\mathbf{r})$

AlloyConfiguration

class AlloyConfiguration(*bravais_lattice*, *sites*, *cartesian_coordinates=None*, *fractional_coordinates=None*)

The Cartesian coordinates and fractional coordinates cannot be given at the same time. The list arguments containing the sites and coordinates must have the same length.

Parameters

•**bravais_lattice** (BravaisLattice) – A lattice of the bulk configuration.

•**sites** (list of type *AlloySite*) – A sequence containing the site information of the alloy.

•**cartesian_coordinates** (*PhysicalQuantity* of type length | None) – A sequence containing a sequence of atomic coordinates for each site in the configuration. Has the dimensionality nx3. **Default:** None

•**fractional_coordinates** (*array(n, 3) | None*) – A sequence containing sequences of fractional coordinates for each site in the configuration. **Default:** None

bravaisLattice()

Returns
The Bravais lattice

Return type
BravaisLattice

cartesianCoordinates()

Returns
The Cartesian coordinates of the sites.

Return type
PhysicalQuantity of type length

fractionalCoordinates()

Returns
The fractional coordinates of the bulk configuration as a nx3 array.

Return type
array of floats

repeat(*na=1*, *nb=1*, *nc=1*)
Repeat the AlloyConfiguration with the integer values na, nb, and nc along the three primitive unit cell vectors.

Parameters

- **na** (*int*) – The repetition along the a-axis. **Default:** 1
- **nb** (*int*) – The repetition along the b-axis. **Default:** 1
- **nc** (*int*) – The repetition along the c-axis. **Default:** 1

Returns
The repeated bulk system.

Return type
AlloyConfiguration

sample(*rng=None*)
Returns a random realization of the alloy as a bulk configuration.

Parameters
rng (*numpy.random.RandomState | None*) – The random number generator to use. If None then the global rng is used.

Returns
A BulkConfiguration with the elements randomly sampled from the AlloySite specifications.

Return type
BulkConfiguration

sites()

Returns
The list of all sites.

Return type
list of type AlloySite

uniqueSites()

Returns
A list of the unique sites.

Return type
list of type AlloySite

uniqueString()

Return a unique string representing the state of the object.

Usage Examples

Define an alloy configuration for a 64 atom InGaAs:sub:2 alloy. The sites containing As will not be optimized.

```
# Set up lattice
vector_a = [11.3074, 0.0, 0.0]*Angstrom
vector_b = [0.0, 11.3074, 0.0]*Angstrom
vector_c = [0.0, 0.0, 11.3074]*Angstrom
lattice = UnitCell(vector_a, vector_b, vector_c)

# Define site types
# Site type with fixed occupancy, sites of these type will NOT be optimized.
site_a = AlloySite(Arsenic=1.0)

# Site type with fractional occupancy, site of these type will be optimized.
site_b = AlloySite(Gallium=0.5, Indium=0.5)

# Define sites
sites = [
    site_b, site_b, site_b, site_b, site_b, site_b, site_b, site_b,
    site_a, site_a, site_a, site_a, site_a, site_a, site_a, site_a,
    site_b, site_b, site_b, site_b, site_b, site_b, site_b, site_b,
    site_a, site_a, site_a, site_a, site_a, site_a, site_a, site_a,
    site_b, site_b, site_b, site_b, site_b, site_b, site_b, site_b,
    site_a, site_a, site_a, site_a, site_a, site_a, site_a, site_a,
    site_b, site_b, site_b, site_b, site_b, site_b, site_b, site_b,
    site_a, site_a, site_a, site_a, site_a, site_a, site_a, site_a,
]

# Define coordinates
cartesian_coordinates = [[ 0.      ,  0.      ,  0.      ],
                         [ 0.      ,  0.      ,  5.6537  ],
                         [ 0.      ,  5.6537  ,  0.      ],
                         [ 0.      ,  5.6537  ,  5.6537  ],
                         [ 5.6537  ,  0.      ,  0.      ],
                         [ 5.6537  ,  0.      ,  5.6537  ],
                         [ 5.6537  ,  5.6537  ,  0.      ],
                         [ 5.6537  ,  5.6537  ,  5.6537  ],
                         [ 1.413425,  1.413425,  1.413425],
                         [ 1.413425,  1.413425,  7.067125],
                         [ 1.413425,  7.067125,  1.413425],
                         [ 1.413425,  7.067125,  7.067125],
```

# Set up configuration
alloy_configuration = AlloyConfiguration(
    bravais_lattice=lattice,
    sites=sites,
    cartesian_coordinates=cartesian_coordinates,
)
```

ingaas_alloy.py

Notes

This configuration type can be used with *EvolutionarySQS* to generate an optimized random alloy, based on the special quasi-random structure (SQS) method[1]. To set up an alloy configuration, you need to specify the Bravais lattice and either the fractional or Cartesian coordinates. This is similar to constructing a *BulkConfiguration*, however, instead of the list of elements, you need to give a list of *AlloySite* objects.

If a lattice site has an *AlloySite* containing only one element with an occupancy of 1, the element will remain fixed during the SQS optimization, whereas for *AlloySite* objects with fractional occupancies (i.e. more than one element and occupancies < 1) the occupation of this site will be optimized according the element ratio specified in the *AlloySite* object. Currently only a single type of alloy site with fractional occupancies is supported and an alloy site can only have binary composition, i.e. at maximum be composed of two elements, or one element and one vacancy.

Note that *AlloyConfiguration* cannot be used in actual calculations. Instead, the *BulkConfiguration* produced by *EvolutionarySQS* should be used.

AlloySite

class AlloySite(***site_info*)

Represents a type of site in an alloy. It is an equivalent to the role PeriodicTableElement plays in configurations.

Parameters
site_info (*dict*) – A dictionary that maps element symbols or name strings to fractional occupancies.

elements()

Returns
The elements that belongs to this site.

Return type
list of type PeriodicTableElement | *Vacancy*

fractionalOccupancy(*element*)

Parameters
element (PeriodicTableElement | Vacancy) – The element to find the fractional occupancy of.

Returns
The fractional occupation for a given element.

Return type
float

[1] A.ăvanăde Walle, P.ăTiwary, M.ădeăJong, D.L. Olmsted, M.ăAsta, A.ăDick, D.ăShin, Y.ăWang, L.-Q. Chen, and Z.-K. Liu. Efficient stochastic generation of special quasirandom structures. *Calphad*, 42:13–18, 2013. URL: http://www.sciencedirect.com/science/article/pii/S0364591613000540.

rgbColor()

Returns
The average color of the elements (equal weighting).

Type
numpy array

sample(*num_atoms*, *rng=None*)

For a given total number of atoms return a random permutation of the elements in this site.

Parameters

- **num_atoms** (*int*) – The total number of elements that will be returned.
- **rng** (*numpy.random.RandomState | None*) – The random number generator to use. If None then the global rng is used.

Returns
A randomly permuted list of elements of length num_atoms.

Return type
list of type PeriodicTableElement | *Vacancy*

uniqueString()

Return a unique string representing the state of the object.

Usage Examples

Define an alloy sites with a single element, two elements with fractional occupancies, and an element and a vacancy.

```
# Site type with fixed occupancy, sites of these type will NOT be optimized
# in EvolutionarySQS.
site_a = AlloySite(Arsenic=1.0)

# Site type with fractional occupancy, site of these type will be optimized
# in EvolutionarySQS.
site_b = AlloySite(Gallium=0.5, Indium=0.5)

# Site type with an element and a vacancy.
site_c = AlloySite(Silicon=0.8, Vacancy=0.2)
```

alloy_site.py

Notes

AlloySite types can be used instead of elements to specify sites with fractional occupancies in alloys. These sites can be passed to an *AlloyConfiguration* which can be used in *EvolutionarySQS* to generate an optimized random alloy, based on the special quasi-random structure (SQS) method[1].

The occupancies of an alloy site are specified by passing the element names as an argument names and the fractional occupancies as argument values to the constructor of the *AlloySite* object. In addition to elements, vacancies can be given to the constructor, as well, using `Vacancy` as argument name.

[1] A.ăvanăde Walle, P.ăTiwary, M.ădeăJong, D.L. Olmsted, M.ăAsta, A.ăDick, D.ăShin, Y.ăWang, L.-Q. Chen, and Z.-K. Liu. Efficient stochastic generation of special quasirandom structures. *Calphad*, 42:13–18, 2013. URL: http://www.sciencedirect.com/science/article/pii/S0364591613000540.

If a lattice site has an *AlloySite* containing only one element with an occupancy of 1, the element will remain fixed during the SQS optimization, whereas for *AlloySite* objects with fractional occupancies (i.e. more than one elements and occupancies < 1) this occupation of this site will be optimized according the element ratio specified in the *AlloySite* object. Currently only a single type of alloy site with fractional is supported and an alloy site can only have binary composition, i.e. at maximum be composed of two elements, or one element and one vacancy.

AlloyTrainingParameters

class AlloyTrainingParameters(*reference_configurations*, *percentages=None*, *new_element=<class 'NL.CommonConcepts.PeriodicTable.Hydrogen'>*, *algorithm=None*, *supercell_repetition=None*, *rattle=None*, *atomic_rattling_amplitudes=None*, *sample_size=None*, *random_seed=None*, *optimize=None*, *optimize_geometry_parameters=None*, *log_filename_prefix=None*, *data_tag=None*)

Class for storing parameters for generating a set of alloy training configurations.

Parameters

- **reference_configurations** (*BulkConfiguration* | sequence of [*BulkConfiguration*]) – One or more bulk reference configurations to be used to generate the training set. This is the unit cell from which a supercell can be defined and additional strain can be applied.
- **percentages** (*float or sequence of floats*) – The percentages the atoms that should be substituted. **Default:** 25.
- **new_element** (*PeriodicTableElement* or None (vacancy)) – The element to change to. **Default:** *Hydrogen*.
- **algorithm** (*FixedFraction | NormalDistribution | None*) – The algorithm to randomly change a percentage of the atoms. NormalDistribution means you assign a number [0,1] from a normal distribution across all atoms and only pick those that have a value below the given percentage. FixedFraction means if you set 25%, you get 25% of the total number of atoms changed. The size of the random sample are the percentage of atoms provided, rounded to nearest integer. **Default:** FixedFraction.
- **supercell_repetition** (*sequence (size 3) of int*) – The supercell to construct for each configuration, given as the number of repetitions of the bulk unit cell along the (a, b, c) directions.
- **rattle** (*bool*) – Switch to turn on rattling of the cell to generate more configurations. **Default:** False.
- **atomic_rattling_amplitudes** (sequence (size 3) of *PhysicalQuantity* of type length) – List of three random displacements (small, medium, large) of the atomic positions. **Default:** `[0.15, 0.275, 0.4] * Angstrom`.
- **sample_size** (*int*) – The number of training configurations to generate. The actual number of returned samples can differ slightly due to rounding. When rattle is not set, the returned number of samples will likely be smaller since duplicates are removed. **Default:** 200.
- **random_seed** (*int*) – The random seed used for generating the displacements. **Default:** Generated automatically.
- **optimize** (bool | *Calculator*) – Switch to turn on optimization of reference configurations using a fast LCAO calculator with SingleZeta basis, KpointDensity(density_a=1.0*Angstrom) and NumericalAccuracyParameters(density_mesh_cutoff=60.0*Hartree). Alternatively a calculator object might be supplied to replace the default one. **Default:** False.
- **optimize_geometry_parameters** (*OptimizeGeometryParameters* or None) – Parameters to be passed to a OptimizeGeometry object. **Default:** None.
- **log_filename_prefix** (*str*) – Filename prefix for the logging output of the tasks associated with this set. **Default:** Defined by the *MomentTensorPotentialTraining* object.
- **data_tag** (*str*) – Label for this training set to enable selection of different data in MTP fitting.

algorithm()

Returns
The algorithm to randomly change a percentage of the atoms.

Return type
FixedFraction | NormalDistribution

atomicRattlingAmplitudes()

Returns
Maximum rattling intensities.

Return type
PhysicalQuantity of type length | None

configurations()

Returns
The list of configurations to be used to generate the training set.

Return type
configuration: *BulkConfiguration*

dataTag()

Returns
The selection tag added to the data in the training set.

Return type
str

logFilenameIdentifier()

Returns
Filename identifier for the logging output of the tasks associated with this set, or None if it hasnt been set yet.

Return type
str | None

logFilenamePrefix()

Returns
Filename prefix for the logging output of the tasks associated with this set, or None if it is to be defined by the *MomentTensorPotentialTraining* object.

Return type
str | LogToStdOut | None

newElement()

Returns
The element to change to.

Return type
PeriodicTable.Element or None (vacancy)

optimize()

Returns
Switch to turn on optimization of interface configurations using the LCAO calculator.

Return type
bool

optimizeGeometryParameters()

Returns
The optimize geometry parameters.

Return type
OptimizeGeometryParameters

percentages()

Returns
The percentages of the atoms that should be changed.

Return type
float or sequence of floats

randomSeed()

Returns
The random seed used for generating the displacements, or None if it should be generated automatically.

Return type
int | None

rattle()

Returns
Switch to turn on rattling of the interfaces to generate more configurations.

Return type
bool | None

referenceConfigurations()

Returns
The list of reference configurations containing the new element.

Return type
list of [*BulkConfiguration*]

sampleSize()

Returns
The number of training configurations for each combination of list parameters.

Return type
int

supercellRepetition()

Returns
The supercell to construct for each configuration, given as the number of repetitions of the bulk unit cell along the (a, b, c) directions.

Return type
tuple (size 3) of int

uniqueString()

Return a unique string representing the state of the object.

Usage Examples

Setup of a training set for a copper/silver alloy using *AlloyTrainingParameters*.

Note: The particular force-field used for optimization in below script is only for demonstration purposes and should be replaced by a higher quality method in actual training.

```
# Set up lattice
lattice = FaceCenteredCubic(3.61496*Angstrom)

# Define elements
elements = [Copper]

# Define coordinates
fractional_coordinates = [[ 0.,  0.,  0.]]

# Set up configuration
bulk_configuration_copper = BulkConfiguration(
    bravais_lattice=lattice,
    elements=elements,
    fractional_coordinates=fractional_coordinates
    )

# Define the substituting element
substitute = Silver

# Define calculator for pre-optimization calculations.
potentialSet = EAM_AgCu_2009()
calculator_ff = TremoloXCalculator(parameters=potentialSet)

optimize_geometry_parameters = OptimizeGeometryParameters(
    max_forces=0.1*eV/Ang,
    max_step_length=0.2*Ang,
    trajectory_interval=1,
    optimize_cell=True,
    optimizer_method=FIRE(),
    enable_optimization_stop_file=True,
    restart_strategy=NoRestart,
)

training_set = AlloyTrainingParameters(
    reference_configurations=bulk_configuration_copper,
    percentages=[10, 20, 30],
    new_element=substitute,
    algorithm=FixedFraction,
    supercell_repetition=(3, 3, 3),
    rattle=True,
    atomic_rattling_amplitudes=[0.275, 0.4, 0.15] * Angstrom,
    sample_size=60,
    random_seed=667,
    optimize=calculator_ff,
    optimize_geometry_parameters=optimize_geometry_parameters,
```

    calculator=calculator,
    calculate_stress=True,
    fitting_parameters_list=fitting_parameters,
    train_test_split=0.8,
    random_seed=13345,
    number_of_processes_per_task=8,
    log_filename_prefix='fit_mtp_Cu-Ge_alloy',
)
moment_tensor_potential_training.update()
```

`alloy-training-sets.py`

Notes

The *AlloyTrainingParameters* class can be used to generate training configurations by generating random alloys from a crystalline host materials and a replacement element using the *substitutionalAlloy* API.

The sample_size parameter (approximately) determines the total number of generated configurations.

It is recommended to pre-optimize the automatically generated alloy configurations by specifying a fast calculator. The optimization parameters can be adjusted by passing an *OptimizeGeometryParameters* object. By default the LCAO method with a single zeta basis set is used.

To achieve a more broadly applicable training set, the generated alloy configurations can be randomly rattled. A set of three displacement amplitudes has to be provided which will be ordered smallest to largest. In addition to the positions, also the cell shape and volume are rattled simultaneously using the smallest atomic displacement. The unrattled configurations are always part of the final set of configurations.

Alternatively the *crystalTrainingRandomDisplacements* protocol can be used with the trajectory of optimized alloy configurations.

For the actual training data generation, a *AlloyTrainingParameters* object needs to be passed into a *MomentTensorPotentialTraining* object.

AnalyticalSplit

class AnalyticalSplit(*base_orbital=None*, *split_norm=None*, *base_orbitial=None*)

Class for representing the analytical split of a confined or polarization orbital,

Parameters

- **base_orbital** (*ConfinedOrbital* | *PolarizationOrbital*) – The basis orbital from which this orbital should be split.
- **split_norm** (*float between 0 and 1*) – The input orbital will be split at the radius where the input orbital has this given norm (`1 - split_norm`).
- **base_orbitial** –

angularMomentum()

Returns
The angular momentum.

Return type
int

baseOrbital()

Returns
The base orbital used for generating this split orbital.

Return type
ConfinedOrbital | *PolarizationOrbital*

baseOrbitial()
Deprecated: Use baseOrbital() instead.

Returns
The base orbital used for generating this split orbital.

Return type
ConfinedOrbital | *PolarizationOrbital*

nlinfo()

Returns
The nlinfo.

Return type
dict

splitNorm()

Returns
The split norm.

Return type
float

uniqueString()
Return a unique string representing the state of the object.

Usage Examples

Define a *BasisSet* for Hydrogen:

```
hydrogen_1s = ConfinedOrbital(
    principal_quantum_number=1,
    angular_momentum=0,
    radial_cutoff_radius=5.28603678847*Bohr,
    confinement_start_radius=0.8 * 5.28603678847*Bohr,
    additional_charge=0.0,
    confinement_strength=20.000*Hartree*Bohr,
    radial_step_size=0.001*Bohr,
    )

hydrogen_1s_split = AnalyticalSplit(hydrogen_1s, split_norm=0.40)

my_hydrogen_basis = BasisSet(
    element=Hydrogen,
    orbitals=[Hydrogen_1s, hydrogen_1s_split],
```

(continues on next page)

(continued from previous page)

```
    occupations=[0.7 , 0.3],
    pseudopotential=NormConservingPseudoPotential('normconserving/H.LDAPZ.zip'),
    )
```

Notes

The *AnalyticalSplit* orbital (ϕ_l^{split}) is obtained by constructing an analytical orbital that matches the `base_orbital` (ϕ_l^{base}) smoothly at the radius r^{split}. The functional form used for the *AnalyticalSplit* orbital is

$$\phi_l^{\text{split}}(r) = \begin{cases} r^l(a_l - b_l r^2) & \text{if } r < r^{\text{split}} \\ \phi_l^{\text{base}}(r) & \text{if } r \geq r^{\text{split}} \end{cases}$$

The radius r^{split} is determined by specifying the `split_norm` (ΔN) of the `base_orbital`, which is defined by

$$\Delta N = \int_{r^{\text{split}}}^{r^c} r^2 |\phi_l^{\text{base}}(r)|^2 dr$$

Further information about the basis functions can be found in *LCAO basis set*.

AndersonMixer

class AndersonMixer(*mixing_fraction=None*, *regularization_parameter=None*)

Class representing a mixer following the Anderson mixing scheme[1].

Parameters

- **mixing_fraction** (*float*) – The mixing fraction. **Default:** Automatically determined in the first step.
- **regularization_parameter** (*float*) – Regularization parameter for numerical stability. **Default:** 0.01

mixingFraction()

Returns
The fraction of the output to be mixed in with the next input.

Return type
float

nlinfo()

Returns
The nlinfo.

Return type
dict

regularizationParameter()

Returns
The stabilization factor to be added to the diagonal of the linear system.

Return type
float

[1] V.ăEyert. A Comparative Study on Methods for Convergence Acceleration of Iterative Vector Sequences. *Journal of Computational Physics*, 124(2):271–285, 1996. doi:10.1006/jcph.1996.0059.

uniqueString()

Return a unique string representing the state of the object.

Usage Examples

Set up an Anderson mixer which automatically sets the mixing fraction optimally:

```
# Iteration control parameters with the default Anderson mixer.
mixer=AndersonMixer()
iteration_control_parameters=IterationControlParameters(algorithm=mixer)
```

Set up an Anderson mixer with a user defined mixing fraction.

```
# Iteration control parameters with a custom Anderson mixer.
mixer=AndersonMixer(mixing_fraction=0.2)
iteration_control_parameters=IterationControlParameters(algorithm=mixer)
```

Notes

AndersonMixer implements the Anderson method[Page 2248, 1,2].

In the Anderson mixing scheme the best guess for the next input is given by

$$h^{\mathrm{in}}_{n+1} = \bar{h}^{\mathrm{in}}_{n} + \eta\Delta\left(\bar{h}^{\mathrm{in}}_{n}\right),$$

where η is the mixing fraction, h^{in}_{i} is the input value of the `mixing_variable` at iteration i, and $\Delta(h^{i}) = h^{\mathrm{out}}_{i} - h^{\mathrm{in}}_{i}$ is the residual vector.

$\bar{h}^{\mathrm{in}}_{n}$ is determined using a linear combination of solutions from the previous `number_of_history_steps`:

$$\bar{h}^{\mathrm{in}}_{n} = h^{\mathrm{in}}_{n} + \sum_{j}^{n_{\mathrm{hist}}} \theta^{n}_{j}\left(h^{\mathrm{in}}_{n-j} - h^{\mathrm{in}}_{n}\right)$$

in which the variables θ^{i}_{n} are determined by minimizing the residual of $\bar{h}^{\mathrm{in}}_{n}$.

Angle1Potential

class Angle1Potential(*particleType1*, *particleType2*, *particleType3*, *k*, *theta0*, *rho1*, *rho2*, *r_cut=None*)

Constructor of the potential.

Parameters

- **particleType1** (ParticleType *or* ParticleIdentifier) – Identifier of the first particle type.
- **particleType2** (ParticleType *or* ParticleIdentifier) – Identifier of the second particle type. This is the central particle (the vertex) when calculating the angle.
- **particleType3** (ParticleType *or* ParticleIdentifier) – Identifier of the second particle type.
- **k** (*PhysicalQuantity of type energy / angle**2*) – Potential parameter.
- **theta0** (*PhysicalQuantity of type angle*) – Potential parameter.

[2] DonaldăG. Anderson. Iterative Procedures for Nonlinear Integral Equations. *J. ACM*, 12(4):547–560, October 1965. doi:10.1145/321296.321305.

•**rho1** (*PhysicalQuantity of type length*) – Potential parameter.

•**rho2** (*PhysicalQuantity of type length*) – Potential parameter.

•**r_cut** (*PhysicalQuantity of type length*) – The cutoff radius of this potential.

classmethod getAllParameterNames()

Return the names of all used parameters as a list.

getAllParameters()

Return all parameters of this potential and their current values as a <parameterName / parameterValue> dictionary.

static getDefaults()

Get the default parameters of this potential and return them in form of a dictionary of <parameter name, default value> key-value pairs.

getParameter(*parameterName*)

Get the current value of the parameter parameterName.

setParameter(*parameterName*, *value*)

Set the parameter parameterName to the given value.

Parameters

•**parameterName** (*str*) – The name of the parameter that will be modified.

•**value** – The new value that will be assigned to the parameter parameterName.

Notes

This potential specifies a three-body potential:

$$E_{ijk}(\theta_{ijk}, r_{ij}, r_{jk}) = \frac{1}{2}k(\theta_{ijk} - \theta_0)^2 \exp[-(r_{ij}/\rho_1 + r_{jk}/\rho_2)]\,,$$

which is often used in core-shell potentials.

AngleCorrection6Potential

class AngleCorrection6Potential(*particleType1*, *particleType2*, *particleType3*, *k0*, *k1*, *k2*, *k3*, *k4*, *k5*, *k6*, *costheta0*, *r_i=None*, *r_cut=None*)

Constructor of the potential.

Parameters

•**particleType1** (ParticleType *or* ParticleIdentifier) – Identifier of the first particle type.

•**particleType2** (ParticleType *or* ParticleIdentifier) – Identifier of the second particle type (central particle when calculating angles)

•**particleType3** (ParticleType *or* ParticleIdentifier) – Identifier of the second particle type.

•**k0** (*PhysicalQuantity of type energy*) – Potential parameter.

•**k1** (*PhysicalQuantity of type energy*) – Potential parameter.

•**k2** (*PhysicalQuantity of type energy*) – Potential parameter.

•**k3** (*PhysicalQuantity of type energy*) – Potential parameter.

•**k4** (*PhysicalQuantity of type energy*) – Potential parameter.

•**k5** (*PhysicalQuantity of type energy*) – Potential parameter.

•**k6** (*PhysicalQuantity of type energy*) – Potential parameter.

•**costheta0** (*float*) – Potential parameter.

•**r_i** (*PhysicalQuantity of type length*) – The inner cutoff radius (distance where the spline-smoothing starts).

•**r_cut** (*PhysicalQuantity of type length*) – Cutoff radius

classmethod getAllParameterNames()

Return the names of all used parameters as a list.

getAllParameters()

Return all parameters of this potential and their current values as a <parameterName / parameterValue> dictionary.

static getDefaults()

Get the default parameters of this potential and return them in form of a dictionary of <parameter name, default value> key-value pairs.

getParameter(*parameterName*)

Get the current value of the parameter parameterName.

setParameter(*parameterName*, *value*)

Set the parameter parameterName to the given value.

Parameters

•**parameterName** (*str*) – The name of the parameter that will be modified.

•**value** – The new value that will be assigned to the parameter parameterName.

Notes

This potential calculates angle-correction terms of the following kind:

$$E_{ijk}(\theta_{ijk}, r_{ij}, r_{jk}) = \frac{1}{2} f_C(r_{ij}, r_{inner}, r_{cut}) f_C(r_{ik}, r_{inner}, r_{cut}) \sum_{d=0}^{6} k_d (\theta_{ijk} - \theta_0)^d,$$

where f_C is a cosine-like cutoff function, which smoothly switches the potential to zero over a range between r_{inner} and r_{cut}.

AngularDistribution

class AngularDistribution(*md_trajectory*, *cutoff_radius=None*, *start_time=None*, *end_time=None*, *triplet_selection=None*, *time_resolution=None*, *info_panel=None*)

Constructor for the AngularDistribution object.

Parameters

•**md_trajectory** (*MDTrajectory* | AtomicConfiguration) – The MDTrajectory or configuration the angular-distribution should be calculated for.

•**cutoff_radius** (*PhysicalQuantity* of type length) – Cutoff radius to define the maximum considered bond distance between the central atom and each of its two neighbors. Either a single value for both neighbors or one value for each pair. **Default:** `2.5 * Angstrom`

•**start_time** (*PhysicalQuantity* of type time) – The start time. **Default:** `0.0 * fs`

- **end_time** (*PhysicalQuantity* of type time.) – The end time. **Default:** the last frame time
- **triplet_selection** (list of *PeriodicTableElement* | list of ints | list of str) – Only consider angles between these atoms. The order must be (central_atom, neighbor_1, neighbor_2). The selection can be given by a list of 3 elements i.e. *PeriodicTableElement* or a list of 3 atom indices i.e. ints or by a list of tags i.e. str. **Default:** first element
- **time_resolution** (*PhysicalQuantity* of type time) – The time interval between snapshots in the MD trajectory that are included in the analysis.
- **info_panel** (*InfoPanel (Plot2D)*) – Info panel to show the calculation progress. **Default:** No info panel

angles()

Return the angles associated with the histogram.

data()

Return the angular distribution histogram.

Usage Examples

Load an *MDTrajectory* containing ethane molecules and calculate the angular distribution for C-C-H angles:

```
md_trajectory = nlread('ethane_md.nc')[-1]

angular_distribution = AngularDistribution(md_trajectory,
                                           cutoff_radius=[2.3*Angstrom, 1.2*Angstrom],
                                           triplet_selection=[Carbon, Carbon, Hydrogen])

# Get the histogram of the angle distribution and the associated angles.
histogram = angular_distribution.data()
angles    = angular_distribution.angles().inUnitsOf(Degrees)

# Plot the data using pylab.
import pylab

pylab.bar(angles, histogram, label='C-C-H angles')
pylab.xlabel('angle (degrees)')
pylab.ylabel('Histogram')
pylab.legend()

pylab.show()
```

angular_distribution.py

Notes

Set the `cutoff_radius` parameter to the maximum bond length that should be considered. A good choice is typically the end of the first peak in the *RadialDistribution* function of the respective elements. If only one value is given, this value is used for both neighbor pairs. As shown in the usage example, you can also specify different cutoff radii for the two neighbor pairs.

Instead of each of the three elements in the `triplet_selection` parameter, you can alternatively specify a list or a tag to select the atoms between which the angular distribution is calculated.

AtomicChemicalPotential

class AtomicChemicalPotential(*element*, *reference_configuration=None*, *internal_energy=None*, *entropy=None*)

A class defining the chemical potential for an atomic species. Used as part of a *ChargedPointDefect* study.

Parameters

- **element** (*PeriodicTableElement*) – The element for which the atomic chemical potential is defined.
- **reference_configuration** (*BulkConfiguration* | *MoleculeConfiguration*) – The reference configuration from which the components of the atomic chemical potential (internal energy and entropy) will be calculated if they havent been specified. The configuration is only allowed to consist of one type of atomic species corresponding to `element`. If a *MoleculeConfiguration* is specified, it will be internally stored as a `BulkConfiguration`. **Default:** Determined by the *ChargedPointDefect* study.
- **internal_energy** (*PhysicalQuantity* of type energy) – The internal energy component of the atomic chemical potential. **Default:** To be calculated by the *ChargedPointDefect* study using the `reference_configuration`.
- **entropy** (*PhysicalQuantity* of type entropy) – The entropy component of the atomic chemical potential. **Default:** To be calculated by the *ChargedPointDefect* study using the `reference_configuration`.

element()

Returns
The element for which the atomic chemical potential is defined.

Return type
PeriodicTableElement

entropy()

Returns
The entropy component of the atomic chemical potential, or None if it will be calculated automatically.

Return type
PhysicalQuantity of type entropy | None

internalEnergy()

Returns
The internal energy component of the atomic chemical potential, or None if it will be calculated automatically.

Return type
PhysicalQuantity of type energy | None

referenceConfiguration()

Returns
The reference configuration from which the components of the atomic chemical potential (internal energy and entropy) will be calculated. If None, either the configuration is not needed because the components have been explicitly specified, or it has not yet been determined by the *ChargedPointDefect* study. MoleculeConfiguration are automatically returned as BulkConfiguration

Return type
BulkConfiguration | None

uniqueString()

Return a unique string representing the state of the object.

Notes

See *Atomic Chemical Potentials* for a description of how to use this object as part of a *ChargedPointDefect* study.

AtomicChemicalPotentialList

class AtomicChemicalPotentialList(*material_specifications*, *atomic_chemical_potential_list*, *dynamical_matrix_processes_per_task=None*)

Constructor for the AtomicChemicalPotentialList object. An AtomicChemicalPotentialList ensures that either heat of formation conditions (when all elements present in the material specification pristine configuration are specified) or rich conditions (when only some are specified) are satisfied. If non native elements are included its atomic chemical potentials will be used directly without assuming either rich or heat of formation conditions for non native elements.

Parameters

- **material_specifications** (*MaterialSpecifications*) – Material specifications involved in the calculations. The atomic chemical potentials from this material specifications are ignored. Only the ones explicitly specified in the atomic_chemical_potentials parameter of this constructor are used.
- **atomic_chemical_potentials** – A list of atomic chemical potential objects to work with.

atomicChemicalPotentials()

Returns
The user provided list of chemical potentials

Return type
list of *AtomicChemicalPotential*

calculatedAtomicChemicalPotentials(*temperature=None*)

This function can only be called on updated objects.

Parameters
temperature (*PhysicalQuantity* of type temperature) – The temperature used for calculating entropies **Default:** `300.0 * Kelvin`

Returns
List of atomic chemical potentials with their properties properly calculated. This list can be directly assigned to a MaterialSpecification for further calculations.

Return type
list of *AtomicChemicalPotential*

dependentStudies()

Returns
The list of dependent studies.

Return type
list of `Study`

dynamicalMatrixProcessesPerTask()

Returns
The number of processes that will be used to execute each task for DynamicalMatrix study objects.

Return type
int

filename()

Returns
The filename where the study object is stored.

Return type
str

logFilenamePrefix()

Returns
The filename prefix for the logging output of the study.

Return type
str | LogToStdOut

materialSpecifications()

Returns
The material specifications associated with the chemical potentials

Return type
MaterialSpecifications

nlprint(*stream=None*)
Print a string containing an ASCII table useful for plotting the Study object.

Parameters
stream (*python stream*) – The stream the table should be written to. **Default:** NLPrintLogger()

numberOfProcessesPerTask()

Returns
The number of processes to be used to execute each task. If None, all available processes execute each task collaboratively.

Return type
int | None | *ProcessesPerNode*

numberOfProcessesPerTaskResolved()

Returns
The number of processes to be used to execute each task. Default values are resolved based on the current execution settings.

Return type
int

objectId()

Returns
The name of the study object in the file.

Return type
str

saveToFileAfterUpdate()

Returns
Whether the study is automatically saved after it is updated.

Return type
bool

tasksFinished()

Returns
how many tasks are finished out of how many

Return type
tuple of int, int

totalEnergyReference()

Function to be called on updated objects only.

Returns
The total energy for the unit cell in the material specifications.

Return type
PhysicalQuantity of type energy.

totalEntropyReference(*temperature=None*)

Function to be called on updated objects only

Parameters
temperature (*PhysicalQuantity* of type temperature) – Temperature for entropy calculation. **Default:** 300K

Returns
The total entropy for the unit cell in the material specifications at the specified temperature. None if not needed (assumed entropies specified).

Return type
PhysicalQuantity of type energy / boltmann_constant | None

uniqueString()

Return a unique string representing the state of the object.

update()

Performs the calculations for the AtomicChemicalPotentialList,

Example

A simple example for a TiN system where Ti-rich conditions are desired is:

```
Ti_rich   = AtomicChemicalPotentialList(TiN,[AtomicChemicalPotential(Titanium)])
Ti_rich.update()
nlprint(Ti_rich)

# update reference material with updated chemical potential - Ti rich condition
TiN_rich = TiN(atomic_chemical_potentials=Ti_rich.calculatedAtomicChemicalPotentials())
```

AtomicCompensationCharge

class AtomicCompensationCharge(*atomic_shifts=None*)

Represents a change in the ion charge of individual atoms, resulting in a different ion electrostatic potential.

Parameters

atomic_shifts (*array of tuples*) – The charge shifts that should be applied to any given atom and/or element. Each charge shift entry should be a tuple with tags and corresponding charge shifts, or a tuple with element and charge shift value. Mixing tuple types is allowed. **Default:** no charge shift for any atom

uniqueString()

Return a unique string representing the state of the object.

Usage Examples

Simulate a p-doped silicon crystal and add a compensation charge to the silicon atoms:

```
# Set up configuration.
bulk_configuration = BulkConfiguration(
    bravais_lattice=FaceCenteredCubic(5.4306*Angstrom),
    elements=[Silicon, Silicon],
    fractional_coordinates=[[ 0.  ,  0.  ,  0.  ],
                            [ 0.25,  0.25,  0.25]]
    )

# Set a negative compensation charge on each atom to compensate for p-doping.
compensation_charge = AtomicCompensationCharge([[Silicon, -0.0005]])
bulk_configuration.setExternalPotential(compensation_charge)

# Calculator
numerical_accuracy_parameters = NumericalAccuracyParameters(
    k_point_sampling=(5, 5, 5),
    )

calculator = LCAOCalculator(
    numerical_accuracy_parameters=numerical_accuracy_parameters,
    )

bulk_configuration.setCalculator(calculator)

bandstructure = Bandstructure(
    configuration=bulk_configuration,
    route=['G', 'X', 'W', 'L', 'G', 'K', 'X', 'U', 'W', 'K', 'L'],
    points_per_segment=20,
    bands_above_fermi_level=All
    )

nlsave('si_pdoped.nc', bandstructure)
```

si_pdoped.py

Notes

The atomic compensation charge controls the charge of the neutral atomic densities used to construct the initial guess for the total density. It is typically used to apply a doping to the system. The total charge of the system is set in the calculator, see for instance the keyword `charge` of the *LCAOCalculator*.

For *SurfaceConfiguration* and *DeviceConfiguration*, the atomic compensation charge of the central region atoms equivalent to the electrode atoms should be similar to the compensation charge of the electrode atoms. For the rest of the atoms, there are no requirements. The atomic compensation charge could for instance be used to model a certain doping distribution of the device.

An atomic compensation charge can be applied to a *MoleculeConfiguration*, *BulkConfiguration*, *SurfaceConfiguration*, and *DeviceConfiguration* via the `setExternalPotential` method.

AtomicShift

class AtomicShift(*atomic_shifts=None*)

Class to represent a potential shift of the orbitals on individual atoms.

Parameters

atomic_shifts (list of tuple (size 2) with elements: int | *PeriodicTableElement*, *PhysicalQuantity* of type energy) – A list of potential shifts to be applied to different atoms/elements. Each entry should be a tuple giving the atoms for which the shift is applied (either by index or by element) and the value of the potential shift. Mixing tuple types is allowed. **Default:** no potential shift for any atom

uniqueString()

Return a unique string representing the state of the object.

Usage Examples

Add a periodic external potential to silicon and calculate the band structure:

```
# Define a periodic potential along z
def potentialShift(f, shift):
    """
    :param  f:      Position in fractional coordinates
    :type  f:       array of floats

    :param shift:   Amplitude of the shift with unit energy
    :type shift:    float

    :returns:   The external potential at fractional coordinate position.
    :rtype:     float
    """
    return shift*numpy.cos(2.*numpy.pi*f[2])

# Set up a silicon lattice
configuration = BulkConfiguration(
    SimpleCubic(5.4306*Angstrom),
    [Silicon,]*8,
    fractional_coordinates = [[0.0, 0.0, 0.0], [0.25, 0.25, 0.25],
                              [0.5, 0.5, 0.0], [0.75, 0.75, 0.25],
```

(continues on next page)

(continued from previous page)

```
                                [0.5, 0.0, 0.5], [0.75, 0.25, 0.75],
                                [0.0, 0.5, 0.5], [0.25, 0.75, 0.75]])

# Repeat the structure along z
configuration = configuration.repeat(1,1,3)

# Define a selfconsistent Huckel calculator
calculator = HuckelCalculator(
    basis_set=CerdaHuckelParameters.Silicon_GW_diamond_Basis,
    numerical_accuracy_parameters = NumericalAccuracyParameters(
    k_point_sampling=(4, 4, 2)),
    iteration_control_parameters = IterationControlParameters()
    )

# Set a calculator on the configuration
configuration.setCalculator(calculator())

# Perform a loop with 4 different shifts
for shift in [0.0, 1.0, 5.0, 10.0]*eV:

    fractional = configuration.fractionalCoordinates()
    atom_potentials = [(i,potentialShift(f, shift)) for i,f in enumerate(fractional)]

    configuration.setExternalPotential(AtomicShift(atom_potentials))

    # Calculate the bandstructure
    bandstructure = Bandstructure(
        configuration=configuration,
        route=['G', 'Z'],
        )

    nlsave('atomic_shift.nc', bandstructure)
```

atomic_shift.py

Notes

The atomic shift adds a term to the tight-binding Hamiltonian of the form

$$\Delta H_{ij} = \frac{1}{2}\left(V_i + V_j\right) S_{ij},$$

where S_{ij} is the overlap matrix and V_i is the atomic shift of orbital i.

An atomic shift can be applied to a *MoleculeConfiguration*, *BulkConfiguration*, *SurfaceConfiguration*, and *DeviceConfiguration* through the `setExternalPotential` method.

AutomaticNEB

class AutomaticNEB(*neb*, *number_of_intermediate_images*, *simultaneous_images=None*, *optimization_parameters=None*, *spring_constant=None*, *climbing_image=None*, *log_filename_prefix=<class 'NL.ComputerScienceUtilities.NLFlag._NLFlag.Automatic'>*, *resolution_ratio=None*, *suppress_warnings=None*)

The automatic NEB optimization algorithm adds images one by one in the largest gap between current images. The NEB segment around the added image is then optimized using the attached calculator. The spring constant of the new segments is calculated to conserve the original spring constant. Thus, the automatic NEB is able to locate the transition state with fewer image optimizations than the traditional NEB.

The name of log and trajectory files is passed through the optimization_parameters keyword. An additional prefix is added to the filenames. The first part of the prefix determines the step in the automatic NEB. This is either the current number of intermediate images or *CI* for the climbing image optimization. The second and third parts of the prefix are the indices of the endpoints of the segment being optimized. For example: *3_1_4_* corresponds to the second step with images 2 and 3 being optimized.

Parameters

- **neb** (*NudgedElasticBand*) – The NEB to optimize. The NEB must have a calculator set. The interpolation algorithm set on the NEB is also used in the automatic optimization. The *class: `~.ImageDependentPairPotential* is recommended for the interpolation. If the NEB has only two images, the initial set of simultaneous images are set all at once. The NEB can not have more intermediate images than simultaneous images at the start of the optimization.
- **number_of_intermediate_images** (*int*) – The total number of intermediate images the NEB should have after the automatic optimization is complete.
- **simultaneous_images** (*int*) – The number of images to optimize simultaneously.
- **optimization_parameters** (*OptimizeGeometryParameters*) – The optimization parameters.
- **spring_constant** (*class: `~.PhysicalQuantity* of type force per length squared) – The spring constant for the new segments. If a single value is provided, it will be used for all new segments. Note that in this case the original distances between images are not conserved. If a list is provided, it must have the same length as the number of segments in the NEB.
- **climbing_image** (*bool*) – Whether to perform a climbing-image optimization around the highest energy image after all intermediate images have been added. **Default:** `False`.
- **log_filename_prefix** (`Automatic` | str | None) – The logging output from each segment will be written to filenames starting with this value. If it is set to Automatic then the prefix will be the name of the calling python script. If it is set to None, then all output will be written to stdout. **Default:** `Automatic`.
- **resolution_ratio** (*float*) – The resolution ratio used to switch between geometry and energy gaps. Energy gaps are furthermore weighted to prefer higher absolute energies closer to the transition state. A value of 0.0 means that a new image is always added in the geometric gap. A very large value means that a new image is always added in the energy gap. The value 1.0 is free of any bias. **Default:** `0.5`.
- **suppress_warnings** (*bool*) – Whether to suppress warnings printed during the optimization of the NEB segments. Warnings that will be ignored include: Detection of additional minima, unconverged images, and drift in the forces. In the majority of cases, these warnings are not relevant for the automatic NEB and can be ignored. **Default:** `True`.

climbingImage()

Returns
Whether to perform a climbing-image optimization around the highest energy image after all intermediate images have been added.

Return type
bool

finalNEB()

Returns
The final nudged elastic band configuration.

Return type
NudgedElasticBand

interpolationAlgorithm()

Returns
The interpolation algorithm used in the NEB.

Return type
InterpolationAlgorithm

logFilenamePrefix()

Returns
The prefix for the log and trajectory filenames.

Return type
str

neb()

Returns
The input nudged elastic band configuration.

Return type
NudgedElasticBand

numberOfIntermediateImages()

Returns
The total number of intermediate images the NEB should have after the automatic optimization is complete.

Return type
int

optimizationParameters()

Returns
The optimization parameters.

Return type
OptimizeGeometryParameters

resolutionRatio()

Returns
The resolution ratio used to switch between the geometric and energy gaps.

Return type
float

run()

Run the main loop of the automatic NEB optimization. In each step of the main loop a subsection of the NEB containing the newest image is optimized. Then another image is added to the largest gap in the NEB. The process is repeated until the desired number of intermediate images have been added.

Returns
The optimized NEB trajectory.

Return type
NudgedElasticBand

simultaneousImages()

Returns
The number of images to optimize simultaneously.

Return type
int

springConstant()

Returns
The input spring constant.

Return type
PhysicalQuantity of type force per length squared

springConstants()

Returns
Return the spring constants of the NEB segments.

Return type
PhysicalQuantity

suppressWarnings()

Returns
Whether to suppress warnings printed during the optimization of the NEB segments.

Return type
bool

Notes

The automatic *NudgedElasticBand* (NEB) method[1] is an alternative to a regular NEB optimization *OptimizeNudgedElasticBand*. It aims to combine both a reduction in computational resources and improved stability in the process of finding the transition state. It achieves this by converging the path segment by segment, rather than all at once. Finally, the region around the transition state is refined to ensure the highest accuracy. If one is interested in converging the the full minimum energy path, the *OptimizeNudgedElasticBand()* function should be used.

Usage Examples

The *AutomaticNEB* has a similar interface as the *OptimizeNudgedElasticBand()* function. However, one key difference is that *AutomaticNEB* is a class and and the simulation is run by calling the *run()* method.

```
optimization_parameters = OptimizeGeometryParameters(
    max_forces=0.02 * eV/Angstrom,
)
auto_neb = AutomaticNEB(
    neb=initial_neb,
    number_of_intermediate_images=5,
```

(continued from previous page)

```
    simultaneous_images=2,
    optimization_parameters=optimization_parameters,
    spring_constant=0.5 * eV/Angstrom**2,
    climbing_image=True
)
final_neb = auto_neb.run()
```

BaderCharges

class BaderCharges(*configuration*, *electron_density*, *electron_density_reference=None*)

Class for performing a Bader charge analysis.

Parameters

- **configuration** (AtomicConfiguration) – The configuration to perform the charge analysis on.
- **electron_density** (*AllElectronDensity*) – The electron density of the configuration.
- **electron_density_reference** (*ElectronDensity*) – If electron_density is actually a valence electron density, then the all electron density can optionally be provided.

class BaderChargesMaximum(*coordinates*, *charge*, *atom*, *distance*)

Create new instance of BaderChargesMaximum(coordinates, charge, atom, distance)

atom

Alias for field number 2

charge

Alias for field number 1

coordinates

Alias for field number 0

count(*value*, */*)

Return number of occurrences of value.

distance

Alias for field number 3

index(*value*, *start=0*, *stop=9223372036854775807*, */*)

Return first index of value.

Raises ValueError if the value is not present.

atomicCharges()

Return the calculated atomic charges.

Returns
The number of valence electrons for each atom.

Return type
numpy.array

maxima()

Return the calculated bader charge maxima.

Returns
An list of tuples that each contain the coordinates of a charge density maximum as a *PhysicalQuantity* of type length, the charge contained in the Bader volume as a float, the index of atom that the maxima was mapped to, and the distance to that atom as *PhysicalQuantity* of type length.

Return type
list of type tuple

`maximaCoordinates()`

Return the coordinates of the calculated bader charge maxima.

Returns
The coordinates of each maxima in an array of shape (*n*, 3) where *n* is the number of maxima.

Return type
PhysicalQuantity of type length

`metatext()`

Returns
The metatext of the object or None if no metatext is present.

Return type
str | None

`nlprint(stream=None)`

Print a string containing an ASCII table useful for plotting the AnalysisSpin object.

Parameters
stream (*python stream*) – The stream the table should be written to. **Default:** `NLPrintLogger()`

`setMetatext(metatext)`

Set a given metatext string on the object.

Parameters
metatext (*str | None*) – The metatext string that should be set. A value of None can be given to remove the current metatext.

`uniqueString()`

Return a unique string representing the state of the object.

Usage Examples

This module requies an all-electron density, which can be obtain from the PlaneWave PAW all-electron density object *AllElectronDensity*

```
# -*- coding: utf-8 -*-
# ------------------------------------------------------------
# Bulk Configuration
# ------------------------------------------------------------

# Set up lattice
lattice = FaceCenteredCubic(4.348*Angstrom)

# Define elements
elements = [Silicon, Carbon]
```

(continues on next page)

(continued from previous page)

```
# Define coordinates
fractional_coordinates = [[ 0.  ,  0.  ,  0.  ],
                          [ 0.25,  0.25,  0.25]]

    damping_factor=0.2,
    number_of_history_steps=5,
    )

calculator = PlaneWaveCalculator(
    basis_set=basis_set,
    numerical_accuracy_parameters=numerical_accuracy_parameters,
    iteration_control_parameters=iteration_control_parameters,
    )

bulk_configuration.setCalculator(calculator)
nlprint(bulk_configuration)
bulk_configuration.update()
nlsave('SiC_bader.hdf5', bulk_configuration)

# ------------------------------------------------------------
# All Electron Density
# ------------------------------------------------------------
all_electron_density = AllElectronDensity(
    configuration=bulk_configuration,
    grid_sampling=5000*Hartree,
    )
```

(continues on next page)

(continued from previous page)

```
nlsave('SiC_bader.hdf5', all_electron_density)

# ------------------------------------------------------------
# Bader Charges
# ------------------------------------------------------------
bader = BaderCharges(
    configuration=bulk_configuration,
    electron_density=all_electron_density,
    )
nlsave('SiC_bader.hdf5', bader)

# Print Bader object
nlprint(bader)
```

`SiC_bader.py`

A similar calculation can be performed using the LCAO-version of the PAW calculator: `SiC_bader_pawlcao.py`

In order for the Bader analysis to be accurate, the all-electron density needs to be sampled on a fine grid due to the rapid variations close to the nuclei. Therefore the all-electron density is constructed with a `grid_sampling` argument. Heavy elements with high atomic numbers require, in general, a finer grid sampling than lighter elements.

A Bader charge object can also be constructed though the **Bader Analysis** plugin on the **LabFloor**. In order to enable the plugin, select a configuration and an all-electron density. Optionally, when used to analyze VASP output files, the electron density files named `AECCAR0` and `AECCAR2` should also be selected. See the notes below for more information.

Notes

This class currently implements the on-grid Bader analysis algorithm developed by Henkelman, et al.[1].

Bader charge analysis can only work properly when an all-electron density is available. This is because the analysis assumes that the charge density maxima correspond to the coordinates of the atomic nuclei, however, pseudo-potential methods remove charge near the nuclei. This means that this type of analysis is currently only useful with the PAW (PlaneWave or LCAO) all-electron density object and VASP (because it supports writing an all-electron density) calculators in QuantumATK.

If you want to perform a Bader charge analysis using VASP, it is important to be aware that the `CHGCAR` files only contain the valence electron density. In order to write out the extra information that is needed, you must add `LAECHG=.TRUE.` to the `INCAR` file. This will cause the atomic core electron density to be written to the file `AECCAR0` and the non-pseudoized valence electron density (i.e. the density that can be added to the core electron density) is written to the file `AECCAR2`.

Bader calculations should be converged with respect the the electron density grid spacing. This means that, in VASP, you should increase the values of `NEGXF`, `NEGYF`, and `NEGYZ` in order to increase the number of grid points in the `CHGCAR` and `AECCAR` files.

[1] G.ăHenkelman, A.ăArnaldsson, and H.ăJonsson. A fast and robust algorithm for Bader decomposition of charge density. *Comput. Mat. Sci.*, 36(3):354–360, 2006. doi:10.1016/j.commatsci.2005.04.010.

Bandstructure

class Bandstructure(*configuration*, *route=None*, *points_per_segment=None*, *kpoints=None*, *bands_above_fermi_level=None*, *projection_list=None*, *processes_per_kpoint=None*, *method=None*, *interpolation_method=None*, *diagonalization_method=None*)

Analysis class for calculating the bandstructure for a bulk configuration.

Parameters

•**configuration** (*BulkConfiguration*) – The bulk configuration with an attached calculator for which to calculate the bandstructure.

•**route** (*list of str*) – The route to take through the Brillouin-zone as a list of symmetry points of the unit cell, e.g. `['G', 'X', 'G']`. This option is mutually exclusive to `kpoints`. **Default:** Unit-cell dependent route.

•**points_per_segment** (*Positive int*) – The number of points per segment of the route. This option is mutually exclusive to `kpoints`. **Default:** `20`.

•**kpoints** (*list of lists of floats*) – A list of 3-dimensional fractional k-points at which to calculate the energies of the bands e.g. `[[0.0, 0.0, 0.0], [0.0, 0.0, 0.1], ...]`. The shape is $(K, 3)$ where K is the number of k-points. This option is mutually exclusive to `route`, and `points_per_segment`. **Default:** Unit-cell dependent route.

•**bands_above_fermi_level** – **Deprecated:** from v2023.09, see `diagonalization_method` and *FullDiagonalizationSolver* instead.

•**projection_list** (*ProjectionList*) – A projection list object defining a projection. **Default:** If no projection list is specified all orbitals will be used.

•**processes_per_kpoint** (int | `None`) – The number of processes to use per kpoint. **Default:** For *PlaneWaveCalculator*, the default is the same number of processes per k-point as used in the SCF calculation. Otherwise, the default is `1`.

•**method** – **Deprecated:** from v2023.09, use `interpolation_method` parameter instead.

•**interpolation_method** (`None` | `Full` | *KDotPExpansion1D* | *KDotPExpansion3D*) – The method used for the bandstructure calculation.

Default is to perform an exact eigenvalue solution for each k-point.

Alternatively, the k.p expansion method can be use to interpolate the eigenvalues at the requested k-points using the exact eigensolution computed for a small subset of the k-points. There are two modes for the k.p method. 1) Using *KDotPExpansion1D*, for each bandstructure path segment, a few exact eigensolution are calculated and the eigenvalues of the remaining k-points are interpolated using a 1D correction term. 2) Using *KDotPExpansion3D*, the eigenvalues for the requested k-points are interpolated from exact solution on a 3D grid. The bands, grid and wave functions of a previous ground state computation can be used in this approach.

Default: `Full` meaning that all k-points will be calculated exactly.

•**diagonalization_method** – Method used for diagonalizing the hamiltonian.

This parameter allows to choose between a full diagonalization solver and an iterative subspace solver. The full diagonalization solver evaluates all bands from the lowest energy one to a given number of bands above fermi level. The iterative subspace solver allows to evaluate a given number of bands around fermi level, or around an energy of choice.

The full diagonalization solver is more robust, but can be proibitively expensive for very large systems.

The iterative solver can deal with very large systems (tens of thousands atoms and beyond) and greatly outperforms when calculating a small number of eigenvalues, but it is also inherently less robust.

Note: the exact method used when selecting *FullDiagonalizationSolver* is defined by the calculator (see *AlgorithmParameters*). *IterativeDiagonalizationSolver* is not supported for *PlaneWaveCalculator*

Default: `FullDiagonalizationSolver`

Type
FullDiagonalizationSolver | *IterativeDiagonalizationSolver*

conductionBandEdge()

Calculate the conduction band edge.

Returns
The conduction band edge.

Return type
PhysicalQuantity of type energy

directBandGap()

Calculate the direct band gap.

Returns
The direct band gap.

Return type
PhysicalQuantity of type energy

energyZero()

The energy zero is equal to the Fermi level. For fixed spin moment calculations it is the average of the Fermi level for spin up and spin down.

Returns
The energy zero.

Return type
`PhysicalQuantity` of type energy

evaluate(*spin=None*)

Return the bandstructure for a given spin.

Parameters
spin (`Spin.Up` | `Spin.Down` | `Spin.All`) – The spin the bandstructure should be returned for. Must be either `Spin.Up` or `Spin.Down`, or for noncollinear calculations `Spin.All`. **Default:** `Spin.All`

Returns
The eigenvalues for the specified `spin`. The shape is (K, B) or (S, K, B) where S is the number of spins, K is the number of k-points, and B is the number of bands.

Return type
`PhysicalQuantity` of type energy | list of `PhysicalQuantity` of type energy

fermiLevel(*spin=None*)

Parameters
spin (`Spin.Up` | `Spin.Down` | `Spin.All`) – The spin the Fermi level should be returned for. Must be either `Spin.Up`, `Spin.Down`, or `Spin.All`. Only when the band structure is calculated with a fixed spin moment will the Fermi level depend on spin. **Default:** `Spin.All`

Returns
The Fermi level in absolute energy.

Return type
`PhysicalQuantity` of type energy

fermiTemperature()

Returns
The Fermi temperature used in this bandstructure.

Return type
PhysicalQuantity of type temperature

indirectBandGap()

Calculate the indirect band gap.

Returns
The indirect band gap.

Return type
PhysicalQuantity of type energy

interpolationMethod()

Returns
The method used for the bandstructure calculation.

Return type
None | Full | *KDotPExpansion1D* | *KDotPExpansion3D*

kpoints()

Returns
The list of 3-dimensional fractional k-points at which the energies of the bands are calculated. The shape is (K, 3) where K is the number of k-points.

Return type
list of lists of floats

metatext()

Returns
The metatext of the object or None if no metatext is present.

Return type
str | None

method()

Deprecated: Deprecated. Use interpolationMethod instead.

Returns
The method used for the bandstructure calculation.

Return type
None | Full | *KDotPExpansion1D* | *KDotPExpansion3D*

Deprecated: Use `interpolationMethod()` instead.

nlinfo()

Returns
Structured information about the Bandstructure.

Return type
dict

nlprint(*stream=None*)

Print a string containing an ASCII table useful for plotting the AnalysisSpin object.

Parameters
stream (*python stream*) – The stream the table should be written to. **Default:** NLPrintLogger()

processesPerKPoint()

Deprecated: from v2019

Returns
The number of processes per k-point used in the calculation.

Return type
int > 0

route()

Returns
The route through the Brillouin-zone as a list of symmetry points of the unit cell.

Return type
list of str

setMetatext(*metatext*)

Set a given metatext string on the object.

Parameters
metatext (*str | None*) – The metatext string that should be set. A value of None can be given to remove the current metatext.

uniqueString()

Return a unique string representing the state of the object.

valenceBandEdge()

Calculate the valence band edge.

Returns
The valence band edge.

Return type
PhysicalQuantity of type energy

Usage Examples

Calculate the bandstructure of silicon and save it to a file:

```
# ------------------------------------------------------------
# Bulk Configuration
# ------------------------------------------------------------
lattice = FaceCenteredCubic(5.4306*Angstrom)
elements = [Silicon, Silicon]
fractional_coordinates = [[ 0.  ,  0.  ,  0.  ],
                          [ 0.25,  0.25,  0.25]]
bulk_configuration = BulkConfiguration(
    bravais_lattice=lattice,
    elements=elements,
    fractional_coordinates=fractional_coordinates
```

(continues on next page)

(continued from previous page)

```
    )

# -----------------------------------------------------------------
# Calculator
# -----------------------------------------------------------------
basis_set = [CerdaHuckelParameters.Silicon_GW_diamond_Basis]
hamiltonian_parametrization = HuckelHamiltonianParametrization(
    basis_set=basis_set)
k_point_sampling = MonkhorstPackGrid(9,9,9)
numerical_accuracy_parameters = NumericalAccuracyParameters(
    k_point_sampling=k_point_sampling,
    density_mesh_cutoff=10.0*Hartree,
    )
calculator = SemiEmpiricalCalculator(
    hamiltonian_parametrization=hamiltonian_parametrization,
    numerical_accuracy_parameters=numerical_accuracy_parameters,
    )
bulk_configuration.setCalculator(calculator)
bulk_configuration.update()

# -----------------------------------------------------------------
# Bandstructure
# -----------------------------------------------------------------
bandstructure = Bandstructure(
    configuration=bulk_configuration,
    route=['G', 'X'],
    points_per_segment=40,
    bands_above_fermi_level=4
    )

# Read the valence and conduction band edges wrt. the Fermi level
edge_valence = bandstructure.valenceBandEdge()
edge_conduction = bandstructure.conductionBandEdge()
print(edge_valence)
# Read the direct and indirect band gaps
gap_direct   = bandstructure.directBandGap()
gap_indirect = bandstructure.indirectBandGap()
print(gap_indirect)
# Print out results
print('Valence band maximum    = %.2f eV' % edge_valence.inUnitsOf(eV))
print('Conduction band minimum = %.2f eV' % edge_conduction.inUnitsOf(eV))
print('Direct band gap   = %.2f eV' % gap_direct.inUnitsOf(eV))
print('Indirect band gap = %.2f eV' % gap_indirect.inUnitsOf(eV))
```

si_band.py

Notes

To export the data of a *Bandstructure*, use the method *nlprint*.

Note that the k-points are given in units of the reciprocal vectors $\mathbf{k}_A$, $\mathbf{k}_B$, and $\mathbf{k}_C$. E.g. the symmetry point X have the fractional k-point coordinates $(\frac{1}{2}, 0, \frac{1}{2})$ since it is described by $X = \frac{1}{2}\mathbf{k}_A + \frac{1}{2}\mathbf{k}_C$.

A query method for the symmetry points of the Brillouin zone can be found in BravaisLattices_common methods of the BravaisLattices class.

For `bands_above_fermi_level` set to a valid integer N_{ba}, the total number of bands above the Fermi level will be N_{ba} for the spin type *unpolarized* and $2N_{\text{ba}}$ for *polarized* and *noncollinear*. This is because there is one spin channel in the former case and two spin channels in the latter two cases. *Spin-orbit* calculations are categorized as non-collinear calculations and therefore follow the same band selection as *noncollinear*. The case where `bands_above_fermi_level` is 1 is illustrated in Fig. 4.9. Note, that all bands below the Fermi level are always selected.

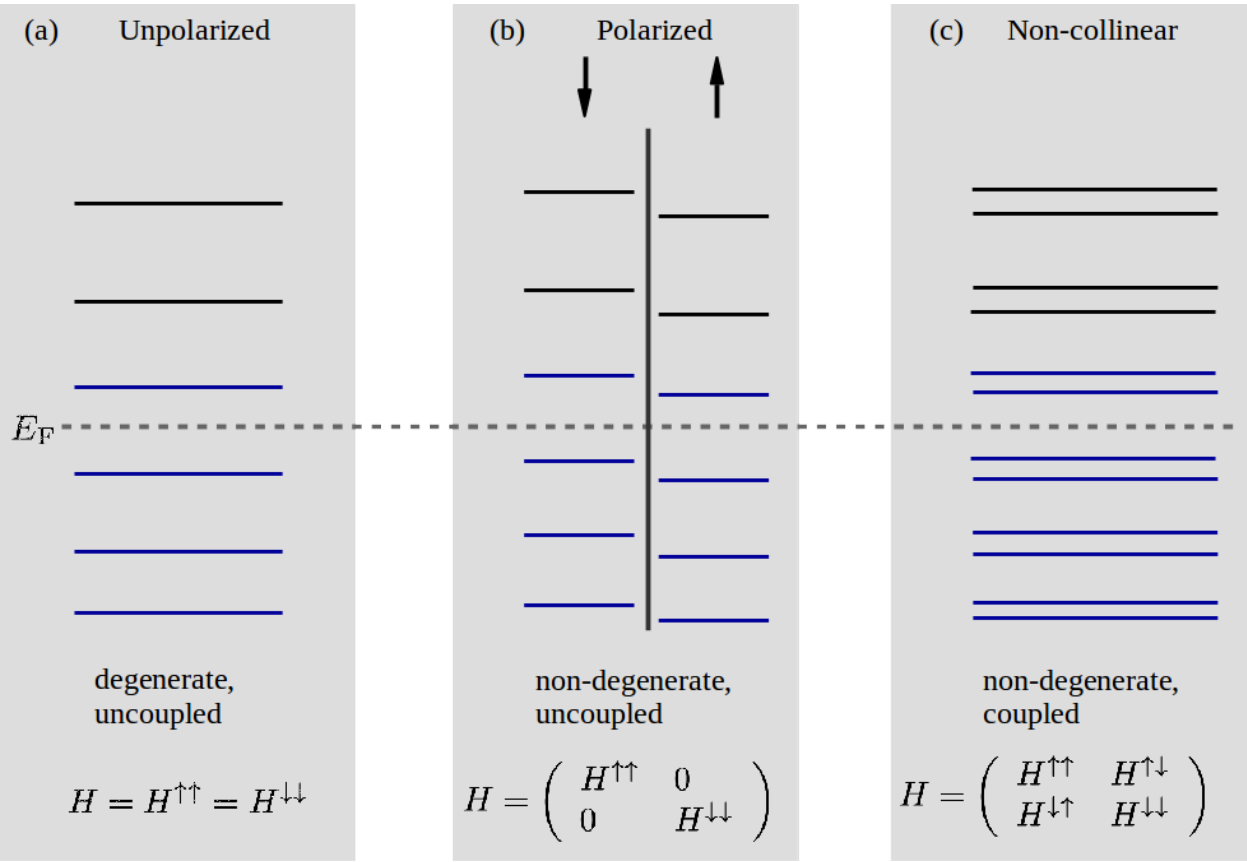

Fig. 4.9: The total number of bands selected (blue lines) by specifying 1 band above the Fermi level for **(a)** an unpolarized, **(b)** a polarized, and **(c)** a non-collinear calculation. The Fermi level E_{F} is shown as a horizontal dashed gray line. The vertical separation line in **(b)** signifies that the bands can be categorized according to spin up or down since there is no coupling. The structure of the Hamiltonian for each of the 3 spin types is shown at the bottom.

BaseChemicalPotential

class BaseChemicalPotential(*element=None*, *reference_temperature=None*)

Create the base class for the chemical potential.

Parameters

- **element** (*PeriodicTableElement*) – The element for which the base class is calculated.
- **reference_temperature** (*PhysicalQuantity* of type temperature) – The temperature for the given reference data.

chemicalPotential(*temperature=None*)

Calculate the chemical potential.

Returns
The chemical potential of the atom calculated from the internal energy and entropy per atom of the specified element in some reference configuration.

Return type
PhysicalQuantity of type energy | None

element()

Returns
The element for which the atomic chemical potential is defined.

Return type
PeriodicTableElement

referenceTemperature()

Returns
The reference temperature for the chemical potential.

Return type
PhysicalQuantity of type temperature.

uniqueString()

Return a unique string representing the state of the object.

Notes

The *BaseChemicalPotential* class is the base class for all of the chemical potential classes. These are classes that define the atomic reference states for elements, and enable the calculation of formation energies and concentrations of defects. The chemical potential definition should reflect the source of the elements in the defect being modeled. This can take into account the surrounding environment of the defect, and whether that environment has appropriate reservoirs for the element. The chemical potential also includes the internal energy of the atom according to the reference calculation method. In density functional theory calculations, this includes the energy required to remove the electrons from the atom.

There are two specific objects that can be used to create a chemical potential. These are:

- *CalculatedChemicalPotential*. In this object the atomic chemical potential is directly calculated from an reference atomic configuration.
- *ReferenceChemicalPotential*. In this object the atomic chemical potential is directly given as input.

The *BaseChemicalPotential* object should not be instantiated. This class is used to refer to any type of atomic chemical potential. As an example, in a Table, the *BaseChemicalPotential* type can be specified for a column type, so that the column can contain both kinds of atomic chemical potentials.

BaseDefectGenerator

class BaseDefectGenerator(*host_configuration*, *symmetry_tolerance=None*)

The base class for an object which describes the possible defects for a given host material.

Parameters

- **host_configuration** (*BulkConfiguration*) – The host configuration.
- **symmetry_tolerance** (*PhysicalQuantity* of type length) – The tolerance to be used when determining the symmetries. **Default:** 0.1 * Angstrom.

filterByDefectGenerators(*defect_generators*)

Method for filtering a defect generator by keeping the defects that are in one or more other defect generators.

Parameters
defect_generators (list of *BaseDefectGenerator*) – The list of defect generators containing the defects to keep after filtering.

Returns
A filtered defect generator.

Return type
VacancyGenerator | *SubstitutionalGenerator* | *InterstitialGenerator* *SplitInterstitialGenerator*

filterByDistinctConfigurations(*top_n_configurations*)

Method for selecting a number of distinct unique defects using the MTP structural descriptor.

Parameters
top_n_configurations (*int*) – Number of most distinct configurations.

Returns
A filtered defect generator.

Return type
VacancyGenerator | *SubstitutionalGenerator* | *InterstitialGenerator* *SplitInterstitialGenerator*

filterByPointDefect(*point_defects*, *keep_defects=True*)

Method for filtering the generator of unique point defects by selecting a specific defects.

Parameters

- **point_defects** (*Sequence of BasePointDefect*) – The sequence of point defects to filter.
- **keep_defects** (*bool*) – Whether or not the given defects are to be kept and all other removed (True) or removed from the generator and all other defect kept (False). **Default:** True

Returns
A filtered defect generator.

Return type
VacancyGenerator | *SubstitutionalGenerator* | *InterstitialGenerator* *SplitInterstitialGenerator*

filterByPositionInZSlices(*start=None*, *end=None*, *resolution=None*, *in_plane_position=None*)

Select defects along the Z-axis of the cell. This method is intended to be used for configurations that are anisotropic along one direction, such as interfaces or surfaces.

Parameters

- **start** (*PhysicalQuantity* of type length) – The start of the position interval. **Default:** 0 * Angstrom.
- **end** (*PhysicalQuantity* of type length) – The end of the position interval. **Default:** length of the cell in z direction.

•**resolution** (*PhysicalQuantity* of type length) – The size of each slice of the interface profile. **Default:** `2.0 * Angstrom`

•**in_plane_position** (*Sequence (2) of type float*) – The selected defect in each slice is as close as possible to this fractional coordinate. Mutually exclusive with parameter *select_distinct*. **Default:** `[0.5, 0.5]`

•**select_distinct** (*bool*) – Select the most distinct defects per slice. This can be used to sample a diverse configuration space with a minimal number of defects. Mutually exclusive with parameter *in_plane_position*. **Default:** `False`

•**defects_per_slice** (*int*) – The number of defects to select per slice. This parameter is only used together with the parameter *select_distinct*. **Default:** 1

Returns
A filtered defect generator.

Return type
VacancyGenerator | *SubstitutionalGenerator* | *InterstitialGenerator* *SplitInterstitialGenerator*

filterBySimilarityInZSlices(*start=None*, *end=None*, *resolution=None*, *defects_per_slice=None*)

Select defects along the Z-axis of the cell. This method is intended to be used for configurations that are anisotropic along one direction, such as interfaces or surfaces.

Parameters

•**start** (*PhysicalQuantity* of type length) – The start of the position interval. **Default:** 0 * Angstrom.

•**end** (*PhysicalQuantity* of type length) – The end of the position interval. **Default:** length of the cell in z direction.

•**resolution** (*PhysicalQuantity* of type length) – The size of each slice of the interface profile. **Default:** `2.0 * Angstrom`

•**defects_per_slice** (*int*) – The number of defects to select per slice. This parameter is only used together with the parameter *select_distinct*. **Default:** 1

Returns
A filtered defect generator.

Return type
VacancyGenerator | *SubstitutionalGenerator* | *InterstitialGenerator* *SplitInterstitialGenerator*

filterBySphere(*center*, *radius*)

Method for filtering unique defects by their position in a sphere.

Parameters

•**center** (*PhysicalQuantity* of type position) – The center of the sphere in Cartesian coordinates.

•**radius** (*PhysicalQuantity* of type length) – The radius of the sphere.

Returns
A filtered defect generator.

Return type
VacancyGenerator | *SubstitutionalGenerator* | *InterstitialGenerator* *SplitInterstitialGenerator*

filterBySymmetryIndex(*symmetry_indices*)

Method for filtering the list of unique point defects by selecting specific symmetry indices.

Parameters
symmetry_indices (*int | list of int*) – The list of symmetry indices to keep after filtering.

Returns
A filtered defect generator.

Return type
VacancyGenerator | *SubstitutionalGenerator* | *InterstitialGenerator* *SplitInterstitialGenerator*

filterByZPositionInterval(*start=None*, *end=None*)

Method for selecting unique defects by their position in an interval of the z axis. Note: The

Parameters

- **start** (*PhysicalQuantity* of type length) – The start of the position interval. **Default:** 0 * Angstrom.
- **end** (*PhysicalQuantity* of type length) – The end of the position interval. **Default:** length of the cell in z direction.

Returns
A filtered defect generator.

Return type
VacancyGenerator | *SubstitutionalGenerator* | *InterstitialGenerator* *SplitInterstitialGenerator*

hostConfiguration()

Returns
The host configuration.

Return type
BulkConfiguration

indices()

Returns
The defect indices for the current defect generator.

Return type
list of int

pointDefects()

Returns
The list of unique point defects.

Return type
Vacancy | *Substitutional* | *Interstitial* | *DefectCluster* | *SplitInterstitial*

symmetryTolerance()

Returns
The symmetry tolerance.

Return type
PhysicalQuantity of type length

uniqueDefects()

Returns
The list of symmetrically unique point defects with their names and symmetry indices, ordered by increasing index.

Return type
list of *NamedPointDefect*

uniqueString()

Return a unique string representing the state of the object.

Notes

The *BaseDefectGenerator* class is the base class for all of the defect generators. These are the classes that generate the symmetrically unique defects of different kinds for a given pristine material. Currently the kinds of defects that can be specified are:

- Vacancy defects, where an atom is removed from the lattice. These can be generated with the *VacancyGenerator* object.
- Substitutional defects, where an atom is exchanged for another. These can be generated with the *Substitutional* object.
- Interstitial defects, where an atom is inserted into a space in the lattice. Interstitial defects at likely lattice positions can be generated using the *InterstitialGenerator* object. This uses Voronoi analysis to find likely positions for interstitial defects.
- Split interstitial defects can be generated using the *SplitInterstitial* object. This defect can be understood as an interstitial defect combined with a displaced lattice atom. The center of the atom pair is positioned at the original lattice cite with the atoms moved in opposite directions along a given axis.
- Pair defects combine a site defect with another point defect. Using pair defects it is possible to create vacancy-interstitial, vacancy-substitution or double substitution defects. These can be generated using the a *DefectPairGenerator*.

The *BaseDefectGenerator* object should not be instantiated. This class is used to refer to any type of defect generator. As an example, in a Table, the *BaseDefectGenerator* type can be specified for a column type, so that the column can contain different types of defect generators.

BasisSet

class BasisSet(*element*, *orbitals*, *occupations*, *hubbard_u=None*, *projector_shift=None*, *filling_method=None*, *pseudopotential=None*, *onsite_spin_orbit_split=None*, *filter_mesh_cutoff=None*, *dft_half_parameters=None*, *gram_schmidt_orthonormalization=True*)

Class for representing the basis set for given element in DFT.

Parameters

- **element** (*PeriodicTableElement*) – The element associated with this basis set.
- **orbitals** (*list*) – The set of orbitals that forms this basis set. Each element in the list should be an instance of *ConfinedOrbital*, *AnalyticalSplit*, *PolarizationOrbital*, *NumericalOrbital*, or *HydrogenOrbital*.
- **occupations** (*list of non-negative float*) – The initial occupation of each basis orbital.
- **hubbard_u** (*PhysicalQuantity* type energy) – The Hubbard U energy for each orbital shell
- **projector_shift** (*PseudoPotentialProjectorShift*) – Pseudopotential projector shift for each angular momentum.
- **filling_method** (`SphericalSymmetric` | `Anisotropic`) – The method used for setting up the initial occupation. **Default:** `SphericalSymmetric`.
- **pseudopotential** (*NormConservingPseudoPotential*) – The pseudopotential to be used for generating this basis set. **Default:** `None`.
- **onsite_spin_orbit_split** (*PhysicalQuantity* of type energy) – Spin-orbit splits for each orbital. **Default:** `numpy.zeros(n_orbitals) * eV` where `n_orbitals` is the number of orbitals.
- **filter_mesh_cutoff** (*PhysicalQuantity* of type energy) – A cutoff for filtering the basis functions. Must not be negative. **Default:** `0.0 * eV`.
- **dft_half_parameters** (*DFTHalfParameters* | `Automatic` | `Disabled`) – The DTF-1/2 parameters used for this basis set in the LCAO calculation. When set to `Automatic` the DFT-1/2 parameters will be populated from a table of optimized parameters. By setting it to `Disabled` DFT-1/2 will not be active for this basis set. This is used to disable

DFT-1/2 for some elements or atomic sites while DFT-1/2 may be active for other atoms in the configuration. **Default:** `Automatic`

- **gram_schmidt_orthonormalization** (*bool*) – Whether or not the basis orbitals should be transformed to an orthonormal basis using the Gram-Schmidt process. **Default:** `True`

angularMomenta()

Return the angular momenta of the basis set.

Returns
The angular momentum (azimuthal quantum number) for each orbital.

Return type
list

dftHalfParameters()

The DFT-1/2 parameters.

Returns
The DFT-1/2 parameters.

Return type
DFTHalfParameters | `Automatic` | `Disabled`

element()

The element for this basis set.

Returns
The atomic element.

Return type
PeriodicTableElement

fillingMethod()

The method using for filling the orbitals.

Returns
The method for filling the orbitals.

Return type
`SphericalSymmetric` | `Anisotropic`

filterMeshCutoff()

The cutoff for the filter function.

Returns
The cutoff.

Return type
PhysicalQuantity of type energy

gramSchmidtOrthonormalization()

Whether the basis set has been orthonormalized.

Returns
True if the basis set is orthonormal.

Return type
bool

hubbardU()

The Hubbard U associated with the orbitals.

Returns
The Hubbard U energies either as a *PhysicalQuantity* with one element for each orbital.

Return type
PhysicalQuantity of type energy.

nlinfo()

Returns
The nlinfo.

Return type
dict

numberOfValenceElectrons()

Function to get the number of electrons in total.

Returns
The total number of valence electrons.

Return type
int

occupations()

The occupations associated with the orbitals.

Returns
The occupations of the orbitals given as a list of non-negative floats.

Return type
list

onsiteSpinOrbitSplit()

List of spin-orbit splits per orbital.

Returns
Spin-orbit splittings with one element for each orbital.

Return type
PhysicalQuantity of type energy

orbitalPermutationList()

Get the orbital permutation list.

Returns
The orbital permutation list.

Return type
list

orbitals()

The orbitals that forms this basis set.

Returns
A list of orbital objects.

Return type
list

projectorShift()

A query method for the pseudopotential projector shift.

Returns
The projector shift energies specified for each angular momentum.

Return type
PseudoPotentialProjectorShift

pseudopotential()

The pseudopotential used in generating the basis set.

Returns
The pseudopotential.

Return type
NormConservingPseudoPotential

uniqueString()

Return a unique string representing the state of the object.

Usage Examples

Use a **SingleZeta** basis set for Hydrogen and the (default) **DoubleZetaPolarized** basis set for Oxygen:

```
basis_set = [
    LDABasis.Hydrogen_SingleZeta,
    LDABasis.Oxygen_DoubleZetaPolarized
]
calculator = LCAOCalculator(basis_set=basis_set)
```

Define a *BasisSet* for Hydrogen:

```
hydrogen_1s = ConfinedOrbital(
    principal_quantum_number=1,
    angular_momentum=0,
    radial_cutoff_radius=5.28603678847*Bohr,
    confinement_start_radius=0.8 * 5.28603678847*Bohr,
    additional_charge=0.0,
    confinement_strength=20.000*Hartree*Bohr,
    radial_step_size=0.001*Bohr,
    )

hydrogen_1s_split = AnalyticalSplit(hydrogen_1s, split_norm = 0.40)

my_hydrogen_basis = BasisSet(
    element=Hydrogen,
    orbitals=[hydrogen_1s, hydrogen_1s_split],
    occupations=[0.7 , 0.3],
    pseudopotential=NormConservingPseudoPotential('normconserving/H.LDAPZ.zip'),
    )

calculator = LCAOCalculator(basis_set=my_hydrogen_basis)
```

Define a *BasisSet* for Hafnium with a hubbard U term for the 5d orbital, and using anisotropic filling:

```
basis_set = [
    GGABasis.Hafnium_SingleZetaPolarized(
        hubbard_u=[5.8,0.0,0.0]*eV,
        filling_method = Anisotropic)
]
```

Notes

•For further info on the different types of basis orbitals, see *LCAO basis set*.

•With the **SphericalSymmetric** filling method, the orbitals in a shell have the same occupation, while with the **Anisotropic** filling method, the low-m values are fully occupied and the high-m values are empty. See also *XC+U mean-field Hubbard term*.

•To see the default parameters for a basis set it is convenient to use the Script Generator tool in QuantumATK and set the script detail to `Show default`.

•For an example of defining a *BasisSet* with a set of custom *DFTHalfParameters*, see *Usage Examples*. More information on the `Automatic` DFT-1/2 parameters and the DFT-1/2 method in general is given in *DFT-1/2 method*.

BasisSetInitialization

class BasisSetInitialization(*basis_set=None*)

The plane-wave basis set initialization method class.

Parameters
basis_set (*BasisSet*) – The basis set to use for the initialization method. Note that this feature is not enabled for PAW calculations, in which case the argument should be left default. **Default:** An automatically generated minimal basis set.

basisSet()

Returns
The basis set.

Return type
list

BasisSetOptimizer

class BasisSetOptimizer(*bulk_configuration*, *kpoint_sampling=None*, *orbitals_per_shell_map=None*, *radial_cutoff_radius_map=None*, *confinement_start_radius_map=None*, *elements=None*, *energy_cutoff=None*, *confinement_strength=None*, *tolerance=None*, *max_number_of_iterations=None*)

Class that know how to optimize a subset of a complete basis set w.r.t. a PlaneWave calculation.

Parameters

•**bulk_configuration** (*BulkConfiguration*) – A bulk configuration with an updated PlaneWave calculator attached.

•**kpoint_sampling** (*KpointDensity* | *MonkhorstPackGrid*) – The k-point sampling to use for the optimization.

- **orbitals_per_shell_map** (*dict | list*) – A map of type {element : [n0, n1, n2, n3]} where n0, n1, are the number of orbitals with angumar momentum 0, 1, 2, to be used for the complete basis set. If a list of numbers is provided, that will be applied to all elements in the optimization. **Default:** [5, 5, 4, 3] applied to all elements.
- **radial_cutoff_radius_map** (*dict of floats*) – For every element, this defines the radius at which the radial function grid stops.
- **confinement_start_radius_map** (*dict of floats*) – For every element, this defines the radius at which the confining potential starts.
- **elements** (*list of strings*) – The elements for which to optimize.
- **energy_cutoff** (*PhysicalQuantity of type energy.*) – The energy cutoff decides how many plane-wave bands will be included when optimizating the basis set.
- **confinement_strength** (*Physical Quantitity of type energy.*) – The strenght of the confining potential.
- **tolerance** (*float*) – The tolerance determines the value of the spilling for each band at which the basis set is deemed converged.
- **max_number_of_iterations** (*int*) – In the conjugate gradient optimizer for the basis set, the max number of iterations can be set. Beyond this it stops even if it isnt converged.

optimize(*spilling_criterion*, *size_criterion_map*, *print_spilling_per_band=False*)

Run the basis set optimization.

Parameters

- **spilling_criterion** (*float*) – Tolerance for when to stop the optimization. When the maximum spilling is below the spilling criterion, the optimization will stop and return the smallest basis set fulfilling this criterion.
- **size_criterion_map** (*dict of type {element: int}*) – A map of elements and maximum allowed basis set size.
- **print_spilling_per_band** (*bool*) – Boolean controlling if band resolved spilling should be printed. **Default:** False

Returns
List of optimized basis set for each element.

Return type
list of *BasisSet*

optimizeForOrbitalConfiguration(*subspace_sizes_map*)

Optimize the basis set for a given orbital configuration, which is the number of orbitals you want in each shell for each element type.

Parameters
subspace_sizes_map (*dict of list of floats*) – For every element type, a list containing the number of functions you want in the basis set for each angular momemntum channel

printCompleteSpilling()

Outputs the spilling of the complete basis set compared to the plane-wave calculation for the energy cutoff specified.

uniqueString()

Return a unique string representing the state of the object.

Usage Examples

The *BasisSetOptimizer* class is used to optimize the basis set for a given configuration. The basis set is optimized by by minimizing the spilling of the LCAO Basis set with respect to a reference plane-wave calculation performed with the same pseudo potential. It was developed to generate high quality basis sets to be used in GW calculations using the *GWCalculator* class.

The following example demonstrates how to optimize the basis set. First we define the configuration:

```
# Set up lattice
lattice = FaceCenteredCubic(5.4306*Angstrom)

# Define elements
elements = [Silicon, Silicon]

# Define coordinates
fractional_coordinates = [[ 0.  ,  0.  ,  0.  ],
                          [ 0.25,  0.25,  0.25]]

# Set up configuration
bulk_configuration = BulkConfiguration(
    bravais_lattice=lattice,
    elements=elements,
    fractional_coordinates=fractional_coordinates)
```

Then we define a plane wave calculator to perform the reference calculation:

```
numerical_accuracy_parameters = NumericalAccuracyParameters(
    k_point_sampling=MonkhorstPackGrid(9,9,9)
)
pw_calculator = PlaneWaveCalculator(
    wave_function_cutoff=50*Hartree,
    numerical_accuracy_parameters=numerical_accuracy_parameters,
    checkpoint_handler=NoCheckpointHandler)

bulk_configuration.setCalculator(pw_calculator)
bulk_configuration.update()
```

Then we define the basis set optimizer and optimize the basis set:

```
basis_set_optimizer = BasisSetOptimizer(
    bulk_configuration,
    orbitals_per_shell_map={Silicon: [6,6,5,4]},
    energy_cutoff=10*eV,
    tolerance=1.0e-5)
```

The energy cutoff decides up to what energy above the Fermi level the bands will be included for the spilling optimization. The orbitals per shell map is a dictionary that maps the elements to the number of orbitals per shell included in the complete basis set, out of which the optimal subset will be selected. This input decides how many angular momentum shells will be included in the basis set optimization. In this example the complete basis set will have 6 s-orbitals, 6 p-orbitals, 5 d-orbitals, and 4 f-orbitals.

Finally we optimize the basis set and save the optimized basis set:

```
opt_basis_set = basis_set_optimizer.optimize()
nlsave("opt_basis_set.hdf5", opt_basis_set)
```

doing this will choose the smallest optimal combination of orbitals that meets the tolerance criterium.

To find the optimal basis set with a given size, you can do the following:

```
subspace_sizes_map = {Silicon: [3,3,2,1]}
optimized_parameter_set = optimizer.optimizeForOrbitalConfiguration(
    subspace_sizes_map=subspace_sizes_map
)
```

This will find an optimal basis set with 3 s-orbitals, 3 p-orbitals, 2 d-orbitals, and 1 f-orbitals. To get a basis set object from the output of the optimization, you can do the following:

```
optimized_basis_set = optimizer._constructBasisSetFromParametersMap(
    parameters_map=optimized_parameter_set.parameters_map,
    subsize_sizes_map=subspace_sizes_map)
nlsave("opt_basis_set.hdf5", opt_basis_set)
```

BlochState

class BlochState(*configuration=None*, *quantum_number=None*, *spin=None*, *k_point=None*, *density_mesh_cutoff=None*)

A class for calculating the wave function of a Bloch state.

Parameters

- **configuration** (*BulkConfiguration*) – The configuration for which the Bloch state should be calculated.
- **quantum_number** (*int*) – The quantum number of the desired Bloch state. **Default:** `0`
- **spin** (`Spin.Up` | `Spin.Down` | `Spin.All`) – The spin to calculate the Bloch state for. **Default:** `Spin.All`
- **k_point** (*list(3) of floats*) – The k-point in fractional coordinates that the Bloch state should be calculated for. **Default:** `[0.0, 0.0, 0.0]`
- **density_mesh_cutoff** (*PhysicalQuantity* of type energy | *GridSampling* | *OptimizedFFTGridSampling*) – The mesh cutoff to be used to determine the grid sampling. The mesh cutoff must be a positive energy or a *GridSampling* object. **Default:** Specific for each calculator.

absolute()

Returns
A new grid containing the absolute values (or modulus) of the current field.

Return type
GridValues

axisProjection(*projection_type='sum'*, *axis='c'*, *spin=None*, *projection_point=None*, *coordinate_type=<class 'NL.ComputerScienceUtilities.NLFlag._NLFlag.Fractional'>*)

Get the values projected on one of the grid axes.

Parameters

- **projection_type** (*str*) –

The type of projection to perform. Should be either

–sum for the sum over the plane spanned by the two other axes.

–average or avg for the average value over the plane spanned by the two other axes.

–line for the value along a line parallel to the axis and through a point specified by the *projection_point* parameter.

Default: sum

•**axis** (*str*) – The axis to project the data onto. Should be either a, b or c. **Default:** c

•**spin** (Spin.Sum | Spin.Z | Spin.X | Spin.Y | Spin.Up | Spin.Down | Spin.RealUpDown | Spin.ImagUpDown) – Which spin component to project on. **Default:** Spin.All

•**projection_point** (sequence, PhysicalQuantity) – Axis coordinates of the point through which to take a line if projection_type is projection_point. Must be given as a sequence of three coordinates *[a, b, c]*. It the numbers have units of length, they are first divided by the length of the respective primitive vectors [A, B, C], and then interpreted as fractional coordinates. Unitless coordinates are immidiately interpreted as fractional.

•**coordinate_type** (Fractional | Cartesian) – Flag to toggle if the returned axis values should be given in units of Angstrom (NLFlag.Cartesian) or in units of the norm of the axis primitive vector (NLFlag.Fractional). **Default:** Fractional

Returns
A 2-tuple of 1D numpy.arrays containing the axis values and the projected data. For Cartesian coordinate type the grid offset is added to the axis values.

Return type
tuple.

derivatives(*x*, *y*, *z*, *spin=None*)

Calculate the derivative of the wave function in the point (x, y, z).

Parameters

•**x** (*PhysicalQuantity* of type length) – The Cartesian x coordinate.

•**y** (*PhysicalQuantity* of type length) – The Cartesian y coordinate.

•**z** (*PhysicalQuantity* of type length) – The Cartesian z coordinate.

•**spin** (Spin.Up | Spin.Down | Spin.All) – The spin component to project on. **Default:** The spin of this Bloch state object.

Returns
The gradient at the specified point for the given spin. For Spin.All, a tuple with (Spin.Up, Spin.Down) components is returned if the calculation is not unpolarized.

Return type
PhysicalQuantity of type energy$^{-3/2}$ Œ length^{-1}

downsample(*downsampling_a=None*, *downsampling_b=None*, *downsampling_c=None*)

Generate a new GridValues object where the grid is downsampled. Along periodic directions an FFT downsampling is performed. Along non-periodic directions antialiasing and downsampling is performed.

Parameters

•**downsampling_a** (*int*) – The new number of grid points along the A direction. **Default:** No downsampling.

•**downsampling_b** (*int*) – The new number of grid points along the B direction. **Default:** No downsampling.

•**downsampling_c** (*int*) – The new number of grid points along the C direction. **Default:** No downsampling.

`eigenvalue`()

Returns the eigenvalue associated with the calculated eigenstate (as absolute energy).

Returns
The eigenvalue associated with the calculated eigenstate (as absolute energy). For a polarized calculation with `Spin.All`, both `Spin.Up` and `Spin.Down` values are returned

Return type
PhysicalQuantity of type energy | list of *PhysicalQuantity* of type energy.

`evaluate`(*x*, *y*, *z*, *spin=None*)

Evaluate the wave function in the point (x, y, z).

Parameters

- **x** (*PhysicalQuantity* of type length) – The Cartesian x coordinate.
- **y** (*PhysicalQuantity* of type length) – The Cartesian y coordinate.
- **z** (*PhysicalQuantity* of type length) – The Cartesian z coordinate.
- **spin** (`Spin.Up` | `Spin.Down` | `Spin.All`) – The spin component to project on. **Default:** The spin of this Bloch state object.

Returns
The value at the specified point for the given spin. For `Spin.All`, a tuple with (`Spin.Up`, `Spin.Down`) components is returned if the calculation is not unpolarized.

Return type
PhysicalQuantity of type energy$^{-3/2}$

`gridCoordinate`(*i*, *j*, *k*)

Return the coordinate for a given grid index.

Parameters

- **i** (*int*) – The grid index in the A direction.
- **j** (*int*) – The grid index in the B direction.
- **k** (*int*) – The grid index in the C direction.

Returns
The Cartesian coordinate of the given grid index.

Return type
PhysicalQuantity of type length.

`kPoint`()

Returns
The k-point to calculate the Bloch state for.

Return type
list(3) of floats

`metatext`()

Returns
The metatext of the object or None if no metatext is present.

Return type
str | None

nlinfo()

Returns
The information.

Return type
dict

nlprint(*stream=None*)

Print a string containing an ASCII table useful for plotting the AnalysisSpin object.

Parameters
stream (*python stream*) – The stream the table should be written to. **Default:** NLPrintLogger()

primitiveVectors()

Returns
The primitive vectors of the grid.

Return type
PhysicalQuantity of type length.

quantumNumber()

Returns
The quantum number of the desired eigenstate.

Return type
int

quantumNumberReference()

Returns
Whether the quantum number is counted starting from the lowest available state (Absolute), or from the first occupied state (Lumo).

Return type
Absolute``|``Lumo

scale(*scale*)

Scale the field with a float.

Parameters
scale (*float*) – The parameter to scale with.

setMetatext(*metatext*)

Set a given metatext string on the object.

Parameters
metatext (*str | None*) – The metatext string that should be set. A value of None can be given to remove the current metatext.

shape()

Returns
The number of grid points in each direction.

Return type
tuple of three int.

spin()

Returns
The spin the Bloch state is calculated for.

Return type
Spin.Up | Spin.Down | Spin.All

spinProjection(*spin=None*)

Construct a new *GridValues* object with the values of this object projected on a given spin component.

Parameters
spin (Spin.All | Spin.Sum | Spin.X | Spin.Y | Spin.Z | Spin.Up | Spin.Down | Spin.RealUpDown | Spin.ImagUpDown) – The spin component to project on. **Default:** The spin the object was created with. If the spin was Spin.All, Spin.Sum will be used for the projection.

Returns
A new *GridValues* object for the specified spin.

Return type
GridValues

toArray()

Returns
The values of the grid as a numpy array slicing off any units.

Return type
numpy.array

uniqueString()

Return a unique string representing the state of the object.

unit()

Returns
The unit of the data in the grid.

Return type
A physical unit.

unitCell()

Returns
The unit cell of the grid.

Return type
PhysicalQuantity of type length.

volumeElement()

Returns
The volume element of the grid represented by three vectors.

Return type
PhysicalQuantity of type length.

Usage Examples

Calculate and save a Bloch state for a gold FCC crystal:

```
# Define lattice
lattice = FaceCenteredCubic(4.08*Angstrom)

# Define elements
elements = [Gold]

# Define coordinates
coordinates = [[2.0, 2.0, 2.0]]*Angstrom

# Set up configuration
bulk_configuration = BulkConfiguration(
    lattice,
    elements,
    coordinates
    )

# Define a a calculator
bulk_configuration.setCalculator(LCAOCalculator())

# Calculate and save the Bloch state with quantum number 5
bloch_state = BlochState(bulk_configuration, quantum_number=5,
                         k_point=[0.0, 0.5, 0.5])
nlsave('bloch_state.nc', bloch_state)
```

blochstate.py

For examples on working with 3D grids, see *HartreePotential* and *ElectronDensity*.

Note: For more advanced options and calculating multiple *BlochState* objects *calculateBlochStates()* is advisable.

BondConstraint

class BondConstraint(*fixed_bonds=None*, *fixed_angles=None*, *inversion_order=4*, *rotation_order=1*)

This constraint fixes the bond lengths of the system in a *MolecularDynamics()* simulation or *OptimizeGeometry()* calculation based on the LINCS method.

Parameters

- **fixed_bonds** (*list*) – The bonds to constrain. These are specified as a list of pairs. If the pair contains two integers, these are taken as the indices of the bond. If the pair contains two strings, these are taken as tags describing two sets of atoms between which the bonds are to be constrained. If the pair contains two elements, these are taken as the elements between which all bonds are to be constrained.
- **fixed_angles** (*list*) – The angles to constrain. These are specified as a list of triples. The angle is constrained by constraining the two bonds and the distance between the end atoms in the angle. In this way small molecules such as water can be constrained to be rigid. If the triple contains to integers, these are taken as the indices of the angle. If the triple contains two strings, these are taken as tags describing three sets of atoms between which the angles are to be

constrained. If the triple contains three elements, these are taken as the elements between which all angles are to be constrained.

- **inversion_order** (*int*) – The number of terms used to approximate the matrix inversion in the LINCS equations. **Default:** 4
- **rotation_order** (*int*) – The number of cycles used in the correction for rotational bond lengthening. **Default:** 1

bondIndices()

Returns
List of indices of the bonds that are constrained

Return type
ndarray

bondLengths()

Returns
List of the constrained bond lengths

Return type
PhysicalQuantity of type length

frozenDegreesOfFreedom(*local_atoms=None*)

The number of constrained degrees of freedom.

Parameters
local_atoms (*list of int | None*) – The group of atoms from which the frozen degrees of freedom should be calculated, e.g. a thermalized group of atoms. **Default:** All atoms.

Returns
The number of degrees of freedom that are frozen by this constraint object.

Return type
int

uniqueString()

Return a unique string representing the state of the object.

Usage Examples

Run a molecular dynamics calculation on a PVC polymer with constrained bonds for all hydrogen atoms. This allows using a longer time-step of 2 femtoseconds.

```
method = NVTNoseHoover(
    time_step=2*femtoSecond,
    reservoir_temperature=300*Kelvin,
    thermostat_timescale=100*femtoSecond,
    heating_rate=0*Kelvin/picoSecond,
    chain_length=3,
    initial_velocity=initial_velocity,
)

# Set bond constraint to constrain all C-H bonds
bond_constraint = BondConstraint([[Carbon, Hydrogen]])
com_constraint = FixCenterOfMass()
```

(continues on next page)

(continued from previous page)

```
# With 2fs time steps 5,000 MD steps corresponds to 10ps of simulation time.
md_trajectory = MolecularDynamics(
    bulk_configuration,
    constraints=[bond_constraint, com_constraint],
    trajectory_filename='PVC_Bond_Constraint.hdf5',
    steps=5000,
    log_interval=500,
    method=method
)
```

PVC_Bond_Constraint.py PVC_Input.hdf5

Notes

The *BondConstraint* class implements the LINCS bond constraint[1] for both molecular dynamics and geometry optimization simulations. In the LINCS algorithm bonds are held rigid by introducing bond distance constraints g:

$$g_i(\mathbf{r}_n) = |\mathbf{r}_{i_1} - \mathbf{r}_{i_2}| - d_i = 0 \quad i = 1, ...K$$

These are then included in the equations of motion using Lagrange multipliers $\lambda_i(t)$ such that:

$$-\mathbf{M}\frac{d^2\mathbf{r}}{dt^2} = \frac{\partial}{\partial \mathbf{r}}\left(\mathbf{V} - \lambda \cdot \mathbf{g}\right)$$

These equations of motion are solved at each step of the simulation, allowing the changes in the selected bond lengths to be projected out of the atomic coordinates. Bond length changes are also projected out of the velocities, forces and stresses calculated during the simulation.

These bond constraints can be used with atoms at relative distances to each other during a simulation. This can aid in locating transition states or other intermediate configurations. The bond constraints can also be used to remove high frequency motion during molecular dynamics. In these kinds of simulations, the necessary time step of the simulation is often determined by the high frequency bond vibrations. This is especially true for bonds containing light elements such as hydrogen. By constraining these bonds it can be possible to increase the time step used for the molecular dynamics simulation, as those high frequency modes no longer have to be represented in the dynamics.

In *BondConstraint*, the bonds to be constrained are specified in the argument `fixed_bonds`. This takes a list of pairs of either elements, tags or atom indices as integers. For elements and tags, all static bonds between those elements or pairs will be constrained. If atom indices are given, the distance between these atoms will be constrained whether or not they are bonded. The constrained bond length will be taken from the starting configuration in the simulation.

It is also possible to constrain bond angles using the argument `fixed_angles`. This argument takes a list of triples of elements, tags or bond indices. The atoms specified in this triple are then constrained in a rigid triangle, approximating a rigid angle. Regardless of the type in input used, a distance constraint is added between the two end atoms whether or not they are bonded. This type of constraint can be used to create rigid small molecules, such as rigid water.

Warning: The solution to the constraint equations is performed using an approximate matrix inverse. Including angle constraints makes this approximation less valid, and increases the number of terms that need to be included to get a good solution. If angle constraints are included the parameter `inversion_order` may need to be significantly increased to account for this.

[1] Berk Hess, Henk Bekker, Herman J.ăC. Berendsen, and Johannes G. E.ăM. Fraaije. LINCS: A Linear Constraint Solver for Molecular Simulations. *J. Comput. Chem.*, 18:1463, Feb 1997. URL: https://onlinelibrary.wiley.com/doi/10.1002/%28SICI%291096-987X%28199709%2918%3A12%3C1463%3A%3AAID-JCC4%3E3.0.CO%3B2-H, doi:10.1002/(SICI)1096-987X(199709)18:12<1463::AID-JCC4>3.0.CO;2-H.

In the LINCS algorithm there are two iterative parts to the solution of the constraint equation. The first is the solution of a matrix inverse, which is approximated as a series. The number of terms in this series is modified using the argument `inversion_order`. Secondly the LINCS algorithm corrects changes in bond length due to rotation using an iterative solution. The number of iterations is modified using the argument `rotation_order`. By default these have values of 4 and 1 respectively. This is suitable for most calculations with just constrained bonds. Including constrained angles or large number of bonds may require increasing these values to obtain stable constraints.

BornEffectiveCharge

class BornEffectiveCharge(*configuration*, *kpoints_a=None*, *kpoints_b=None*, *kpoints_c=None*, *atomic_displacement=None*, *use_symmetry=None*, *non_selfconsistent_update=None*, *polarization_cartesian_directions=None*, *atom_indices=None*, *processes_per_displacement=None*)

Class for calculating the Born effective charge of a configuration.

Parameters

- **configuration** (*BulkConfiguration*) – The configuration with attached calculator that supports Berry-phase polarization calculations.
- **kpoints_a** (sequence (size 3) of int | *MonkhorstPackGrid* | *KpointDensity*) – The k-point sampling to use for integrating along the first direction. **Default:** `MonkhorstPackGrid(n_aa, n_ab, n_ac)`, where *n_aa*, *n_ab*, and *n_ac* are determined from the sampling `(na, nb, nc)` used for the self consistent calculation as follows: `n_aa = 2 * na + 1, n_ab = nb, n_ac = nc`.
- **kpoints_b** (sequence (size 3) of int | *MonkhorstPackGrid* | *KpointDensity*) – The k-point sampling to use for integrating along the second direction. **Default:** `MonkhorstPackGrid(n_ba, n_bb, n_bc)`, where *n_ba*, *n_bb*, and *n_bc* are determined from the sampling `(na, nb, nc)` used for the self consistent calculation as follows: `n_ba = na, n_bb = 2 * nb + 1, n_bc = nc`.
- **kpoints_c** (sequence (size 3) of int | *MonkhorstPackGrid* | *KpointDensity*) – The k-point sampling to use for integrating along the third direction. **Default:** `MonkhorstPackGrid(n_ca, n_cb, n_cc)`, where *n_ca*, *n_cb*, and *n_cc* are determined from the sampling `(na, nb, nc)` used for the self consistent calculation as follows: `n_ca = na, n_cb = nb, n_cc = 2 * nc + 1`.
- **atomic_displacement** (*PhysicalQuantity* of type length) – The distance the atoms are displaced in the finite difference method. **Default:** `0.01*Angstrom`
- **use_symmetry** (*bool*) – If enabled, only the symmetrically unique atoms are displaced and the remaining born effective charges are calculated using symmetry. **Default:** `True`
- **non_selfconsistent_update** (*bool*) – If True, the displaced configurations are updated non-self-consistently. This leads to a computational speed-up, but the results should be carefully checked against self-consistent calculations. **Default:** `False`
- **polarization_cartesian_directions** (list of `CartesianDirection.{X,Y,Z}`) – Restrict the evaluation of the Polarization to specific Cartesian directions. For example, if `[CartesianDirection.X]` is specified, only the `xx, xy, xz` components of the born effective charge tensor are calculated. This option can be used to speed up the calculation if only such components are required. **Default:** `[CartesianDirection.X, CartesianDirection.Y, CartesianDirection.Z]`
- **atom_indices** (`All` | list of ints.) – The atom indices for which to calculate the Born effective charges. If not `All`, the use of symmetries will be disabled. **Default:** `All` i.e. all atoms in the configuration.
- **processes_per_displacement** (`Automatic` | int) – The number of processes to use per atomic displacement. When set to `Automatic` the number will be determined automatically maximizing the number of displacements calculated in parallel and minimizing the number of idle processes. One may set this number manually in order to reduce the memory requirements for each process. **Default:** `Automatic`

atomIndices()

Returns
The atom indices.

Return type
list of int.

atomicDisplacement()

Returns
The distance the atoms are displaced in the finite difference method.

Return type
PhysicalQuantity of type length

evaluate(*charge_sum_rule_method=None*)

The Born effective charge $Z_{\alpha,ij}$ for the ion α displaced in direction *j* leading to the Polarization in direction *i*.

Parameters
charge_sum_rule_method (None | DistributeEvenly | DistributeRelative.) – Keyword specifying if a charge sum-rule should be applied to the Born effective charges. Can be None for no sum-rule application. Alternatively the charge error is either distributed evenly (DistributeEvenly) or relative (DistributeRelative) to the Born effective charges on the atoms. **Default:** None

Returns
The Born effective charge as an array of shape (*n*, 3, 3), where *n* is the number of atoms. The second last entry is the Cartesian direction of polarization and the last is the direction in which the ion is displaced.

Return type
PhysicalQuantity of type charge

kpointsA()

Returns
The k-point sampling used for integrating along the first direction.

Return type
MonkhorstPackGrid

kpointsB()

Returns
The k-point sampling used for integrating along the second direction.

Return type
MonkhorstPackGrid

kpointsC()

Returns
The k-point sampling used for integrating along the third direction.

Return type
MonkhorstPackGrid

metatext()

Returns
The metatext of the object or None if no metatext is present.

Return type
str | None

nlprint(*stream=None*)

Print a string containing an ASCII table useful for plotting the AnalysisSpin object.

Parameters
stream (*python stream*) – The stream the table should be written to. **Default:** `NLPrintLogger()`

nonSelfconsistentUpdate()

Returns
True if the displaced configurations are updated non-selfconsistently.

Return type
bool

polarizationCartesianDirections()

Returns
The Cartesian components for which the polarization is evaluated.

Return type
list of `CartesianDirection.{X,Y,Z}`

setMetatext(*metatext*)

Set a given metatext string on the object.

Parameters
metatext (*str | None*) – The metatext string that should be set. A value of None can be given to remove the current metatext.

uniqueString()

Return a unique string representing the state of the object.

useSymmetry()

Returns
True if the use of crystal symmetry to reduce the number of displacements is enabled.

Return type
bool

Usage Examples

Calculate the born effective charge of GaAs:

```
# ------------------------------------------------------------
# Bulk Configuration
# ------------------------------------------------------------

# Set up lattice
lattice = FaceCenteredCubic(5.6537*Angstrom)

# Define elements
elements = [Gallium, Arsenic]

# Define coordinates
fractional_coordinates = [[ 0.  ,  0.  ,  0.  ],
                          [ 0.25,  0.25,  0.25]]
```

(continues on next page)

(continued from previous page)

```
# Set up configuration
bulk_configuration = BulkConfiguration(
    bravais_lattice=lattice,
    elements=elements,
    fractional_coordinates=fractional_coordinates
    )

# ------------------------------------------------------------
# Calculator
# ------------------------------------------------------------
#----------------------------------------
# Exchange-Correlation
#----------------------------------------
exchange_correlation = LDA.PZ

k_point_sampling = MonkhorstPackGrid(
    na=14,
    nb=14,
    nc=14,
    )
numerical_accuracy_parameters = NumericalAccuracyParameters(
    density_mesh_cutoff=30.0*Hartree,
    k_point_sampling=k_point_sampling,
    occupation_method=FermiDirac(100.0*Kelvin*boltzmann_constant),
    )

calculator = LCAOCalculator(
    exchange_correlation=exchange_correlation,
    numerical_accuracy_parameters=numerical_accuracy_parameters,
    )

bulk_configuration.setCalculator(calculator)
nlprint(bulk_configuration)
bulk_configuration.update()
nlsave('GaAs.hdf5', bulk_configuration)

# ------------------------------------------------------------
# Born Effective Charge
# ------------------------------------------------------------
born_effective_charge = BornEffectiveCharge(
    configuration=bulk_configuration,
    kpoints_a=MonkhorstPackGrid(21, 5, 5),
    kpoints_b=MonkhorstPackGrid(5, 21, 5),
    kpoints_c=MonkhorstPackGrid(5, 5, 21),
    atomic_displacement=0.01*Angstrom,
    )
nlsave('GaAs.hdf5', born_effective_charge)
```

born_effective_charge.py

The output from the calculation is:

```
+-------------------------------------------------------------------------------+
| Born Effective Charge Report                                                  |
+-------------------------------------------------------------------------------+
|                                                                               |
| 0 Ga:                                                                         |
|                                                                               |

+-------------------------------------------------------------------------------+
```

The calculated Born effective charge tensors are diagonal with a diagonal value of around ± 2.1 for Ga and As, respectively, in agreement with experiments and previous calculations[1].

Notes

The Born effective charge tensor is defined as the derivative of the polarization with respect to the atomic coordinate

$$Z^*_{\mu,ij} = \Omega_0 \frac{\partial \mathbf{P}_i}{\partial \mathbf{r}_{\mu,j}},$$

where Ω_0 is the unit cell volume, $\mathbf{P}_i$ is the ith Cartesian component of the Polarization and $\mathbf{r}_{\mu,j}$ is the jth Cartesian component of the position of atom μ.

When calculating the Born effective charge notice the following

- Perform the calculation with a low electronic broadening (e.g. 100 K). The default of 1000 K can lead to wrong results for small band gap materials.
- Carefully check the results agaist the parameter *atomic_displacement*. Ususally the default value of *0.01*Angstrom* is a good choice but you might need to either increase or decrease it.

BornEffectiveChargeParameters

class BornEffectiveChargeParameters(*kpoints_a=None*, *kpoints_b=None*, *kpoints_c=None*, *atomic_displacement=None*, *use_symmetry=None*, *non_selfconsistent_update=None*, *polarization_cartesian_directions=None*, *atom_indices=None*, *processes_per_displacement=None*)

Class for parameters used to evaluate `BornEffectiveCharge` analysis.

Parameters

[1] R.ăD. King-Smith and D.ăVanderbilt. Theory of polarization of crystalline solids. *Phys. Rev. B*, 47:1651–1654, Jan 1993. doi:10.1103/PhysRevB.47.1651.

- **kpoints_a** (sequence (size 3) of int | *MonkhorstPackGrid* | *KpointDensity*) – The k-point sampling to use for integrating along the first direction. **Default:** `MonkhorstPackGrid(n_aa, n_ab, n_ac)`, where *n_aa*, *n_ab*, and *n_ac* are determined from the sampling `(na, nb, nc)` used for the self consistent calculation as follows: `n_aa = 2 * na + 1, n_ab = nb, n_ac = nc`.
- **kpoints_b** (sequence (size 3) of int | *MonkhorstPackGrid* | *KpointDensity*) – The k-point sampling to use for integrating along the second direction. **Default:** `MonkhorstPackGrid(n_ba, n_bb, n_bc)`, where *n_ba*, *n_bb*, and *n_bc* are determined from the sampling `(na, nb, nc)` used for the self consistent calculation as follows: `n_ba = na, n_bb = 2 * nb + 1, n_bc = nc`.
- **kpoints_c** (sequence (size 3) of int | *MonkhorstPackGrid* | *KpointDensity*) – The k-point sampling to use for integrating along the third direction. **Default:** `MonkhorstPackGrid(n_ca, n_cb, n_cc)`, where *n_ca*, *n_cb*, and *n_cc* are determined from the sampling `(na, nb, nc)` used for the self consistent calculation as follows: `n_ca = na, n_cb = nb, n_cc = 2 * nc + 1`.
- **atomic_displacement** (*PhysicalQuantity* of type length) – The distance the atoms are displaced in the finite difference method. **Default:** `0.01*Angstrom`
- **use_symmetry** (*bool*) – If enabled, only the symmetrically unique atoms are displaced and the remaining born effective charges are calculated using symmetry. **Default:** `True`
- **non_selfconsistent_update** (*bool*) – If True, the displaced configurations are updated non-self-consistently. This leads to a computational speed-up, but the results should be carefully checked against self-consistent calculations. **Default:** `False`
- **polarization_cartesian_directions** (List of list of `CartesianDirection.{X,Y,Z}`) – Restrict the evaluation of the Polarization to specific cartesian directions. For example, if `[CartesianDirection.X]` is specified, only the `xx, xy, xz` components of the born effective charge tensor are calculated. This option can be used to speed up the calculation if only such components are required. **Default:** `[CartesianDirection.X, CartesianDirection.Y, CartesianDirection.Z]`
- **processes_per_displacement** (`Automatic` | int) – The number of processes to use per atomic displacement. When set to `Automatic` the number will be determined automatically maximizing the number of displacements calculated in parallel and minimizing the number of idle processes. One may set this number manually in order to reduce the memory requirements for each process. **Default:** `Automatic`

asDict()

Returns
The input parameters as keyword, value dictionary.

Return type
dict

atomIndices()

Returns
The atom indices.

Return type
list of int | `All`

atomicDisplacement()

Returns
The distance the atoms are displaced in the finite difference method.

Return type
PhysicalQuantity of type length

kpointsA()

Returns
The k-point sampling used for integrating along the first direction.

Return type
MonkhorstPackGrid

kpointsB()

Returns
The k-point sampling used for integrating along the second direction.

Return type
MonkhorstPackGrid

kpointsC()

Returns
The k-point sampling used for integrating along the third direction.

Return type
MonkhorstPackGrid

nlinfo()

Returns
The nlinfo.

Return type
dict

nonSelfconsistentUpdate()

Returns
True if the displaced configurations are updated non-selfconsistently.

Return type
bool

polarizationCartesianDirections()

Returns
The Cartesian components for which the tensor is evaluated.

Return type
List of list of `CartesianDirection.{X,Y,Z}`

processesPerDisplacement()

Returns
The number of processes per displacement.

Return type
`Automatic` | int

uniqueString()

Return a unique string representing the state of the object.

useSymmetry()

Returns
True if the use of crystal symmetry to reduce the number of displacements is enabled.

Return type
bool

BoxRegion

class BoxRegion(*value*, *xmin*, *xmax*, *ymin*, *ymax*, *zmin*, *zmax*)

Class for representing an orthorhombic region, i.e. a rectangular box of metallic or dielectric material.

Parameters

- **value** (float | *PhysicalQuantity* compatible with Volt) – The value that should be assigned to the box. Either the voltage or the dielectric constant of the region.
- **xmin** (*PhysicalQuantity* of type length) – The lower boundary of the box along the x-axis.
- **xmax** (*PhysicalQuantity* of type length) – The upper boundary of the box along the x-axis.
- **ymin** (*PhysicalQuantity* of type length) – The lower boundary of the box along the y-axis.
- **ymax** (*PhysicalQuantity* of type length) – The upper boundary of the box along the y-axis.
- **zmin** (*PhysicalQuantity* of type length) – The lower boundary of the box along the z-axis.
- **zmax** (*PhysicalQuantity* of type length) – The upper boundary of the box along the z-axis.

nlinfo()

Returns
The nlinfo.

Return type
dict

nlprint(*stream=<_io.TextIOWrapper name='<stdout>' mode='w' encoding='utf-8'>*, *header=True*)

Print a string containing an ASCII description of the SpatialRegion.

Parameters

- **stream** (*Stream based object*) – The io to write to.
- **header** (*bool*) – Option to emphasize the description as a header or not.

toGLObject(*color*)

Create the necessary object(s) to pass back into the GLConfiguration.

Parameters
color (*GLColor*) – The region type-specific color.

Returns
The box.

Return type
GLBox

uniqueString()

Return a unique string representing the state of the object.

value()

Function for asking for the value of the box region.

Returns
The value of the box region.

Return type
float | *PhysicalQuantity* compatible with Volt

xmax()

Returns
The maximum x-value of the box.

Return type
PhysicalQuantity of type length

xmin()

Returns
The minimum x-value of the box.

Return type
PhysicalQuantity of type length

ymax()

Returns
The maximum y-value of the box.

Return type
PhysicalQuantity of type length

ymin()

Returns
The minimum y-value of the box.

Return type
PhysicalQuantity of type length

zmax()

Returns
The maximum z-value of the box.

Return type
PhysicalQuantity of type length

zmin()

Returns
The minimum z-value of the box.

Return type
PhysicalQuantity of type length

Usage Examples

Define a dielectric region with dielectric constant $4\varepsilon_0$:

```
dielectric_region = BoxRegion(
    4.0,
    xmin=0*Angstrom, xmax=41.439*Angstrom,
    ymin=0.5*Angstrom, ymax=3.57914*Angstrom,
    zmin=5*Angstrom, zmax=50.4135*Angstrom
    )
```

dielectric_boxregion.py

Define two metallic regions where the second metallic region is constructed by cloning the first:

```
metallic_region1 = BoxRegion(
    1*Volt,
    xmin=0*Angstrom, xmax=41.439*Angstrom,
    ymin=0*Angstrom, ymax=0.5*Angstrom,
    zmin=5*Angstrom, zmax=15.*Angstrom
    )

metallic_region2 = metallic_region1(
    value=-1*Volt,
    ymin=10*Angstrom, ymax=12*Angstrom
    )
```

metal_boxregion.py

Notes

The following spatial regions are available:

- *BoxRegion*
- *SphereRegion*
- *TubeRegion*

BravaisLatticeConstraint

class BravaisLatticeConstraint

This constraint preserves the bravais lattice in constant stress simulations or optimization.

frozenDegreesOfFreedom(*local_atoms=None*)

Parameters
local_atoms (*list of int | None*) – The group of atoms from which the frozen degrees of freedom should be calculated, e.g. a thermalized group of atoms. **Default:** All atoms.

Returns
The number of degrees of freedom that are frozen by this constraint object.

Return type
int

uniqueString()

Return a unique string representing the state of the object.

Usage Examples

Run a geometry optimization of a rutile crystal with the Bravais lattice type fixed.

```
constraints = [BravaisLatticeConstraint()]

bulk_configuration = OptimizeGeometry(
    bulk_configuration,
    max_forces=0.05*eV/Ang,
    max_stress=0.1*GPa,
    max_steps=200,
    max_step_length=0.2*Ang,
    constraints=constraints,
    trajectory_filename=None,
    optimizer_method=LBFGS(),
)
```

bravais_lattice_constraint.py

Notes

- *BravaisLatticeConstraint* can be used in *OptimizeGeometry* to constrain the Bravais lattice type. This means that the stress is symmetrized according to the lattice type. The lattice vectors will still be optimized, but the lattice type will not change.

BrennerCalculator

class BrennerCalculator(*dynamical_matrix_parameters=None*)

Class for representing a Brenner Potential 2002 calculator.

Parameters
dynamical_matrix_parameters (*not used*) – **Deprecated:** from v2015, see the *DynamicalMatrix* analysis object.

dynamicalMatrixParameters()

This method is deprecated.

Returns
None always.

Return type
None

metatext()

Returns
The metatext of the object or None if no metatext is present.

Return type
str | None

nlinfo()

Returns
The nlinfo.

Return type
dict

setMetatext(*metatext*)

Set a given metatext string on the object.

Parameters
metatext (*str | None*) – The metatext string that should be set. A value of None can be given to remove the current metatext.

supportedElements()

This function queries the calculator for the elements it supports.

Returns
A list of chemical symbols for each element supported.

Return type
list of str

uniqueString()

Return a unique string representing the state of the object.

upgrade(*configuration*)

Method to upgrade the current calculator based on the given configuration.

Parameters
configuration (AtomicConfiguration sub-class) – The configuration the calculator will be used for.

Usage Examples

Define a Brenner calculator:

```
calculator = BrennerCalculator()
```

Notes

The calculator uses the classical Brenner potential version 2002[1] and is limited to the elements: Hydrogen, Carbon, Silicon, and Germanium.

The implementation uses the ASE-ASAP code.

BuckinghamPotential

class BuckinghamPotential(*particleType1*, *particleType2*, *A*, *rho*, *r_i=None*, *r_cut=None*)

Constructor of the potential.

Parameters

- **particleType1** (ParticleType *or* ParticleIdentifier) – Identifier of the first particle type.
- **particleType2** (ParticleType *or* ParticleIdentifier) – Identifier of the second particle type.
- **A** (*PhysicalQuantity of type energy*) – Potential parameter.

[1] D.ăW. Brenner, O.ăShenderova, J.ăHarrison, S.ăJ. Stuart, B.ăNi, and S.ăB Sinnott. A second-generation reactive empirical bond order (REBO) potential energy expression for hydrocarbons. *J. Phys.: Condensed Matter*, 14(4):783–802, 2002. arXiv:S0953-8984(02)31186-X, doi:10.1088/0953-8984/14/4/312.

•**rho** (*PhysicalQuantity of type length*) – Potential parameter.

•**r_i** (*PhysicalQuantity of type length*) – The inner cutoff radius where the smoothing of the potential starts. r_i must be smaller than r_cut.

•**r_cut** (*PhysicalQuantity of type length*) – The cutoff radius of this potential.

classmethod getAllParameterNames()

Return the names of all used parameters as a list.

getAllParameters()

Return all parameters of this potential and their current values as a <parameterName / parameterValue> dictionary.

static getDefaults()

Get the default parameters of this potential and return them in form of a dictionary of <parameter name, default value> key-value pairs.

getParameter(*parameterName*)

Get the current value of the parameter parameterName.

setParameter(*parameterName*, *value*)

Set the parameter parameterName to the given value.

Parameters

•**parameterName** (*str*) – The name of the parameter that will be modified.

•**value** – The new value that will be assigned to the parameter parameterName.

Usage Examples

Define a potential for Quartz by adding particle types and interaction functions to the *TremoloXPotentialSet*.

```
# ------------------------------------------------------------
# Set up a SiO2 Quartz crystal
# ------------------------------------------------------------

# Set up lattice
lattice = Hexagonal(4.916*Angstrom, 5.4054*Angstrom)

# Define elements
elements = [Silicon, Silicon, Silicon, Oxygen, Oxygen, Oxygen, Oxygen, Oxygen,
            Oxygen]

# Define coordinates
fractional_coordinates = [[ 0.4697,  0.0000,  0.0000    ],
                          [ 0.0000,  0.4697,  0.66666667],
                          [ 0.5303,  0.5303,  0.33333333],
                          [ 0.4135,  0.2669,  0.1191    ],
                          [ 0.2669,  0.4135,  0.547567  ],
                          [ 0.7331,  0.1466,  0.785767  ],
                          [ 0.5865,  0.8534,  0.214233  ],

Notes

The *BuckinghamPotential* defines a pair potential of the form

$$V_{ij}(r) = Ae^{-r/\rho}\,.$$

Note that this potential form uses a repulsive term only. In general, Buckingham potentials often also include an attractive dispersion term of the form $-C/r^6$.

We have not included such a term in the **TremoloX** *BuckinghamPotential* implementation, as this can easily be achieved by adding a *LennardJonesMNPotential*, for example, as shown in the example above.

This permits combinations of the *BuckinghamPotential* with all kinds of attractive terms avaliable in the *TremoloXPotentialSet*, providing extended flexibility.

At long distances this potential is brought smoothly to zero between the inner cutoff `r_i` and the outer cutoff `r_cut`, using a 5$^{\text{th}}$ order spline function. This ensures that there are no discontinuites in the forces as atoms are brought closer together, and that the energy is properly conserved. The applied potential $U(r)$ is given as:

$$U(r) = V_{ij}(r) \times S(r)$$

where $V_{ij}(r)$ is the pair potential and $S(r)$ is the spline function. The values of the spline function are:

- 1 when $r \leq r_i$
- In the range $[0, 1]$ when $r_i < r < r_{cut}$
- 0 when $r \geq r_{cut}$

BulkConfiguration

class BulkConfiguration(*bravais_lattice*, *elements*, *cartesian_coordinates=None*, *fractional_coordinates=None*, *ghost_atoms=None*, *velocities=None*, *tag_data=None*, *fast_init=False*, *bonds=None*, *dielectric_regions=None*, *metallic_regions=None*, *partial_charges=None*, *improper_dihedral_indices=None*)

Class for representing a periodic structure, i.e bulk configuration.

Construction of a bulk configuration from a `BravaisLattice` object. The additional arguments are the elements, the Cartesian coordinates or fractional coordinates. The Cartesian coordinates and fractional coordinates cannot be given at the same time. The list arguments containing the elements and coordinates must have the same length.

Parameters

- **bravais_lattice** (`BravaisLattice`) – A lattice of the bulk configuration.
- **elements** (*PeriodicTableElement*) – A sequence containing the elements of the configuration.
- **cartesian_coordinates** (*PhysicalQuantity* of type length | None) – A sequence containing a sequence of atomic coordinates for each element in the configuration. Has the dimensionality nx3. **Default:** None
- **fractional_coordinates** (*array(n, 3) | None*) – A sequence containing sequences of fractional coordinates for each element in the configuration. **Default:** None

- **ghost_atoms** (*int(n)*) – A list of atom indices to treat as ghost atoms. **Default:** None
- **velocities** (*PhysicalQuantity* of type length/time | None) – The velocities of the atoms. Has the dimensionality nx3. **Default:** None
- **tag_data** (*dict*) – A dict of tag data, linking tags to a list of atom indices. **Default:** None
- **fast_init** (*bool*) – Skip checking types and do not copy the arguments (i.e. only store references to them. This is an advanced option that should only be used internally. **Default:** False
- **bonds** (*array with shape (n,2) or (n,5) | None*) – An array with two atom indices for each bond along with the vector which periodic images this bond connects to.
- **dielectric_regions** (list of *BoxRegion* | *SphereRegion* | *TubeRegion*) – The list of dielectric regions to set.
- **metallic_regions** (list of *BoxRegion* | *SphereRegion* | *TubeRegion*) – The list of metallic regions to set.
- **partial_charges** (*PhysicalQuantity of type charge | None*) – A PhysicalQuantity array of the atomic partial charge for each atom.
- **improper_dihedral_indices** (*list or array with shape (m, 4) | None*) – The list of the 4 indices defining the connectivity for each improper dihedral or None to delete the current dihedral connectivity.

addBonds(*bond_list*)

Add bonds.

Parameters
bond_list (*numpy.ndarray*) – The list of bonds to add.

addTags(*tags*, *indices=None*)

Add a set of tags to atoms matching a collection of indices.

Parameters

- **tags** (*list | str*) – The list of tags to add to matching atoms.
- **indices** (*list | int | None*) – The list of indices to match atoms against. **Default:** All indices.

atomicMasses()

Returns
The masses of the atoms in the configuration.

Return type
PhysicalQuantity of type mass

atomicNumbers()

Returns
The list of atomic numbers associated with the elements.

Return type
list of ints

bonds()

Get the list of bond connections that can be used for bonded potentials in ATK-ForceField.

The connectivity indices refer to the wrapped configuration.

Returns
An array with the the two atom indices for each bond along with the vector which periodic images this bond connects.

Return type
array

bravaisLattice()

Returns
The bravais lattice of the configuration.

Return type
BravaisLattice

calculator()

Returns
The calculator attached to the configuration, i.e. the calculator that will be used for both simulation and analysis.

Return type
Calculator

cartesianCoordinates()

Returns
The Cartesian coordinates of the atoms as an nx3 array.

Return type
PhysicalQuantity of type length

center(*x_axis=True*, *y_axis=True*, *z_axis=True*)

Create a new *BulkConfiguration* by centering the atoms and the vacuum around the system.

The centered system is constructed with a cell of the type UnitCell.

Parameters

- **x_axis** (*bool*) – Boolean indicating if the system should be centered along the x-axis. **Default:** True.
- **y_axis** (*bool*) – Boolean indicating if the system should be centered along the y-axis. **Default:** True.
- **z_axis** (*bool*) – Boolean indicating if the system should be centered along the z-axis. **Default:** True.

Returns
The centered bulk system.

Return type
BulkConfiguration

cleave(*h=1*, *k=0*, *l=0*, *max_perpendicular_repeats=100*, *outer_atom_index=0*, *surface_transformation=None*, *layers=None*, *top_vacuum=None*, *bottom_vacuum=None*, *outer_atom_placement=None*)

Method to cleave the bulk system along the plane given by the Miller indices h, k, and l. Per the usual convention, the Miller indices defined a plane in the conventional unit cell.

Parameters

- **h** (*int*) – The first Miller index. **Default:** 1.
- **k** (*int*) – The second Miller index. **Default:** 0.
- **l** (*int*) – The third Miller index. **Default:** 0.
- **max_perpendicular_repeats** (*int*) – The maximum number of times the crystal lattice should be repeated in order to become perpendicular to the surfaces plane. Will throw an exception if it is not possible. These repetitions are only used when *layers* is *None*. **Default:** 100
- **outer_atom_index** (*int*) – The index of the configuration which should be the outer atom in the surface. This is the atom which intersects the cleave plane. **Default:** 0

- **surface_transformation** (*array of type float*) – A 2x2 array that transforms the lattice vectors perpendicular to the surface normal (i.e. the surface vectors). This defaults to the identity matrix, which leaves them unchanged. If the values are non integral, this will result in a strained surface. **Default:** *[[1, 0], [0, 1]]*
- **layers** (*float*) – The number of atomic layers in the repeated structure. By default the smallest number of layers that yields perpendicular unit cell (c-axis purely along the z-axis) is used. **Default:** None
- **top_vacuum** (*PhysicalQuantity* of type length) – The vacuum padding to add to the top of the cell. **Default:** 0.0*Angstrom
- **bottom_vacuum** (*PhysicalQuantity* of type length) – The vacuum padding to add to the bottom of the cell. **Default:** 0.0*Angstrom
- **outer_atom_placement** (*float*) – The fractional c-coordinate of the outer atom. By default the location of this atom will be at c=1.0 if no top or bottom vacuum is used. If vacuum is used, then the atom will be located at the correct place in the unit cell to accommodate the vacuum settings. **Default:** None

Returns
The cleaved bulk configuration.

Return type
BulkConfiguration

coarseGrainDescriptors()

Returns
The list of either elements or coarse grain particles for each element. Isotopes are returned as just their base element, UnitedAtoms and Particle are given as their specific type.

Return type
list of type ParticleDescriptor or *PeriodicTableElement*

copy()

Returns
A copy of the current configuration.

Return type
MoleculeConfiguration | *BulkConfiguration* | *DeviceConfiguration* | *SurfaceConfiguration*

copyAndDeleteAtoms(*indices*)

Create a new configuration by deleting some atoms from this configuration.

Parameters
indices (*list of int*) – The indices of the atoms to delete.

Returns
The configuration with some atoms deleted.

Return type
MoleculeConfiguration | *BulkConfiguration* | *DeviceConfiguration* | *SurfaceConfiguration*

copyAndMerge(*other*)

Create a new configuration by merging this configuration with another configuration.

Parameters
other (*MoleculeConfiguration* | *BulkConfiguration* | *DeviceConfiguration* | *SurfaceConfiguration*) – The other configuration.

Returns
The merged configuration.

Return type
MoleculeConfiguration | *BulkConfiguration* | *DeviceConfiguration* | *SurfaceConfiguration*

copyAndShiftAtoms(*displacement*, *indices=None*)

Create a new configuration with some atoms translated.

Parameters

- **displacement** (*PhysicalQuantity* of type length) – The displacement that should be applied to the atom positions.
- **indices** (*list of int*) – The indices to shift. **Default:** All.

Returns
The configuration with the translation applied.

Return type
MoleculeConfiguration | *BulkConfiguration* | *DeviceConfiguration* | *SurfaceConfiguration*

deleteAtoms(*indices*)

Delete atoms from the configuration by specifying their indices.

Parameters
indices (*array of int*) – The indices to delete.

deleteBonds(*bond_list=None*, *pair_selection=None*)

Delete bonds connected to atomic indices.

Parameters

- **bond_list** (*A two-dimensional sequence*) – The pairs of bonds indices.
- **pair_selection** (*list | None*) – Specifies two groups between which bonds are delete. Selectable groups are elements, index lists, tag names, or None (all atoms).

dielectricRegions()

Returns
The dielectric regions in the configuration.

Return type
list of *BoxRegion* | *SphereRegion* | *TubeRegion*

elements()

Returns
The elements in configuration.

Return type
list of *PeriodicTableElement*

externalPotential()

Returns
The external potential present on the configuration.

Return type
AtomicShift | *AtomicCompensationCharge* | None

findBonds(*fuzz_factor=1.1*, *pair_selection=None*, *periodic_boundaries=None*)

Find bonds in the configuration according to the combined covalent radii of the element pairs, multiplied with a fuzz factor. Optionally, find bonds only between two specified sub-groups of atoms. The bonds are primarily used in to set the topology of bonded potentials in the TremoloX-calculator.

Parameters

- **fuzz_factor** (*float*) – The factor by which the covalent radii are multiplied to determine the cutoff distance for a bond.
- **pair_selection** (list(2) of type *PeriodicTableElement*, list of int, or str) – Specifies two groups between which bonds are detected. Selectable groups are elements, index lists, tag names, or None (all atoms). By default bonds between all atoms in the configuration are taken into account.
- **periodic_boundaries** (*3-tuple of bool*) – The periodic boundaries **Default:** The periodic boundaries for the configuration.

fixedSpinDirections()

Returns
The fixed spin directions for the configuration.

Return type
FixedSpin | None

fractionalCoordinates()

Returns
The fractional coordinates of the bulk configuration as a nx3 array.

Return type
array of floats

generateShifts()

Method for generating a list of origin shifts along all 3 lattice directions.

It will create a list of 27 shifts of the supercell origin (-1 to 1) in the three periodic directions.

Returns
The array of shifts

Return type
PhysicalQuantity of type length

ghostAtoms()

Returns
The list of ghost atoms.

Return type
list of ints

improperDihedralIndices()

Returns
The list of atom indices for each improper dihedral or None if no improper dihedrals are defined. Improper dihedrals are mainly used in bonded force fields.

Return type
numpy array | None

indices()

Returns
The indices of the atoms.

Return type
list of int

indicesFromIsotopes(*isotopes*)

Parameters
isotopes (*list of type PeriodicTableElement or Isotope*) – The isotopes to select.

Returns
The indices of the selected isotopes.

Return type
list of type int

indicesFromTags(*tags=None*)

List the indices associated with a given collection of tags.

Parameters
tags (*list | str*) – A list of tags for which all matching indices should be extracted.

Returns
The list of indices corresponding to the specified tag name(s).

Return type
list of ints

magneticMoments()

Returns
The magnetic moments of the atoms. Has the dimensionality nx3.

Return type
PhysicalQuantity of type Bohr magneton.

massDensity()

Returns
The mass density.

Return type
PhysicalQuantity of type mass per volume

merge(*other*)

Merge configuration with another configuration.

Parameters
other (*MoleculeConfiguration* | *BulkConfiguration* | *DeviceConfiguration* | *SurfaceConfiguration*) – A different configuration.

metallicRegions()

Returns
The metallic regions for the configuration.

Return type
list of *BoxRegion* | *SphereRegion* | *TubeRegion*

metatext()

Returns
The metatext of the object or None if no metatext is present.

Return type
str | None

nlinfo()

Returns
The configuration information.

Return type
dict

nlprint(*stream=None*)

Print a string containing an ASCII table useful for plotting the AtomicConfiguration object.

Parameters
stream (*python stream*) – The stream the table should be written to. **Default:** NLPrintLogger().

numberOfAtoms()

Returns
The total number of atoms in the configuration.

Return type
int

partialCharges(*indices=None*)

Get the list of partial atomic charges that can be used for representing electrostatic interactions in ATK-ForceField.

Parameters
indices (*list | int | None*) – The indices for which to return the partial charges. **Default:** All indices.

Returns
A PhysicalQuantity array of the atomic partial charge for each atom.

Return type
PhysicalQuantity of type charge | None

particleDescriptors()

Returns
The list of particle descriptors for each atom. This should return the exact same list as was given in the constructor argument elements.

Return type
list of type ParticleDescriptor or *PeriodicTableElement*

static periodicBoundaries()

Returns
The periodic boundary conditions of the configuration.

Return type
list

primitiveVectors()

Returns
The primitive lattice vectors.

Return type
PhysicalQuantity of type length

reduce(*na=1*, *nb=1*, *nc=1*, *stack_systems=True*)

Reduce the *BulkConfiguration* with the integer values na, nb, and nc along the three primitive unit cell vectors. The reduced system is constructed with a cell of the type UnitCell.

Parameters

- **na** (*int*) – The repetition along the a-axis. **Default:** 1.
- **nb** (*int*) – The repetition along the b-axis. **Default:** 1.
- **nc** (*int*) – The repetition along the c-axis. **Default:** 1.
- **stack_systems** (*bool*) – If True the basis atoms are reduced as a unit, i.e. a0 and b0 are reduced as: a0,b0,a1,b1, If False the basis atom are reduced individually, i.e. a0 and b0 are reduced as: a0,a1,, b0,b1, **Default:** True.

Returns
The reduced bulk system.

Return type
BulkConfiguration

removeTags(*tags=None*, *indices=None*, *purge=False*)

Remove a set of tags from atoms matching a collection of indices.

Parameters

- **tags** (*list | str*) – The list of tags to add to matching atoms. **Default:** All tags.
- **indices** (*list | int*) – The list of indices to match atoms against. **Default:** All indices.
- **purge** (*bool*) – When removing tags from the configuration, delete the tag completely when not associated with any atoms anymore. **Default:** False.

repeat(*na=1*, *nb=1*, *nc=1*, *stack_systems=True*, *transfer_density_matrix=True*)

Repeat the *BulkConfiguration* with the integer values na, nb, and nc along the three primitive unit cell vectors. The repeated system is constructed with a cell of the type UnitCell.

Parameters

- **na** (*int*) – The repetition along the a-axis. **Default:** 1.
- **nb** (*int*) – The repetition along the b-axis. **Default:** 1.
- **nc** (*int*) – The repetition along the c-axis. **Default:** 1.
- **stack_systems** (*bool*) – If True the basis atoms are repeated as a unit, i.e. a0 and b0 are repeated as: a0,b0,a1,b1, If False the basis atom are repeated individually, i.e. a0 and b0 are repeated as: a0,a1,, b0,b1, **Default:** True.
- **transfer_density_matrix** (*bool*) – If True, the density matrix (or rather the schroedinger container) of the non-repeated system is used to set up the density matrix of the repeated system. **Default:** True.

Returns
The repeated bulk system.

Return type
BulkConfiguration

scalePartialCharges(*scale_factor*, *indices=None*)

Scale the partial charges with a given scale factor. These partial charges are used with Forcefield calculators.

Parameters

- **scale_factor** (*float*) – The factor for scaling charges.
- **indices** (*list | int | None*) – The indices for which to set the total charge. **Default:** All indices.

scalePrimitiveVectors(*scale_a=None*, *scale_b=None*, *scale_c=None*)

Scale the length of each lattice vector. The fractional coordinates of the atoms and the Bravais lattice type will be remain unchanged if possible.

Parameters

- **scale_a** (*float*) – The scaling factor for the a-axis to apply. **Default:** 1.0.
- **scale_b** (*float*) – The scaling factor for the b-axis to apply. **Default:** 1.0.
- **scale_c** (*float*) – The scaling factor for the c-axis to apply. **Default:** 1.0.

scaleVolume(*scaling_factor*)

Scale the volume of the crystal by an isotropic expansion of the lattice vectors. The fractional coordinates of the atoms and the Bravais lattice type will be unchanged.

Parameters

scaling_factor (*float*) – The scaling factor to apply. A value of `1.01` leads to a 1% increase in the volume.

setBonds(*bond_list*, *skip_checks=False*)

Set the bonds on the configuration. The bonds are primarily used in to set the topology of bonded potentials in the TremoloX-calculator.

Parameters

- **bond_list** (*list(n, 2) | list(n, 5) | None*) – A list which contains for each bond the indices of the two connected atoms. Optionally, three more integers can be specified for each bond, which must be between -1 and 1, and which denote to which neighboring image cell the bond is connected. Without these additional indices, the minimum image convention is obeyed.
- **skip_checks** (*bool*) – Skip argument type checking and just directly assign the value. **Default:** False.

setBravaisLattice(*bravais_lattice*, *conserve_coordinates=<class 'NL.ComputerScienceUtilities.NLFlag._NLFlag.Cartesian'>*, *skip_checks=False*)

Change the bravais lattice.

Parameters

- **bravais_lattice** (`BravaisLattice`) – The new lattice.
- **conserve_coordinates** (`Cartesian` | `Fractional`) – The type of coordinates to conserve.. **Default:** `Cartesian`.
- **skip_checks** (*bool*) – If True, ignores bond connectivity and input argument checks. **Default:** False.

setCalculator(*calculator*, *initial_state=None*, *initial_spin=None*)

Attach a *Calculator* to the configuration which will be used in calculations involving the configuration.

Parameters

- **calculator** (*Calculator* | None) – The calculator object that should be attached to the configuration.
- **initial_state** (*MoleculeConfiguration* | *BulkConfiguration* | *DeviceConfiguration* | *SurfaceConfiguration* with a calculator | None) – The initial state to be used for this configuration. **Default:** No initial state.
- **initial_spin** (*InitialSpin* | None) – The initial InitialSpin object to be used for this configuration. **Default:** `InitialSpin()`, except when used with a calculator of type *HuckelCalculator*, *SlaterKosterCalculator*, *SemiEmpiricalCalculator*, *DeviceHuckelCalculator*, *DeviceSlaterKosterCalculator*, *DeviceSemiEmpiricalCalculator*. In this case `InitialSpin([0., 0., ...])` is used, i.e. the scaled spins for each atom are set to 0.

setCartesianCoordinates(*cartesian_coordinates*, *indices=None*, *skip_checks=False*)

Set the Cartesian coordinates of the atoms.

Parameters

- **cartesian_coordinates** (*PhysicalQuantity* of type length) – The new coordinates of the atoms in each image.

- **indices** (*list*) – The indices of the atoms to set the positions of. **Default:** All indices.
- **skip_checks** (*bool*) – Skip argument type checking and just directly assign the value. **Default:** False.

setDielectricRegions(*dielectric_regions*)

Set the dielectric regions for the configuration.

Parameters
dielectric_regions (list of *BoxRegion* | *SphereRegion* | *TubeRegion*) – The list of dielectric regions to set.

setExternalPotential(*external_potential*)

Set an external potential on the configuration that will be used in calculations involving the configuration.

Parameters
external_potential (*AtomicShift* | *AtomicCompensationCharge*) – The external potential to apply.

setFractionalCoordinates(*fractional_coordinates*, *indices=None*, *skip_checks=False*)

Set the Cartesian coordinates of the atoms.

Parameters

- **fractional_coordinates** (*array of floats*) – The new coordinates of the atoms as a nx3 array.
- **indices** (*array of ints | None*) – The indices of the atoms to set the positions of. **Default:** All indices.
- **skip_checks** (*bool*) – If True, ignores bond connectivity and input argument checks. **Default:** False.

setImproperDihedralIndices(*improper_dihedral_indices*)

Set the list of atom indices for each improper dihedral in bonded force fields.

Parameters
improper_dihedral_indices (*list or array with shape (m, 4) | None*) – The list of the 4 indices defining the connectivity for each improper dihedral or None to delete the current dihedral connectivity.

setMagneticField(*magnetic_field*)

Set local magnetic field. The spins will be forced to point in the directions given by the magnetic_field object. The magnetic field can be defined for each atom. This only has an effect for Noncollinear or Spinorbit calculations.

Parameters
magnetic_field (*FixedSpin*) – The magnetic field to be applied.

setMagneticMoments(*magnetic_moments=None*, *skip_checks=False*)

Function to set magnetic moments on the configuration.

Parameters

- **magnetic_moments** (*PhysicalQuantity* of type Bohr magneton.) – The magnetic_moments to set on the configuration. Has the dimensionality nx3. **Default:** None.
- **skip_checks** (*bool*) – Skip argument type checking and just directly assign the value. **Default:** False.

setMetallicRegions(*metallic_regions*)

Set the metallic regions for the configuration.

Parameters
metallic_regions (list of *BoxRegion* | *SphereRegion* | *TubeRegion*) – The list of metallic regions to set.

setMetatext(*metatext*)

Set a given metatext string on the object.

Parameters
metatext (*str | None*) – The metatext string that should be set. A value of None can be given to remove the current metatext.

setPartialCharges(*charge_list*, *indices=None*, *skip_checks=False*, *update_calculator=True*)

Set the partial charges on the configuration. The partial charges are used primarily to model electrostatic interactions in the TremoloX-calculator.

Parameters

•**charge_list** (*PhysicalQuantity of type charge | None*) – A list of atomic partial charges which contains a charge for each atom.

•**indices** (*list | int | None*) – The indices for which to set the partial charges. **Default:** All indices.

•**skip_checks** (*bool*) – Skip argument type checking and just directly assign the value. **Default:** False.

•**update_calculator** (*bool*) – Whether to update and attached Forcefield calculator with the new charges. **Default:** True.

setPrimitiveVectors(*a*, *b*, *c*, *conserve_coordinates=<class 'NL.ComputerScienceUtilities.NLFlag._NLFlag.Cartesian'>*, *skip_checks=False*)

Set the primitive lattice vectors for the configuration. This will change the `BravaisLattice` to a `UnitCell`. By default the Cartesian coordinates are not changed, which means that the relative positions of the atoms will change when the lattice vectors change.

Parameters

•**a** (*PhysicalQuantity* of type length) – The first lattice vector.

•**b** (*PhysicalQuantity* of type length) – The second lattice vector.

•**c** (*PhysicalQuantity* of type length) – The third lattice vector.

•**conserve_coordinates** (`Cartesian` | `Fractional`) – The type of coordinates to conserve. **Default:** `Cartesian`.

•**skip_checks** (*bool*) – If True, ignores bond connectivity and input argument checks. **Default:** True.

setVelocities(*velocities=None*, *skip_checks=False*)

Function to set velocities on the configuration.

Parameters

•**velocities** (*PhysicalQuantity* of type velocity | None) – The velocities to set on the configuration. Has the dimensionality nx3. **Default:** None.

•**skip_checks** (*bool*) – Skip argument type checking and just directly assign the value. **Default:** False.

shiftAtoms(*displacement*, *indices=None*, *skip_checks=False*)

Shift atoms by indices.

Parameters

•**displacement** (*PhysicalQuantity* of type length | array) – The displacement that should be applied to the atom positions. Can be given as cartesian or fractional coordinates.

•**indices** (*NoneType | list of ints*) – The indices to shift.

•**skip_checks** (*bool*) – True, if all consistency checks should be skipped.

shiftPartialCharges(*total_charge*, *indices=None*)

Shift the partial charges so that their sum is the given total charge value. These partial charges are used with Forcefield calculators.

Parameters

•**total_charge** (*PhysicalQuantity of type charge*) – The new total charge.

•**indices** (*list | int | None*) – The indices for which to set the total charge. **Default:** All indices.

sortAlongC()

Method for sorting the atoms along C.

symbols()

Returns
The element symbols of the configuration.

Return type
list of str

tags(*indices=None*)

List the tags associated with a given collection of indices. The list returned is the set union of tags associated with the given indices. If no collection of indices is provided, then all tags on the configuration are returned.

Parameters
indices (*list | int*) – The indices to check. **Default:** All indices.

Returns
The set union of tags present on the provided indices.

Return type
set

toMoleculeConfiguration()

Method for converting the BulkConfiguration to a MoleculeConfiguration.

Returns
The molecule configuration corresponding to the original bulk with the unitcell removed.

Return type
BulkConfiguration

uniqueElements(*ordered=False*)

Parameters
ordered (*bool*) – If the elements should be returned in ascending order by atomic number.

Returns
The unique elements contained in the configuration.

Return type
list of *PeriodicTableElement*

uniqueString()

Return a unique string representing the state of the object.

update(*force_restart=False*)

A self-consistent solution is generated, using the currently set calculator.

Parameters
force_restart (*bool*) – Force the self-consistent calculation to restart. **Default:** False.

velocities()

Returns
The velocities of the atoms. Has the dimensionality nx3.

Return type
PhysicalQuantity of type velocity

Usage Examples

Define the geometry of a lithium BCC crystal:

```
lattice = BodyCenteredCubic( 3.509 * Ang)
li_bcc_bulk = BulkConfiguration(
    lattice,
    [Lithium],
    [ ( 0.0, 0.0, 0.0 ) * Ang ]
    )
```

li_bcc.py

Specify the geometry of a diamond crystal:

```
elements = [ Carbon ] * 2
coordinates = [
    ( 0.00, 0.00, 0.00 ),
    ( 0.25, 0.25, 0.25 )
    ]
diamond_lattice = FaceCenteredCubic( 3.567 * Ang )
diamond = BulkConfiguration(
    diamond_lattice,
    elements,
    fractional_coordinates = coordinates
    )
```

si_diamond.py

Notes

ATK recognizes four types of atomic geometries:

•Molecules (*MoleculeConfiguration*)

•Bulk (*BulkConfiguration*)

•One Probe (*SurfaceConfiguration*)

•Two Probe (*DeviceConfiguration*)

1D or 2D periodic geometries, such as nanotubes, slabs, and atomic chains must be represented as a *BulkConfiguration* with sufficient vacuum to isolate the system in the non-periodic directions.

It is possible to specify vacuum basis sets (ghost atoms) by adding an additional atom and include the index of that atom in the `ghost_atom` list. In this case the valence basis set of the atom is included in the orbital list, but there will be no atomic potential at the site.

COMB3FieldCorrection

class COMB3FieldCorrection(*particleType1*, *particleType2*, *Pchi*, *PJ*, *r_i=None*, *r_cut=None*)

Constructor of the potential.

Parameters

- **particleType1** (ParticleType *or* ParticleIdentifier) – Identifier of the first particle type.
- **particleType2** (ParticleType *or* ParticleIdentifier) – Identifier of the second particle type.
- **Pchi** (*PhysicalQuantity of length**2 * charge*) – Potential parameter.
- **PJ** (*PhysicalQuantity of length**4*) – Potential parameter.
- **r_i** (*PhysicalQuantity of type length*) – Inner cutoff radius (distance where the smoothing starts)
- **r_cut** (*PhysicalQuantity of type length*) – The cutoff radius of this potential.

classmethod getAllParameterNames()

Return the names of all used parameters as a list.

getAllParameters()

Return all parameters of this potential and their current values as a <parameterName / parameterValue> dictionary.

static getDefaults()

Get the default parameters of this potential and return them in form of a dictionary of <parameter name, default value> key-value pairs.

getParameter(*parameterName*)

Get the current value of the parameter parameterName.

setParameter(*parameterName*, *value*)

Set the parameter parameterName to the given value.

Parameters

- **parameterName** (*str*) – The name of the parameter that will be modified.
- **value** – The new value that will be assigned to the parameter parameterName.

Usage Examples

Define a COMB3 potential for a TiN rocksalt crystal by adding particle types and interaction functions to the *TremoloX-PotentialSet*.

```
# Set up a Titanium-Nitride cell

vector_a = [4.235, 0.0, 0.0]*Angstrom
vector_b = [0.0, 4.235, 0.0]*Angstrom
vector_c = [0.0, 0.0, 4.235]*Angstrom
lattice = UnitCell(vector_a, vector_b, vector_c)

# Define elements
elements = [Titanium, Nitrogen, Titanium, Nitrogen, Titanium, Nitrogen,
            Titanium, Nitrogen]

# Define coordinates
```

COMB3PairPotential

class COMB3PairPotential(*particleType1*, *particleType2*, *A*, *B0*, *B1*, *B2*, *l*, *mu0*, *mu1*, *mu2*, *beta*, *b0*, *b1*, *b2*, *b3*, *b4*, *b5*, *b6*, *c0*, *c1*, *c2*, *c3*, *N*, *r_i=None*, *r_cut=None*)

Constructor of the potential.

Note: COMB3Particle must be added for BOTH particle types!

Parameters

- **particleType1** (ParticleType *or* ParticleIdentifier) – Identifier of the first particle type.

•**particleType2** (ParticleType *or* ParticleIdentifier) – Identifier of the second particle type.

•**A** (*PhysicalQuantity of type energy*) – Potential parameter.

•**B0** (*PhysicalQuantity of type energy*) – Potential parameter.

•**B1** (*PhysicalQuantity of type energy*) – Potential parameter.

•**B2** (*PhysicalQuantity of type energy*) – Potential parameter.

•**l** (*PhysicalQuantity of type length**-1*) – Potential parameter (lambda).

•**mu0** (*PhysicalQuantity of type length**-1*) – Potential parameter.

•**mu1** (*PhysicalQuantity of type length**-1*) – Potential parameter.

•**mu2** (*PhysicalQuantity of type length**-1*) – Potential parameter.

•**beta** (*PhysicalQuantity of type length**-1*) – Potential parameter.

•**b0** (*float*) – Potential parameter.

•**b1** (*float*) – Potential parameter.

•**b2** (*float*) – Potential parameter.

•**b3** (*float*) – Potential parameter.

•**b4** (*float*) – Potential parameter.

•**b5** (*float*) – Potential parameter.

•**b6** (*float*) – Potential parameter.

•**c0** (*float*) – Potential parameter.

•**c1** (*float*) – Potential parameter.

•**c2** (*float*) – Potential parameter.

•**c3** (*float*) – Potential parameter.

•**N** (*float*) – Potential parameter.

•**r_i** (*PhysicalQuantity of type length*) – The inner cutoff radius (distance where the smoothing starts).

•**r_cut** (*PhysicalQuantity of type length*) – The cutoff radius of this potential.

classmethod getAllParameterNames()

Return the names of all used parameters as a list.

getAllParameters()

Return all parameters of this potential and their current values as a <parameterName / parameterValue> dictionary.

static getDefaults()

Get the default parameters of this potential and return them in form of a dictionary of <parameter name, default value> key-value pairs.

getParameter(*parameterName*)

Get the current value of the parameter parameterName.

setParameter(*parameterName*, *value*)

Set the parameter parameterName to the given value.

Parameters

•**parameterName** (*str*) – The name of the parameter that will be modified.

•**value** – The new value that will be assigned to the parameter parameterName.

Usage Examples

Define a COMB3 potential for a TiN rocksalt crystal by adding particle types and interaction functions to the TremoloxPotentialSet.

```
# Set up a Titanium-Nitride cell

vector_a = [4.235, 0.0, 0.0]*Angstrom
vector_b = [0.0, 4.235, 0.0]*Angstrom
vector_c = [0.0, 0.0, 4.235]*Angstrom
lattice = UnitCell(vector_a, vector_b, vector_c)

# Define elements
elements = [Titanium, Nitrogen, Titanium, Nitrogen, Titanium, Nitrogen,
            Titanium, Nitrogen]

# Define coordinates
fractional_coordinates = [[ 0. ,  0. ,  0. ],
                          [ 0.5,  0.5,  0.5],
                          [ 0.5,  0.5,  0. ],
                          [ 0. ,  0. ,  0.5],
                          [ 0.5,  0. ,  0.5],
                          [ 0. ,  0.5,  0. ],
                          [ 0. ,  0.5,  0.5],
                          [ 0.5,  0. ,  0. ]]

# Set up configuration
bulk_configuration = BulkConfiguration(
    bravais_lattice=lattice,
    elements=elements,
    fractional_coordinates=fractional_coordinates
    )

# ------------------------------------------------------------
# Calculator
# ------------------------------------------------------------

potentialSet = TremoloXPotentialSet(name = 'COMB_NTi_2014')
potentialSet.addParticleType(ParticleType(
    symbol='N',
    mass=14.0067 * atomic_mass_unit,

COMB3Particle

class COMB3Particle(*particleType*, *l*, *mu*, *m*, *n*, *QL*, *QU*, *DL*, *DU*, *nB*, *J1*, *J2*, *J3*, *J4*, *q0*, *xi*, *Z*, *P*, *uniformCharge=False*)

Constructor of the potential.

Parameters

- **particleType** (ParticleType *or* ParticleIdentifier) – Identifier of the particle type
- **l** (*PhysicalQuantity of type length**-1*) – Potential parameter (lambda).
- **mu** (*PhysicalQuantity of type length**-1*) – Potential parameter.
- **m** (*int*) – Potential parameter.
- **n** (*float*) – Potential parameter.
- **QL** (*PhysicalQuantity of type charge*) – Potential parameter.
- **QU** (*PhysicalQuantity of type charge*) – Potential parameter.
- **DL** (*PhysicalQuantity of type length*) – Potential parameter.
- **DU** (*PhysicalQuantity of type length*) – Potential parameter.
- **nB** (*even int*) – Potential parameter.
- **J1** (*PhysicalQuantity of type energy / charge*) – Potential parameter.
- **J2** (*PhysicalQuantity of type energy / charge**2*) – Potential parameter.
- **J3** (*PhysicalQuantity of type energy / charge**3*) – Potential parameter.
- **J4** (*PhysicalQuantity of type energy / charge**4*) – Potential parameter.
- **q0** (*PhysicalQuantity of type charge*) – Potential parameter.
- **xi** (*PhysicalQuantity of type length**-1*) – Potential parameter.
- **Z** (*PhysicalQuantity of type charge*) – Potential parameter.
- **P** (*PhysicalQuantity of type length**3*) – Potential parameter.
- **uniformCharge** (*bool*) – Specifies whether all particles of this type must have the same charge.

classmethod getAllParameterNames()

Return the names of all used parameters as a list.

getAllParameters()

Return all parameters of this potential and their current values as a <parameterName / parameterValue> dictionary.

static getDefaults()

Get the default parameters of this potential and return them in form of a dictionary of <parameter name, default value> key-value pairs.

getParameter(*parameterName*)

Get the current value of the parameter parameterName.

setParameter(*parameterName*, *value*)

Set the parameter parameterName to the given value.

Parameters

- **parameterName** (*str*) – The name of the parameter that will be modified.
- **value** – The new value that will be assigned to the parameter parameterName.

Usage Examples

Define a COMB3 potential for a TiN rocksalt crystal by adding particle types and interaction functions to the *TremoloXPotentialSet*.

```
# Set up a Titanium-Nitride cell

vector_a = [4.235, 0.0, 0.0]*Angstrom
vector_b = [0.0, 4.235, 0.0]*Angstrom
vector_c = [0.0, 0.0, 4.235]*Angstrom
lattice = UnitCell(vector_a, vector_b, vector_c)

# Define elements
elements = [Titanium, Nitrogen, Titanium, Nitrogen, Titanium, Nitrogen,
            Titanium, Nitrogen]

# Define coordinates
fractional_coordinates = [[ 0. ,  0. ,  0. ],
                          [ 0.5,  0.5,  0.5],
                          [ 0.5,  0.5,  0. ],
                          [ 0. ,  0. ,  0.5],
                          [ 0.5,  0. ,  0.5],
                          [ 0. ,  0.5,  0. ],
                          [ 0. ,  0.5,  0.5],
                          [ 0.5,  0. ,  0. ]]

# Set up configuration
bulk_configuration = BulkConfiguration(
    bravais_lattice=lattice,
    elements=elements,
    fractional_coordinates=fractional_coordinates
    )

COMBCoulombOption

class COMBCoulombOption(*alpha*, *r_cut*)

Constructor of the option.

Parameters

- **alpha** (*PhysicalQuantity of type length**-1*) – Splitting parameter for the Wolf summation that is used internally to deal with long-range interactions.
- **r_cut** (*PhysicalQuantity of type length*) – Cutoff for all electrostatic interactions for which no explicit cutoff is given.

classmethod getAllParameterNames()

Return the names of all used parameters as a list.

getAllParameters()

Return all parameters of this potential and their current values as a <parameterName / parameterValue> dictionary.

static getDefaults()

Get the default parameters of this potential and return them in form of a dictionary of <parameter name, default value> key-value pairs.

getParameter(*parameterName*)

Get the current value of the parameter parameterName.

setParameter(*parameterName*, *value*)

Set the parameter parameterName to the given value.

Parameters

- **parameterName** (*str*) – The name of the parameter that will be modified.
- **value** – The new value that will be assigned to the parameter parameterName.

COMBMixitPotential

class COMBMixitPotential(*particleType1*, *particleType2*, *K=None*, *r0=None*)
Constructor of the potential.

Note: COMBParticle must be added for BOTH particle types!

Parameters

- **particleType1** (ParticleType *or* ParticleIdentifier) – Identifier of the first particle type.
- **particleType2** (ParticleType *or* ParticleIdentifier) – Identifier of the second particle type.
- **K** (*float*) – Potential parameter.
- **r0** (*PhysicalQuantity of type length*) – Potential parameter.

classmethod getAllParameterNames()
Return the names of all used parameters as a list.

getAllParameters()
Return all parameters of this potential and their current values as a <parameterName / parameterValue> dictionary.

static getDefaults()
Get the default parameters of this potential and return them in form of a dictionary of <parameter name, default value> key-value pairs.

getParameter(*parameterName*)
Get the current value of the parameter parameterName.

setParameter(*parameterName*, *value*)
Set the parameter parameterName to the given value.

Parameters

- **parameterName** (*str*) – The name of the parameter that will be modified.
- **value** – The new value that will be assigned to the parameter parameterName.

Usage Examples

Define a COMB potential for a SiO2 quartz crystal by adding particle types and interaction functions to the *TremoloX-PotentialSet*.

```
# ------------------------------------------------------------
# Set up a SiO2 Quartz crystal
# ------------------------------------------------------------

# Set up lattice
lattice = Hexagonal(4.916*Angstrom, 5.4054*Angstrom)

# Define elements
elements = [Silicon, Silicon, Silicon, Oxygen, Oxygen, Oxygen, Oxygen, Oxygen,
            Oxygen]

# Define coordinates
fractional_coordinates = [[ 0.4697,  0.0000,  0.0000    ],
                          [ 0.0000,  0.4697,  0.66666667],
```

```

See also ref.combcommon.notes.

COMBOptimizationOption

class COMBOptimizationOption(*maxIterations=None*, *relFTol=None*, *gradTol=None*, *linEqTol=None*, *disableOptimization=None*)

Constructor of the option.

Parameters

- **maxIterations** (*int*) – The maximal number of iterations that are allowed during the optimization of the COMB potential.
- **relFTol** (*float*) – Stop the optimization of the COMB potential if the relative change in the objective function value is smaller than this value. If set to < 0, this stopping criterion is disabled.
- **gradTol** (*float*) – Stop the optimization of the COMB potential if the 2-norm of the gradient of the objective function is smaller than this value. If set to < 0, this stopping criterion is disabled.

- **linEqTol** (*float*) – The tolerance that is passed to the linear equation solver that is called when dipoles are calculated.
- **disableOptimization** (*bool*) – If set to True, the calculation of the dynamical charges in the COMB potential is disabled. Instead, the charges of the corresponding particle types are used.

classmethod getAllParameterNames()

Return the names of all used parameters as a list.

getAllParameters()

Return all parameters of this potential and their current values as a <parameterName / parameterValue> dictionary.

static getDefaults()

Get the default parameters of this potential and return them in form of a dictionary of <parameter name, default value> key-value pairs.

getParameter(*parameterName*)

Get the current value of the parameter parameterName.

setParameter(*parameterName*, *value*)

Set the parameter parameterName to the given value.

Parameters

- **parameterName** (*str*) – The name of the parameter that will be modified.
- **value** – The new value that will be assigned to the parameter parameterName.

Usage Examples

Set up a COMB potential and add an optimization option to stop the internal optimization of the dynamical charges after 20 iterations.

```
# Set up a new COMB potential.
comb_potential = COMB_OSi_2007()

# Set up an optimization option to stop the optimization after 20 iterations.
comb_optimization_option = COMBOptimizationOption(
    maxIterations=20,
)

# Add the option to the potential.
comb_potential.addOption(comb_optimization_option)
```

Notes

This option can be used to specify the details of the internal optimization of the dynamic charges in a COMB potential. It can be added to a *TremoloXPotentialSet* via the `addOption()` method.

COMBOverCoordinationCorrection

class COMBOverCoordinationCorrection

Currently unsupported.

Usage Examples

Define a COMB potential for a SiO2 quartz crystal by adding particle types and interaction functions to the *TremoloX-PotentialSet*.

```
# ------------------------------------------------------------
# Set up a SiO2 Quartz crystal
# ------------------------------------------------------------

# Set up lattice
lattice = Hexagonal(4.916*Angstrom, 5.4054*Angstrom)

# Define elements
elements = [Silicon, Silicon, Silicon, Oxygen, Oxygen, Oxygen, Oxygen, Oxygen,
            Oxygen]

# Define coordinates
fractional_coordinates = [[ 0.4697,  0.0000,  0.0000    ],
                          [ 0.0000,  0.4697,  0.66666667],
                          [ 0.5303,  0.5303,  0.33333333],
                          [ 0.4135,  0.2669,  0.1191    ],
                          [ 0.2669,  0.4135,  0.547567  ],

COMBPairPotential

class COMBPairPotential(*particleType1*, *particleType2*, *A*, *B*, *R*, *S*, *l*, *mu*, *K=None*, *r0=None*)

Constructor of the potential.

Parameters

- **particleType1** (ParticleType *or* ParticleIdentifier) – Identifier of the first particle type.
- **particleType2** (ParticleType *or* ParticleIdentifier) – Identifier of the second particle type.
- **A** (*PhysicalQuantity of type energy*) – Potential parameter.
- **B** (*PhysicalQuantity of type energy*) – Potential parameter.
- **R** (*PhysicalQuantity of type length*) – Potential parameter.
- **S** (*PhysicalQuantity of type length*) – Potential parameter.
- **l** (*PhysicalQuantity of type length**-1*) – Potential parameter (lambda).
- **mu** (*PhysicalQuantity of type length**-1*) – Potential parameter.
- **K** (*float*) – Potential parameter.
- **r0** (*PhysicalQuantity of type length*) – Potential parameter.

classmethod getAllParameterNames()

Return the names of all used parameters as a list.

getAllParameters()

Return all parameters of this potential and their current values as a <parameterName / parameterValue> dictionary.

static getDefaults()

Get the default parameters of this potential and return them in form of a dictionary of <parameter name, default value> key-value pairs.

getParameter(*parameterName*)

Get the current value of the parameter parameterName.

setParameter(*parameterName*, *value*)

Set the parameter parameterName to the given value.

Parameters

- **parameterName** (*str*) – The name of the parameter that will be modified.
- **value** – The new value that will be assigned to the parameter parameterName.

Usage Examples

Define a COMB potential for a SiO2 quartz crystal by adding particle types and interaction functions to the *TremoloXPotentialSet*.

```
# ------------------------------------------------------------
# Set up a SiO2 Quartz crystal
# ------------------------------------------------------------

# Set up lattice
lattice = Hexagonal(4.916*Angstrom, 5.4054*Angstrom)

# Define elements
elements = [Silicon, Silicon, Silicon, Oxygen, Oxygen, Oxygen, Oxygen, Oxygen,
            Oxygen]

# Define coordinates
fractional_coordinates = [[ 0.4697,  0.0000,  0.0000    ],
                          [ 0.0000,  0.4697,  0.66666667],
                          [ 0.5303,  0.5303,  0.33333333],
                          [ 0.4135,  0.2669,  0.1191    ],
                          [ 0.2669,  0.4135,  0.547567  ],
                          [ 0.7331,  0.1466,  0.785767  ],
                          [ 0.5865,  0.8534,  0.214233  ],
                          [ 0.8534,  0.5865,  0.452433  ],
                          [ 0.1466,  0.7331,  0.8809    ]]

# Set up configuration
bulk_configuration = BulkConfiguration(
    bravais_lattice=lattice,
    elements=elements,
    fractional_coordinates=fractional_coordinates
    )

# ------------------------------------------------------------
# Calculator
# ------------------------------------------------------------

COMBParticle

class COMBParticle(*particleType*, *A*, *B*, *R*, *S*, *l*, *mu*, *beta*, *m*, *n*, *c*, *d*, *h*, *QL*, *QU*, *DL*, *DU*, *nB*, *J1*, *J2*, *J3*, *J4*, *q0*, *uniformCharge=False*)

Constructor of the potential.

Parameters

•**particleType** (*ParticleType or ParticleIdentifier*) – Identifier of the particle type

•**A** (*PhysicalQuantity of type energy*) – Potential parameter.

•**B** (*PhysicalQuantity of type energy*) – Potential parameter.

•**R** (*PhysicalQuantity of type length*) – Potential parameter.

•**S** (*PhysicalQuantity of type length*) – Potential parameter.

•**l** (*PhysicalQuantity of type length**-1*) – Potential parameter (lambda).

•**mu** (*PhysicalQuantity of type length**-1*) – Potential parameter.

•**beta** (*float*) – Potential parameter.

•**m** (*int*) – Potential parameter.

•**n** (*float*) – Potential parameter.

•**c** (*float*) – Potential parameter.

•**d** (*float*) – Potential parameter.

•**h** (*float*) – Potential parameter.

•**QL** (*PhysicalQuantity of type charge*) – Potential parameter.

•**QU** (*PhysicalQuantity of type charge*) – Potential parameter.

•**DL** (*PhysicalQuantity of type length*) – Potential parameter.

•**DU** (*PhysicalQuantity of type length*) – Potential parameter.

•**nB** (*even int*) – Potential parameter.

•**J1** (*PhysicalQuantity of type energy / charge*) – Potential parameter.

•**J2** (*PhysicalQuantity of type energy / charge**2*) – Potential parameter.

•**J3** (*PhysicalQuantity of type energy / charge**3*) – Potential parameter.

•**J4** (*PhysicalQuantity of type energy / charge**4*) – Potential parameter.

•**q0** (*PhysicalQuantity of type charge*) – Potential parameter.

•**uniformCharge** (*bool*) – Specifies whether all particles of this type must have the same charge.

classmethod getAllParameterNames()

Return the names of all used parameters as a list.

getAllParameters()

Return all parameters of this potential and their current values as a <parameterName / parameterValue> dictionary.

static getDefaults()

Get the default parameters of this potential and return them in form of a dictionary of <parameter name, default value> key-value pairs.

getParameter(*parameterName*)

Get the current value of the parameter parameterName.

setParameter(*parameterName*, *value*)

Set the parameter parameterName to the given value.

Parameters

- **parameterName** (*str*) – The name of the parameter that will be modified.
- **value** – The new value that will be assigned to the parameter parameterName.

Usage Examples

Define a COMB potential for a SiO2 quartz crystal by adding particle types and interaction functions to the *TremoloX-PotentialSet*.

```
# ------------------------------------------------------------
# Set up a SiO2 Quartz crystal
# ------------------------------------------------------------

# Set up lattice
lattice = Hexagonal(4.916*Angstrom, 5.4054*Angstrom)

# Define elements
elements = [Silicon, Silicon, Silicon, Oxygen, Oxygen, Oxygen, Oxygen, Oxygen,
            Oxygen]

# Define coordinates
fractional_coordinates = [[ 0.4697,  0.0000,  0.0000    ],
                          [ 0.0000,  0.4697,  0.66666667],
                          [ 0.5303,  0.5303,  0.33333333],
                          [ 0.4135,  0.2669,  0.1191    ],
                          [ 0.2669,  0.4135,  0.547567  ],
                          [ 0.7331,  0.1466,  0.785767  ],
                          [ 0.5865,  0.8534,  0.214233  ],
                          [ 0.8534,  0.5865,  0.452433  ],
                          [ 0.1466,  0.7331,  0.8809    ]]

# Set up configuration
bulk_configuration = BulkConfiguration(
    bravais_lattice=lattice,
    elements=elements,
    fractional_coordinates=fractional_coordinates
    )

# ------------------------------------------------------------

COMBPointWiseCoulomb

class COMBPointWiseCoulomb(*particleType1*, *particleType2*, *R*, *S*, *eta*)

Constructor of the potential.

Note: COMBParticle must be added for BOTH particle types!

Parameters

- **particleType1** (ParticleType *or* ParticleIdentifier) – Identifier of the first particle type.
- **particleType2** (ParticleType *or* ParticleIdentifier) – Identifier of the second particle type.
- **R** (*PhysicalQuantity of type length*) – Potential parameter.
- **S** (*PhysicalQuantity of type length*) – Potential parameter.
- **eta** (*float*) – Potential parameter.

classmethod getAllParameterNames()

Return the names of all used parameters as a list.

getAllParameters()

Return all parameters of this potential and their current values as a <parameterName / parameterValue> dictionary.

static getDefaults()

Get the default parameters of this potential and return them in form of a dictionary of <parameter name, default value> key-value pairs.

getParameter(*parameterName*)

Get the current value of the parameter parameterName.

setParameter(*parameterName*, *value*)

Set the parameter parameterName to the given value.

Parameters

- **parameterName** (*str*) – The name of the parameter that will be modified.
- **value** – The new value that will be assigned to the parameter parameterName.

Usage Examples

Define a COMB potential for a SiO2 quartz crystal by adding particle types and interaction functions to the *TremoloX-PotentialSet*.

```
# ------------------------------------------------------------
# Set up a SiO2 Quartz crystal
# ------------------------------------------------------------

# Set up lattice
lattice = Hexagonal(4.916*Angstrom, 5.4054*Angstrom)

# Define elements
elements = [Silicon, Silicon, Silicon, Oxygen, Oxygen, Oxygen, Oxygen, Oxygen,
            Oxygen]

# Define coordinates
fractional_coordinates = [[ 0.4697,  0.0000,  0.0000    ],
                          [ 0.0000,  0.4697,  0.66666667],
                          [ 0.5303,  0.5303,  0.33333333],
                          [ 0.4135,  0.2669,  0.1191    ],
                          [ 0.2669,  0.4135,  0.547567  ],
                          [ 0.7331,  0.1466,  0.785767  ],
                          [ 0.5865,  0.8534,  0.214233  ],
                          [ 0.8534,  0.5865,  0.452433  ],
                          [ 0.1466,  0.7331,  0.8809    ]]

COMBSMCoulomb

class COMBSMCoulomb(*particleType1*, *particleType2*, *xii*, *xij*)

Constructor of the potential.

Note: COMBParticle must be added for BOTH particle types!

Parameters

- **particleType1** (ParticleType *or* ParticleIdentifier) – Identifier of the first particle type.
- **particleType2** (ParticleType *or* ParticleIdentifier) – Identifier of the second particle type.
- **xii** (*PhysicalQuantity of type length**-1*) – Potential parameter.
- **xij** (*PhysicalQuantity of type length**-1*) – Potential parameter.

classmethod getAllParameterNames()

Return the names of all used parameters as a list.

getAllParameters()

Return all parameters of this potential and their current values as a <parameterName / parameterValue> dictionary.

static getDefaults()

Get the default parameters of this potential and return them in form of a dictionary of <parameter name, default value> key-value pairs.

getParameter(*parameterName*)

Get the current value of the parameter parameterName.

setParameter(*parameterName*, *value*)

Set the parameter parameterName to the given value.

Parameters

- **parameterName** (*str*) – The name of the parameter that will be modified.
- **value** – The new value that will be assigned to the parameter parameterName.

Usage Examples

Define a COMB potential for a SiO2 quartz crystal by adding particle types and interaction functions to the *TremoloX-PotentialSet*.

```
# ------------------------------------------------------------
# Set up a SiO2 Quartz crystal
# ------------------------------------------------------------

# Set up lattice
lattice = Hexagonal(4.916*Angstrom, 5.4054*Angstrom)

# Define elements
elements = [Silicon, Silicon, Silicon, Oxygen, Oxygen, Oxygen, Oxygen, Oxygen,
            Oxygen]
```

(continues on next page)

(continued from previous page)

```
# Define coordinates
fractional_coordinates = [[ 0.4697,  0.0000,  0.0000    ],
                          [ 0.0000,  0.4697,  0.66666667],
                          [ 0.5303,  0.5303,  0.33333333],
                          [ 0.4135,  0.2669,  0.1191    ],
                          [ 0.2669,  0.4135,  0.547567  ],
                          [ 0.7331,  0.1466,  0.785767  ],
                          [ 0.5865,  0.8534,  0.214233  ],
                          [ 0.8534,  0.5865,  0.452433  ],
                          [ 0.1466,  0.7331,  0.8809    ]]

COMBSelfEnergyCorrection

class COMBSelfEnergyCorrection(*particleType1*, *particleType2*, *a*, *b*, *r_cut=None*)

Constructor of the potential.

Note: COMBParticle must be added for BOTH particle types!

Parameters

- **particleType1** (ParticleType *or* ParticleIdentifier) – Identifier of the first particle type.
- **particleType2** (ParticleType *or* ParticleIdentifier) – Identifier of the second particle type.
- **a** (*PhysicalQuantity of length**2 / charge*) – Potential parameter.

- **b** (*PhysicalQuantity of type length**4 / charge**2*) – Potential parameter.
- **r_cut** (*PhysicalQuantity of type length*) – The cutoff radius of this potential.

classmethod getAllParameterNames()

Return the names of all used parameters as a list.

getAllParameters()

Return all parameters of this potential and their current values as a <parameterName / parameterValue> dictionary.

static getDefaults()

Get the default parameters of this potential and return them in form of a dictionary of <parameter name, default value> key-value pairs.

getParameter(*parameterName*)

Get the current value of the parameter parameterName.

setParameter(*parameterName*, *value*)

Set the parameter parameterName to the given value.

Parameters

- **parameterName** (*str*) – The name of the parameter that will be modified.
- **value** – The new value that will be assigned to the parameter parameterName.

Usage Examples

Define a COMB potential for a SiO2 quartz crystal by adding particle types and interaction functions to the *TremoloX-PotentialSet*.

```
# ------------------------------------------------------------
# Set up a SiO2 Quartz crystal
# ------------------------------------------------------------

# Set up lattice
lattice = Hexagonal(4.916*Angstrom, 5.4054*Angstrom)

# Define elements
elements = [Silicon, Silicon, Silicon, Oxygen, Oxygen, Oxygen, Oxygen, Oxygen,
            Oxygen]

# Define coordinates
fractional_coordinates = [[ 0.4697,  0.0000,  0.0000    ],
                          [ 0.0000,  0.4697,  0.66666667],
                          [ 0.5303,  0.5303,  0.33333333],
                          [ 0.4135,  0.2669,  0.1191    ],
                          [ 0.2669,  0.4135,  0.547567  ],
                          [ 0.7331,  0.1466,  0.785767  ],
                          [ 0.5865,  0.8534,  0.214233  ],
                          [ 0.8534,  0.5865,  0.452433  ],
                          [ 0.1466,  0.7331,  0.8809    ]]

# Set up configuration
bulk_configuration = BulkConfiguration(
    bravais_lattice=lattice,
```

COMBSelfEnergyCorrectionShan

class COMBSelfEnergyCorrectionShan(*particleType1*, *particleType2*, *a*, *b*, *r_cut=None*)

Constructor of the potential.

Note: COMBParticle must be added for BOTH particle types!

Parameters

- **particleType1** (ParticleType *or* ParticleIdentifier) – Identifier of the first particle type.
- **particleType2** (ParticleType *or* ParticleIdentifier) – Identifier of the second particle type.
- **a** (*PhysicalQuantity of length**4 * charge*) – Potential parameter.
- **b** (*PhysicalQuantity of type length**4*) – Potential parameter.
- **r_cut** (*PhysicalQuantity of type length*) – The cutoff radius of this potential.

classmethod getAllParameterNames()

Return the names of all used parameters as a list.

getAllParameters()

Return all parameters of this potential and their current values as a <parameterName / parameterValue> dictionary.

static getDefaults()

Get the default parameters of this potential and return them in form of a dictionary of <parameter name, default value> key-value pairs.

getParameter(*parameterName*)

Get the current value of the parameter parameterName.

setParameter(*parameterName*, *value*)

Set the parameter parameterName to the given value.

Parameters

- **parameterName** (*str*) – The name of the parameter that will be modified.
- **value** – The new value that will be assigned to the parameter parameterName.

Usage Examples

Define a COMB potential for a SiO2 quartz crystal by adding particle types and interaction functions to the *TremoloX-PotentialSet*.

```
# ------------------------------------------------------------
# Set up a SiO2 Quartz crystal
# ------------------------------------------------------------

# Set up lattice
lattice = Hexagonal(4.916*Angstrom, 5.4054*Angstrom)

# Define elements
elements = [Silicon, Silicon, Silicon, Oxygen, Oxygen, Oxygen, Oxygen, Oxygen,
            Oxygen]

# Define coordinates
fractional_coordinates = [[ 0.4697,  0.0000,  0.0000    ],
                          [ 0.0000,  0.4697,  0.66666667],
                          [ 0.5303,  0.5303,  0.33333333],
                          [ 0.4135,  0.2669,  0.1191    ],
                          [ 0.2669,  0.4135,  0.547567  ],
                          [ 0.7331,  0.1466,  0.785767  ],
                          [ 0.5865,  0.8534,  0.214233  ],

COMBTriplePotential

class COMBTriplePotential(*particleType1*, *particleType2*, *particleType3*, *cosTheta*, *K0=None*, *K1=None*, *K2=None*, *K3=None*, *K4=None*, *K5=None*, *K6=None*)

Constructor of the potential.

Note: COMBParticle must be added for ALL THREE particle types!

Parameters

- **particleType1** (ParticleType *or* ParticleIdentifier) – Identifier of the first particle type. This particle type corresponds to the central particle in the calculation of the angle (the vertex).
- **particleType2** (ParticleType *or* ParticleIdentifier) – Identifier of the second particle type.
- **particleType3** (ParticleType *or* ParticleIdentifier) – Identifier of the third particle type.
- **cosTheta** (*float*) – Potential parameter (cosine of the equilibrium angle).
- **K0** (*PhysicalQuantity of type energy*) – Potential parameter.
- **K1** (*PhysicalQuantity of type energy*) – Potential parameter.
- **K2** (*PhysicalQuantity of type energy*) – Potential parameter.
- **K3** (*PhysicalQuantity of type energy*) – Potential parameter.
- **K4** (*PhysicalQuantity of type energy*) – Potential parameter.
- **K5** (*PhysicalQuantity of type energy*) – Potential parameter.
- **K6** (*PhysicalQuantity of type energy*) – Potential parameter.

classmethod getAllParameterNames()

Return the names of all used parameters as a list.

getAllParameters()

Return all parameters of this potential and their current values as a <parameterName / parameterValue> dictionary.

static getDefaults()

Get the default parameters of this potential and return them in form of a dictionary of <parameter name, default value> key-value pairs.

getParameter(*parameterName*)

Get the current value of the parameter parameterName.

setParameter(*parameterName*, *value*)

Set the parameter parameterName to the given value.

Parameters

- **parameterName** (*str*) – The name of the parameter that will be modified.
- **value** – The new value that will be assigned to the parameter parameterName.

Usage Examples

Define a COMB potential for a SiO2 quartz crystal by adding particle types and interaction functions to the *TremoloX-PotentialSet*.

```
# ------------------------------------------------------------
# Set up a SiO2 Quartz crystal
# ------------------------------------------------------------

# Set up lattice
lattice = Hexagonal(4.916*Angstrom, 5.4054*Angstrom)

# Define elements
elements = [Silicon, Silicon, Silicon, Oxygen, Oxygen, Oxygen, Oxygen, Oxygen,
            Oxygen]

# Define coordinates
fractional_coordinates = [[ 0.4697,  0.0000,  0.0000    ],
                          [ 0.0000,  0.4697,  0.66666667],
                          [ 0.5303,  0.5303,  0.33333333],
                          [ 0.4135,  0.2669,  0.1191    ],
                          [ 0.2669,  0.4135,  0.547567  ],
                          [ 0.7331,  0.1466,  0.785767  ],
                          [ 0.5865,  0.8534,  0.214233  ],
                          [ 0.8534,  0.5865,  0.452433  ],
                          [ 0.1466,  0.7331,  0.8809    ]]

# Set up configuration
bulk_configuration = BulkConfiguration(
    bravais_lattice=lattice,
    elements=elements,
    fractional_coordinates=fractional_coordinates
    )

# ------------------------------------------------------------
# Calculator

CalculatedChemicalPotential

class CalculatedChemicalPotential(*element*, *calculator*, *phonon_calculator=None*, *configuration=None*, *k_points=None*, *include_vibrations=None*, *repetitions=None*, *reference_temperature=None*)

A class defining the chemical potential for an atomic species. Used as part of a *ChargedPointDefect* study.

Parameters

- **element** (*PeriodicTableElement*) – The element for which the atomic chemical potential is defined.
- **calculator** (`All calculators`) – The calculator used to calculate the reference thermodynamics.
- **phonon_calculator** (`All calculators` | None) – The calculator used to calculate the vibrational energies. If not specified the reference calculator is used. The argument `include_vibrations` must also be `True` to include vibrational energies.
- **configuration** (*BulkConfiguration*) – The thermodynamic reference configuration for the element. **Default:** The reference configuration is taken from an elemental reference material. In that case an optimization is automatically performed.
- **k_points** (*KpointDensity* | *MonkhorstPackGrid* | None) – k-points used in the calculator for calculator. This may need to be set in cases where the reference material is a conductor, and therefore requires a higher number of k-points.
- **optimization_parameters** (*OptimizeGeometryParameters*) – The parameters to use to optimize the reference configuration.
- **include_vibrations** (*bool*) – Whether to include vibrational energies in the atomic free energy. The configuration will be optimized with the phonon calculator before calculating vibrations. **Default:** False.
- **repetitions** (*list of ints | None*) – The number of repetitions of the system in the A, B, and C-directions used in determining the vibrational frequencies. If not given repetitions are selected so that the cell is large enough to calculate the vibrations using a finite difference method.
- **reference_temperature** (*PhysicalQuantity* of type temperature) – The temperature used to calculate the free energy. **Default:** 300 Kelvin.

calculator()

Returns
The calculator used to calculate the chemical potential.

Return type
`All calculators`

chemicalPotential(*temperature=None*)

Calculate the chemical potential.

Returns
The chemical potential of the atom calculated from the internal energy and entropy per atom of the specified element in some reference configuration.

Return type
PhysicalQuantity of type energy | None

electronicInternalEnergy()

Returns the electronic internal energy.

Returns
The electronic energy per atom of the specified element in some reference configuration, or None if it has not been evaluated.

Return type
PhysicalQuantity of type energy | None

element()

Returns
The element for which the atomic chemical potential is defined.

Return type
PeriodicTableElement

entropy(*temperature=None*)

Returns the entropy from vibrational corrections, if included. If not included then the entropy is zero. If the object has not been updated then None is returned.

Parameters
temperature (*PhysicalQuantity* of type temperature) – The temperature at which the vibrational corrections are calculated.

Returns
The entropy component of the atomic chemical potential or None if it has not been evaluated.

Return type
PhysicalQuantity of type energy per temperature | None

includeVibrations()

Returns
Whether vibrational terms are included in the chemical potential.

Return type
bool

phononCalculator()

Returns
The calculator used to calculate the chemical potential.

Return type
`All calculators`

referenceConfiguration()

Returns
The reference configuration from which the components of the atomic chemical potential are calculated.

Return type
BulkConfiguration | None

referenceTemperature()

Returns
The reference temperature for the chemical potential.

Return type
PhysicalQuantity of type temperature.

repetitions()

Returns
The number of repetitions of the system in the A, B, and C-directions.

Return type
list of ints | None

uniqueString()

Return a unique string representing the state of the object.

update()

Perform the calculation to add data to the object.

vibrationalInternalEnergy(*temperature=None*)

Returns the internal energy from vibrations.

Parameters
temperature (*PhysicalQuantity* of type temperature) – The temperature at which the vibrational corrections are calculated.

Returns
The energy per atom of the specified element in some reference configuration, or None if it has not been evaluated.

Return type
PhysicalQuantity of type energy | None

Notes

The *CalculatedChemicalPotential* object defines an atomic chemical potential used in a *ChargedPointDefectConfiguration* calculation. The *CalculatedChemicalPotential* provides the reservoir energy for the element being added or removed from the pristine material to form the defect. This energy is used in calculating the formation energy and concentration of the defect. The value of the reservoir energy can depend on the nature of the environment around the defect. The atomic chemical potential also depends on the reference calculator used in the calculation, as it also includes the energy of the isolated atom according to the specific calculator.

The *CalculatedChemicalPotential* allows calculating the atomic chemical potential from an appropriate elemental reference configuration. The *CalculatedChemicalPotential* is created by supplying an element and the calculator to be used for calculating the elemental energy. A reference configuration can also be given, using the argument `configuration`. If a configuration is not given a standard reference structure is used. The k-points used in the energy calculation can be expressly set using the `k_points` argument. This is useful in cases where a different k-point sampling is required for the elemental reference material e.g. metals. Vibrational energies can be included by setting the argument `include_vibrations` to `True`. A specific calculator for the vibrations can be given with the argument `phonon_calculator`, otherwise the energy calculator is also used for the vibrations. The repetitions used in the vibration calculation can also be set with the `repetitions` argument.

ChargedPointDefect

class ChargedPointDefect(*bulk_configuration*, *filename*, *object_id*, *formation_energy_calculator=None*, *relaxation_calculator=None*, *band_gap_calculator=None*, *point_defect=None*, *charge_states=None*, *atomic_chemical_potentials=None*, *supercell_repetitions_list=None*, *relax_atomic_coordinates=None*, *dielectric_constant=None*, *log_filename_prefix=None*, *number_of_processes_per_task=None*, *elastic_correction_method=None*, *optimize_geometry_parameters=None*, *model_charge_correction=None*, *random_seed=None*, *resume=None*, *use_ghost=None*, *calculate_defect_symmetry=None*)

Constructor for the ChargedPointDefect object.

Parameters

- **bulk_configuration** (*BulkConfiguration*) – The reference bulk unit cell configuration to be used to generate the supercell configurations.
- **filename** (*str*) – The full or relative filename path the Study object should be saved to. See *nlsave()*.
- **object_id** (*str*) – The name of the study that the Study object should be saved to within the file. This needs to be a unique name in this file. See *nlsave()*.
- **formation_energy_calculator** (*Calculator*) – The calculator used for calculating the formation energy of the defect charge states. All total energies, band positions and finite-size corrections are calculated using this calculator. The calculator must contain a basis set for the elements in both the defect and pristine configurations. Note that the calculator is taken as a reference corresponding to the bulk unit cell given in `bulk_configuration`; the `density_mesh_cutoff` and `k_point_sampling` parameters of the *NumericalAccuracyParameters* of the calculator will be scaled consistently with the supercell size. The `k_point_sampling` will be scaled to maintain the k-point density approximately equal to the reference. The k-point grid will always be shifted such that the Gamma point is included, i.e., `shift_to_gamma=True`. **Default:** The calculator given in `relaxation_calculator`. At least one of the two calculators must be provided.
- **relaxation_calculator** (*Calculator*) – The calculator used for relaxing the atomic coordinates of the defect supercells. The calculator must contain a basis set for the elements in the defect configuration. Note that the calculator is taken as a reference corresponding to the bulk unit cell given in `bulk_configuration`; the `density_mesh_cutoff` and `k_point_sampling` parameters of the *NumericalAccuracyParameters* of the calculator will be scaled consistently with the supercell size. The `k_point_sampling` will be scaled to maintain the k-point density approximately equal to the reference. The k-point grid will always be shifted such that the Gamma point is included, i.e., `shift_to_gamma=True`. **Default:** The calculator given in `formation_energy_calculator`. At least one of the two calculators must be provided.
- **band_gap_calculator** – The calculator used for calculating the band gap in which the transition levels will be placed. The calculator is only used for the pristine configuration, so only needs to contain a basis set for the elements in this configuration. Note that the calculator is taken as a reference corresponding to the bulk unit cell given in `bulk_configuration`; the `density_mesh_cutoff` and `k_point_sampling` parameters of the *NumericalAccuracyParameters* of the calculator will be scaled consistently with the supercell size. The `k_point_sampling` will be scaled to maintain the k-point density approximately equal to the reference. The k-point grid will always be shifted such that the Gamma point is included, i.e., `shift_to_gamma=True`. **Default:** The calculator given in `formation_energy_calculator`.
- **point_defect** (*Vacancy* | *Substitutional* | *Interstitial* | *DefectCluster* | *SplitInterstitial*) – The point defect to embed in the host supercell. **Default:** `Vacancy()`
- **charge_states** – The list of charge states of the defect, as a discrete multiple of elementary charge. A charge of `-1` corresponds to one extra electron. **Default:** `0`

- **atomic_chemical_potentials** (sequence of *AtomicChemicalPotential*) – The chemical potentials for the atomic species involved in the creation of the defect (i.e., any species for which the number of atoms changes between the pristine and defect supercell). **Default:** All necessary atomic chemical potentials will be calculated using the pristine configuration (when possible) or a default elemental reference configuration.
- **supercell_repetitions_list** (*sequence (size 3) of int | sequence of sequence (size 3) of int*) – The list of supercells of the bulk unit cell to calculate, each given as the number of repetitions of the bulk unit cell along the (a, b, c) directions. **Default:** `[(1, 1, 1)]`
- **relax_atomic_coordinates** (*bool*) – Whether to relax the atomic coordinates of the defect supercells. **Default:** `True`
- **dielectric_constant** (*float*) – The dielectric constant of the host material. Only needed to calculate the finite-size correction terms. **Default:** `1.0`
- **log_filename_prefix** (str | `LogToStdOut`) – Filename prefix for the logging output of charged point defect calculations. If `LogToStdOut`, all logging will instead be sent to standard output. **Default:** `'chargedpointdefect_'`
- **number_of_processes_per_task** (int | *ProcessesPerNode* | `AllProcesses`) – The number of processes that will be used to execute each task. If this value is greater than or equal to the total number of available processes, each single task will be executed collaboratively over all processes. Otherwise, a delegator-worker scheme is used; in this case, one process will be set aside as the delegator, and the remaining ones will be grouped into workers and execute tasks concurrently. **Default:** `AllProcesses`, all available processes execute each task collaboratively.
- **elastic_correction_method** (*ImageStressCorrection*) – Specify a finite size elastic energy correction. If not specified, no finite size elastic energy correction will be applied. **Default:** None
- **optimize_geometry_parameters** (*OptimizeGeometryParameters*) – The parameters to use for optimizing the geometry. Note that `pre_step_hook` and `post_step_hook` must be left unset. Also note that `max_stress`, `target_stress`, `restart_strategy` and `enable_optimization_stop_file` do not have any effect since stress is not optimized, and the restart mechanism within *OptimizeGeometry()* is disabled. Only constraints of type *FixAtomConstraints* and *RigidBody* will be maintained, others will be discarded. **Default:** `OptimizeGeometryParameters()`
- **model_charge_correction** (*ModelChargeCorrection*) – Specify a finite size model charge correction. **Default:** ModelChargeCorrection()
- **random_seed** (*int | None*) – The random seed to rattle atomic coordinates. `None` for the system to pick different ones for you. **Default:** None
- **resume** (*bool*) – Whether rerunning the simulation will resume non converged results. **Default:** False
- **use_ghost** (*bool*) – Whether ghost atoms will be used (for LCAO calculators only). **Default:** True
- **calculate_defect_symmetry** (*bool*) – Whether to calculate the symmetry of the defect. **Default:** `False`

atomNumberDifferences()

Returns
The atom number differences for each element.

Return type
dict of type {*PeriodicTableElement* : int}

atomicChemicalPotentials()

Returns
The atomic chemical potential for all the required elements. If an element for which the atomic chemical potential needs to be calculated is not present, it is calculated from the pristine cell at each supercell size.

Return type
list of *AtomicChemicalPotential*

bandShift(*supercell_repetitions*, *charge_state*)

Retrieve the band shift for a given defect supercell with respect to the pristine supercell.

This result will only be available after the calculation ran successfully.

Parameters

- **supercell_repetitions** (*sequence (size 3) of int*) – The number of repetitions of the bulk unit cell along the (a, b, c) directions.
- **defect_charge_state** (*int*) – The charge state of the defect.

Returns
The band shift for the supercell. If not available, returns None.

Return type
PhysicalQuantity of type energy | None

calculateDefectSymmetry()

Returns
Whether the defect symmetry is calculated.

Return type
bool

calculatedChargeStates(*supercell_repetitions=None*)

Retrieve the list of calculated charge states, either for the entire study or for a given supercell.

Parameters
supercell_repetitions (sequence (size 3) of int | *ExtrapolationScheme*) – The supercell given as the number of repetitions of the bulk unit cell along the (a, b, c) directions for which to return the list of calculated charge states. For an extrapolation scheme, the charge states for all supercells are returned. **Default:** All supercells.

Returns
The list of calculated charge states. The charge states are ordered from the most positive to the most negative.

Return type
list of int

calculatedSupercells(*charge_state=None*)

Retrieve the list of calculated supercells, either for the entire study or for a given charge state.

Parameters
charge_state (*int*) – The charge state for which to return the list of calculated supercells. **Default:** All charge states.

Returns
The list of calculated supercells, each given as the number of repetitions of the bulk unit cell along the (a, b, c) directions. The supercells are ordered from the smallest to the largest in terms of the number of atoms; if multiple supercells have the same number of atoms they are ordered according to the repetitions in the (a, b, c) directions, in that order.

Return type
list of tuple (size 3) of int

chargeStates()

Returns
The list of all calculated and not calculated charge states. Any charge state which has not yet been calculated will be calculated the next time the object is updated.

Return type
list of int

conductionBandMinimum(*supercell_repetitions*)

Retrieve the conduction band minimum of the pristine unit cell configuration associated with a given supercell.

This result will only be available after the calculation ran successfully.

Parameters
supercell_repetitions (*sequence (size 3) of int*) – The number of repetitions of the bulk unit cell along the (a, b, c) directions.

Returns
The conduction band minimum of the pristine unit cell configuration. If not available, returns None.

Return type
PhysicalQuantity of type energy | None

defectConfiguration(*supercell_repetitions*, *charge_state*, *symmetry_index=None*, *unit_cell_translation=None*)

Retrieve the defect supercell configuration for a given supercell.

This result will only be available after the calculation ran successfully.

Parameters

- **supercell_repetitions** (*sequence (size 3) of int*) – The number of repetitions of the bulk unit cell along the (a, b, c) directions.
- **defect_charge_state** (*int*) – The charge state of the defect.
- **symmetry_index** (*int*) – The index of the symmetry operation for the pristine unit cell to apply to the defect supercell configuration. Note that this can only be used if the calculate_defect_symmetry option has been enabled for the calculation. **Default:** No transformation (i.e., the identity operation)
- **unit_cell_translation** (*sequence (size 3) of int*) – An additional translation to apply in terms of the unit cell vectors. **Default:** No translation

Returns
The defect supercell configuration. If not available, returns None.

Return type
BulkConfiguration | None

defectConfigurationCalculator(*supercell_repetitions*, *charge_state*)

Retrieve the calculator of the defect supercell configuration for a given supercell.

This result will only be available after the calculation ran successfully.

Parameters

- **supercell_repetitions** (*sequence (size 3) of int*) – The number of repetitions of the bulk unit cell along the (a, b, c) directions.
- **defect_charge_state** (*int*) – The charge state of the defect.

Returns
The calculator of the defect supercell configuration. If not available, returns None.

Return type
Calculator | None

defectSymmetry(*supercell_repetitions*, *charge_state*)

Calculate the symmetry information for the defect supercell.

This result will only be available after the calculation ran successfully.

Parameters

- **supercell_repetitions** (*sequence (size 3) of int*) – The number of repetitions of the bulk unit cell along the (a, b, c) directions.
- **defect_charge_state** (*int*) – The charge state of the defect.

Returns
The symmetry information for the defect supercell. If not available, returns None.

Return type
dict | None

defectTotalEnergy(*supercell_repetitions*, *charge_state*)

Retrieve the total energy of the defect supercell configuration for a given supercell.

This result will only be available after the calculation ran successfully.

Parameters

- **supercell_repetitions** (*sequence (size 3) of int*) – The number of repetitions of the bulk unit cell along the (a, b, c) directions.
- **defect_charge_state** (*int*) – The charge state of the defect.

Returns
The total energy of the defect supercell configuration. If not available, returns None.

Return type
TotalEnergy | None

dependentStudies()

Returns
The list of dependent studies.

Return type
list of Study

dielectricConstant()

Returns
The dielectric constant of the host material is updated.

Return type
float

elasticCorrectionEnergy(*supercell_repetitions*, *charge_state*)

Retrieve the value of the elastic energy correction for a given supercell. This result will only be available after the calculation ran successfully. If no correction was applied, None is returned.

Parameters

- **supercell_repetitions** (*sequence (size 3) of int*) – The number of repetitions of the bulk unit cell along the (a, b, c) directions.
- **defect_charge_state** (*int*) – The charge state of the defect.

Returns
The image stress correction. If not available, returns None.

Return type
PhysicalQuantity of type energy | None

elasticCorrectionMethod()

Returns
The method used to evaluate the finite size elastic energy correction.

Return type
None | *ImageStressCorrection*

filename()

Returns
The filename where the study object is stored.

Return type
str

formationEnergy(*charge_state*, *electronic_chemical_potential=None*, *electronic_chemical_potential_reference=None*, *defect_type=None*, *supercell_repetitions=None*, *enable_finite_size_corrections=None*)

The formation energy for a given charge state q of the defect, defined as

$E_f^q = E^{\mathrm{def},q} - E^{\mathrm{bulk},q} - \sum_i \Delta n_i \mu_i + q\left(\mu_e^{\mathrm{ref}} + \Delta\mu_e\right)$.

The first two terms are the total energy of the supercell with and without the defect, respectively. Δn_i is the difference in the number of atoms between the two supercells for species i, and μ_i is the atomic chemical potential for that species. μ_e^{ref} is the absolute position of the reference level for the electronic chemical potential (either the valence band maximum or the conduction band minimum), and $\Delta\mu_e$ is the electronic chemical potential relative to it. Note that correction terms have not been included here (see Notes below for details).

Parameters

- **charge_state** (*int*) – The charge state of the defect.
- **electronic_chemical_potential** (*PhysicalQuantity* of type energy) – The electronic chemical potential relative to electronic_chemical_potential_reference. **Default:** 0.0 * eV
- **electronic_chemical_potential_reference** (ValenceBandEdge | ConductionBandEdge) – The reference level for the electronic chemical potential. **Default:** ValenceBandEdge
- **defect_type** (DeepLevelDefect | ShallowAcceptor | ShallowDonor) – The assumption of the type of defect to use for aligning the transition levels in the band gap calculated with band_gap_calculator; see Notes below for details. Note that this parameter only has an effect if band_gap_calculator is different from formation_energy_calculator. **Default:** DeepLevelDefect
- **supercell_repetitions** (sequence (size 3) of int | *ExtrapolationScheme*) – The number of repetitions of the bulk unit cell along the (a, b, c) directions. If ExtrapolationScheme, the extrapolation to the infinite supercell size limit is used. **Default:** The largest calculated supercell.
- **enable_finite_size_corrections** (*bool*) – Whether to include finite size corrections for the supercell in the calculation of the formation energy. **Default:** True

Returns
The calculated formation energy.

Return type
PhysicalQuantity of type energy

logFilenamePrefix()

Returns
The filename prefix for the logging output of the study.

Return type
str | LogToStdOut

modelChargeCorrection(*supercell_repetitions*, *charge_state*)

Retrieve the model charge correction parameters for the FNV correction for a given supercell and charge state.

Parameters

- **supercell_repetitions** (*sequence (size 3) of int*) – The number of repetitions of the bulk unit cell along the (a, b, c) directions.
- **charge_state** (*int*) – The charge state of the defect.

Returns
The parameters used to define the model charge correction. If not available, returns None.

Return type
ModelChargeCorrection | None

nlprint(*stream=None*)

Print a string containing an ASCII table useful for plotting the Study object.

Parameters
stream (*python stream*) – The stream the table should be written to. **Default:** NLPrintLogger()

numberOfProcessesPerTask()

Returns
The number of processes to be used to execute each task. If None, all available processes execute each task collaboratively.

Return type
int | None | *ProcessesPerNode*

numberOfProcessesPerTaskResolved()

Returns
The number of processes to be used to execute each task. Default values are resolved based on the current execution settings.

Return type
int

objectId()

Returns
The name of the study object in the file.

Return type
str

optimizeGeometryParameters()

Returns
Parameters required to optimize the geometry.

Return type
OptimizeGeometryParameters

periodicChargeCorrection(*supercell_repetitions*, *charge_state*)

Retrieve the periodic charge correction for a given supercell.

This result will only be available after the calculation ran successfully.

Parameters

- **supercell_repetitions** (*sequence (size 3) of int*) – The number of repetitions of the bulk unit cell along the (a, b, c) directions.
- **defect_charge_state** (*int*) – The charge state of the defect.

Returns
The periodic charge correction for the supercell. If not available, returns None.

Return type
PhysicalQuantity of type energy | None

pointDefect()

Returns
The point defect associated with the charged point defect study.

Return type
Vacancy | *Substitutional* | *Interstitial* | *DefectCluster* | *SplitInterstitial*

pristineConfiguration(*supercell_repetitions*)

Retrieve the pristine unit cell configuration associated with a given supercell.

This result will only be available after the calculation ran successfully.

Parameters
supercell_repetitions (*sequence (size 3) of int*) – The number of repetitions of the bulk unit cell along the (a, b, c) directions.

Returns
The pristine unit cell configuration. If not available, returns None.

Return type
BulkConfiguration | None

pristineConfigurationCalculator(*supercell_repetitions*)

Retrieve the calculator of the pristine unit cell configuration associated with a given supercell.

This result will only be available after the calculation ran successfully.

Parameters
supercell_repetitions (*sequence (size 3) of int*) – The number of repetitions of the bulk unit cell along the (a, b, c) directions.

Returns
The calculator of the pristine unit cell configuration. If not available, returns None.

Return type
Calculator | None

pristineFermiLevel(*supercell_repetitions*)

Retrieve the Fermi level of the pristine unit cell configuration associated with a given supercell.

This result will only be available after the calculation ran successfully.

Parameters
supercell_repetitions (*sequence (size 3) of int*) – The number of repetitions of the bulk unit cell along the (a, b, c) directions.

Returns
The Fermi level of the pristine unit cell configuration. If not available, returns None.

Return type
PhysicalQuantity of type energy | None

pristineSymmetryData()

Retrieve the symmetry information for the pristine unit cell.

This result will only be available after the calculation ran successfully.

Returns
The symmetry information for the pristine unit cell. If not available, returns None.

Return type
dict | None

pristineTotalEnergy(*supercell_repetitions*)

Retrieve the total energy of the pristine unit cell configuration associated with a given supercell.

This result will only be available after the calculation ran successfully.

Parameters
supercell_repetitions (*sequence (size 3) of int*) – The number of repetitions of the bulk unit cell along the (a, b, c) directions.

Returns
The total energy of the pristine unit cell configuration. If not available, returns None.

Return type
TotalEnergy | None

randomSeed()

Returns
The random seed used for rattling coordinates

Return type
None | int

relaxAtomicCoordinates()

Returns
Whether the atomic coordinates of the defect supercells are relaxed.

Return type
bool

resume()

Returns
whether the resume option was specified

Return type
bool

saveToFileAfterUpdate()

Returns
Whether the study is automatically saved after it is updated.

Return type
bool

setModelChargeCorrection(*supercell_repetitions*, *charge_state*, *model_charge_correction=None*)

Set the model charge correction parameters for the FNV correction for a given supercell and charge state.

Parameters

- **supercell_repetitions** (*sequence (size 3) of int*) – The number of repetitions of the bulk unit cell along the (a, b, c) directions.
- **charge_state** (*int*) – The charge state of the defect.
- **model_charge_correction** (*ModelChargeCorrection*) – The parameters used to define the model charge correction. **Default:** `ModelChargeCorrection()`

stableChargeState(*electronic_chemical_potential*, *electronic_chemical_potential_reference=None*, *defect_type=None*, *supercell_repetitions=None*, *enable_finite_size_corrections=None*)

The stable charge state at a given electronic chemical potential.

Parameters

- **electronic_chemical_potential** (*PhysicalQuantity* of type energy) – The electronic chemical potential relative to `electronic_chemical_potential_reference`.
- **electronic_chemical_potential_reference** (`ValenceBandEdge | ConductionBandEdge`) – The reference level for the electronic chemical potential. **Default:** `ValenceBandEdge`
- **defect_type** (`DeepLevelDefect | ShallowAcceptor | ShallowDonor`) – The assumption of the type of defect to use for aligning the transition levels in the band gap calculated with `band_gap_calculator`; see Notes below for details. Note that this parameter only has an effect if `band_gap_calculator` is different from `formation_energy_calculator`. **Default:** `DeepLevelDefect`
- **supercell_repetitions** (sequence (size 3) of int | *ExtrapolationScheme*) – The number of repetitions of the bulk unit cell along the (a, b, c) directions. If ExtrapolationScheme, the extrapolation to the infinite supercell size limit is used. **Default:** The largest calculated supercell.
- **enable_finite_size_corrections** (*bool*) – Whether to include finite size corrections for the supercell in the calculation of the formation energy. **Default:** `True`

Returns
The calculated stable charge state.

Return type
int

stableTransitions(*electronic_chemical_potential_reference=None*, *defect_type=None*, *supercell_repetitions=None*, *enable_finite_size_corrections=None*)

The list of transitions between stable charge states across the whole range of the electronic chemical potential. The transition levels are given relative to `electronic_chemical_potential_reference`.

Parameters

- **electronic_chemical_potential_reference** (`ValenceBandEdge | ConductionBandEdge`) – The reference level for the electronic chemical potential. **Default:** `ValenceBandEdge`
- **defect_type** (`DeepLevelDefect | ShallowAcceptor | ShallowDonor`) – The assumption of the type of defect to use for aligning the transition levels in the band gap calculated with `band_gap_calculator`; see Notes below for details. Note that this parameter only has an effect if `band_gap_calculator` is different from `formation_energy_calculator`. **Default:** `DeepLevelDefect`
- **supercell_repetitions** (sequence (size 3) of int | *ExtrapolationScheme*) – The number of repetitions of the bulk unit cell along the (a, b, c) directions. If ExtrapolationScheme, the extrapolation to the infinite supercell size limit is used. **Default:** The largest calculated supercell.

- **enable_finite_size_corrections** (*bool*) – Whether to include finite size corrections for the supercell in the calculation of the formation energy. **Default:** `True`

Returns
The list of transitions between stable charge states in order as the electronic chemical potential is increased.

Return type
list of list (size 2) of int

supercellRepetitionsList()

Returns
The list of all calculated and not calculated supercells of the bulk unit cell, each given as the number of repetitions of the bulk unit cell along the (a, b, c) directions. Any supercell which has not yet been calculated will be calculated the next time the object is updated.

Return type
list of tuple (size 3) of int

supercellSymmetryData(*repetitions*)

Retrieve the symmetry information for the pristine unit cell.

This result will only be available after the calculation ran successfully.

Parameters
supercell_repetitions (*sequence (size 3) of int | None*) – The number of repetitions of the bulk unit cell along the (a, b, c) directions. If None returns the symmetry of the pristine unit cell.

Returns
The symmetry information for the pristine unit cell. If not available, returns None.

Return type
dict | None

symmetricDefect(*supercell_repetitions*, *charge_state*, *symmetry_index=None*, *unit_cell_translation=None*)

Retrieve the defect supercell configuration for a given supercell.

This result will only be available after the calculation ran successfully.

Parameters

- **supercell_repetitions** (*sequence (size 3) of int*) – The number of repetitions of the bulk unit cell along the (a, b, c) directions.
- **defect_charge_state** (*int*) – The charge state of the defect.
- **symmetry_index** (*int*) – The index of the symmetry operation for the pristine unit cell to apply to the defect supercell configuration. Note that this can only be used if the calculate_defect_symmetry option has been enabled for the calculation. **Default:** No transformation (i.e., the identity operation)
- **unit_cell_translation** (*sequence (size 3) of int*) – An additional translation to apply in terms of the unit cell vectors. **Default:** No translation

Returns
The defect supercell configuration. If not available, returns None.

Return type
BulkConfiguration | None

tasksFinished()

Returns
finished task, unfinished tasks

Return type
tuple of list of str, list of str

transitionLevel(*charge_states*, *electronic_chemical_potential_reference=None*, *defect_type=None*, *supercell_repetitions=None*, *enable_finite_size_corrections=None*)

The transition level between two calculated charge states m and n, defined as

$E\left(m/n\right) = \frac{E_f^n(\Delta\mu_e=0) - E_f^m(\Delta\mu_e=0)}{m-n}$.

The transition level is given relative to `electronic_chemical_potential_reference`.

Parameters

- **charge_states** (*sequence (size 2) of int*) – The two charge states to calculate the transition level for.
- **electronic_chemical_potential_reference** (`ValenceBandEdge | ConductionBandEdge`) – The reference level for the electronic chemical potential. **Default:** `ValenceBandEdge`
- **defect_type** (`DeepLevelDefect | ShallowAcceptor | ShallowDonor`) – The assumption of the type of defect to use for aligning the transition levels in the band gap calculated with `band_gap_calculator`; see Notes below for details. Note that this parameter only has an effect if `band_gap_calculator` is different from `formation_energy_calculator`. **Default:** `DeepLevelDefect`
- **supercell_repetitions** (sequence (size 3) of int | *ExtrapolationScheme*) – The number of repetitions of the bulk unit cell along the (a, b, c) directions. If ExtrapolationScheme, the extrapolation to the infinite supercell size limit is used. **Default:** The largest calculated supercell.
- **enable_finite_size_corrections** (*bool*) – Whether to include finite size corrections for the supercell in the calculation of the formation energy. **Default:** `True`

Returns
The calculated transition level.

Return type
PhysicalQuantity of type energy

uniqueString()

Return a unique string representing the state of the object.

update()

Run the calculations for the study object.

useGhost()

Returns
Whether ghost atoms are used (for LCAO calculations involving vacancies)

Return type
bool

valenceBandMaximum(*supercell_repetitions*)

Retrieve the valence band maximum of the pristine unit cell configuration associated with a given supercell.

This result will only be available after the calculation ran successfully.

Parameters
supercell_repetitions (*sequence (size 3) of int*) – The number of repetitions of the bulk unit cell along the (a, b, c) directions.

Returns
The valence band maximum of the pristine unit cell configuration. If not available, returns None.

Return type
PhysicalQuantity of type energy | None

Notes

Note: Study objects behave differently from analysis objects. See the *Study object* overview for more details.

The *ChargedPointDefect* object can be used to perform a detailed study of a single point defect in bulk material in its various charge states. The defect can be a simple vacancy, substitutional, or interstitial, or a more complex defect cluster made from multiple simple defects.

The main results are the formation energy of the defect for different charge states as a function of the electronic chemical potential, and the corresponding stable charge transition levels (sometimes referred to as the thermodynamic transition levels, occupancy levels, or trap levels).

Performing accurate simulations of point defects, especially for non-neutral charge states, can be challenging. In particular, it is generally very important to ensure that the physical quantities of interest are properly converged with respect to the size of the supercell of bulk crystal in which the point defect is placed (as periodic boundary conditions are used, there will be spurious interactions between periodic replicas of the defect site). *ChargedPointDefect* aims to assist the user in automatically simulating a range of supercell sizes and analyzing the convergence with size for each charge state. It will also apply the correction by Freysoldt, Neugebauer and Van De Walle (FNV)[1] to mitigate the effects of these finite size interactions.

The object is initialized by specifying the primitive unit cell of the host crystal (without the defect) as a *BulkConfiguration*, the list of supercells of this primitive cell to generate for the study, and the defect to study as an instance of the desired defect class (`Vacancy` | `Substitutional` | `Interstitial` | `DefectCluster` | `SplitInterstitial`). The defect will be inserted into each supercell of the bulk material. The list of charge states of the defect to simulate must also be given.

The calculator which is used to calculate the formation energy is given by `formation_energy_calculator`. The atomic coordinates of the defect supercells are relaxed by default (this is controlled with `relax_atomic_coordinates`); it is possible to specify a separate calculator to perform the relaxations with `relaxation_calculator`, as these usually represent the most computationally intensive part of the study. Both calculators are automatically adjusted for each supercell to ensure a consistent level of accuracy.

One can optionally calculate an elastic strain correction to the formation energy by using a *ImageStressCorrection* object as the `elastic_correction_method`. The correction is described is more detail in Section *Finite-size scaling and correction terms*.

Finally, it is possible to specify a separate calculator to calculate the band gap of the host material with `band_gap_calculator`, in order to overcome the underestimation of the band gap from standard DFT functionals.

Note: The calculators must contain a basis/pseudopotential for all species in both the pristine and defect supercells.

Defining the point defect

This is specified by `point_defect`. The defect is defined in an abstract way, independently of the material it is embedded in or the supercell size. The study will combine it with the reference unit cell of the pristine material (`bulk_configuration`) and the various supercell sizes (`supercell_repetitions_list`) to create the defect supercells.

There are three simple point defect types: *Vacancy*, *Substitutional*, and *Interstitial*. The first two require a `site_index` at which to create the defect; the index refers to the atom index of the list of atoms of the reference unit cell. The third, instead, is not tied to a site but is defined by specifying a position in space (either in absolute coordinates or as fractional coordinates of the reference unit cell).

More complex defects can also be specified by using a *DefectCluster*; this is defined by providing a list of simple defects which will be combined together to form a composite defect. Examples of this include a divacancy (2 vacancies) or a Frenkel pair (vacancy + interstitial). Larger clusters can also be defined.

Although a *DefectCluster* can still be considered a point defect (it is not periodic in any direction), it has a size depending on the largest distance between any of the constituent defects. It is therefore possible for a cluster to be larger than the reference unit cell. In order to define such clusters, one can make use of the `unit_cell_index` argument for *Vacancy* and *Substitutional*, which allows for the constituent defects to be shifted to different unit cells. Similarly, *Interstitial* defects can be defined by giving a position outside of the unit cell. When the study generates the actual defect supercell configuration, the constituent defects are wrapped within the supercell. Therefore, all supercells used in the study must be large enough to accommodate the cluster.

Atomic Chemical Potentials

The chemical potentials for the atomic species involved in the creation of the defect (i.e., any species for which the number of atoms changes between the pristine and defect supercell) need to be determined in order to calculate the formation energy. Note that the atomic chemical potentials are only used for the final post-processing calculation of the formation energy; although the absolute value of the formation energy is affected, the differences between charge states (and, hence, the transition levels) are not.

The study will automatically try to make a reasonable choice for the values of the atomic chemical potentials. The default choice taken by the study for each element is as follows:

- If possible, the atomic chemical potential is calculated as the energy per atom of the pristine configuration at each supercell size. This will be the case if (a) the element is present in the pristine configuration, and (b) all the elements of the pristine configuration are either added or removed in their stoichiometric ratio in the creation of the defect.
- Otherwise, the atomic chemical potential is calculated as the energy per atom of a default elemental reference configuration. This default configuration is taken from the Δ-test[2] suite of elemental crystals. Note that the calculation is performed with the same calculator parameters as specified in `formation_energy_calculator`.

These automatic values can, however, be changed for one or more elements by providing an *AtomicChemicalPotential* object for each element in `atomic_chemical_potentials`. This allows the user to provide either an explicit hard-coded value of the energy per atom, or an alternative elemental reference configuration for the study to use in calculating the atomic chemical potential. In compound materials the class *AtomicChemicalPotentialList* can be used to compute heat of formation or rich conditions.

Results

The study provides a number of methods for processing the available results and returning the physical quantities of interest:

- `formationEnergy`: the formation energy for a given charge state as a function of the electronic chemical potential. The mathematical definition is given in the method description above.
- `stableChargeState`: the stable charge state at a given electronic chemical potential.
- `transitionLevel`: the transition level between two charge states. The mathematical definition is given in the method description above.
- `stableTransitions`: the list of transitions between stable charge states across the whole range of the electronic chemical potential.

Finite-size scaling and correction terms

All the post-processing methods given above take two optional arguments, `supercell_repetitions` and `enable_finite_size_corrections`. By default, the largest supercell is used and finite-size corrections are automatically included.

As previously mentioned, the FNV correction scheme[Page 2389, 1] is used. This scheme introduces two additional terms in the definition of the formation energy: a correction for the electrostatic interaction between periodic replicas of the charged defect center, and a band shift correction to the defect supercell to align the bands to a common reference with the neutral bulk. Moreover, we add an optional strain correction, which accounts for the elastic distortion of the surrounding lattice due to the defect.

The first correction term is added to the total energy of the defect supercell $E^{\mathrm{def},q}$, while the second is substracted from the absolute position of the reference level for the electronic chemical potential μ_e^{ref}. The complete definition of the formation energy therefore becomes

$$E_f^q = E^{\mathrm{def},q} + E_1^{\mathrm{FNV},q} + E^{\mathrm{strain},q} - E^{\mathrm{bulk},q} - \sum_i \Delta n_i \mu_i + q\left(\mu_e^{\mathrm{ref}} - E_2^{\mathrm{FNV},q} + \Delta\mu_e\right),$$

where $E_{1,2}^{\mathrm{FNV},q}$ are the two FNV correction terms, which depend both on the charge state and the supercell. The term $E^{\mathrm{strain},q}$ is the optional strain energy correction, which is given by

$$E^{\mathrm{strain},q} = -\frac{V}{2K}(P^{\mathrm{def}} - P^{\mathrm{bulk}})^2,$$

where V is the volume of the supercell, K is the bulk modulus of the host material, P^{def} is the external hydrostatic pressure in the supercell with the defect, and P^{bulk} is the external hydrostatic pressure for the pristine system. See equation 57 and related discussion in[4] for a more detailed description of the elastic correction and the underlying approximations.

Note: The elastic strain correction is only calculated if the parameter `elastic_correction_method` is explicitly set. If the parameter is not specified, $E^{\mathrm{strain},q}$ is set to zero in the formation energy calculation.

Note: The FNV correction terms only apply to non-neutral charge states. The neutral charge state results will be unaffected by the use of the correction.

The FNV correction works by approximating the additional charge on the defect site with a Gaussian distribution in a dielectric background. The width of this distribution can be set manually with the `setModelChargeCorrection` method; by default, it is fitted for each charge state and supercell size so as to best reproduce the long-range electrostatic potential profile of the defect supercell far away from the defect.

Note: In some cases it is not possible to reproduce the calculated potential profile with a Gaussian charge; the fitting procedure will then set an infinite width, effectively switching off the first correction term.

Extrapolating to infinite size

In addition to the finite-size corrections, it is possible to attempt an extrapolation of the formation energy to the limit of infinite system size. This can be specified by providing an instance of *ExtrapolationScheme* as `supercell_repetitions` in the post-processing methods. The extrapolation scheme will use the available results at different supercell sizes to fit a polynomial.

The form of the extrapolating function is somewhat empirical; the rationale behind it and its reliability for some practical test cases are discussed by Lany and Zunger[5]. Care should be taken when making use of the extrapolation results.

Band gap correction

Standard DFT functionals are known to severely underestimate band gaps; this can be a problem for interpreting defect transition levels, which are typically measured relative to the band edges. One solution is to use the HSE functional, which can predict band gaps very accurately; however, it has a much higher computational cost with respect to the standard functionals, and this will be particularly noticeable when performing defect calculations in large supercells.

Alternatively, one can employ a band-gap correction scheme for *ChargedPointDefect* by specifying a separate `band_gap_calculator`; this will perform an additional calculation of the band gap of the host material with this calculator, and position the defect transition levels within it for all post-processing methods. The calculation of the host band gap is computationally inexpensive as it is done only once per study and uses the primitive unit cell, not the supercell needed for the defect. Therefore, we suggest using either HSE or other methods available in QuantumATK for accurately calculating band gaps (*DFT-1/2*, *PPS*, *TB09-MGGA* or *DFT+U*).

When using `band_gap_calculator` there are three possibilities for how the transition levels will be aligned to the corrected band gap; this is specified in all post-processing methods with the `defect_type` argument. For deep defects (the default) the levels will be aligned to the Fermi level of the pristine host material, while for shallow defects they will be aligned either to the valence band edge (for acceptors) or the conduction band edge (for donors). In particular, the default option for deep defects has been shown to work remarkably well over a large range of defects and host materials[6][7][8], reproducing the transition levels calculated with HSE at a small fraction of the computational cost.

Usage Example

This example script shows how to perform a simple study of the vacancy in bulk silicon and display a summary of results:

```
from SMW import *

# Setup the reference bulk unit cell configuration.
lattice = FaceCenteredCubic(5.4306*Angstrom)

elements = [Silicon, Silicon]

fractional_coordinates = [[ 0.  ,  0.  ,  0.  ],
                          [ 0.25,  0.25,  0.25]]

bulk_configuration = BulkConfiguration(
    bravais_lattice=lattice,
    elements=elements,
    fractional_coordinates=fractional_coordinates,
)

# Setup the calculator.
basis_set = getattr(LDABasis, 'Silicon_SingleZeta')
calculator = LCAOCalculator(
    basis_set=basis_set,
    exchange_correlation=LDA.PZ,
    numerical_accuracy_parameters=NumericalAccuracyParameters(
        k_point_sampling=MonkhorstPackGrid(1, 1, 1))
)

# Initialize the ChargedPointDefect object.
charged_point_defect = ChargedPointDefect(
    bulk_configuration=bulk_configuration,
    filename='chargedpointdefect.hdf5',
    formation_energy_calculator=calculator,
    object_id='Si_vacancy',
    point_defect=Vacancy(0),
    charge_states=[2, 1, 0, -1, -2],
    supercell_repetitions_list=[(1, 1, 1), (2, 2, 2), (3, 3, 3), (4, 4, 4)],
    relax_atomic_coordinates=False,
    dielectric_constant=11.68,
)

# Run the calculation.
charged_point_defect.update()

# Print a summary of results.
nlprint(charged_point_defect)
```

charged_point_defect.py

No stress correction is used in this example. Here is the resulting output from the `nlprint` command:

```

```

It is important to note that this example is only intended to give an overview of the capabilities of *ChargedPointDefect*; it does not relax the atomic coordinates of the defect supercell, and makes use of a fast calculator.

ChargedPointDefectConfiguration

class ChargedPointDefectConfiguration(*pristine_configuration*, *point_defect*, *atomic_chemical_potentials*, *charge_states=None*, *pre_relaxation_calculator=None*, *pre_relaxation_parameters=None*, *relax_atomic_coordinates=None*, *relaxation_parameters=None*, *rattle_atomic_coordinates=None*, *random_seed=None*, *use_ghost_atoms=None*, *fix_atom=None*)

Create a charge point defect based on a specific configuration.

Parameters

- **pristine_configuration** (*PristineConfiguration*) – The original material without defects.
- **point_defect** (*NamedPointDefect*) – The named point defect used to generate the defected structure.
- **atomic_chemical_potentials** (Sequence or table of *CalculatedChemicalPotential* | *ReferenceChemicalPotential*) – List of chemical potentials for the elements in the defect configuration.
- **charge_states** (*Sequence of int*) – The integer charge states to calculate.
- **relax_atomic_coordinates** (*bool*) – Whether to relax the atomic coordinates. **Default:** True.
- **pre_relaxation_calculator** (`All calculators` | None) – The calculator used for relaxing the atomic coordinates. If not specified and relaxation is enabled the reference calculator is used.
- **pre_relaxation_parameters** (*OptimizeGeometryParameters* | None) – The parameters for the atomic pre-relaxation, if enabled. Only constraints of type *FixAtomConstraints* and *RigidBody* will be maintained, others will be discarded.
- **relaxation_parameters** (*OptimizeGeometryParameters* | None) – The parameters for the atomic relaxation, if enabled. The parameters will also be used when calculating the vibrations if a phonon calculator has been supplied. Only constraints of type *FixAtomConstraints* and *RigidBody* will be maintained, others will be discarded.
- **rattle_atomic_coordinates** (*bool*) – Whether to rattle the atomic coordinates before relaxation to destroy symmetry. **Default:** False
- **random_seed** (*int | None*) – The random seed for the atomic rattling.
- **use_ghost_atoms** (*bool*) – Whether to use ghost atoms when generating single vacancy defects. For other defect types ghost atoms are not supported. **Default:** False
- **fix_atom** – **Deprecated:** from v2024.09, has no effect and should no longer be used.

allConverged()

Returns
Whether all calculated SCF loops and geometry optimizations are converged.

Return type
bool

atomicChemicalPotentials(*element=None*)

Return one or all of the atomic chemical potentials used to define the zero of energy in the defect system.

Parameters
element (*PeriodicTableElement* | None) – The element for which the chemical potential is sought. If not given a list of all chemical potentials is returned.

Returns
The atomic chemical potentials used to define the zero energy in the configuration.

Return type
list | ReferenceChemcialPotential | *CalculatedChemicalPotential*

chargeStates()

Returns
The charge states, in integer electron charges, calculated for the defect.

Return type
tuple of int

concentration(*charge_state=0*, *element_in_pristine=None*, *electronic_chemical_potential=None*, *electronic_chemical_potential_reference=None*, *temperature=PhysicalQuantity(300.0, K)*, *equivalent_defects=None*, *internal_degrees_of_freedom=1*)

Calculates the concentration of the defect in the given charge state and at the given temperature.

Parameters

- **charge_state** (*int*) – The charge state of the defect.
- **element_in_pristine** (None | All | *PeriodicTableElement*) – The element whose chemical potential value is taken from the pristine material. Can be None (elemental reference), All (thermodynamic reference), or an element in the pristine material (element poor reference).
- **electronic_chemical_potential** (*PhysicalQuantity* of type energy) – The electronic chemical potential relative to electronic_chemical_potential_reference. **Default:** 0.0 * eV
- **electronic_chemical_potential_reference** (ValenceBandEdge | ConductionBandEdge) – The reference level for the electronic chemical potential. **Default:** ValenceBandEdge
- **temperature** (*PhysicalQuantity* of type temperature) – The temperature at which the concentration should be calculated. **Default:** 300K.
- **equivalent_defects** (*int*) – The number of equivalent sites for this defect in the primitive host cell. **Default:** Automatically determined using symmetry.
- **internal_degrees_of_freedom** (*int*) – The internal degrees of freedom of the defect. E.g. spin states or equivalent orientations (self-interstitials). **Default:** 1.

Returns
The concentration of the defect.

Return type
PhysicalQuantity of type inverse volume

defectCenterConfiguration(*charge_state=None*, *symmetry_group_index=0*, *symmetry_operation_index=0*, *unit_cell_translation=None*, *symmetry_type=<class 'NL.ComputerScienceUtilities.NLFlag._NLFlag.DefectSuperCell'>*)

Retrieve the calculated position of the defect center for a given supercell, in the form of a bulk configuration (the configuration has a single hydrogen atom at the defect center).

This result will only be available after the calculation ran successfully.

Parameters

- **charge_state** (*int*) – The charge state of the defect. **Default:** 0
- **symmetry_group_index** (*int*) – The index of the group of symmetry operations that give the same configuration.
- **symmetry_operation_index** (*int*) – The index of the operation within the group to apply.
- **unit_cell_translation** (*sequence (size 3) of int*) – An additional translation to apply in terms of the unit cell vectors. **Default:** No translation.

- **symmetry_type** (*DefectUnitCell | DefectSuperCell*) – Whether the supercell or unit cell symmetry is used to transform the defect position. **Default:** DefectSuperCell.

Returns
The defect center configuration. If not available, returns None.

Return type
BulkConfiguration | None

defectConfiguration(*charge_state=None*)

The defect configuration associated with a given change state.

Parameters
charge_state (*int*) – The charge of the defect.

Returns
The configuration of the defect.

Return type
BulkConfiguration

defectSymmetryData(*charge_state=None*)

Return information about the symmetry of the optimized defect.

Parameters
charge_state (*int*) – The charge state of the defect. **Default:** 0

Returns
The symmetry information for the defect supercell. If not available, returns None.

Return type
dict | None

finiteSizeCorrection(*charge_state=None*)

The finite size correction for the defect.

Parameters
charge_state (*int*) – The charge of the defect.

Returns
The band shift correction.

Return type
IsotropicFiniteSizeCorrection | InterfaceFiniteSizeCorrection

fitConcentrationArrheniusParameters(*charge_state=None*, *element_in_pristine=None*, *electronic_chemical_potential=None*, *electronic_chemical_potential_reference=None*, *temperatures=None*, *equivalent_defects=None*, *internal_degrees_of_freedom=1*)

Fit Arrhenius parameters describing concentration at a particular charge state or the intrinsic concentration. The Arrhenius equation is given as:

$C = A \exp(B/T)$

Parameters

- **charge_state** (*int | None*) – The charge state at which the parameters are calculated. If None is given parameters are calculated for the intrinsic concentration.
- **element_in_pristine** (None | All | *PeriodicTableElement*) – The element whose chemical potential value is taken from the pristine material. Can be None (elemental reference), All (thermodynamic reference), or an element in the pristine material (element poor reference).

•**electronic_chemical_potential** (*PhysicalQuantity* of type energy) – The electronic chemical potential relative to `electronic_chemical_potential_reference`. **Default:** `0.0 * eV`

•**electronic_chemical_potential_reference** (`ValenceBandEdge | ConductionBandEdge`) – The reference level for the electronic chemical potential. **Default:** `ValenceBandEdge`

•**temperatures** (*PhysicalQuantity* of type temperature) – A list of temperatures at which the concentration is calculated for fitting. **Default:** Temperature range of 300K to 1500K in 100K increments.

•**equivalent_defects** (*int*) – The number of equivalent sites for this defect in the primitive host cell. **Default:** Automatically determined using symmetry.

•**internal_degrees_of_freedom** (*int*) – The internal degrees of freedom of the defect. E.g. spin states or equivalent orientations (self-interstitials).

Returns
Tuple of the Arrhenius pre-factor and barrier.

Return type
tuple of *PhysicalQuantity* of type inverse volume and *PhysicalQuantity* of type temperature.

fixAtom()

Deprecated: Drift automatically removed in the structure relaxation without fixing an atom.

Deprecated: Drift automatically removed in the structure relaxation without fixing an atom.

formationEnergyCalculator()

Returns
The calculator used to calculate the formation energy.

Return type
Calculator

formationEntropy(*charge_state=None*, *temperature=None*, *element_in_pristine=None*)

Determines the formation entropy for a given defect, defined as

$S_f^{\mathrm{harmonic}} = S_{\mathrm{vib}}^{\mathrm{def}} - S_{\mathrm{vib}}^{\mathrm{pr}} - \sum_i \Delta n_i s_i$

where the first and second terms correspond to the defect and pristine entropies, respectively, and the third term is the sum of the atomic partial entropies.

Parameters

•**charge_state** (*int*) – The charge of the defect.

•**temperature** (*PhysicalQuantity* of type temperature) – The temperature used for calculating the formation entropy. **Default:** `300.0 * Kelvin`

•**element_in_pristine** (`None | All |` *PeriodicTableElement*) – The element whose chemical potential value is taken from the pristine material. Can be `None` (elemental reference), `All` (thermodynamic reference), or an element in the pristine material (element poor reference).

Returns
The calculated formation entropy.

Return type
PhysicalQuantity of type energy per temperature.

formationFreeEnergy(*charge_state=None*, *element_in_pristine=None*, *electronic_chemical_potential=None*, *electronic_chemical_potential_reference=None*, *defect_type=None*, *enable_finite_size_corrections=None*, *temperature=None*, *include_vibrations=None*)

Return the Helmholtz formation free energy. This is calculated as:

$F_f = U_f - TS_f$

If vibrations are not included, the entropy S_f is zero and the formation internal energy and free energy is simply the electronic formation energy of the defect. If vibrations are included, vibrational corrections are included with both U_f and S_f. These are calculated based on the change in vibrational modes between the defect, pristine and reference materials.

Parameters

•**charge_state** (*int*) – The charge of the defect.

•**element_in_pristine** (None | All | *PeriodicTableElement*) – The element whose chemical potential value is taken from the pristine material. Can be None (elemental reference), All (thermodynamic reference), or an element in the pristine material (element poor reference).

•**electronic_chemical_potential** (*PhysicalQuantity* of type energy) – The electronic chemical potential relative to electronic_chemical_potential_reference. **Default:** 0.0 * eV

•**electronic_chemical_potential_reference** (ValenceBandEdge | ConductionBandEdge) – The reference level for the electronic chemical potential. **Default:** ValenceBandEdge

•**defect_type** (DeepLevelDefect | ShallowAcceptor | ShallowDonor) – The assumption of the type of defect to use for aligning the transition levels in the band gap calculated with band_gap_calculator; see Notes below for details. Note that this parameter only has an effect if band_gap_calculator is different from formation_energy_calculator. **Default:** DeepLevelDefect

•**enable_finite_size_corrections** (*bool*) – Whether to include finite size corrections for the supercell in the calculation of the formation energy. **Default:** True

•**temperature** (*bool*) – The temperature used for calculating vibrational energy **Default:** 300K

•**include_vibrations** (*bool*) – Whether vibrational terms are included, if available. **Default:** True

Returns
The calculated formation energy.

Return type
PhysicalQuantity of type energy

formationInternalEnergy(*charge_state*, *element_in_pristine=None*, *electronic_chemical_potential=None*, *electronic_chemical_potential_reference=None*, *defect_type=None*, *enable_finite_size_corrections=None*, *temperature=None*, *include_vibrations=None*)

The internal formation energy for a given charge state q of the defect, defined as

$U_f^q = U^{\mathrm{def},q} - U^{\mathrm{bulk},q} - \sum_i \Delta n_i \, \mu_i + q \left(\mu_e^{\mathrm{ref}} + \Delta\mu_e\right)$.

The first two terms are the total internal energy of the supercell with and without the defect, respectively. Δn_i is the difference in the number of atoms between the two supercells for species i, and μ_i is the atomic chemical potential for that species. μ_e^{ref} is the absolute position of the reference level for the electronic chemical potential (either the valence band maximum or the conduction band minimum), and $\Delta\mu_e$ is the electronic chemical potential relative to it.

Parameters

•**charge_state** (*int*) – The charge state of the defect.

•**element_in_pristine** (None | All | *PeriodicTableElement*) – The element whose chemical potential value is taken from the pristine material. Can be None (elemental reference), All (thermodynamic reference), or an element in the pristine material (element poor reference).

•**electronic_chemical_potential** (*PhysicalQuantity* of type energy) – The electronic chemical potential relative to electronic_chemical_potential_reference. **Default:** 0.0 * eV

•**electronic_chemical_potential_reference** (ValenceBandEdge | ConductionBandEdge) – The reference level for the electronic chemical potential. **Default:** ValenceBandEdge

•**defect_type** (DeepLevelDefect | ShallowAcceptor | ShallowDonor) – The assumption of the type of defect to use for aligning the transition levels in the band gap calculated with band_gap_calculator. Note that this parameter only has an effect if band_gap_calculator is different from formation_energy_calculator. **Default:** DeepLevelDefect

•**enable_finite_size_corrections** (*bool*) – Whether to include finite size corrections for the supercell in the calculation of the formation energy. **Default:** True

•**temperature** (*bool*) – The temperature used for calculating vibrational energy **Default:** 300K

•**include_vibrations** (*bool*) – Whether vibrational terms are included, if available. **Default:** True

Returns
The calculated formation energy.

Return type
PhysicalQuantity of type energy

geometryConverged(*charge_state*)

Return whether a specific geometry optimization converged.

Parameters
charge_state (*int*) – The charge of the defect.

Returns
Whether the geometry optimization converged for this defect.

Return type
bool

intrinsicConcentration(*element_in_pristine=None*, *electronic_chemical_potential=None*, *electronic_chemical_potential_reference=None*, *temperature=PhysicalQuantity(300.0, K)*, *equivalent_defects=None*, *internal_degrees_of_freedom=1*)

The sum of concentrations of all available charge states.

Parameters

•**element_in_pristine** (None | All | *PeriodicTableElement*) – The element whose chemical potential value is taken from the pristine material. Can be None (elemental reference), All (thermodynamic reference), or an element in the pristine material (element poor reference).

•**electronic_chemical_potential** (*PhysicalQuantity* of type energy) – The electronic chemical potential relative to electronic_chemical_potential_reference. **Default:** 0.0 * eV

•**electronic_chemical_potential_reference** (ValenceBandEdge | ConductionBandEdge) – The reference level for the electronic chemical potential. **Default:** ValenceBandEdge

•**temperature** (*PhysicalQuantity* of type temperature) – The temperature at which the concentration should be calculated.

•**equivalent_defects** (*int*) – The number of equivalent sites for this defect in the primitive host cell. **Default:** Automatically determined using symmetry.

•**internal_degrees_of_freedom** (*int*) – The internal degrees of freedom of the defect. E.g. spin states or equivalent orientations (self-interstitials).

isConverged(*charge_state*)

Return whether a specific SCF loop and geometry optimization are converged.

Parameters
charge_state (*int*) – The charge of the defect.

Returns
Whether the SCF loop converged for this defect.

Return type
bool

namedPointDefect()

Returns
The named point defect used to generate the defected configuration.

Return type
NamedPointDefect

nlinfo()

Returns
Information summarizing the defect calculation.

Return type
dict

nlprint(*stream*)

Print a string containing an ASCII table summarizing the available results for the defect.

Parameters
stream (*file-like*) – The stream to write to. This should be an object that supports strings being written to it using a `write` method.

numberOfSymmetricDefects(*charge_state=None*, *symmetry_type=<class 'NL.ComputerScienceUtilities.NLFlag._NLFlag.DefectSuperCell'>*)

Return the number of distinct but symmetrically equivalent defect configurations.

Parameters

- **charge_state** (*int*) – The charge state of the defect.
- **symmetry_type** (*DefectSuperCell | DefectUnitCell.*) – Whether the nunber of defects is according to the unit cell or supercell symmetry. **Default:** DefectSuperCell

Returns
The total number of symmetrically equivalent defects.

Return type
int

numberOfSymmetryOperations(*charge_state=None*, *symmetry_group_index=0*, *symmetry_type=<class 'NL.ComputerScienceUtilities.NLFlag._NLFlag.DefectSuperCell'>*)

Return the number of symmetry operations that produce identical defects.

Parameters

- **charge_state** (*int*) – The charge state of the defect.
- **symmetry_group_index** (*int*) – The index of the unique defect.
- **symmetry_type** (*DefectSuperCell | DefectUnitCell*) – Whether the number of defects is according to the unit cell or supercell symmetry. **Default:** DefectSuperCell.

Returns
The total number of symmetry operations that produce the same defect.

Return type
int

phononDensityOfStates(*charge_state=None*)

Phonon density of states of the defect.

Parameters
charge_state (*int*) – The charge of the defect.

Returns
The phonon DOS if vibrational corrections are enabled. None if not.

Return type
PhononDensityOfStates | None

pointDefect()

Returns
The point defect used to generate the defected configuration.

Return type
BasePointDefect

possibleTransition(*other*)

Check to see if there is a possible transition path between the current and another defect.

Parameters
other (*ChargedPointDefectConfiguration*) – The other defect to test.

Returns
Whether a transition is possible.

Return type
bool

preRelaxationCalculator()

Returns
The calculator used to relax the atomic coordinates in the pre-optimization step.

Return type
Calculator

preRelaxationParameters()

Returns
The parameters of the optimization used to pre-relax the defect configuration.

Return type
OptimizeGeometryParameters

pristineConfiguration()

Returns
The reference pristine configuration from which the defect is formed.

Return type
PristineConfiguration

randomSeed()

Returns
Random seed used for generating random numbers.

Return type
int

rattleAtomicCoordinates()

Returns
Whether the atomic coordinates are rattled before optimization to break symmetry.

Return type
bool

relaxAtomicCoordinates()

Returns
Whether the atomic coordinates are relaxed using the formation energy calculator.

Return type
bool

relaxationParameters()

Returns
The parameters of the optimization used to relax the atomic coordinates.

Return type
OptimizeGeometryParameters

sameFormationEnergyCalculators(*other*)

Check that the same formation energy calculator was used in two different defects.

Parameters
other (*ChargedPointDefectConfiguration*) – The other defect to test for possible transitions to.

Returns
Whether the formation energy calculators are the same.

Return type
bool

scfConverged(*charge_state*)

Return whether a specific SCF loop converged.

Parameters
charge_state (*int*) – The charge of the defect.

Returns
Whether the SCF loop converged for this defect.

Return type
bool

stableChargeState(*electronic_chemical_potential*, *electronic_chemical_potential_reference=None*, *defect_type=None*, *enable_finite_size_corrections=None*, *temperature=None*, *include_vibrations=None*)

The stable charge state at a given electronic chemical potential.

Parameters

- **electronic_chemical_potential** (*PhysicalQuantity* of type energy) – The electronic chemical potential relative to `electronic_chemical_potential_reference`.
- **electronic_chemical_potential_reference** (`ValenceBandEdge | ConductionBandEdge`) – The reference level for the electronic chemical potential. **Default:** `ValenceBandEdge`

•**defect_type** (DeepLevelDefect | ShallowAcceptor | ShallowDonor) – The assumption of the type of defect to use for aligning the transition levels in the band gap calculated with band_gap_calculator; see Notes below for details. Note that this parameter only has an effect if band_gap_calculator is different from formation_energy_calculator. **Default:** DeepLevelDefect

•**enable_finite_size_corrections** (*bool*) – Whether to include finite size corrections for the supercell in the calculation of the formation energy. **Default:** True

•**temperature** (*bool*) – The temperature used for calculating vibrational energy **Default:** 300K

•**include_vibrations** (*bool*) – Whether vibrational terms are included, if available. **Default:** True

Returns
The calculated stable charge state.

Return type
int

stableTransitions(*electronic_chemical_potential_reference=None*, *defect_type=None*, *enable_finite_size_corrections=None*, *temperature=None*, *include_vibrations=None*)

The list of transitions between stable charge states across the whole range of the electronic chemical potential. The transition levels are given relative to electronic_chemical_potential_reference.

Parameters

•**electronic_chemical_potential_reference** (ValenceBandEdge | ConductionBandEdge) – The reference level for the electronic chemical potential. **Default:** ValenceBandEdge

•**defect_type** (DeepLevelDefect | ShallowAcceptor | ShallowDonor) – The assumption of the type of defect to use for aligning the transition levels in the band gap calculated with band_gap_calculator; see Notes below for details. Note that this parameter only has an effect if band_gap_calculator is different from formation_energy_calculator. **Default:** DeepLevelDefect

•**supercell_repetitions** (sequence (size 3) of int | *ExtrapolationScheme*) – The number of repetitions of the bulk unit cell along the (a, b, c) directions. If ExtrapolationScheme, the extrapolation to the infinite supercell size limit is used. **Default:** The largest calculated supercell.

•**enable_finite_size_corrections** (*bool*) – Whether to include finite size corrections for the supercell in the calculation of the formation energy. **Default:** True

•**temperature** (*bool*) – The temperature used for calculating vibrational energy **Default:** 300K

•**include_vibrations** (*bool*) – Whether vibrational terms are included, if available. **Default:** True

Returns
The list of transitions between stable charge states in order as the electronic chemical potential is increased, and the values of the corresponding transition levels.

Return type
tuple of (list of list (size 2) of int, list of float)

symmetricDefect(*charge_state=None*, *symmetry_group_index=0*, *symmetry_operation_index=0*, *unit_cell_translation=None*, *symmetry_type=<class 'NL.ComputerScienceUtilities.NLFlag._NLFlag.DefectSuperCell'>*)

Generate a symmetrically equivalent defect configuration using the symmetry operations of the pristine material.

Parameters

•**charge_state** (*int*) – The charge state of the defect. **Default:** 0

•**symmetry_group_index** (*int*) – The index of the group of symmetry operations that give the same configuration.

•**symmetry_operation_index** (*int*) – The index of the operation within the group to apply.

•**unit_cell_translation** (*Sequence of int of size 3*) – An additional translation to apply in terms of the unit cell vectors. This can be used move the defect within the supercell.

•**symmetry_type** (*DefectUnitCell | DefectSuperCell*) – Whether the supercell or unit cell symmetry is used to transform the defect position. **Default:** DefectSuperCell.

Returns
The symmetrically equivalent defect.

Return type
BulkConfiguration

symmetricDefectPosition(*charge_state=0*, *symmetry_group_index=0*, *symmetry_operation_index=0*, *unit_cell_translation=None*, *coordinate_type=<class 'NL.ComputerScienceUtilities.NLFlag._NLFlag.Fractional'>*, *symmetry_type=<class 'NL.ComputerScienceUtilities.NLFlag._NLFlag.DefectSuperCell'>*)

Get the symmetrically equivalent defect position using the symmetry operations of the pristine cell.

Parameters

•**charge_state** (*int*) – The charge state of the defect. **Default:** 0

•**symmetry_group_index** (*int*) – The index of the group of symmetry operations that give the same configuration.

•**symmetry_operation_index** (*int*) – The index of the operation within the group to apply.

•**unit_cell_translation** (*Sequence of int of size 3*) – An additional translation to apply in terms of the unit cell vectors. This can be used move the defect within the supercell.

•**coordinate_type** (*Fractional | Cartesian*) – Whether the defect coordinates are given in Cartesian or fractional coordinates. Fractional coordinates are given in reference to the supercell translation vectors.

•**symmetry_type** (*DefectUnitCell | DefectSuperCell*) – Whether the supercell or unit cell symmetry is used to transform the defect position. **Default:** DefectSuperCell.

Returns
The symmetrically equivalent defect position.

Return type
PhysicalQuantity of type length | numpy.ndarray

totalEnergy(*charge_state=None*)

The defect total energy associated with a given charge state.

Parameters
charge_state (*int*) – The charge of the defect.

Returns
The total energy analysis of the defect.

Return type
TotalEnergy

transitionLevel(*charge_states*, *electronic_chemical_potential_reference=None*, *defect_type=None*, *enable_finite_size_corrections=None*, *temperature=None*, *include_vibrations=None*)

The transition level between two calculated charge states m and n, defined as

$E\left(m/n\right) = \frac{E_f^n(\Delta\mu_e=0) - E_f^m(\Delta\mu_e=0)}{m-n}$.

The transition level is given relative to `electronic_chemical_potential_reference`.

Parameters

•**charge_states** (*sequence (size 2) of int*) – The two charge states to calculate the transition level for.

- **electronic_chemical_potential_reference** (ValenceBandEdge | ConductionBandEdge) – The reference level for the electronic chemical potential. **Default:** ValenceBandEdge
- **defect_type** (DeepLevelDefect | ShallowAcceptor | ShallowDonor) – The assumption of the type of defect to use for aligning the transition levels in the band gap calculated with band_gap_calculator; see Notes below for details. Note that this parameter only has an effect if band_gap_calculator is different from formation_energy_calculator. **Default:** DeepLevelDefect
- **enable_finite_size_corrections** (*bool*) – Whether to include finite size corrections for the supercell in the calculation of the formation energy. **Default:** True
- **temperature** (*bool*) – The temperature used for calculating vibrational energy **Default:** 300K
- **include_vibrations** (*bool*) – Whether vibrational terms are included, if available. **Default:** True

Returns
The calculated transition level.

Return type
PhysicalQuantity of type energy

uniqueString()

Return a unique string representing the state of the object.

update()

Perform the calculation.

useGhostAtoms()

Returns
Whether ghost atoms replace lattice atoms in vacancy defects.

Return type
bool

vibrations(*charge_state=None*)

Vibrational frequencies of the defect.

Parameters
charge_state (*int*) – The charge of the defect.

Returns
The vibrations if vibrational corrections are enabled. None if not.

Return type
PhysicalQuantity of type inverse time | None

Usage Examples

In this example the vacancy and anti-site defects in silicon carbide are calculated using the *ChargedPointDefectConfiguration* object. Note that the DFT calculations can take several hours.

A workflow for the calculation can be downloaded here with a corresponding python script SiC_Defects_Example.py.

Notes

The *ChargedPointDefectConfiguration* object calculates the properties of a defect at one or more charge states. The defect configuration can be optimized for each charge state.

The *ChargedPointDefectConfiguration* is created by supplying a *PristineConfiguration*, a *NamedPointDefect* that defines the defect and a *BaseChemicalPotential* for each element in the defect. Additional arguments set the optimization procedure for the defects and also whether or not ghost atoms are used in vacancy defects. The calculation of the defects is started by calling the `update` method.

Once the calculation is completed the *ChargedPointDefectConfiguration* object can be analyzed in the *Charged Point Defect Analyzer*. Derived properties of the defects such as +formation energy, defect concentration and trap levels can be queried individually using the +corresponding methods.

ChebyshevExpansionSolver

class ChebyshevExpansionSolver(*maximum_order*, *tolerance*, *temperature=None*)

Calculate the density matrix using the Chebyshev expansion method.

Parameters

- **maximum_order** (*int > 0*) – The highest order used in the Chebyshev expansion.
- **tolerance** (*float*) – The threshold to treat Chebyshev coefficients as zero.
- **temperature** (*PhysicalQuantity* of type temperature.) – The smearing of the Fermi distribution. **Default:** 300*Kelvin

maximumOrder()

Returns
The highest order used in the Chebyshev expansion.

Return type
int

temperature()

Returns
The smearing temperature of the Fermi distribution.

Return type
PhysicalQuantity of type temperature

tolerance()

Returns
The threshold where the Chebyshev coefficients are treated as zero.

Return type
float

uniqueString()

Return a unique string representing the state of the object.

Notes

The implemented Chebyshev expansion method is based on the work of Baer et al., J.Chem.Phys.107(23),1997. The method has a $O(N^2)$ complexity.

The method decomposes the density matrix as a sum of Chebyshev polynomials

$$D = \sum_{n=0}^{P-1} a_n(\beta, \varepsilon_F) T_n(H)$$

with a_n the Chebyshev coefficients as a function of the inverse temperature β and Fermi energy ε_F. The Chebyshev polynomials T_n are evaluated as a function of the systems Hamiltonian H for each k-point.

In contrast to the method of Baer et al., the order of the Chebyshev expansion is dynamically changed to obtain density matrix results within the requested accuracy. On construction the caller needs to be specify the maximum number of terms in the Chebyshev expansion and the tolerance at which trailing Chebyshev coefficients are considered zero.

CheckpointHandler

class CheckpointHandler(*file_name=None*, *time_interval=None*)

Class for representing the parameters used for saving the configuration and calculator at regular intervals during self-consistent iterations.

Parameters

- **file_name** (*str*) – The name of the checkpoint file. The file can be given as an absolute path or a relative path interpreted relative to the current working directory. The path of the checkpoint file is written in the output log of the calculator. The extension can be either nc for a NetCDF file or hdf5 for an HDF5 file. **Default:** File of the form: `'TEMP/checkpointXXXXXXXX.hdf5'`, where `TEMP` is the temporary folder on the computer and `X` is a random digit.
- **time_interval** (*PhysicalQuantity* of type time interval | `Disabled`) – The approximate time between saving. The program will check if the time since last save exceeds the time interval after each self-consistent iteration. **Default:** `0.5 * Hour`.

fileName()

Returns
The name of the checkpoint file.

Return type
str

nlinfo()

Returns
The nlinfo.

Return type
dict

timeInterval()

Returns
The length of the time interval or `Disabled` if theres no checkpoint handling.

Return type
PhysicalQuantity of type time interval | `Disabled`

uniqueString()

Return a unique string representing the state of the object.

Usage Examples

Set the checkpoint file to */home/checkpoint.nc* and tell the calculator to store itself every 20 minutes.

```
checkpoint_handler = CheckpointHandler('/home/checkpoint.nc', 20*Minute)
calculator = LCAOCalculator(checkpoint_handler=checkpoint_handler)
```

Turn off checkpoint handling for a calculator.

```
calculator = LCAOCalculator(checkpoint_handler=NoCheckpointHandler)
```

ChemicalCompositionProfile

class ChemicalCompositionProfile(*md_trajectory*, *start_time=None*, *end_time=None*, *resolution=None*, *direction_index=None*, *time_resolution=None*, *info_panel=None*)

Constructor for the ChemicalCompositionProfile object.

Parameters

- **md_trajectory** (*MDTrajectory* | AtomicConfiguration) – The MDTrajectory or configuration to calculate the density profile for.
- **start_time** (*PhysicalQuantity* of type time) – The start time. **Default:** `0.0 * fs`
- **end_time** (*PhysicalQuantity* of the type time) – The end time. **Default:** the last time frame.
- **resolution** (*PhysicalQuantity* of type length) – The bin size, which determines the resolution of the profile. **Default:** `2.0 * Angstrom`
- **direction_index** (*int*) – The index of the cell vector along which the profile should be calculated. Can only be an element of [0, 1, 2]. **Default:** `2`
- **time_resolution** (*PhysicalQuantity* of type time) – The time interval between snapshots in the MD trajectory that are included in the analysis.
- **info_panel** (*InfoPanel (Plot2D)*) – Info panel to show the calculation progress. **Default:** No info panel

data()

Returns
A dictionary containing the composition profile of each element as a percentage of the total composition

Return type
dict

zValues()

Returns
The positions of the bins associated with the density profile.

Return type
PhysicalQuantity of type length

Usage Examples

Load an *BulkConfiguration* and calculate the chemical composition profile along the C-vector of the cell:

```
# Load the configuration for analysis
configuration = nlread('Si-Si3N4_interface.hdf5')[-1]

# Calculate the mass density profile along the C-vector of the cell.
composition_profile = ChemicalCompositionProfile(
    configuration,
    direction_index=2,
    resolution=2.0 * Angstrom,
    start_time=0.0 * fs
)

# Get the chemical composition and the positions of the bin centers.
chemical_composition = composition_profile.data()
bin_centers = composition_profile.zValues()

# Create the plot model
model = Plot.PlotModel(x_unit=Angstrom)
model.title().setText('Chemical composition')
model.xAxis().setLabel('C axis')
model.yAxis().setLabel('Element Percentage')
model.legend().setVisible(True)

# Add line for each element
for key in chemical_composition.keys():
    line = Plot.Line(bin_centers, chemical_composition[key])
    line.setLabel(f'Percentage of {key}')
    model.addItem(line)

# Set different colors for each line
Plot.Colors.applyToItems(model.items(plot_item_type=Plot.Line))

# Set the ranges and show the plot
model.setLimits()
Plot.show(model)
```

`composition_profile.py Si-Si3N4_interface.hdf5`

Notes

The fraction of each element within a bin is given as a percentage value with respect to the total number of atoms.

ChemicalPotential

class ChemicalPotential(*configuration=None*)

A class for representing the ChemicalPotential.

Parameters
configuration (*MoleculeConfiguration* | *BulkConfiguration* | *DeviceConfiguration* | *SurfaceConfiguration*) – The configuration for which the chemical potential should be calculated.

evaluate(*spin=None*)

Get the chemical potential(s).

Parameters
spin (Spin.Up | Spin.Down | Spin.All) – The spin channel the chemical potential should be returned for. Must be either Spin.Up, Spin.Down or Spin.All. The chemical potential will only depend on spin when the calculation has been done with a fixed spin moment. In that case if Spin.All is chosen a list of both chemical potentials is returned. **Default:** Spin.All

Returns
The chemical potential. For a device the chemical potentials of the electrodes are returned.

Return type
PhysicalQuantity of type energy

metatext()

Returns
The metatext of the object or None if no metatext is present.

Return type
str | None

nlinfo()

Returns
The chemical potential information.

Return type
dict

nlprint(*stream=None*)

Print a string containing an ASCII table useful for plotting the AnalysisSpin object.

Parameters
stream (*python stream*) – The stream the table should be written to. **Default:** NLPrintLogger()

setMetatext(*metatext*)

Set a given metatext string on the object.

Parameters
metatext (*str | None*) – The metatext string that should be set. A value of None can be given to remove the current metatext.

uniqueString()

Return a unique string representing the state of the object.

Usage Examples

Calculate the chemical potential of a bulk system and print the result:

```
chemical_potential_object = ChemicalPotential(bulk_configuration)
fermi_level = chemical_potential_object.evaluate()[0]
print 'Fermi level = ', fermi_level.inUnitsOf(eV), ' eV'
```

Calculate the chemical potentials of a device system and print the results:

```
chemical_potential_object = ChemicalPotential(device_configuration)
left_chemical_potential = chemical_potential_object.evaluate()[0]
right_chemical_potential = chemical_potential_object.evaluate()[1]
print 'left chemical potential = ', left_chemical_potential.inUnitsOf(eV), ' eV'
print 'right chemical potential = ', right_chemical_potential.inUnitsOf(eV), ' eV'
```

CleanVacuumRegion

class CleanVacuumRegion(*fuzz_factor=1.5*, *substrate_search_radius=PhysicalQuantity(2.0, Ang)*)

Removes any atoms that are not in the same bonding graph as the fixed atoms. Atoms whose distance is less than the fuzz factor times the sum of covalent radii are considered bonded. So a larger fuzz factor is more conservative when determining which atoms are removed.

Parameters

- **fuzz_factor** (*float*) – The factor by which the covalent radii are multiplied to determine the cutoff distance for a bond. **Default:** 1.5.
- **substrate_search_radius** (PhysicalQuantity of type distance | None) – Search radius for finding substrate atoms that have become unbonded from the substrate structure. Unbound atoms that have substrate atoms above them within a cylinder of the given radius are considered to be part of the substrate structure and therefore not removed. Setting this argument to None disables this additional check. **Default:** 2 Angstrom.

uniqueString()

Return a unique string representing the state of the object.

Usage Examples

Run an etching simulation of nitrogen on a silica surface using a ReaxFF potential, with an additional CleanVacuumRegion hook function.

```
# Attach ReaxFF calculator.
potentialSet = ReaxFF_CHONSSi_2012(strict_bondpairs = None)
calculator = TremoloXCalculator(parameters=potentialSet)
calculator.setVerletListsDelta(0.25*Angstrom)
bulk_configuration.setCalculator(calculator)

surface_process_simulation = SurfaceProcessSimulation(
    substrate=bulk_configuration,
    filename='sio2_n_etching.hdf5',
    object_id='sps_0',
    random_seed=7,
```

(continues on next page)

(continued from previous page)

```
    temperature=300.0*Kelvin,
    fixed_thickness=4.0*Angstrom,
    thermostat_thickness=8*Angstrom,
    log_interval=10,
)

# Run 5 deposition events, each 20 ps long.
surface_process_simulation.addSequence(
    molecule=Nitrogen,
    number_of_events=5,
    md_time=20*ps,
    time_step=1.0*fs,
    mean_kinetic_energy=25*eV,
    std_kinetic_energy=0.3*eV,
    mean_incident_angle=0*Degrees,
    std_incident_angle=2*Degrees,
    post_md_hooks=[CleanVacuumRegion()],
)

surface_process_simulation.update()
```

sio2_n_etching.py

The results from the simulation can be visualized using the Movie Tool on the QATK LabFloor.

See also ref.spshookscommon.notes.

CoarseGrainMapper

class CoarseGrainMapper

Define a mapping object for converting an all-atom configuration to a coarse grain one. Rules need to be added to define the mapping, and then configuration can be converted.

addMappingRule(*template*, *bead_size*, *bead_indices*, *context_indices=None*, *martini_label=None*)

Add a definition of a coarse grain bead.

Parameters

- **template** (*MoleculeConfiguration* | *BulkConfiguration*) – A configuration that contains an example of the bead.
- **bead_size** (str | *PhysicalQuantity* of type length) – The size of the resulting bead. This can be specified as a Martini bead size (R, S or T) or given explicitly as a bead radius.
- **bead_indices** (*list of int*) – Indices of the atoms in the configuration that are united in the bead.
- **context_indices** (*list of int*) – Additional atoms in the configuration that helps define an instance of the bead.
- **martini_label** (*str*) – A label describing polarity of the bead according to the Martini typing scheme. This requires that the bead size is also specified with a Martini label.

beadIndices(*configuration*, *rule*, *use_precedence=True*)

Return the indices of the atoms that are included in each bead.

Parameters

•**configuration** (*MoleculeConfiguration* | *BulkConfiguration*) – Configuration for which the beads are being sought.

•**rule** (*int*) – The index of the rule for which the beads are sought.

•**use_precedence** (*bool*) – Whether or not precedence is used to exclude already mapped atoms.

Returns
List of sets of the atoms that form each bead.

Return type
list of sets

coarseGrainConfiguration(*atomic_configuration*, *bead_center=None*, *maintain_mass=False*)

Use the mapping rules to create a coarse-grain configuration from a all-atom configuration.

Parameters

•**atomic_configuration** (*MoleculeConfiguration* | *BulkConfiguration*) – The configuration to be converted.

•**bead_center** (`CenterOfGeometry` | `CenterOfMass` | `None`) – Whether the center of geometry or the center of mass of the mapped atoms are used to place each bead. The default None corresponds to using the center of geometry. **Default:** `CenterOfGeometry`

•**maintain_mass** (*bool*) – Whether or not exact bead masses are maintained for beads of the same type. The default is to use the most frequent mass for all beads of a particular type.

Returns
The configuration with mapped atoms converted to coarse grain beads.

Return type
MoleculeConfiguration | *BulkConfiguration*

coarseGrainForces(*atomic_configuration*, *forces*)

Use the mapping rules to create a coarse-grain forces from a all-atom forces.

Parameters

•**atomic_configuration** (*MoleculeConfiguration* | *BulkConfiguration*) – The configuration whose forces are being converted.

•**forces** (`PhysicalQuantity` array of type energy per distance) – The all atom forces being converted

Returns
The configuration with mapped atoms converted to coarse grain beads.

Return type
MoleculeConfiguration | *BulkConfiguration*

coarseGrainTrajectory(*trajectory*, *bead_center=None*, *maintain_mass=False*)

Use the mapping rules to create a coarse-grain trajectory from an all-atom trajectory. This method converts both Trajectory and MDTrajectory objects.

Parameters

•**atomic_configuration** (*Trajectory* | *MDTrajectory*) – The trajectory to be converted.

•**bead_center** (*CenterOfGeometry | CenterOfMass | None*) – Whether the center of geometry or the center of mass of the mapped atoms are used to place each bead. The default None corresponds to using the center of geometry **Default:** CenterOfGeometry

•**maintain_mass** (*bool*) – Whether or not exact bead masses are maintained for beads of the same type. The default is to use the most frequent mass for all beads of a particular type.

Returns
The configuration with mapped atoms converted to coarse grain beads.

Return type
MoleculeConfiguration | *BulkConfiguration*

numberOfRules()

Returns
The number of rules added to the mapping object.

Return type
int

uniqueString()

Return a unique string representing the state of the object.

Usage Examples

Create a coarse-grain model of polystyrene from an existing all-atom configuration.

```
# Load the bulk all-atom configuration
aa_configuration = nlread('bulk_polystyrene.hdf5')[0]

# Load a template that helps to define the mapping
template = nlread('template.hdf5')[0]

# Create a mapping object and define mapping rules for the three different beads
# Each bead is set to the Martini Small (S) size.
mapper = CoarseGrainMapper()
mapper.addMappingRule(template, 'S', [0, 2, 3, 4, 15, 16, 17, 18])
mapper.addMappingRule(template, 'S', [1, 5, 7, 13, 14], context_indices=[0])
mapper.addMappingRule(template, 'S', [6, 8, 9, 10, 11, 12])

# Create the coarse-grain structure using the defined mapping rules
cg_configuration = mapper.coarseGrainConfiguration(aa_configuration)

# Save the configuration
nlsave('cg_polystyrene.hdf5', cg_configuration)
```

polystyrene_coarse_grain.py

The given script converts an all-atom configuration of bulk polystyrene into a coarse-grain one. The mapping follows the scheme in the figure below. Each bead corresponds to one full heavy atom and two halves, which are shared with neighboring beads. The backbone beads are centered on the carbons connected to the benzene ring. A second bead is then centered on the carbon in the benzene ring that connects to the backbone. Finally, two of the same bead types are used to map the remaining four carbon atoms in the benzene ring. All hydrogen atoms are included with their attached carbon.

Once the mapping object is created, the mapping scheme is created by adding rules that define each bead. This is done by giving a configuration, the size of the bead and the indices of the atoms in the configuration that define the bead. When the all-atom configuration is mapped to a coarse-grain one, graph matching is used to convert all groups of atoms whose bond graph matches the atoms given in the rule. Additional atoms can also be given that help to identify the atoms being converted, without being included in the bead itself. This is done in the example above in defining the

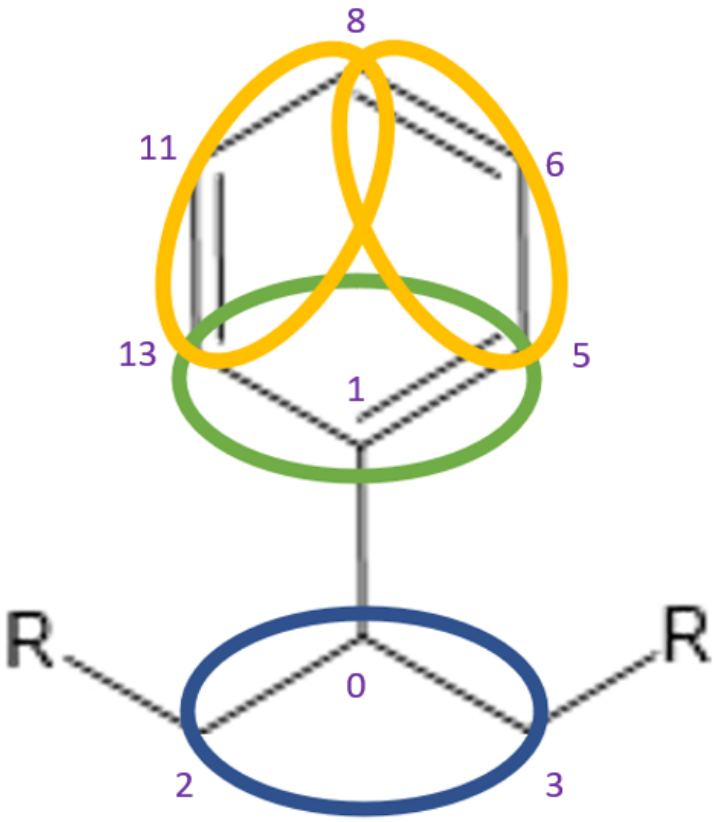

Fig. 4.10: Coarse-grain mapping of polystyrene. The numbers correspond to the indices of the carbon atoms in the polystyrene template.

second bead using the argument `context_indices`. Here the connecting carbon chain atom is also given so that the bead is centered on the connection between the benzene ring and the carbon chain.

Once the mapping is defined the coarse-grain representation is simply created by giving a configuration and calling the `coarseGrainConfiguration` method.

Notes

The *CoarseGrainMapper* class can be used to define a mapping between all-atom and coarse-grain structures that can be then used to convert different configurations or trajectories. The mapping is constructed by adding rules that define each bead. A bead is defined by giving an example of one or more atoms in a configuration that map to the bead. The mapping algorithm can then use graph matching to find all the occurrences of this bond pattern and convert it into a bead. For each rule a template configuration, a bead size and the indices in the configuration that define the bead must be given. The size of the bead can be specified using the Martini formalism of `R` (regular) `S` (small) or `T` (tiny) or by simply giving a particle radius. In cases where the same or similar bonding patterns are used for different beads, additional atoms can be specified using the `context_indices` argument. These atoms are added to the graph pattern but are not included in the bead definition. An optional label for each bead can be also added with the `martini_label` argument.

Once the rules are defined a coarse-grain configuration or trajectory can be created from an all-atom one using the `coarseGrainConfiguration` and `coarseGrainTrajectory` methods. In addition to the configuration these also optionally take a definition of the bead center. New beads can either be placed at the center of mass of the mapped atom, or simply at the average Cartesian coordinates ignoring mass weighting. These options are specified with the flags `CenterOfMass` and `CenterOfGeometry`, respectively. Whether or not the the exact mass of the beads is maintained can also be specified. When converting polymers or other chain structures, beads on the end will often have different numbers of hydrogens or not have the same atom sharing as beads in the center. By default the most frequent mass of each bead type is used. In the case of a simple polyethylene polymer, this results in the whole polymer being represented by C_2H_4 beads. This ignores the additional hydrogens on each end. Setting the argument `maintain_mass` to `True` creates additional beads types for the terminal beads, that map the correct C_2H_5 end group.

When the configuration is converted the rules are applied in order to convert the structure. The graph matching algorithm is able to share atoms between different beads, to enable the creation of symmetric mappings. In the given example, a symmetric mapping of polystyrene is generated by sharing atoms between beads, allowing beads be be centered on the atoms that connect the carbon chain and the benzene ring.

Similar to configurations, all-atom forces can be mapped into coarse-grain forces. This is done assuming that the atoms of the bead form a rigid unit, and so the total force on the bead is the vector sum of the forces acting on the atoms.

CohesiveEnergyDensity

class CohesiveEnergyDensity(*md_trajectory*, *polymer_tags=None*, *start_time=None*, *end_time=None*, *time_resolution=None*, *nonbond_cutoff=None*, *electrostatic_cutoff=None*, *electrostatic_accuracy=None*, *use_coulomb_dsf=False*, *memory_cache=True*, *calculate_interaction=False*, *gui_worker=None*)

Create an analyzer to calculate the cohesive energy density of polymer chains.

Parameters

- **md_trajectory** (*MDTrajectory* | *BulkConfiguration*) – The MDTrajectory or AtomicConfiguration that contains the polymers.
- **polymer_tags** (*list of type str | None | Automatic*) – A list of tags for the polymers. If not specified default tags are used.
- **start_time** (*PhysicalQuantity* of the type time) – The start time. **Default:** `0.0 * fs`.

•**end_time** (*PhysicalQuantity* of the type time) – The end time. **Default:** The last time image.

•**time_resolution** (*PhysicalQuantity* of type time) – The time interval between snapshots in the MD trajectory that are included in the analysis.

•**nonbond_cutoff** (*PhysicalQuantity* of type length) – The cutoff used to calculate Lennard-Jones interactions. **Default:** The existing Lennard-Jones cutoff

•**electrostatic_cutoff** (*PhysicalQuantity* of type length) – The cutoff used to calculate, either DSF or SPME. **Default:** The existing electrostatic cutoff

•**electrostatic_accuracy** (*float*) – The accuracy of the electrostatic summation when using SPME. **Default:** The existing SPME accuracy

•**use_coulomb_dsf** (*bool*) – Whether to use DSF to evaluate electrostatic interactions. **Default:** False

•**memory_cache** (*bool*) – Whether to cache the entire trajectory in memory. **Default:** True

•**calculate_interaction** (*bool*) – Whether to calculate the individual interaction energy of each molecule. This can take significant additional time to calculate. **Default:** False

•**gui_worker** (*PolymerAnalysisWorker*) – Handle to the worker, for displaying the calculation progress. **Default:** None.

averageCohesiveEnergy()

Returns
The average configuration cohesive energy in the selected images.

Return type
PhysicalQuantity of type energy

averageCohesiveEnergyDensity()

Returns
The average configuration cohesive energy density in the selected images.

Return type
PhysicalQuantity of type pressure

averageInteractionEnergy(*molecule_tag*)

Parameters
molecule_tag (*str*) – The tag of the molecule in the system used to identify it

Returns
The average interaction energy in the selected images of the selected molecule.

Return type
PhysicalQuantity of type energy

averageMoleculeEnergy(*molecule_tag*)

Parameters
molecule_tag (*str*) – The tag of the molecule in the system used to identify it

Returns
The average molecular energy in the selected images of the selected molecule.

Return type
PhysicalQuantity of type energy

averageNonMolecularEnergy()

Returns
The average energy of the non-molecular components in the selected images.

Return type
PhysicalQuantity of type energy

averageSolubility()

Returns
The average Hildebrand solubility in the selected images.

Return type
PhysicalQuantity of type pressure to the power of 1/2.

averageTotalEnergy()

Returns
The average configuration total energy in the selected images.

Return type
PhysicalQuantity of type energy

averageVolume()

Returns
The average unit cell volume in the selected images.

Return type
PhysicalQuantity of type volume

cohesiveEnergies()

Returns
A 1-D array of the cohesive energies of each image in the trajectory.

Return type
PhysicalQuantity of type energy

cohesiveEnergyDensities()

Returns
A 1-D array of the cohesive energy density of each image in the trajectory.

Return type
PhysicalQuantity of type energy per volume

interactionEnergies(*molecule_tag*)

Return the interaction energy of a specific molecule with other molecules. Requires that the option calculate_interaction is set to True

Parameters
molecule_tag – The tag of the molecule in the system used to identify it

Returns
A 1-D array of the interaction energy of the molecular in each image of the trajectory.

Return type
PhysicalQuantity of type energy

`moleculeEnergies`(*molecule_tag*)

Return the internal energy of a specific molecule.

Parameters
molecule_tag (*str*) – The tag of the molecule in the system used to identify it

Returns
A 1-D array of the energy of the molecule in each image of the trajectory.

Return type
PhysicalQuantity of type energy

`nonMolecularEnergies`()

Return the energy of the non-polymer component of the system.

Returns
A 1-D array of the surface energy in each image of the trajectory.

Return type
PhysicalQuantity of type energy

`polymerTags`()

Return the polymer tags used for the analysis.

Returns
A list of the polymer tags.

Return type
list

`solubilities`()

Returns
A 1-D array of the Hildebrand solubility parameters of each image.

Return type
PhysicalQuantity of type pressure to the power of 1/2.

`times`()

Returns
Times for each image used in the analysis.

Return type
`PhysicalQuantity` of type time

`totalEnergies`()

Returns
A 1-D array of the total energy of each image in the trajectory.

Return type
PhysicalQuantity of type pressure to the power of 1/2.

`volumes`()

Returns
A 1-D array of the unit cell volumes used in the calculation of energy density.

Return type
PhysicalQuantity of type volume

Usage Examples

Calculate the Hildebrand solubility from the cohesive energy density of a PVC melt during a molecular dynamics simulation starting from an equilibrated structure.

```
# ------------------------------------------------------------
# Initial Configuration
# ------------------------------------------------------------
bulk_configuration = nlread('PolyVinylChloride.hdf5')[-1]

# ------------------------------------------------------------
# OPLS-AA Calculator
# ------------------------------------------------------------
potential_builder = OPLSPotentialBuilder()
calculator = potential_builder.createCalculator(bulk_configuration)
bulk_configuration.setCalculator(calculator)

# ------------------------------------------------------------
# Molecular Dynamics
# ------------------------------------------------------------
initial_velocity = ConfigurationVelocities(
    remove_center_of_mass_momentum=True
)

method = NPTMartynaTobiasKlein(
    time_step=1*femtoSecond,

model.axis('y').setLabel('Hildebrand Solubility')
model.legend().setVisible(False)

line = Plot.Line(analyzer.times(), analyzer.solubilities())
line.setColor('red')
model.addItem(line)

model.setLimits('x', 0*ps, 0.1*ps)
model.setLimits('y', 10*Joule**0.5/cm**1.5, 20*Joule**0.5/cm**1.5)

Plot.save(model, 'CohesiveEnergyDensity_Plot.png')
```

`CohesiveEnergyDensity_Example.py` `PolyVinylChloride.hdf5`

The script will run a short molecular dynamics calculation from the given starting structure and then calculate the Hildebrand solubility for the polymer system. This is shown in the two plot below.

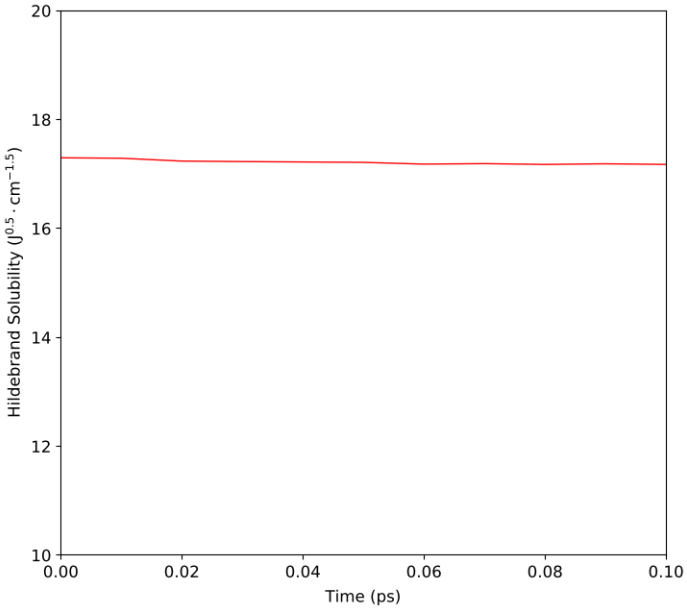

Fig. 4.11: Calculated Hildebrand solubility of PVC.

Notes

This class enables the calculation of the cohesive energy density of a polymer system from either a *MDTrajectory* or *BulkConfiguration*.

The cohesive energy of a polymer system is the energy required to completely separate all of the polymer chains from each other. It therefore consists of the non-bonding interactions between polymer chains, and gives a measure of their attractiveness to each other. In bulk systems this energy is normally expressed per unit of volume of the material, giving the cohesive energy density. The relative differences in cohesive energy densities of different polymers indicates their miscibility or immiscibility with each other. One important measure of the solubility of a polymer is the Hildebrand solubility parameter, δ_h. This is simply given as:

$$\delta_h = \sqrt{\frac{E_{coh}}{V}}$$

Here $E_{coh}$is the cohesive energy density of the unit cell and V is the cell volume. Polymers with a difference in solubility of less than 2MPa$^{0.5}$ are generally expected to be miscible[1].

A more precise measure of miscibility is given through the Flory-Huggins parameter χ[2]. For a binary mixture composed of polymers A and B, the volume fraction of each polymer ϕ can be given as:

$$\phi_A = \frac{n_A r_A}{n_A r_A + n_B r_B}$$

Here n is the number of polymer chains and r is the number of monomers per polymer chain. Given the volume fraction of each polymer, the free energy of mixing ΔG can be approximated as:

$$\Delta G = RT\left(\frac{\phi_A}{r_A}\ln\phi_A + \frac{\phi_B}{r_B}\ln\phi_B + +\phi_A\phi_B\chi_{AB}\right)$$

Here χ_{AB} is the Flory-Huggins parameter for the polymer mixture. In this equation the first two terms specify the entropy of mixing, while the last term approximates the enthalpy of mixing. The Flory-Huggins parameter is therefore a measure of the enthalpy of mixing.

Using a mean-field approximation the Flory-Huggins parameter can be given as:

$$\chi_{AB} = \frac{V_{mono}}{RT}\left[\phi_A\left(\frac{E_{coh}}{V}\right)_A + \phi_B\left(\frac{E_{coh}}{V}\right)_B - \left(\frac{E_{coh}}{V}\right)_{mix}\right]$$

Here V_{mono} is the average volume per monomer. In this approximation it is assumed that both monomers have similar sizes, and so size difference does not need to be taken into account when calculating thermodynamics of mixing. This definition also assumes that the two systems are in contact both with themselves and each other. This is not the case in dilute solutions where one polymer chain may be completely surrounded by others. To calculate the Flory-Huggins parameter the cohesive energy densities of both the pure polymers and the polymer blend is required. In this way, specific interactions between polymers, such as hydrogen bonding, is taken into account in the estimation of miscibility. It should also be noted that, unlike the Hildebrand solubility, the Flory-Huggins parameter is also explicitly a function of temperature. Temperature changes in the system can also indirectly alter the amount of cohesive energy in the system, as thermal motions push the configuration away from equilibrium. Polymer blends with a Flory-Huggins parameter below the critical value are expected to be miscible[Page 2425, 1]. The critical Flory-Huggins value χ_c can be given as:

$$\chi_c = \frac{1}{2}\left(\frac{1}{\sqrt{r_A}} + \frac{1}{\sqrt{r_B}}\right)^2$$

To calculate the cohesive energy density of a polymer system a *CohesiveEnergyDensity* object first needs to be created. This takes a *MDTrajectory* or *BulkConfiguration* representing the polymer system. The specific images in

[1] Zhonglin Luo and Jianwen Jiang. Molecular dynamics and dissipative particle dynamics simulations for the miscibility of poly(ethylene oxide)/poly(vinyl chloride) blends. *Polymer*, 51:291, 2010. URL: https://www.sciencedirect.com/science/article/abs/pii/S0032386109010040, doi:10.1016/j.polymer.2009.11.024.

[2] PaulăJ. Flory. *Statistical thermodynamics of polymer solutions*, pages 495–540. Cornell University Press, 1953.

the *MDTrajectory* to analyzed can be selected using the start_time, end_time and time_resolution arguments. The polymer chains analyzed in the configuration can be specified with the polymer_tags argument. This takes a list of tags of polymer molecules in the configuration. By default polymers tagged with POLYMER_MOLECULE_# are analyzed, where # is a numerical index. The flag Automatic can also be used to automatically identify polymer chains using the bond graph in the configuration.

To calculate the interaction energy of the polymers, the existing forcefield calculator on the trajectory is used. The accuracy of this calculator can be modified with some additional arguments. The argument nonbond_cutoff controls the cutoff used to evaluate the non-bonding Lennard-Jones potentials. Likewise it is possible to change the electrostatic summation method. By default the summation method defined in the calculator is used. If no electrostatic summation method is set and no electrostatic summation arguments are given, then electrostatic interactions are not included in the calculation of cohesive energy. SPME summation can be used by setting the accuracy of this summation with the argument electrostatic_accuracy. Damped shifted-force electrostatic summation can also be used by setting the argument use_coulomb_dsf to True and giving a cutoff using the electrostatic_cutoff argument. By default the same methods in the attached calculator are used to calculate the cohesive energy. This is also generally the most appropriate use as this is the potential that was used to construct the system.

In addition to the cohesive energy density of the whole system, it is also possible to calculate the interaction energy of each individual polymer chain with the remainder of the system. This is specified by setting the argument calculate_interaction to True. Finally it is possible to set whether the MDTrajectory used to calculate the cohesive energy is cached in memory or read from disk during the calculation. Caching in memory is faster, but for very large trajectories may exhaust available memory. By default trajectories are cached in memory. To force reading from disk, set the argument memory_cache to False.

Once the object is created the properties of the polymer system can be returned using query methods. The unit cell volumes of each selected image can be returned with the volumes methods. The cohesive energy and cohesive energy density can be returned with the methods cohesiveEnergies and cohesiveEnergyDensities respectively. The Hildebrand solubility can be returned with the method solubilities. The method totalEnergies returns the total non-bonding energy of each image. The method nonMolecularEnergies returns the internal non-bonding energy of the atoms in each image that are not associated with a polymer tag. For example, in the case where the system contains a metal surface, nonMolecularEnergies returns the internal non-bonding energy of that surface. Finally the methods moleculeEnergies and interactionEnergies return the internal non-bonding energy and the interaction energy of each polymer molecule respectively. In these methods the polymer molecules are indexed using their tags. The method interactionEnergies is also only available if the calculation of interaction energies was specified when the *CohesiveEnergyDensity* object was created by setting the argument calculate_interaction to True.

ColdSmearing

class ColdSmearing(*broadening*)

Parameters
broadening (*PhysicalQuantity* of type energy or temperature) – The broadening of the distribution.

broadening()

Returns
The broadening of the distribution.

Return type
PhysicalQuantity of type energy

Usage Examples

Use the cold smearing occupation function with a broadening of 0.1 eV on an LCAOCalculator:

```
numerical_accuracy_parameters = NumericalAccuracyParameters(
    occupation_method=ColdSmearing(0.1*eV))

calculator = LCAOCalculator(numerical_accuracy_parameters=numerical_accuracy_parameters)
```

Notes

Note: For comparison of different occupation methods and suggestions for which one to choose, see *Occupation Methods*.

In the cold smearing scheme[1] one replaces the delta function in the density of states by the function:

$$\tilde{\delta}(x) = \frac{1}{\sqrt{\pi}} e^{-(x-1/\sqrt{2})^2} (2 - \sqrt{2}x),$$

The integer occupation numbers are then replaced by fractional occupations determined by the distribution

$$f(x_i) = \frac{1}{2}\left[\sqrt{\frac{2}{\pi}} e^{-x_i^2 - \sqrt{2}x_i - 1/2} + 1 - \mathrm{erf}\left(x_i + \frac{1}{\sqrt{2}}\right)\right],$$

where $x_i = \frac{\epsilon_i - \mu}{\sigma}$ with σ the broadening. In this context the generalized entropy becomes

$$S = \frac{1}{\sqrt{\pi}} \sum_i e^{-(x_i + 1/\sqrt{2})^2} (1 + \sqrt{2}x_i)$$

with $x_i = \frac{\epsilon_i - \mu}{\sigma}$.

Like in the Methfessel-Paxton scheme (see `MethfesselPaxton`) the benefit of the cold smearing scheme is that contributions to the free energy from the broadening, lower than second order, are eliminated. Therefore, the total energy and forces are quite close to the real (zero temperature) value even for large values of the broadening parameter. Compared to the Methfessel-Paxton scheme, cold smearing has the additional benefit that negative occupations can not occur.

It is possible to extrapolate the total energy to zero broadening by including the term

$$\Delta E_{\sigma \to 0}(\sigma) = \frac{5}{6}\sigma S.$$

CollectiveVariableHyperdynamics

class CollectiveVariableHyperdynamics(*distortions*, *temperature=None*, *global_exponent=None*, *global_cut=None*, *gaussian_width=None*, *gaussian_height=None*, *gaussian_frequency=None*, *bias_damping_temperature=None*, *gaussian_limit=None*, *reaction_steps=None*, *optimize_new_state=None*, *measurement_frequency=None*, *tracked_atoms_tag=None*, *allow_no_variables=None*)

Hook function implementing collective variable hyperdynamics.

[1] Nicola Marzari, David Vanderbilt, Alessandro DeăVita, and M.ăC. Payne. Thermal Contraction and Disordering of the Al(110) Surface. *Phys. Rev. Lett.*, 82(16):3296–3299, April 1999. doi:10.1103/PhysRevLett.82.3296.

Parameters

•**distortions** (Sequence of HyperdynamicsBaseDistortion) – The geometric distortions used to create the collective variable.

•**temperature** (*PhysicalQuantity* of type temperature | None) – The temperature of the simulation, used for calculating the hypertime. **Default:** 300 Kelvin

•**global_exponent** (*float*) – The exponent used to create the global distortion. **Default:** 6

•**global_cut** – The value of the global distortion at the transition state. This can be used to set the position of the transition state where individual distortions do not range from 0 to 1. One example of this is when using a bond distortion without a maximum bond length. **Default:** 1

•**gaussian_width** (*float*) – The width of the added Gaussian bias potential. **Default:** 0.025

•**gaussian_height** (*PhysicalQuantity* of type energy) – The height of the added Gaussian bias potential. **Default:** 0.01 eV

•**gaussian_frequency** (*int*) – The number of steps between adding new Gaussian bias potentials. **Default:** 1000

•**bias_damping_temperature** (*PhysicalQuantity* of type temperature | None) – The temperature used to scale the bias potential using well-temperated metadynamics. None does not damp the added potential, resulting the in same size potential being added at each step. **Default:** None

•**gaussian_limit** (*float*) – The upper limit in the collective variable where Gaussians are added to the hyperdynamic bias potential. Gaussians are not added at values above this limit in order to avoid biasing the transition state. **Default:** 1.0

•**reaction_steps** (*int*) – The number of steps at the maximum collective variable before a reaction takes place. **Default:** 5000

•**optimize_new_state** (*bool*) – Use an optimized configuration to reset the distortions after a reaction is detected. **Default:** True

•**measurement_frequency** (*int*) – The step frequency with which measurements are added to the trajectory. **Default:** 10

•**tracked_atoms_tag** (*str*) – Tag giving the indices of atoms for which the position is measured during the simulation. None results in no atoms being tracked. **Default:** None

•**allow_no_variables** (*bool*) – Continue in cases where no variables are found for acceleration. The simulation continues the number of reaction steps without bias before trying again to find variables to accelerate. **Default:** True

allowNoVariables()

Returns
True if the simulation continues in cases where no variables are found for acceleration.

Return type
bool

biasDampingTemperature()

Returns
The temperature used to scale the bias potential.

Return type
PhysicalQuantity of type temperature

callInterval()

Returns
The call interval of this hook function.

Return type
int

`distortions()`

Returns
The geometric distortions used to create the collective variable.

Return type
Sequence of `HyperdynamicsBaseDistortion`

`gaussianCenters()`

Returns
The center of the Gaussian potentials added to form the bias potential.

Return type
ndarray

`gaussianFrequency()`

Returns
The frequency at which new Gaussian bias potentials are added.

Return type
int

`gaussianHeight()`

Returns
The height of the Gaussian bias potential.

Return type
PhysicalQuantity of type energy

`gaussianHeights()`

Returns
The height of the Gaussian potentials added to form the bias potential.

Return type
PhysicalQuantity of type energy

`gaussianLimit()`

Returns
The limit in the collective variable above which Gaussians are not added.

Return type
float

`gaussianWidth()`

Returns
The width of the Gaussian bias potential.

Return type
float

`gaussianWidths()`

Returns
The widths of the Gaussian potentials added to form the bias potential.

Return type
ndarray

globalCut()

Returns
The value of the global distortion at the transition state.

Return type
float

globalExponent()

Returns
The global exponent used in the collective variable.

Return type
float

measurementFrequency()

Returns
The step frequency with which measurements are saved to the trajectory.

Return type
int

numberOfGaussians()

Returns
The number of Gaussian potentials added to form the hyperdynamic bias potential.

Return type
int | None

numberOfVariables()

Returns
The total number of geometric coordinates being accelerated. If the geometric coordinates are not set with a configuration None is returned.

Return type
int | None

optimizeNewState()

Returns
True if the configuration is optimized before setting new distortions.

Return type
bool

reactionSteps()

Returns
The number of steps at the maximum collective variable before a reaction takes place.

Return type
int

temperature()

Returns
The simulation temperature.

Return type
PhysicalQuantity of type temperature

`trackedAtomsTag()`

Returns
The tag for the atoms that are tracked during the simulation.

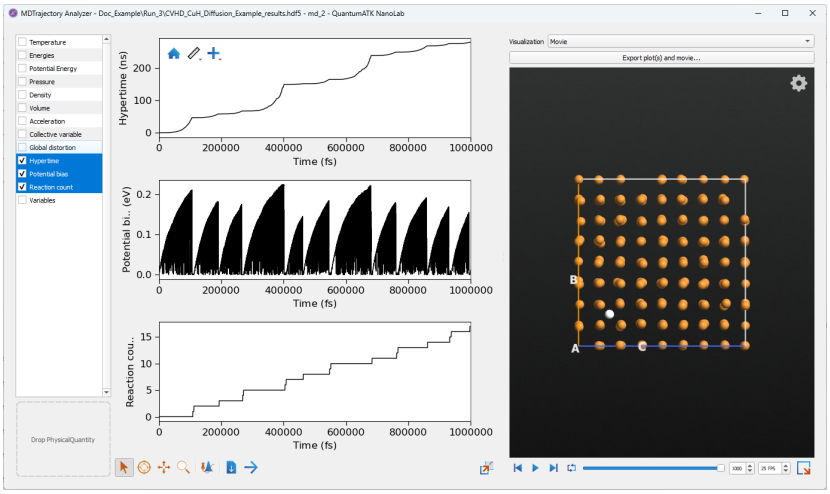
Return type
str

`uniqueString()`

Return a unique string representing the state of the object.

Usage Examples

In this example collective variable hyperdynamics is used to study the diffusion of a single hydrogen atom in a copper crystal lattice. A position distortion is used to add a bias potential to push the atom through the lattice. The results of the simulation are recorded in the resulting *MDTrajectory* and can be viewed in the **Movie Tool**. The resulting diffusivity can also be calculated using the *IrregularTimeMeanSquareDisplacement* object.



This simulation may take several hours to run. Note that the simulation performs a limited amount of sampling, using only a million steps or 1ns of simulation time. The hypertime of the simulation however is over 250ns, meaning that the simulation was able to effectively sample this time for the cost of only 1ns of simulation. At 300 Kelvin the diffusion of hydrogen in copper is around $8.5 \times 10^{-14} m^2/s$ so very long trajectories are needed to measure the slow diffusion[1]. For accurate results it is necessary to use either more steps or to run multiple simulations. Running multiple simulations can enable a faster turn-around time, as the simulations can be run parametrically in parallel. The workflow for this example can be `downloaded here` with the corresponding Python script `CVHD_CuH_Diffusion_Example.py`.

[1] Hans Magnusson and Karin Frisk. Diffusion, Permeation and Solubility of Hydrogen in Copper. *Journal of Phase Equilibria and Diffusion*, 38:65, Jan 2017. URL: https://link.springer.com/article/10.1007/s11669-017-0518-y, doi:https://doi.org/110.1007/s11669-017-0518-y.

Notes

Hyperdynamics is a method for sampling rare events using molecular dynamics. In hyperdynamics a bias potential is added to degrees of freedom separating different states. The bias potential aids in lowering the energy barrier between these states, allowing the system to sample different states more freely. In this way the biased degrees of freedom move at elevated temperature, while the rest of the system moves at the simulation temperature. The acceleration factor given to the system by the bias potential can be calculated as the ensemble average of the bias potential. When this boost factor is multiplied by the simulation time it gives the effective sampling time, known as the hypertime.

In using the hypertime to estimate reaction rates, it is important that the bias potential is not applied at the transition state. If bias is applied both at the reactant and transition state it obscures the relative free energy barrier between two states. This can lead to errors in estimations of the rate constant. This also applies to kinetic based processes such as diffusion.

In collective variable hyperdynamics the bias potential is built up during the simulation by adding Gaussian functions to the potential at the value of the collective variable during the simulation[2]. By building up the potential it avoids requiring knowledge of the the appropriate shape or height of the bias potential. This is distinct from *StaticHyperdynamics*, which requires some knowledge of the transition state barrier height. In this way collective variable hyperdynamics is similar to metadynamics. The main difference is that in metadynamics a single bias potential is built up during the simulation. This is converged to create an estimate of the total free energy of a process in the system. In hyperdynamics the bias potential is simply used to accelerate a defined reaction. Once the reaction occurs, the bias potential is reset to zero and is built up again at the new reactant. Rather than the free energy profile, the important results from hyperdynamics simulations are the trajectory and the effective hypertime of the simulation.

In order to create the bias potential, one or more important geometric features, known as distortions, are first identified in the configuration. These can be things such as the position of atoms or the bond lengths between specific atoms. These distortions are generally constructed so that they range from 0 to 1 when moving from reactant to transition state. The different distortions are then combined into a global distortion through the equation:

$$\chi_t = \left(\sum_{i=1}^{N} \chi_i^p \right)^{1/p}$$

Here χ_t is the global distortion and χ_i are the individual distortions. The power p increases the contribution of the larger distortions to the global distortion. In the *CollectiveVariableHyperdynamics* class the distortions are given as a list using the `distortions` argument. These can be either *HyperdynamicsPositionDistortion* objects or *HyperdynamicsBondDistortion* objects. The exponent p is set using the `global_exponent` keyword argument.

To ensure that the gradients at the boundaries are zero, the collective variable is then defined using a cosine function such that:

$$\eta = \begin{cases} \frac{1}{2}\left[1 - \cos\left(\pi \left(\frac{\chi_t}{\chi_c}\right)^2\right)\right] & \chi_t \leq 1 \\ 1 & \chi_t > 1 \end{cases}$$

Here η is the collective variable and χ_c is a cutoff value of the global distortion. This is the value of the global distortion at the transition state. In the simplest case in which one distortion that ranges from 0 to 1 is used, this is simply one. If a combination of distortions are used, or if the distortions do not range from 0 to 1 the χ_c is used to make the collective variable range from 0 to 1. This cutoff value is set using the `global_cut` keyword argument. The collective variable is also used to determine when a reaction has occurred in the configuration. When the collective variable is greater than 1 for a set number of steps the system is considered to have reacted, and the references for distortions and the bias potential is reset to zero. The number of steps used to determine if a reaction has occurred is set with the `reaction_steps` keyword argument. By default this is set to 5000 steps. In setting the new distortions the reference configuration can first be optimized using the current calculator. This ensures that the distortions are set from a local energy minimum. In the case of bonds it ensures that the correct bonds are selected for boosting. Likewise in the case

[2] KristofăM. Bal and ErikăC. Neyts. Merging Metadynamics into Hyperdynamics: Accelerated Molecular Simulations Reaching Time Scales from Microseconds to Seconds. *Journal of Chemical Theory and Computation*, 11(10):4545–4554, 2015.

of positions that the reference positions are at a potential minimum. This optimized reference configuration is not used in the dynamics simulation, as to do so would alter the sampling of different states. It is in general recommended to optimize the reference configuration. Enabling optimization after reactions is done with the `optimize_new_state` keyword argument, which is `True` by default.

After each reaction the distortion definitions are reset to the new reference configuration. In some cases, such as bonds being boosted, it means that a different number of distortions may be selected. This can also include cases where no available distortions are found that can be accelerated. In this case the simulation can simply continue the number of steps between reactions and try again to find some applicable distortions. Alternatively the simulation can simply end if no distortions indicates that something has gone wrong with the simulation. Stopping on no distortions being found is controlled with the `allow_no_variables` keyword argument. By default this is set to `True`, meaning that the simulation will continue.

The total bias potential $\Delta V(\eta)$ is calculated by adding Gaussians at time intervals τ_G. This gives the expression for the total bias potential:

$$\Delta V(\eta) = \sum_{k=1}^{n_G} w_k \exp\left[-\frac{(\eta - \eta(k\tau_G))^2}{2\delta^2}\right]$$

Here w_k is the height of the Gaussian and δ is the Gaussian width. These can be set with the keyword arguments `gaussian_height` and `gaussian_width` respectively. The number of steps between adding Gaussians is also set with the `gaussian_frequency` keyword argument. Together with the Gaussian height and width this sets the rate of energy deposition into the bias during the simulation. The optimal energy deposition rate depends on the depth of the local potential well and the temperature of the simulation. The energy deposition rate should be low enough to allow for effective sampling of the reactant potential energy surface so that a reliable estimate of the hypertime is obtained.

The height of each added Gaussian can also be scaled down depending on the amount of bias already added at the collective variable.This is similar to the well-tempered metadynamics method, where the bias potential converges to a value based on a temperature used to set the rate of reducing the size of the added Gaussians. Using this method the temperature is proportional to the maximum effective temperature of the motion of the collective variable. Reducing the temperature reduces the energy deposition rate into the bias potential. The temperature used to set the height of the Gaussians is given with the `bias_damping_temperature` keyword argument. Here `None` means that no damping is done and that all added Gaussians have the same height. In order to avoid adding bias at the transition state, Gaussians can be added up to a limit in the collective variable. This limit depends on the width of the Gaussians and how close to the true transition state the collective variable extends to. This limit is set with the `gaussian_limit` keyword argument.

For each reaction the hypertime is calculated as the simulation time multiplied by the ensemble average of the bias potential. This is given as:

$$t_h = t_s \int_0^{t_s} \exp(\Delta V(\eta, t)/k_B T) dt$$

Here t_h is the hypertime, t_s is the simulation time and T is the simulation temperature. This is set with the `temperature` keyword argument. Note that as the bias potential is built up over the simulation, it is dependent on the time. When a new reaction is found the bias potential starts off as zero. At this point both the simulation time and hypertime move at the same rate. As the bias potential is built up the hypertime moves increasingly faster until a new reaction is found and the bias potential is reset. To get an accurate measure of the hypertime it is important to have sufficient sampling of areas of high bias. This can limit the bias energy deposition rate. If is is too high sufficient sampling of the bias potential may not occur.

When running a collective variable hyperdynamics simulation in *MolecularDynamics*, information about the simulation, such as the hypertime, current bias potential and collective variable value are added to the trajectory as measurements. These are shown in the **Movie Tool** when opening the trajectory. The number of steps between adding measurements is set using the `measurement_frequency` keyword argument. Additionally the positions of select atoms can be added as a measurement. This is useful in cases where the diffusion of single atom impurities is being studied. These are added with the measurement name `tracked_atoms`. As this is an array of atomic coordinates it

cannot be displayed in the **Movie Tool**. The tag of the atoms to track is given with the `tracked_atoms_tag` keyword argument. If no tag is given atom tracking is not added to the trajectory.

To calculate diffusion from a hyperdynamics simulation the *IrregularTimeMeanSquareDisplacement* class can be used. This class can access both the hypertime and tracked atomic positions from the trajectory and calculated the resulting mean square displacement of the tracked atoms. As diffusion is a stochastic process, it is often useful to run several simulations to fully sample the motion of the atoms. This is especially true for amorphous systems or systems lacking long-range order.

CombinedCalculator

class CombinedCalculator(*calculators=None*, *weights=None*)

Class for representing combinations of calculators for configurations of the type MoleculeConfiguration and BulkConfiguration.

Parameters

- **calculators** (sequence of `Calculator`) – The input calculators.
- **weights** (*sequence of float and/or int (same sequence length as the number of input calculators).*) – Weight for the calculators. **Default:** `[1.0, .. ,1.0]`

calculators()

Returns
The input calculators.

Return type
Sequence of `Calculator`

isConverged()

Returns
True when the call to update() resulted in a converged SCF loop.

Return type
bool

metatext()

Returns
The metatext of the object or None if no metatext is present.

Return type
str | None

nlinfo()

Returns
The nlinfo.

Return type
dict

setCheckpointHandler(*checkpoint_handler*)

Set the checkpoint handler. Not applicable and will be passed on.

Parameters
checkpoint_handler (*CheckpointHandler*) – The checkpoint handler to use.

setMetatext(*metatext*)

Set a given metatext string on the object.

Parameters
metatext (*str | None*) – The metatext string that should be set. A value of None can be given to remove the current metatext.

setWeights(*weights*)

Parameters
weights – The weights for calculators.

Rtype weights
list of float.

uniqueString()

Return a unique string representing the state of the object.

upgrade(*configuration*)

Method for upgrading the configuration. The upgrade method is used when applying setCalculator for each encapsulated calculator.

Private method for updating the calculator from the configuration, if it is possible. @private

versionUsed()

Returns
The version of ATK used to update the calculator.

Return type
str

weights()

Returns
The weights for calculators

Return type
list of float

Usage Examples

The *CombinedCalculator* takes in as many calculators needed.

```
# Two arbitrary calculators are defined for the purpose of this example.
Icalculator = LCAOCalculator()

IIpotential_set = Tersoff_Si_1988()
IIcalculator = TremoloXCalculator(potential_set=IIpotential_set)

list_of_calculators = [Icalculator, IIcalculator]

# In case of specific weights, define them as well.
weights = [1, -0.5]

# Define CombinedCalculator with the two calculators and respective weights.
combined_calculator = CombinedCalculator(
```

(continues on next page)

(continued from previous page)

```
    calculators=list_of_calculators,
    weights=weights,
    )
```

Now the CombinedCalculator may be set on a configuration as usual and used in MD analysis, geometry optimization etc.

Notes

The *CombinedCalculator* adds energy, forces, and stress of the given list of calculators with the given weights. It can be used in simulations like MolecularDynamics, OptimizeGeometry, and can be used with analysis and study objects that require only energy, forces, or stress, such as Forces, TotalEnergy, Stress, ElasticConstants, PhononBandStructre, or PhononDensityOfStates. The CombinedCalculator does not support analysis objects that require the electronic structure.

ComplexBandstructure

class ComplexBandstructure(*configuration*, *energies=None*, *k_point=None*, *energy_zero_parameter=None*)

Analysis class for calculating the complex bandstructure for a bulk configuration.

Parameters

- **configuration** (*BulkConfiguration*) – The bulk configuration with an attached calculator for which to calculate the complex bandstructure.
- **energies** (PhysicalQuantity of type energy) – The energies for which to calculate the complex bandstructure. **Note**: energies are relative to energy_zero_parameter. **Default:** numpy.linspace(-2, 2, 101) * eV
- **k_point** (*tuple of floats*) – The 2-dimensional fractional k-point (in the kA-kB plane) for which to calculate the complex bandstructure. The k-point is given as a tuple of length 2. **Default:** (0, 0)
- **energy_zero_parameter** (FermiLevel | AbsoluteEnergy) – The choice for the energy zero. **Note**: This also affects the energies parameter. **Default:** FermiLevel

energies()

Returns
The energies for which the complex bandstructure is calculated.

Return type
PhysicalQuantity of type energy

energyZero()

Returns
The energy zero.

Return type
PhysicalQuantity of type energy

evaluate(*spin=None*)

Method for obtaining the complex bandstructure for a specific spin. The complex bandstructure has two components, propagating modes and decaying modes. Both types of modes can be characterized by a value k. For propagating modes k is real, giving the Bloch phase factor in the reciprocal C-direction, whereas decaying modes have a complex value of k.

Parameters
spin (Spin.Up | Spin.Down | Spin.All) – The spin to calculate for. **Default:** Spin.All

Returns
A tuple with two lists, the first corresponding to the propagating modes and the second corresponding to the decaying modes. The lists are ordered according to energy and each entry is a PhysicalQuantity with a (1/Angstrom) unit. The lists have different lengths (and can have zero length) corresponding to the number of modes at this energy.

Return type
tuple of lists

fermiLevel(*spin=None*)

Parameters
spin (Spin.Up | Spin.Down | Spin.All) – The spin the Fermi level should be returned for. Must be either Spin.Up, Spin.Down, or Spin.All. Only when the band structure is calculated with a fixed spin moment will the Fermi level depend on spin. **Default:** Spin.All

Returns
The Fermi level in absolute energy.

Return type
PhysicalQuantity of type energy

fermiTemperature()

Returns
The Fermi temperature.

Return type
PhysicalQuantity of type temperature

kPoint()

Returns
The 2-dimensional fractional k-koint for which the complex bandstructure is calculated.

Return type
tuple of floats

layerSeparation()

Returns
The distance between layers of the crystal in the transport direction. The transport direction is perpendicular to the AB-plane. This value is called L in the GUI.

Return type
PhysicalQuantity of type length

metatext()

Returns
The metatext of the object or None if no metatext is present.

Return type
str | None

nlprint(*stream=None*)
Print a string containing an ASCII table useful for plotting the AnalysisSpin object.

Parameters
stream (*python stream*) – The stream the table should be written to. **Default:** NLPrintLogger()

repetition()

Deprecated

setMetatext(*metatext*)

Set a given metatext string on the object.

Parameters
metatext (*str | None*) – The metatext string that should be set. A value of None can be given to remove the current metatext.

spins()

Returns
The available spin components.

Return type
tuple of Spin.Up | Spin.Down | Spin.All

uniqueString()

Return a unique string representing the state of the object.

Usage Examples

Calculate the complex bandstructure of silicon in the (100) direction, using a fast semi-empirical method, and save it to a file:

```
# Set up a Si (100) minimal configuration
vector_a = [3.84001408591, 0.0, 0.0]*Angstrom
vector_b = [0.0, 3.84001408591, 0.0]*Angstrom
vector_c = [1.92000704296, 1.92000704296, 2.7153]*Angstrom
lattice = UnitCell(vector_a, vector_b, vector_c)

elements = [Silicon, Silicon]

fractional_coordinates = [[  2.50000000e-01,   7.50000000e-01,   5.00000000e-01],
                          [  3.33066907e-16,   2.22044605e-16,   1.00000000e+00]]

bulk_configuration = BulkConfiguration(
    bravais_lattice=lattice,
    elements=elements,
    fractional_coordinates=fractional_coordinates
    )

# Define calculator - fast Slater-Koster method
calculator = SlaterKosterCalculator(
    basis_set=Vogl.Si_Basis,
    numerical_accuracy_parameters=NumericalAccuracyParameters(
                k_point_sampling=(4, 4, 2))
     )
bulk_configuration.setCalculator(calculator)

# Calculate, save, and print the complex band structure
complex_bandstructure = ComplexBandstructure(
    configuration=bulk_configuration,
```

(continues on next page)

(continued from previous page)

```
    energies=numpy.linspace(-2,5,501)*eV,
    k_point=(0,0),
    )
nlsave('si_100_cbs.hdf5', complex_bandstructure)
nlprint(complex_bandstructure)
```

si_complex_band.py

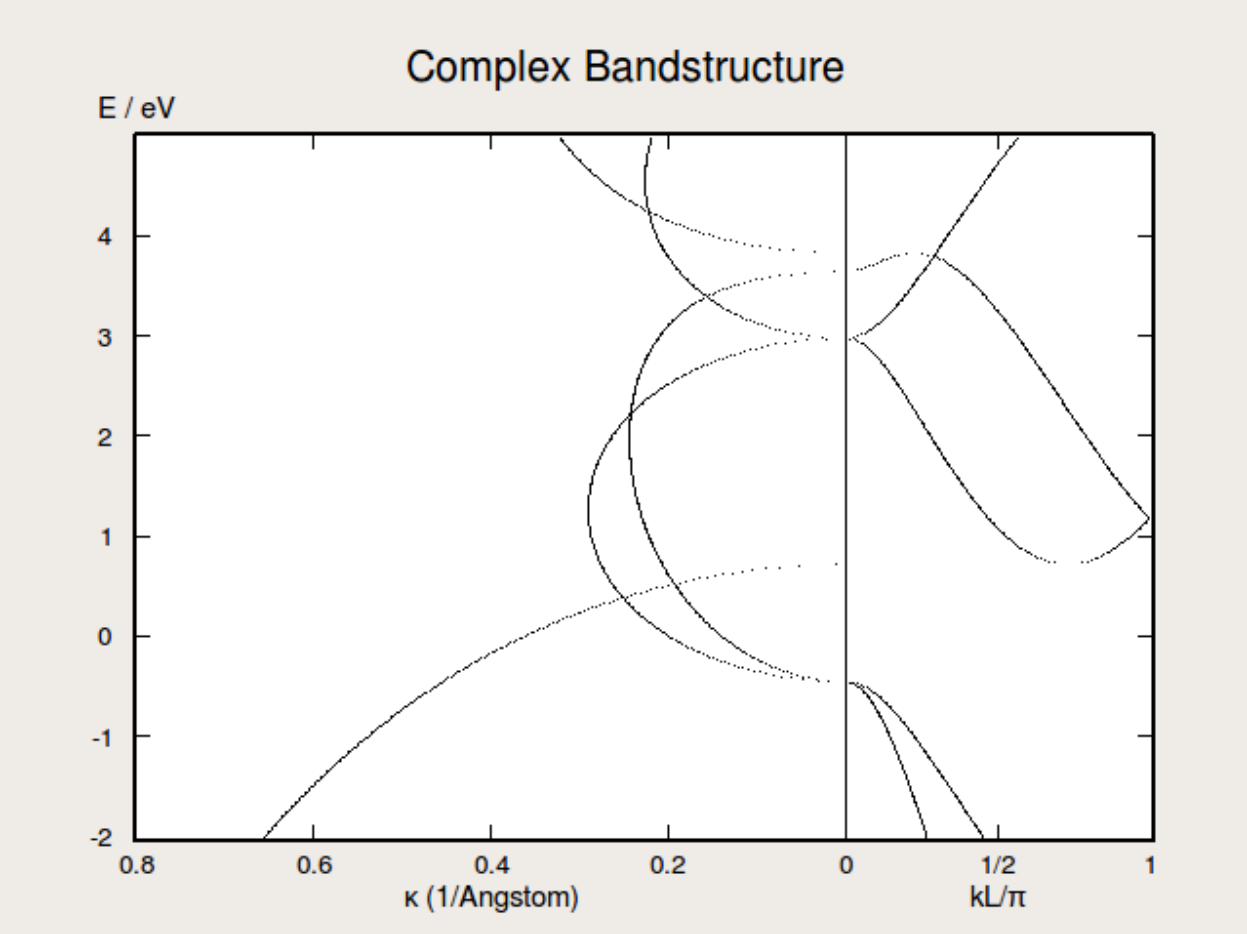


Fig. 4.12: Complex bandstructure for silicon along the (100) direction. The right-hand side of the plots illustrates the real bands while the left-hand side of the plot shows the imaginary part of k_C for the complex bands.

Notes

•The *ComplexBandstructure* is calculated for a specified energy, E, and k-point, k_A, k_B, in the plane spanned by the reciprocal A and B vectors. These are provided as input parameters for the calculation. The solutions are the eigenstates, $\psi_{n\mathbf{k}}$, of the Schrödinger equation

$$H\psi_{n\mathbf{k}} = E\psi_{n\mathbf{k}}$$

with no boundary conditions imposed in the direction perpendicular to the plane spanned by the unit cell vectors $\mathbf{A}$ and $\mathbf{B}$. We may write these eigenstates as

$$\psi_{n\mathbf{k}}(\mathbf{r}) = u_{\mathbf{k}}(\mathbf{r}) e^{-i\mathbf{k}_{AB}\mathbf{r}_{AB}} e^{-ik_C r_C},$$

where $u_{\mathbf{k}}$ is a periodic function and k_C, in general, is a complex number. The solutions with a purely real k_C are the usual Bloch states and we thus obtain the normal band structure. The solutions with a complex k_C form the complex band structure.

- The solutions, k_C, can be obtained after the calculation by using the method `evaluate()`. To print the data, use the method *nlprint*. In the figure above, which is obtained by plotting the complex band structure in QuantumATK, the k-values for the real band structure are normalized by L , the layer separation perpendicular to the AB-plane. The value of L can be extracted by using the method `layerSeparation()`.
- The *ComplexBandstructure* (and the real bands) is computed along the reciprocal C vector, which is perpendicular to the $\mathbf{A}$ and $\mathbf{B}$ unit cell vectors. Thus, if the *ComplexBandstructure* is desired in a particular direction, like (100) as in the example above, the unit cell should be set up such that this direction is perpendicular to the AB-plane. This is most easily achieved by using the **Surface** tool in the **Builder** in QuantumATK and choosing a *Periodic (bulk-like)* type of cell with a minimal number of layers.
- The implementation of the computation of the complex band structure in QuantumATK follows the method described in Ref.[1].

ConfigurationDataContainer

class ConfigurationDataContainer(*path=None*, *group_name=None*)

Constructor for the ConfigurationDataContainer that contains the different configurations.

Parameters

- **path** (*str | None*) – The path to the HDF5 file. If the path is None then all data will be stored in memory and no file will be written. **Default:** None
- **group_name** (*str | None*) – The name of the HDF5 group to store the data in. If the value is None then a new group will be automatically made. **Default:** None

allCoordinates()

Returns
The Cartesian coordinates of all images. A MxNx3 array is returned where M is the number of images and N is the number of atoms per image.

Return type
list of *PhysicalQuantity* of type length

calculator()

Returns
The calculator if one is available, otherwise None.

Return type
Calculator | None

cell(*idx*)

Parameters
idx (*int*) – The index to return.

[1] Y.-C. Chang and J.ăN. Schulman. Complex band structures of crystalline solids: An eigenvalue method. *Phys. Rev. B*, 25:3975–3986, Mar 1982. doi:10.1103/PhysRevB.25.3975.

Returns
The cell vectors of images with index idx or None if the trajectory length is zero or the configuration is a MoleculeConfiguration.

Return type
PhysicalQuantity of type length | None

coordinates(*idx*)

Parameters
idx (*int*) – The index to return.

Returns
The Cartesian coordinates of the images or None if the trajectory length is zero.

Return type
PhysicalQuantity of type length | None

elements(*idx*)

Parameters
idx (*int*) – The index to return.

Returns
The elements of the images as a list of length n or None if the trajectory length is zero.

Return type
list of type *PeriodicTableElement*

forces(*idx=None*)

Parameters
idx (*int | None*) – The index to return.

Returns
The forces of the image. If the trajectory length is zero or the forces were not written then None is returned.

Return type
PhysicalQuantity of type energy/length | list of *PhysicalQuantity* of type energy/length | None

image(*image_index*, *set_calculator=True*, *set_velocities=True*, *ignore_cache=False*)

Parameters

- **image_index** (*int*) – The index of the configuration that should be extracted.
- **set_calculator** (*bool*) – If True, the calculator is set on the returned image. This can be disabled to increase the performance when iterating over images, because the overhead of copying and setting up a new calculator can be large. **Default:** True
- **set_velocities** (*bool*) – DEPRECATED, only kept for compatibility. The velocities are always set on the configuration.
- **ignore_cache** – If True, the image is not read from the cache.

Returns
A copy of the configuration with the image_index.

Return type
BulkConfiguration | *MoleculeConfiguration*

imageEnergy(*idx=Ellipsis*)

Parameters
idx (*int | slice*) – The index or slice to return. **Default:** All indices

Returns
The potential energies of the images or None the trajectory length is zero.

Return type
PhysicalQuantity of type energy | None

imageForces(*idx=None*)

Parameters
idx (*int | None*) – The index to return.

Returns
The forces of the image. If the trajectory length is zero or the forces were not written then None is returned.

Return type
PhysicalQuantity of type energy/length | list of *PhysicalQuantity* of type energy/length | None

imageStress(*idx=None*)

Parameters
idx (*int | None*) – The index to return.

Returns
The stresses of the image. If the trajectory length is zero or the stresses were not written then None is returned. None is also returned if the configuration is a MoleculeConfiguration.

Return type
PhysicalQuantity of type energy/length | list of *PhysicalQuantity* of type energy/length | None

images(*set_calculator=True*, *set_velocities=True*, *ignore_cache=False*)

Parameters

- **set_calculator** (*bool*) – If True, the calculator is set on the returned image. This can be disabled to increase the performance when iterating over images, because the overhead of copying and setting up a new calculator can be large. **Default:** True.
- **set_velocities** (*bool*) – If True, the velocities are set on the returned image. This can be disabled to increase performance. **Default:** True.

Returns
All the configurations in the trajectory.

Return type
list of *MoleculeConfiguration* | *BulkConfiguration* | *DeviceConfiguration* | *SurfaceConfiguration*

kineticEnergies(*idx=Ellipsis*)

Parameters
idx (*int | slice*) – The index or slice to return. **Default:** All indices

Returns
The kinetic energies of the images or None the trajectory length is zero.

Return type
PhysicalQuantity of type energy | None

lastImage()

Returns
The last image in the trajectory with the calculator attached.

Return type
BulkConfiguration | *MoleculeConfiguration*

lastStep()

Returns
The step number of the last step.

Return type
int

lastTime()

Returns
The time associated with the last step.

Return type
PhysicalQuantity of type time

length()

Returns
The number of images in the trajectory.

Return type
int

masses(*idx*)

Parameters
idx (*int*) – The index to return.

Returns
The masses of the atoms of image with index idx with shape (num_atoms,) or None if the trajectory length is zero.

Return type
PhysicalQuantity of type mass

measurement(*name*, *idx=Ellipsis*)

Parameters

- **name** (*str*) – The name of the measurement.
- **idx** (*int | slice*) – The index or slice to return. **Default:** All indices

Returns
A 2-tuple of the time and the measurement.

Return type
tuple

measurementNames()

Returns
The names of the measurements.

Return type
list of type str

metatext()

Returns
The metatext of the object or None if no metatext is set.

Return type
str | None

nlinfo()

Returns
The trajectory information.

Return type
dict

nlprint(*stream=<_io.TextIOWrapper name='<stdout>' mode='w' encoding='utf-8'>*)

Write a text description of the trajectory to the stream.

Parameters
stream (*file-like object*) – The stream to write to. **Default:** sys.stdout

numberOfAtoms(*idx*)

Parameters
idx (*int*) – The index to return.

Returns
The number of atoms in the system.

Return type
int

partialCharges(*idx*)

Parameters
idx (*int*) – The index to return.

Returns
The partial charges of the atoms with shape (num_atoms,) or None if the trajectory length is zero.

Return type
PhysicalQuantity of type mass

potentialEnergies(*idx=Ellipsis*)

Parameters
idx (*int | slice*) – The index or slice to return. **Default:** All indices

Returns
The potential energies of the images or None the trajectory length is zero.

Return type
PhysicalQuantity of type energy | None

pressure(*idx*)

Parameters
idx (*int*) – The index to return.

Returns
The pressure value of the image with index idx or None if the trajectory length is zero.

Return type
PhysicalQuantity of type pressure | None

`pressureTensor(idx)`

Parameters
idx (*int*) – The index to return.

Returns
The pressure tensor of the image as a vector with shape (1, 3, 3) or None if the trajectory length is zero.

Return type
PhysicalQuantity of type pressure | None

`pressures()`

Returns
The pressure values of all images as a vector with shape (m) or None if the trajectory length is zero.

Return type
PhysicalQuantity of type pressure | None

`reservoirPressures(idx=Ellipsis)`

Parameters
idx (*int | slice*) – The index or slice to return. **Default:** All indices

Returns
The reservoir pressure of the MD barostat. If the trajectory length is zero or this trajectory was not generated from a NPT simulation then None is returned. NaN is returned for indices for which no temperature data is available.

Return type
PhysicalQuantity of type temperature

`reservoirTemperatures(idx=Ellipsis)`

Parameters
idx (*int | slice*) – The index or slice to return. **Default:** All indices

Returns
The reservoir temperature of the MD thermostat. If the trajectory length is zero or this trajectory was generated from a NVE simulation then None is returned. NaN is returned for indices for which no temperature data is available.

Return type
PhysicalQuantity of type temperature

`setMetatext(text)`
Set a given metatext string on the object.

Parameters
text (*str | None*) – The metatext string that should be set. A value of None can be given to remove the current metatext.

`steps(idx=Ellipsis)`

Parameters
idx (*int | slice*) – The index or slice to return. **Default:** All indices

Returns
The step numbers of the images or None if the trajectory length is zero.

Return type
array of type int | None

`stresses`(*idx=None*)

Parameters
idx (*int | None*) – The index to return.

Returns
The stresses of the image. If the trajectory length is zero or the stresses were not written then None is returned. None is also returned if the configuration is a MoleculeConfiguration.

Return type
PhysicalQuantity of type energy/length | list of *PhysicalQuantity* of type energy/length | None

`tagData`(*idx*)

Parameters
idx (*int*) – The index to return.

Returns
The tag data of the image or None if the trajectory length is zero or the tags are not stored in the trajectory.

Return type
ndarray of type int | None

`temperatures`(*idx=Ellipsis*)

Parameters
idx (*int | slice*) – The index to return. **Default:** All indices

Returns
The instantaneous kinetic temperatures of the images. If the trajectory length is zero or the temperatures were not written during the MolecularDynamics run then None is returned. NaN is returned for indices for which no temperature data is available.

Return type
PhysicalQuantity of type temperature

`timeInterval`()

Returns
The time interval between two images.

Return type
PhysicalQuantity of type time

`timeStep`()

Returns
The time step of the simulation.

Return type
PhysicalQuantity of type time or None if times are not available.

`times`(*idx=Ellipsis*)

Parameters
idx (*int | slice*) – The index or slice to return. **Default:** All indices

Returns
The simulation times of the images or None if the trajectory length is zero.

Return type
PhysicalQuantity of type time | None

trajectoryInterval()

Returns
The interval at which snapshots are saved.

Return type
int

uniqueElements(*idx=None*)

Parameters
idx (*int | None*) – The index to return. If None, all images are considered.

Returns
The unique elements of the images, sorted after their atomic numbers or None if the trajectory length is zero.

Return type
list of type *PeriodicTableElement*

velocities(*idx*)

Parameters
idx (*int*) – The index to return.

Returns
The velocities of the images. If the trajectory length is zero or the velocities were not written during the MolecularDynamics run then None is returned.

Return type
PhysicalQuantity of type length/time

volume(*idx*)

Parameters
idx (*int*) – The index to return.

Returns
The volume of the unit cell of index idx. If this was a simulation of molecules, then None will be returned.

Return type
PhysicalQuantity of type length**3 | None

volumes()

Returns
The volume of all unit cells. If this was a simulation of molecules, then None will be returned.

Return type
PhysicalQuantity of type length**3 | None

Notes

The *MDTrajectory* format is very efficient but does not support storage of heterogeneous data such as configurations with different numbers and types of atoms. The *ConfigurationDataContainer* format is designed to overcome this limitation. However, it does so in a more efficient way than *Trajectory* which stores every configuration as an individual image.

ConfigurationVelocities

class ConfigurationVelocities(*remove_center_of_mass_momentum=None*)

The ConfigurationVelocities object uses the velocities saved in the configuration as initial velocities in a *MolecularDynamics()* simulation.

Parameters

remove_center_of_mass_momentum (*bool*) – If True, the center-of-mass momentum should be removed, otherwise kept.

uniqueString()

Return a unique string representing the state of the object.

Usage Examples

Perform a molecular dynamics run of a silicon crystal, using the velocities defined in the bulk configuration as initial velocities in the MD simulation.

```
# Set up lattice
lattice = FaceCenteredCubic(5.4306*Angstrom)

# Define elements
elements = [Silicon, Silicon]

# Define coordinates

configuration_velocities.py

Notes

Pass this object as `initial_velocity` parameter in the MD method (e.g. *NVEVelocityVerlet*), if you want to use to velocities stored in the configuration (e.g from a previous MD run, or explicitly specified in the constructor of the configuration, cf. *BulkConfiguration*) as initial velocities in an MD simulation.

If the configuration does not have any velocities, the initial velocities will be set to zero.

ConfinedOrbital

class ConfinedOrbital(*principal_quantum_number=None*, *angular_momentum=None*, *radial_cutoff_radius=None*, *confinement_start_radius=None*, *additional_charge=None*, *confinement_strength=None*, *confinement_power=None*, *radial_step_size=None*)

Class for representing a confined atomic orbital.

Parameters

- **principal_quantum_number** (*int*) – The all electron principal quantum number (n) of the orbital.
- **angular_momentum** (*int*) – The angular momentum quantum Number (l) of the orbital.
- **radial_cutoff_radius** (*PhysicalQuantity* of type length) – The distance from the core where the basis orbital is zero (compact support radius).
- **confinement_start_radius** (*PhysicalQuantity* of type length) – Radial distance to where the confinement potential starts. The `confinement_start_radius` must be less than or equal to the `radial_cutoff_radius`.
- **additional_charge** (*float*) – Charge of the atom when generating the basis function. **Default:** `0.0`
- **confinement_strength** (*PhysicalQuantity* of type energy) – The confinement strength of the potential confining the atomic orbital. **Default:** `20 * Hartree`
- **confinement_power** (*int*) – The confinement power for the potential. **Default:** `1`
- **radial_step_size** (*PhysicalQuantity* of type length) – The radial step size determining the distance between grid points on the linear radial grid. **Default:** `0.01 * Bohr`

additionalCharge()

Returns
The additional charge used for generating this *ConfinedOrbital* instance.

Return type
float

angularMomentum()

Returns
The angular momentum.

Return type
int

confinementPower()

Returns
The power of the confinement potential.

Return type
int

confinementStartRadius()

Returns
The radius where the confinement potential starts.

Return type
PhysicalQuantity of type length

confinementStrength()

Returns
The strength of the confinement potential.

Return type
PhysicalQuantity of type energy

nlinfo()

Returns
The nlinfo.

Return type
dict

principalQuantumNumber()

Returns
The principal quantum number.

Return type
int

radialCutoffRadius()

Returns
The radial cutoff radius.

Return type
PhysicalQuantity of type length

radialStepSize()

Returns
The radial grid spacing.

Return type
PhysicalQuantity of type length

uniqueString()
Return a unique string representing the state of the object.

Usage Examples

Define a *BasisSet* for Hydrogen:

```
hydrogen_1s = ConfinedOrbital(
    principal_quantum_number = 1,
    angular_momentum = 0,
    radial_cutoff_radius = 5.28603678847*Bohr,
    confinement_start_radius = 0.8 * 5.28603678847*Bohr,
    additional_charge = 0.0,
    confinement_strength = 20.000*Hartree,
    confinement_power = 1,
    radial_step_size = 0.001*Bohr,
    )

my_hydrogen_basis = BasisSet(
    element = Hydrogen,
    orbitals = [hydrogen_1s],
    occupations = [1.0],
    pseudopotential = NormConservingPseudoPotential('normconserving/H.LDAPZ.zip'),
    )
```

Notes

The basis functions are found by solving the radial Schrödinger equation for the atom with a confinement potential $V_c(r)$. The confinement potential is defined by the parameters `confinement_strength` (V_0), `confinement_power` (n), `confinement_start_radius` (r_i), and `radial_cutoff_radius` (r_c) through the equation

$$V_c(r) = \begin{cases} 0 & \text{if } r < r_i \\ V_0 \left(\frac{r_c - r_i}{r_c - r}\right)^n \exp[-\frac{r_c - r_i}{r - r_i}] & \text{if } r_i < r < r_c \\ \infty & \text{if } r_c < r \end{cases}$$

Fig. 4.13 shows the confinement potential and the corresponding basis functions used for constructing the LDA standard basis set for hydrogen.

For backwards compatibility, if V_0 is given in units of energy×length (as was the convention in QuantumATK 12.2 and earlier, where a slightly different expression was used for the confinement potential), the rescaled value $V_0/(r_c - r_i)$ is used for the confinement strength, to conform to the new formula given above. Further information about the basis functions can be found in *LCAO basis set*.

ConstantPotential

class ConstantPotential(*particleType*, *c*)

Constructor of the potential.

Parameters

- **particleType** (ParticleType *or* ParticleIdentifier) – Identifier of the particle type.
- **c** (*PhysicalQuantity of type energy*) – Potential parameter.

classmethod getAllParameterNames()

Return the names of all used parameters as a list.

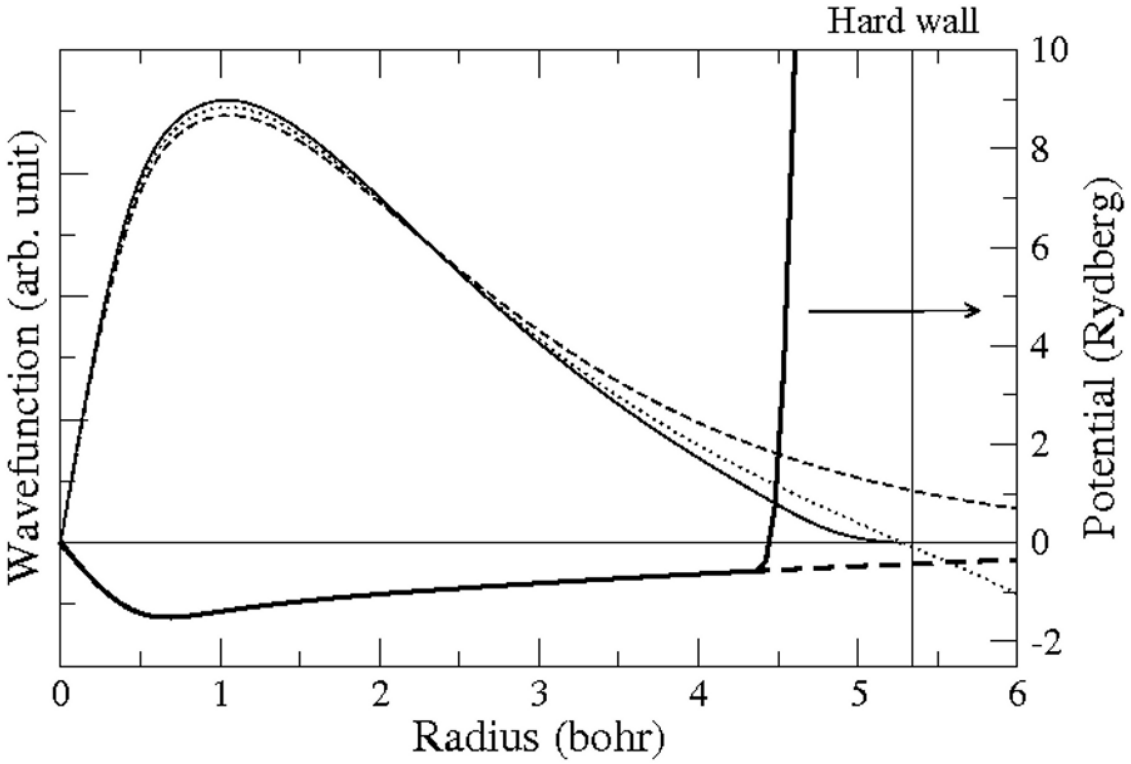

Fig. 4.13: The lower part of the plot shows the $\ell = 0$ effective potential for hydrogen (dashed) with the soft confinement potential (solid). The upper part shows the lowest occupied eigenstate of the confined potential (solid line), and the atomic s-wave function is indicated by the dashed curve (note that $r \cdot \psi(r)$ are plotted).The dotted curve shows the radial wave function with energy 0.01 Ry above the atomic eigenenergy. The position of the first node of this solution defines the position of r_c .

getAllParameters()

Return all parameters of this potential and their current values as a <parameterName / parameterValue> dictionary.

static getDefaults()

Get the default parameters of this potential and return them in form of a dictionary of <parameter name, default value> key-value pairs.

getParameter(*parameterName*)

Get the current value of the parameter parameterName.

setParameter(*parameterName*, *value*)

Set the parameter parameterName to the given value.

Parameters

•**parameterName** (*str*) – The name of the parameter that will be modified.

•**value** – The new value that will be assigned to the parameter parameterName.

Notes

Add a constant offset to the potential energy. This potential has no effect on the forces or stress.

ContinuousRandomNetwork

class ContinuousRandomNetwork(*temperature=None*, *heating_rate=None*, *chain_length=None*, *find_bonds=None*, *optimize_geometry_parameters=None*, *random_seed=None*)

Define a continuous random network (CRN) Monte Carlo method.

Parameters

•**temperature** (*PhysicalQuantity* of type temperature) – The initial temperature of the Monte Carlo simulation. **Default:** `300.0 * Kelvin`

•**heating_rate** (*PhysicalQuantity* of type temperature) – The change in temperature per step. A negative temperature results in the simulation cooling at each step. **Default:** `0.0 * Kelvin`

•**chain_length** (*int*) – The length of the chain between the two bonds to switch. **Default:** `1`

•**find_bonds** (*bool*) – Whether the bonding network will be automatically determined using the initial configuration; otherwise, the bonds to use must already be set on the configuration. **Default:** `True`

•**optimize_geometry_parameters** (*OptimizeGeometryParameters*) – The parameters to use for relaxing configurations. Note that *pre_step_hook* and *post_step_hook* must be left unset. Also note that only *max_forces*, *max_steps*, *max_step_length*, *constraints* and *optimizer_method* will be used; all other parameters will be ignored. **Default:** `OptimizeGeometryParameters()`

•**random_seed** (*int*) – The random seed used for generating trial Monte Carlo steps. **Default:** Generated automatically.

chainLength()

Returns
The length of the chain between the two bonds to switch.

Return type
int

findBonds()

Returns
Whether the bonding network will be automatically determined using the initial configuration.

Return type
bool

heatingRate()

Returns
The change in temperature per step, or None for no heating.

Return type
PhysicalQuantity of type temperature | None

monteCarloStep(*configuration*, *energy*)

Perform a bond switch Monte Carlo step and relax the configuration with the new bonding network.

Parameters

- **configuration** (*MoleculeConfiguration* | *BulkConfiguration* | *DeviceConfiguration* | *SurfaceConfiguration*) – The current configuration.
- **energy** (*PhysicalQuantity* of type energy) – The current energy.

Returns
The new configuration and energy resulting from the trial step.

Return type
tuple (size 2) of (*MoleculeConfiguration* | *BulkConfiguration* | *DeviceConfiguration* | *SurfaceConfiguration*, *PhysicalQuantity* of type energy)

optimizeGeometryParameters()

Returns
Parameters required to optimize the geometry.

Return type
OptimizeGeometryParameters

randomSeed()

Returns
The random seed used for performing Monte Carlo steps.

Return type
int

temperature()

Returns
The initial temperature of the Monte Carlo simulation.

Return type
PhysicalQuantity of type temperature

uniqueString()

Return a unique string representing the state of the object.

Usage Examples

Perform a Metropolis Monte Carlo simulation of 100 steps using the ContinuousRandomNetwork model.

```
# Define the Monte Carlo method. Note here the temperature changes from the initial␣
↪50500 to
# 500K
monte_carlo_method = ContinuousRandomNetwork(
    temperature=50500.0*Kelvin,
    heating_rate=-500.0*Kelvin,
    chain_length=1
)

# Perform the Monte Carlo simulation
monte_carlo_trajectory = MetropolisMonteCarlo(
    configuration=alpha_silicon,
    trajectory_filename='Amorphous_Silicon.hdf5',
    steps=100,
    max_trial_moves=5000,
    log_interval=1,
    method=monte_carlo_method,
    trajectory_object_id=None
)
last_image = monte_carlo_trajectory.lastImage()
nlsave('Amorphous_Silicon.hdf5', last_image)
```

continuous_random_network_example.py

In the above example the simulation starts with crystalline alpha-silicon. During the simulation changing the bonding between silicon atoms generates an amorphous structure while still preserving the number of bonds at each silicon. Note that in this simulation a high initial temperature is used so that the configuration is able to get out of the global energy minimum. As the simulation progress the temperature is lowered as less energy is required to perform subsequent bond swap moves. At low temperatures the selected can also lower the overall energy of the amorphous structure.

Notes

The *ContinuousRandomNetwork* class defines a Monte Carlo model that can be used in the *MetropolisMonteCarlo()* method. This Monte Carlo model defines bond swap moves that can be used to generate amorphous configurations. In each trial move, a pair of bonds that are separated by a set number of bonds are exchanged. A relaxation is then performed with an added bond and angle potential on the swapped bonds to return the new bonds back to equilibrium bond lengths and angles. The main advantage of generating trial configurations in this way is that it helps to preserve the bonding geometry around each atom while also moving atoms away from their lattice positions.

The number of bonds between swapped bonds is set by the argument `chain_length`. This can be set so that only like bonds in the material are swapped. For single element materials, such as silicon, the default value of 1 is appropriate. For binary materials, such as silica, a value of 2 should be used to ensure that only silicon-oxygen bonds are exchanged.

ContourParameters

class ContourParameters(*equilibrium_contour=None*, *non_equilibrium_contour=None*, *method=None*)

Generic object representing the contour segments to use in a device calculation.

Parameters

- **equilibrium_contour** (*OzakiContour* | *SemiCircleContour*) – The equilibrium contour to use.
- **non_equilibrium_contour** (*RealAxisContour*) – The non-equilibrium contour to use.
- **method** (*SingleContour* | *DoubleContour*) – The contour method to use, either a single contour or a double contour. **Default:** *DoubleContour* for finite bias, *SingleContour* for zero bias.

equilibriumContour()

Returns
The equilibrium contour.

Return type
OzakiContour | *SemiCircleContour*

method()

Returns
The contour method used.

Return type
SingleContour | *DoubleContour*

nlinfo()

Returns
The nlinfo.

Return type
dict

nonEquilibriumContour()

Returns
The non-equilibrium contour.

Return type
RealAxisContour

uniqueString()

Return a unique string representing the state of the object.

Usage Example

The ContourParameters class sets the contours used to calculate the density matrix. Both the equilibrium and non-equilibrium contour can be specified, e.g. to combine an *OzakiContour* with a *RealAxisContour*:

```
equilibrium_contour = OzakiContour(number_of_poles=128)

non_equilibrium_contour = RealAxisContour(
    real_axis_point_density=0.002*Hartree,
    real_axis_infinitesimal=0.003*Hartree,
```

(continues on next page)

(continued from previous page)

```
    real_axis_kbt_padding_factor=10.0)

contour_parameters = ContourParameters(
    equilibrium_contour=equilibrium_contour,
    non_equilibrium_contour=non_equilibrium_contour)
```

The keyword `method` is used to specify how to deal with the numerical inaccuracy which causes a discrepancy between the left and right approach to obtain the density matrix, e.g.:

```
contour_parameters = ContourParameters(
    method=SingleContour(direction=Left))
```

will only calculate the Left part (see *SingleContour*). If the DoubleContour option is specified:

```
contour_parameters = ContourParameters(method=DoubleContour())
```

the left and right parts are both calculated and added up with a special weighting to obtain the best result (See *DoubleContour*).

Notes

The ContourParameters object specifies the contour points for integrating the density matrix in a DeviceConfiguration with or without bias.

The equilibrium part of the density matrix is obtained by integrating up to the left (right) Fermi level $\mu_{L(R)}$:

$$D_L = \Im\left[-\frac{2}{\pi}\int_{-\infty}^{+\infty} dE\; f(E-\mu_L)\; G(E+i0^+)\right] ,$$
$$D_R = \Im\left[-\frac{2}{\pi}\int_{-\infty}^{+\infty} dE\; f(E-\mu_R)\; G(E+i0^+)\right] ,$$

in which $f(E-\mu)$ is the Fermi-Dirac distribution. The equilibrium density matrix is calculated with an *EquilibriumContour* method. At zero bias D^L and D^R yield identical results.

The non-equilibrium contribution to the density matrix is calculated using a *NonEquilibriumContour* method, which integrates the spectral density matrix from states in the left (right) electrode between the two Fermi levels:

$$\Delta^R_{\mu\nu} = \int_{-\infty}^{+\infty} d\epsilon\; \rho^L_{\mu\nu}(\epsilon)\left[f(\epsilon-\mu_R) - f(\epsilon-\mu_L)\right] ,$$
$$\Delta^L_{\mu\nu} = \int_{-\infty}^{+\infty} d\epsilon\; \rho^R_{\mu\nu}(\epsilon)\left[f(\epsilon-\mu_L) - f(\epsilon-\mu_R)\right] ,$$

in which $\rho^{L(R)}$ is the left (right) spectral density matrix.

It follows there are two equivalent ways to calculate the total density matrix D:

$$D = D^L + \Delta^R ,$$
$$D = D^R + \Delta^L ,$$

When there is a finite bias in the system both expressions yield different estimates for the density matrix due to the finite accuracy of the integration. The `method` parameter determines how the density matrix is obtained from both expressions.

CoordinationNumber

class CoordinationNumber(*md_trajectory*, *cutoff_radius=None*, *start_time=None*, *end_time=None*, *pair_selection=None*, *time_resolution=None*, *info_panel=None*, *analysis_type=None*, *calculate_distribution=None*)

Class for calculating the coordination number for an MD simulation.

Parameters

- **md_trajectory** (*MDTrajectory* | AtomicConfiguration) – The MDTrajectory or configuration to calculate the coordination number for.
- **cutoff_radius** (*PhysicalQuantity* of type length) – Cut off distance for nearest neighbors (must be positive). **Default:** 2.5 * Angstrom.
- **start_time** (*PhysicalQuantity* of type time) – The start time. **Default:** 0.0 * fs.
- **end_time** (*PhysicalQuantity* of type time) – The end time. **Default:** The last time frame.
- **pair_selection** (*sequence*) – Only include contributions between this selection of atoms. A sequence has to contain two of the following types: Element, tag name, list of indices, or None. If None is given instead of a list then all atom pairs will be considered. **Default:** None.
- **time_resolution** (*PhysicalQuantity* of type time) – The time interval between snapshots in the MD trajectory that are included in the analysis. If time_resoultion is None then it will be the same as the MD time step. **Default:** None.
- **info_panel** (*InfoPanel (Plot2D)*) – Info panel to show the calculation progress. **Default:** No info panel.
- **analysis_type** (*Distribution | Profile | TimeEvolution | None*) – The type of coordination number analysis to perform. **Default:** None.
- **calculate_distribution** (*bool*) – A flag to determine whether the distribution of coordination numbers or the time-dependent evolution of coordination numbers along the trajectory should be calculated. DEPRECATED, use analysis_type instead. **Default:** None.

coordinationNumbers()

Returns
The coordination numbers associated with the histogram.

Return type
numpy.array | *PhysicalQuantity*

data()

Returns
The coordination number distribution if calculate_distribution has been selected, The coordination number profile if calculate_profile has been selected, otherwise an array with the time-dependent evolution of the average coordination number.

Return type
numpy array

distances()

Returns
The distances associated with coordination number profile.

Return type
numpy.array | *PhysicalQuantity*

times()

Returns
The MD-times in case the time-evolution has been calculated, None otherwise.

Return type
PhysicalQuantity of type time | None

Usage Examples

Load an *MDTrajectory* and calculate the coordination number distribution of the first atom with all surrounding hydrogen atoms:

```
md_trajectory = nlread('ethane_md.nc')[-1]

coordination_number = CoordinationNumber(md_trajectory,
                                         cutoff_radius=1.2*Angstrom,
                                         start_time=10000.0*fs,
                                         end_time=50000.0*fs,
                                         pair_selection=[[0], Hydrogen])

# Get the histogram and the associated the coordination numbers.
bin_edges = coordination_number.coordinationNumbers() - 0.4
histogram = coordination_number.data()

# Plot the data using pylab.
import pylab

pylab.bar(bin_edges, histogram, label='Coordination of the first atom', width=0.8)
pylab.xlabel('Coordination number')
pylab.ylabel('Histogram')
pylab.legend()

pylab.show()
```

coordination_number.py

Notes

Set the `cutoff_radius` parameter to the maximum bond length that should be considered. A good choice is typically the end of the first peak in the *RadialDistribution* function of the respective elements.

Use the `pair_selection` parameter to select the atom interactions that are included in the calculation of the coordination number distribution. The first entry specifies the group of central atoms, while the second entry specifies which of the surrounding atoms are considered. You can use elements, lists of indices, tags, or `None` (selecting all atoms) for each entry.

This analysis has two modes, distribution and time evolution, which can be switched via the `calculate distribution` argument. In the distribution analysis the histogram of the coordination numbers is plotted. In the time evolution analysis, the change of the number of atoms associated with each coordination number is analyzed as a function the simulation time. This analysis is performed each coordination number detected in the snapshots of the simulation, as shown in the second example, this yields $CN_{max}+1$ data sets, where CN_{max} is the largest coordination number found in the simulation.

CoreShellHarmonicPotential

class CoreShellHarmonicPotential(*particleType1*, *particleType2*, *K*, *r0*)

Constructor of the potential.

Parameters

- **particleType1** (ParticleType *or* ParticleIdentifier) – Identifier of the core particle type.
- **particleType2** (ParticleType *or* ParticleIdentifier) – Identifier of the shell particle type.
- **K** (*PhysicalQuantity of type energy * length**-2*) – Potential parameter.
- **r0** (*PhysicalQuantity of type length*) – Potential parameter.

classmethod getAllParameterNames()

Return the names of all used parameters as a list.

getAllParameters()

Return all parameters of this potential and their current values as a <parameterName / parameterValue> dictionary.

static getDefaults()

Get the default parameters of this potential and return them in form of a dictionary of <parameter name, default value> key-value pairs.

getParameter(*parameterName*)

Get the current value of the parameter parameterName.

setParameter(*parameterName*, *value*)

Set the parameter parameterName to the given value.

Parameters

- **parameterName** (*str*) – The name of the parameter that will be modified.
- **value** – The new value that will be assigned to the parameter parameterName.

Usage Examples

Define a core-shell potential for TiO2-rutile by adding particle types and interaction functions to the *TremoloXPotentialSet*.

```
# Set up lattice
lattice = SimpleTetragonal(4.593*Angstrom, 2.959*Angstrom)

# Define elements
elements = [Titanium, Titanium, Oxygen, Oxygen, Oxygen, Oxygen]

# Define coordinates
fractional_coordinates = [[-0.002453289082, -0.007907909466,  0.008991998629],
                          [ 0.486821568998,  0.505349605489,  0.498303421225],
                          [ 0.313234905089,  0.31385912058 , -0.002386305869],
                          [ 0.708385881142,  0.705329563593,  0.004823488804],
                          [ 0.801244040623,  0.185105024712,  0.48201997633 ],
                          [ 0.183768385074,  0.808268364353,  0.489566273637]]

# Set up configuration

CoreShellMorsePotential

class CoreShellMorsePotential(*particleType1*, *particleType2*, *E0*, *k*, *r0*)

Constructor of the potential.

Parameters

- **particleType1** (ParticleType *or* ParticleIdentifier) – Identifier of the core particle type.
- **particleType2** (ParticleType *or* ParticleIdentifier) – Identifier of the shell particle type.
- **E0** (*PhysicalQuantity of type energy*) – Potential parameter.
- **k** (*PhysicalQuantity of type length**-1*) – Potential parameter.
- **r0** (*PhysicalQuantity of type length*) – Potential parameter.

classmethod getAllParameterNames()

Return the names of all used parameters as a list.

getAllParameters()

Return all parameters of this potential and their current values as a <parameterName / parameterValue> dictionary.

static getDefaults()

Get the default parameters of this potential and return them in form of a dictionary of <parameter name, default value> key-value pairs.

getParameter(*parameterName*)

Get the current value of the parameter parameterName.

setParameter(*parameterName*, *value*)

Set the parameter parameterName to the given value.

Parameters

- **parameterName** (*str*) – The name of the parameter that will be modified.
- **value** – The new value that will be assigned to the parameter parameterName.

Usage Examples

Define a core-shell potential for TiO2-rutile by adding particle types and interaction functions to the *TremoloXPotentialSet*.

```
# Set up lattice
lattice = SimpleTetragonal(4.593*Angstrom, 2.959*Angstrom)

# Define elements
elements = [Titanium, Titanium, Oxygen, Oxygen, Oxygen, Oxygen]

# Define coordinates
fractional_coordinates = [[-0.002453289082, -0.007907909466,  0.008991998629],
                          [ 0.486821568998,  0.505349605489,  0.498303421225],
                          [ 0.313234905089,  0.31385912058 , -0.002386305869],
                          [ 0.708385881142,  0.705329563593,  0.004823488804],
                          [ 0.801244040623,  0.185105024712,  0.48201997633 ],
                          [ 0.183768385074,  0.808268364353,  0.489566273637]]

# Set up configuration
bulk_configuration = BulkConfiguration(
    bravais_lattice=lattice,
    elements=elements,
    fractional_coordinates=fractional_coordinates
    )

# ------------------------------------------------------------
# Adding the core-shell potential.
# ------------------------------------------------------------

potentialSet = TremoloXPotentialSet(name = 'TiO2_CoreShell')

# Add a particle for the oxygen-shell.
# The shell must have zero mass.
potentialSet.addParticleType(ParticleType(symbol='O_shell',
                                          mass=0.0*atomic_mass_unit,

CoreShellOptimizationOption

class CoreShellOptimizationOption(*maxIterations=None*, *relFTol=None*, *gradTol=None*)

Constructor of the option.

Parameters

- **maxIterations** (*int*) – The maximal number of iterations that are allowed during the optimization of the core-shell potential.
- **relFTol** (*float*) – Stop the optimization of the core-shell potential if the relative change in the objective function value is smaller than this value. If set to < 0, this stopping criterion is disabled.
- **gradTol** (*float*) – Stop the optimization of the core-shell potential if the 2-norm of the gradient of the objective function is smaller than this value. If set to < 0, this stopping criterion is disabled.

classmethod getAllParameterNames()

Return the names of all used parameters as a list.

getAllParameters()

Return all parameters of this potential and their current values as a <parameterName / parameterValue> dictionary.

static getDefaults()

Get the default parameters of this potential and return them in form of a dictionary of <parameter name, default value> key-value pairs.

getParameter(*parameterName*)

Get the current value of the parameter parameterName.

setParameter(*parameterName*, *value*)

Set the parameter parameterName to the given value.

Parameters

- **parameterName** (*str*) – The name of the parameter that will be modified.
- **value** – The new value that will be assigned to the parameter parameterName.

Usage Examples

Set up a core-shell potential and add an optimization option to stop the internal optimization of the shell positions charges after 20 iterations.

```
# Set up a new core-shell potential.
coreshell_potential = Pedone_AlCaNaOSi_2012()

# Set up an optimization option to stop the optimization of the shell positions
# after 20 iterations.
optimization_option = CoreShellOptimizationOption(
    maxIterations=20,
)

# Add the option to the potential.
coreshell_potential.addOption(optimization_option)
```

Notes

This option can be used to specify the details of the internal optimization of the shell-positions in a Core-Shell potential. It can be added to a *TremoloXPotentialSet* via the `addOption()` method.

CosineAnglePotential

class CosineAnglePotential(*particleType1*, *particleType2*, *particleType3*, *k*, *n*)

Constructor of the potential.

Parameters

- **particleType1** (ParticleType *or* ParticleIdentifier) – Identifier of the first particle type.
- **particleType2** (ParticleType *or* ParticleIdentifier) – Identifier of the second particle type. This is the central particle (the vertex) when calculating the angle.
- **particleType3** (ParticleType *or* ParticleIdentifier) – Identifier of the third particle type.
- **k** (*PhysicalQuantity of type energy*) – Potential parameter.
- **n** (*int*) – Potential parameter.

classmethod getAllParameterNames()

Return the names of all used parameters as a list.

getAllParameters()

Return all parameters of this potential and their current values as a <parameterName / parameterValue> dictionary.

static getDefaults()

Get the default parameters of this potential and return them in form of a dictionary of <parameter name, default value> key-value pairs.

getParameter(*parameterName*)

Get the current value of the parameter parameterName.

setParameter(*parameterName*, *value*)

Set the parameter parameterName to the given value.

Parameters

- **parameterName** (*str*) – The name of the parameter that will be modified.
- **value** – The new value that will be assigned to the parameter parameterName.

Notes

- This potential class is a bonded potential. This means it requires a bond topology to be specified on the configuration which the potential should be used for. Bonds can be set using the `findBonds()` method on configurations (*MoleculeConfiguration*, *BulkConfiguration*, *DeviceConfiguration*, or *SurfaceConfiguration*), which automatically adds bonds for atoms which are closer than their combined covalent radii (multiplied by a `fuzz_factor` of 1.1 by default). Alternatively bonds can be set manually by passing a list of the atom index pairs that form the bonds to the `setBonds()` method on the configuration. If no bonds are specified on the configuration bonded potentials have no effect.
- An angle potential is calculated for a triple *(a,b,c)* of atoms, which are connected by two adjacent bonds *(a,b)* and *(b,c)*. The potential acts on the angle θ formed by these two bonds:

$$U_{ijk} = k_{ijk} \cos(n_{ijk}\theta_{ijk})$$

CosinePowerTorsionPotential

class CosinePowerTorsionPotential(*particleType1*, *particleType2*, *particleType3*, *particleType4*, *c*)

Constructor of the potential.

Parameters

- **particleType1** (ParticleType *or* ParticleIdentifier) – Identifier of the first particle type.
- **particleType2** (ParticleType *or* ParticleIdentifier) – Identifier of the second particle type.
- **particleType3** (ParticleType *or* ParticleIdentifier) – Identifier of the third particle type.
- **particleType4** (ParticleType *or* ParticleIdentifier) – Identifier of the fourth particle type.
- **c** (*Sequence of PhysicalQuantity of type energy or PhysicalQuantity array of type energy.*) – Potential parameter. The length of this list must not exceed 10.

classmethod getAllParameterNames()

Return the names of all used parameters as a list.

getAllParameters()

Return all parameters of this potential and their current values as a <parameterName / parameterValue> dictionary.

static getDefaults()

Get the default parameters of this potential and return them in form of a dictionary of <parameter name, default value> key-value pairs.

getParameter(*parameterName*)

Get the current value of the parameter parameterName.

setParameter(*parameterName*, *value*)

Set the parameter parameterName to the given value.

Parameters

•**parameterName** (*str*) – The name of the parameter that will be modified.

•**value** – The new value that will be assigned to the parameter parameterName.

CosineTorsionPotential

class CosineTorsionPotential(*particleType1*, *particleType2*, *particleType3*, *particleType4*, *k*, *n*, *delta*)

Constructor of the potential.

Parameters

•**particleType1** (ParticleType *or* ParticleIdentifier) – Identifier of the first particle type.

•**particleType2** (ParticleType *or* ParticleIdentifier) – Identifier of the second particle type.

•**particleType3** (ParticleType *or* ParticleIdentifier) – Identifier of the third particle type.

•**particleType4** (ParticleType *or* ParticleIdentifier) – Identifier of the fourth particle type.

•**k** (*Sequence of PhysicalQuantity of type energy or PhysicalQuantity array of type energy.*) – Potential parameter. The length of this list must not exceed 10.

•**n** (*Sequence of int*) – Potential parameter. Must be of the same length as k.

•**delta** (*Sequence of PhysicalQuantity of type angle or PhysicalQuantity array of type angle.*) – Potential parameter. Must be of the same length as k.

classmethod getAllParameterNames()

Return the names of all used parameters as a list.

getAllParameters()

Return all parameters of this potential and their current values as a <parameterName / parameterValue> dictionary.

static getDefaults()

Get the default parameters of this potential and return them in form of a dictionary of <parameter name, default value> key-value pairs.

getParameter(*parameterName*)

Get the current value of the parameter parameterName.

setParameter(*parameterName*, *value*)

Set the parameter parameterName to the given value.

Parameters

•**parameterName** (*str*) – The name of the parameter that will be modified.

•**value** – The new value that will be assigned to the parameter parameterName.

Usage Examples

Set up a bonded potential with a CosineTorsionPotential for an ethane molecule.

```
# Set up a new TremoloXPotentialSet
potential_set = TremoloXPotentialSet(name='Ethane_bonded')

# Add particle types for Carbon and Hydrogen.
potential_set.addParticleType(
```

(continues on next page)

(continued from previous page)

```
    ParticleType.fromElement(Carbon, charge=-0.3*elementary_charge)
)
potential_set.addParticleType(
    ParticleType.fromElement(Hydrogen, charge=0.1*elementary_charge)
)
# Set up a new torsion potential for H-C-C-H groups and add it to the potential set.
# This potential has a multiplicity of 1.
torsion_potential = CosineTorsionPotential(
    particleType1='H',
    particleType2='C',
    particleType3='C',
    particleType4='H',
    k=[0.0067455*eV],
    n=[3],
    delta=[0.0]
)
potential_set.addPotential(torsion_potential)
# Create a new TremoloXCalculator with this potential.
calculator = TremoloXCalculator(parameters=potential_set)
```

Here, only the CosineTorsionPotential block of the script is shown. The full script can be found found in the file `ethane_bonded_potential.py`.

Notes

- This potential class is a bonded potential. This means it requires a bond topology to be specified on the configuration which the potential should be used for. Bonds can be set using the `findBonds()` method on configurations (*MoleculeConfiguration*, *BulkConfiguration*, *DeviceConfiguration*, or *SurfaceConfiguration*), which automatically adds bonds for atoms which are closer than their combined covalent radii (multiplied by a `fuzz_factor` of 1.1 by default). Alternatively bonds can be set manually by passing a list of the atom index pairs that form the bonds to the `setBonds()` method on the configuration. If no bonds are specified on the configuration bonded potentials have no effect.
- Each torsion potential is calculated for a quadruple *(a,b,c,d)* of atoms, which are connected by three bonds *(a,b)* , *(b,c)*, and *(c,d)*. The potential acts on the torsion angle ϕ around the central bond:

$$\phi(\mathbf{r}_{a,b}, \mathbf{r}_{b,c}, \mathbf{r}_{c,d}) = \arccos\left(\frac{(\mathbf{r}_{a,b} \times \mathbf{r}_{b,c}) \cdot (\mathbf{r}_{b,c} \times \mathbf{r}_{c,d})}{|\mathbf{r}_{a,b} \times \mathbf{r}_{b,c}||\mathbf{r}_{b,c} \times \mathbf{r}_{c,d}|}\right)$$

where $\mathbf{r}_{i,j}$, $\{i,j\} \subset \{a,b,c,d\}$ is the distance vector from atom *i* to atom *j*.

The torsion potential is calculated as

$$V(\phi) = \sum_{i=1}^{\text{mult}} k_i \left(1 + \cos(n_i\phi - \delta_i)\right)$$

where $\text{mult} < 6$ is the multiplicity of the torsion potential for the given quadruple of atom types. Each of the parameters *k*, *n*, and δ is given as a list of length mult.

CosmoRS

class CosmoRS(*configuration*, *solvation_energy*)

Class for creating a COSMO-RS species that contains the configuration information needed for the COSMO-RS method. This can either be returned or added directly to the COSMO-RS species database.

Parameters
configuration (*MoleculeConfiguration* | *SurfaceConfiguration* | *BulkConfiguration*) – Configuration with a calculator that supports COSMO-RS calculations.

evaluate()

Returns
The COSMO Real Species that represents the configuration.

Return type
CosmoRealSpecies

metatext()

Returns
The metatext of the object or None if no metatext is present.

Return type
str | None

nlinfo()

Returns
Information about the calculated COSMO real species object.

Return type
dict

nlprint(*stream=None*)

Print a string containing an ASCII table useful for plotting the AnalysisSpin object.

Parameters
stream (*python stream*) – The stream the table should be written to. **Default:** NLPrintLogger()

setMetatext(*metatext*)

Set a given metatext string on the object.

Parameters
metatext (*str | None*) – The metatext string that should be set. A value of None can be given to remove the current metatext.

uniqueString()

Return a unique string representing the state of the object.

Usage Examples

Create a *CosmoRS* object for carbon dioxide. When opened in the QuantumATK **Data Tool**, the CosmoRS analysis object can be added to the COSMO-RS molecule database. Simply drag and drop the analysis object onto the *Import* tab of the COSMO-RS database.

```
# Calculate the solvation energy
solvation_energy = SolvationEnergy(
    configuration=optimized_configuration
)
nlsave('co2_cosmors_example.hdf5', solvation_energy)

# Create the CosmoRS analysis object
cosmo_rs = CosmoRS(
    configuration=optimized_configuration,
    solvation_energy=solvation_energy
)
nlsave('co2_cosmors_example.hdf5', cosmo_rs)
```

co2_cosmors_example.py

Notes

The *CosmoRS* analysis class is designed to package the calculations necessary to create a *CosmoRealSpecies* object. This is the representation of molecules used in all COSMO-RS calculations. Saving this information as a single analysis object makes it simple to add molecules to the COSMO-RS molecule database. To add molecules to the database in QuantumATK, open the molecule database in the **COSMO-RS Analyzer**. This is one of the *Supplementary Tools* available in the **Data Tool**. In the COSMO-RS molecule database, select the *Import* tab. This has an area where you can add molecules by dragging the *CosmoRS* analysis object from the **Data Tool** onto the *Import* tab.

To create a *CosmoRS* analysis object, both a configuration and a *SolvationEnergy* object are required. The configuration must also contain an updated COSMO calculation. Once the object is created, the `evaluate` method can be used to return the stored *CosmoRealSpecies* object. If working entirely in scripting the *CosmoRealSpecies* object can also be created directly without requiring a *CosmoRS* analysis.

CosmoRSMixture

class CosmoRSMixture(*mixture_components=None*)

Create a mixture to be used as input in COSMO-RS methods. This object takes a list of tuples of input. Each tuple specifies first mixture component as either a *CosmoRealSpecies* or a *MoleculeConfiguration*. Secondly the mole fraction of the component is given, as a float ranging from 0 to 1. The mole fractions must add to 1.

Parameters
mxiture_components (*Sequence of tuples.*) – The list of mixture components.

addMixtures(*ratio*, *other*)

Add two mixtures with a given ratio into a new mixture. Duplicates are added together into the one component.

Parameters

- **ratio** (*float*) – The fraction of the current mixture in the final one. The ratios of the two components should add to 1.
- **other** (*[type]*) – The other component to be added to the new mixture.

Returns
The new mixture created by adding the given two together. If both mixtures share a common component, these will be added together in the new mixture.

Return type
CosmoRSMixture

componentMoleFraction(*index*)

Return a specific component mole fraction.

Parameters
index (*int*) – The index of the mole fraction to return.

Returns
The requested mole fraction.

Return type
float

componentSpecies(*index*)

Return a specific component species.

Parameters
index (*int*) – The index of the component to return.

Returns
The requested species.

Return type
CosmoRealSpecies

components()

Returns
The components in the mixture, given as tuples of species and mole fraction.

Return type
Sequence of tuples

density()

Returns
The molar mass weighted density of the mixture.

Return type
PhysicalQuantity of type mass per volume

molarMass()

The mole fraction weighted molar mass of the mixture.

Returns
The mole fraction weighted molar mass of the mixture.

Return type
PhysicalQuantity of type mass per mole.

molarVolume()

The mole fraction weighted molar volume of the mixture.

Returns
The mole fraction weighted molar mass of the mixture.

Return type
PhysicalQuantity of type mass per mole.

moleFractions()

Returns
The mole fractions of each component.

Return type
Sequence of float

numberOfComponents()

Returns
The number of components in the mixture.

Return type
int

species()

Returns
The species included in the mixture.

Return type
Sequence of *CosmoRealSpecies*

uniqueString()

Return a unique string representing the state of the object.

Usage Examples

Create a *CosmoRSMixture* object.

```
# Create a mixture.
mixture = CosmoRSMixture([
    (water, 0.6), (methanol, 0.4)
])

# Get the mixture density.
density = mixture.density()
nlprint(f'The density of the mixture is {density}')

# Get the molar volume.
molar_volume = mixture.molarVolume()
nlprint(f'The molar volume of the mixture is {molar_volume}')

# Get the molar mass.
molar_mass = mixture.molarMass()
nlprint(f'The molar mass of the mixture is {molar_mass}')

# Create another mixture.
another_mixture = CosmoRSMixture([
    (methanol, 0.4), (acetonitrile, 0.6)
])
```

(continues on next page)

(continued from previous page)

```
# Combine them to create a new mixture.
new_mixture = mixture.addMixtures(0.5, another_mixture)
for i, x in enumerate(new_mixture.moleFractions()):
    nlprint(f'The mole fraction of component {i} is {x}')
```

mixture_example.py

Notes

The *CosmoRSMixture* object contains information about a mixture composition. The object can be passed on to any other solvent related COSMO-RS object such as *LiquidEquilibrium*. The molar mass of the mixture is defined as the weighted molar mass of the mixture, $\overline{M}$.

$$\overline{M} = \sum_i x_i M_i$$

Here M is the molar mass and x the mole fraction of component species i.

It is also possible to calculate the weighted molar volume of a solvent mixture $\overline{V_m}$. V_m is defined as the volume occupied by 1 mole of species. This property can be determined based on the individual component densities their respective mole fractions.

$$\overline{V_m} = \sum_i x_i V_{m,i}$$

If all of the component species are provided with densities, the molar volume is calculated as

$$V_{m,i} = \frac{M_i}{\rho_i}$$

Here ρ is the density. If the density is not given for a species the molar volume is approximated from the COSMO cavity volume.

$$V_{m,i} = N_A V_i^{COSMO}$$

N_A is Avogadro constant.

The mixture density is then calculated based on the previous properties.

$$\rho = \frac{\overline{M}}{\overline{V_m}}$$

Finally, *CosmoRSMixture* objects may be combined to form a new mixture. This is done using `addMixtures` method where a mixture ratio is also needed. If the mixtures have a component species in common this will be added together to form a single component of the new mixture.

CosmoRSParameterSets

class CosmoRSParameterSets

deleteParameterSet(*name*)

Delete the the given named entry from the available parameter sets. This can only be done for user added entries.

Parameters
name (*str*) – The name of the parameter set to delete.

loadParameterSet(*name*)

Return the parameter set for the given named entry.

Parameters
name (*str*) – The name of the parameter set to return.

Returns
The parameter set.

Return type
CosmoRSParameters

parameterSets()

Returns
A list of the names of the available parameter sets.

Return type
list of str

saveParameterSet(*name*, *parameter_set*, *reference=None*, *description=None*)

Save a parameter set into the set of available parameter sets.

Parameters

- **name** (*str*) – The name to be given to the parameter set.
- **parameter_set** (*CosmoRSParameters*) – The data for the parameter set.
- **reference** (*str*) – An optional reference for where the parameters were obtained.
- **description** (*str*) – An optional description of the parameter set.

Usage Examples

List the available parameter sets and load a parameter set to calculate the chemical potential of water.

```
# Load the parameters database
param_database = CosmoRSParameterSets()

# Print the names of the available parameter sets
parameter_names = param_database.parameterSets()
nlprint('Available parameter set names:')
for name in parameter_names:
    nlprint(name)
nlprint('')

# Load a specific parameter set
parameters = param_database.loadParameterSet('klamt_1998')

# Calculate the chemical potential of water with the new parameter set
molecule_database = CosmoRSSpeciesDatabase()
water = molecule_database.exportSpecies('water')
solvent = CosmoRealSolvent(298*Kelvin, water, parameters)
chemical_potential = solvent.chemicalPotential(water)
nlprint(f'The estimated chemical potential of water is {chemical_potential}')
```

load_parameters_example.py

Save a parameter set into the database and then delete it again.

```
# Create the custom CosmoRSParameters object
parameters = CosmoRSParameters(
    hydrogen_bond_donors=Hydrogen,
    hydrogen_bond_acceptors=(Nitrogen, Oxygen, Fluorine),
    r_average=0.334*Ang,
    alpha_prime=1428.3*kiloCaloriePerMol*Ang**2/elementary_charge**2,
    f_correlation=2.784,
    c_hydrogen_bonding=8800*kiloCaloriePerMol*Ang**2/elementary_charge**2,
    sigma_hydrogen_bonding=0.869*elementary_charge/nm**2,
    hydrogen_bond_temperature=False,
    a_effective=7.79*Ang**2,
    lambda_comb=0.13,
    omega_ring=-0.216*kiloCaloriePerMol,
    eta_gas=-10.05,
    lambda_reg=0.611,
    lambda_ortho=0.820,
    pka_scale=1.0,
    pka_offset=0.0,
    dispersion={
        Hydrogen: -3.59*kiloCaloriePerMol/nm**2,
        Carbon: -3.47*kiloCaloriePerMol/nm**2,
        Nitrogen: -2.26*kiloCaloriePerMol/nm**2,
        Oxygen: -3.17*kiloCaloriePerMol/nm**2,
        Chlorine: -5.00*kiloCaloriePerMol/nm**2,
    },
)

# Save the parameters to the database
database = CosmoRSParameterSets()
database.saveParameterSet(
    'custom_parameter_set',
    parameters,
    reference='DOI: 10.1139/V09-008',
    description=(
        'Taken from "C. C. Pye, T. Zeigler, E. van Lenthe and J. L. Louwen. '
        'Can. J. Chem., 87, 790-797 (2009).'
    )
)

# Print the names of the available parameter sets
parameter_names = database.parameterSets()
nlprint('Available parameter set names:')
for name in parameter_names:
    nlprint(name)
nlprint('')

# Remove the entry from the database again
database.deleteParameterSet('custom_parameter_set')
```

save_delete_parameters_example.py

Notes

The *CosmoRSParameterSets* object functions as an interface to a local database of COSMO-RS parameter sets. This database can also be accessed by the *COSMO-RS Parameters* dialog in the **COSMO-RS Analyzer**. Parameter sets added to the *CosmoRSParameterSets* object also become available in the **COSMO-RS Analyzer**.

Parameter sets can be stored or retrieved with a simple save and load interface. The method `parameterSets` lists the available parameter sets. A parameter set is obtained from the database using the `loadParameterSet` method. This returns a *CosmoRSParameters* object which can be used directly in COSMO-RS calculations. Likewise, a parameter set can be saved using the `saveParameterSet` method, which takes along with it a a *CosmoRSParameters* object that defines the parameter set. Optional text information about the parameter set can also be provided. Once saved, a parameter set can be removed with the `deleteParameterSet` method. Only parameter sets added by the user can be deleted.

CosmoRSParameters

class CosmoRSParameters(*alpha_prime=None*, *a_effective=None*, *f_correlation=None*, *lambda_ortho=None*, *c_hydrogen_bonding=None*, *sigma_hydrogen_bonding=None*, *hydrogen_bond_temperature=None*, *hydrogen_bond_donors=None*, *hydrogen_bond_acceptors=None*, *r_average=None*, *lambda_comb=None*, *lambda_reg=None*, *omega_ring=None*, *eta_gas=None*, *dispersion=None*, *pka_scale=None*, *pka_offset=None*, *sigma_potential_tolerance=None*, *sigma_potential_max_steps=None*, *bin_size=None*)

Constructor for COSMO-RS parameters class. These parameters are used for calculating chemical potentials of different states. The default parameters are the generally recommended ones.

Parameters

- **alpha_prime** (*PhysicalQuantity* of type energy per area) – Weak/misfit interaction coefficient.
- **a_effective** (*PhysicalQuantity* of type area) – The thermodynamically independent contact area.
- **f_correlation** (*float*) – Amount of correlation charge density to include in the misfit energy.
- **lambda_ortho** (*float*) – Amount of local charge density that contributes to the orthogonal charge density.
- **c_hydrogen_bonding** (*PhysicalQuantity* of type energy per area) – Hydrogen bonding coefficient for strong electrostatic interactions.
- **sigma_hydrogen_bonding** (`PhysicalQuantity` of type charge per area) – The charge density threshold above which the interaction is considered as including hydrogen bonding.
- **hydrogen_bond_temperature** (*bool*) – Whether or not the strength of hydrogen bonding is scaled according to the temperature.
- **hydrogen_bond_donors** (Sequence of *PeriodicTableElement*) – The elements that can act as donors for hydrogen bonding.
- **hydrogen_bond_acceptors** (Sequence of *PeriodicTableElement*) – The elements that can act as acceptors for hydrogen bonding.
- **r_average** (*PhysicalQuantity* of type length) – The sphere radius in which the surface charges are averaged.
- **lambda_comb** (*float*) – Factor used in calculating the combinatoral chemical potential.
- **lambda_reg** (*float*) – Factor for the energy difference between the exact and sigma-averaged screening charges.
- **omega_ring** (*PhysicalQuantity* of type energy) – Gas phase energy contribution for atoms in rings.
- **eta_gas** (*float*) – Scaling of the gas phase chemical potential with temperature.

•**dispersion** (*dict*) – The dispersion energy densities for elements.

•**pka_scale** (*float*) – The gradient of the pKa linear correction.

•**pka_offset** (*float*) – The offset of the pKa linear correction.

•**sigma_potential_tolerance** (*PhysicalQuantity* of type charge per area) – The convergence threshold for the sigma potential.

•**sigma_potential_max_steps** (*int*) – The maximum number of steps before the sigma potential is evaluated as non-converged.

•**bin_size** (Sequence of *PhysicalQuantity* of type charge per area) – The bin size for the sigma profile histogram.

aEffective()

Returns
The thermodynamically independent contact area.

Return type
PhysicalQuantity of type area

alphaPrime()

Returns
Weak/misfit interaction coefficient.

Return type
PhysicalQuantity of type energy per area

binSize()

Returns
The histogram bin size of the charge densities.

Return type
PhysicalQuantity of type charge per area

cHydrogenBonding()

Returns
Hydrogen bonding coefficient for strong electrostatic interactions.

Return type
PhysicalQuantity of type energy per area

createDatabaseEntry(*file_path*, *name*, *reference=None*, *description=None*)
Create a parameter database file.

Parameters

•**file_path** (*str*) – The location of where the database entry file is to be saved.

•**name** (*str*) – The name of the parameter database entry.

•**reference** (str | None) – The optional reference for the source of the data.

•**description** (str | None) – Optional description of the database entry.

defaultDispersion()

Returns
The average of the elemental dispersion parameters, used when the dispersion for the given element is undefined.

Return type
PhysicalQuantity of type energy per area

dictionary()

Returns
A dictionary of the parameters that defines the model.

Return type
dict

difference(*other*, *rel_tol=0.0001*)

Return a dictionary of all of the parameters in the object that differ by the given factor from the parameters in another object.

dispersion()

Returns
The dispersion energy densities for elements.

Return type
dict

etaGas()

Returns
Scaling of the gas phase chemical potential with temperature.

Return type
float

fCorrelation()

Returns
Amount of correlation charge density to include in the misfit energy.

Return type
float

hydrogenBondAcceptors()

Returns
The elements that can act as acceptors of hydrogen bonding

Return type
Sequence of *PeriodicTableElement*

hydrogenBondDonors()

Returns
The elements that can act as donors of hydrogen bonding

Return type
Sequence of *PeriodicTableElement*

hydrogenBondTemperature()

Returns
Whether or not hydrogen bonding is scaled with temperature.

Return type
bool

lambdaComb()

Returns
Factor used in calculating the combinatoral chemical potential.

Return type
float

lambdaOrtho()

Returns
Amount of local charge density that contributes to the orthogonal charge density.

Return type
float

lambdaReg()

Returns
Factor for the energy difference between the exact and averaged screening charges.

Return type
float

nlinfo()

Returns
The nlinfo.

Return type
dict

omegaRing()

Returns
Gas phase energy contribution for atoms in rings.

Return type
PhysicalQuantity of type energy

pkaOffset()

Returns
The intercept of the linear correction for the pKa.

Return type
float

pkaScale()

Returns
The gradient of the linear correction for the pKa

Return type
float

rAverage()

Returns
The sphere radius for which the surface charges are averaged.

Return type
PhysicalQuantity of type length

sigmaHydrogenBonding()

Returns
The charge density hydrogen bonding threshold.

Return type
PhysicalQuantity of type charge per area

sigmaPotentialMaxSteps()

Returns
The number of steps before the sigma potential is evaluated as non-converged.

Return type
int

sigmaPotentialTolerance()

Returns
The threshold under which the sigma potential is evaluated as converged.

Return type
PhysicalQuantity of type charge per area

uniqueString()

Return a unique string representing the state of the object.

Usage Examples

Set some custom parameters for the COSMO-RS model and use them to calculate the vapor pressure of water at 300K.

```
# Load the water COSMO-RS species
database = CosmoRSSpeciesDatabase()
water = database.exportSpecies('water')

# Create the parameter set with custom parameters for the gas chemical potential
parameters = CosmoRSParameters(
    r_average=0.5*Ang,
    omega_ring=-0.21*kiloCaloriePerMol,
    eta_gas=-9.15,
    lambda_reg=0.8,
    lambda_ortho=0.816,
    dispersion={
        Hydrogen: -4.10*kiloCaloriePerMol/nm**2,
        Oxygen: -4.20*kiloCaloriePerMol/nm**2,
    }
)

# Calculate the vapor pressure using the different parameters
liquid = CosmoRealSolvent(300*Kelvin, water, parameters)
gas = CosmoRealGas(300*Kelvin, parameters)
mu_liquid = liquid.chemicalPotential(water)
mu_gas = gas.chemicalPotential(water)
vapor_pressure = numpy.exp((mu_liquid - mu_gas) / (300 * Kelvin * boltzmann_constant)) *␣
↪bar
```

(continues on next page)

(continued from previous page)

```
nlprint(f'The calculated vapor pressure is {vapor_pressure}')
```

cosmors_parameters_example.py

Notes

The *CosmoRSParameters* class is a container class for the parameters used in the COSMO-RS method. These parameters are used in the calculation of the chemical potential of molecules in different states. They are mostly empirical parameters that are fitted to large sets of experimental data. The equations used in COSMO-RS are published in a number of places[1234]. Care must be taken when reading these sources however, as there are some mistakes and oversights in the original literature.

A number of the parameters are used for calculating either the liquid or solvent chemical potentials. When taking surface charges from a COSMO-DFT calculation the surface charge densities σ^* may fluctuate in an nonphysical manner. This is due to the linear fitting algorithm used to calculate the charge densities. The charge densities used in the COSMO-RS method are smoothed using a sigma averaging method. Here the smoothed charge densities σ are calculated as:

$$\sigma_i = \frac{\sum_j \sigma_j^* I_{ij}}{\sum_j I_{ij}}$$

$$I_{ij} = \frac{r_j^2}{r_j^2 + r_{av}^2} \exp\left(-\frac{d_{ij}^2}{r_{av}^2}\right)$$

Here d_{ij} is the distance between two surface segments, r_j is the average radius of the surface segment and r_{av} is the averaging radius. The averaging radius is one of the parameters in the COSMO-RS model, and can be set using the argument `r_average`.

In addition to the sigma averaged charge densities σ, COSMO-RS also uses orthogonal charges $\sigma^\perp$. These are created by first creating a set of charge densities σ° that averaged from the σ^* charge densities using double the averaging radius. The orthogonal charges are then defined as:

$$\sigma^\perp = \sigma^\circ - \lambda_{ortho}\sigma$$

Here λ_{ortho} is another COSMO-RS parameter. This can be set in the *CosmoRSParameters* object using the argument `lambda_ortho`.

With these two charge densities, the σ-potential $\bar{\mu}(\sigma, \sigma^\perp)$ is then calculated by iteratively summing over all of the surface segments of each component of the solvent. The equation for this can be given as:

$$\bar{\mu}(\sigma, \sigma^\perp) = -\ln\left[\frac{1}{\sum_i x_i A_i}\sum_i x_i \sum_{\nu \in X_i} s_\upsilon \exp\left(\bar{\mu}(\sigma_\nu, \sigma_\nu^\perp) - \frac{a_{eff}}{RT} E(\sigma, \sigma^\perp, \sigma_\nu, \sigma_\nu^\perp)\right)\right]$$

Here x_i is the mole fraction of each solvent component, A_i is the total molecule surface area, $E(\sigma, \sigma^\perp, \sigma_\nu, \sigma_\nu^\perp)$ is the surface segment interaction energy. The effective contact area a_{eff} is another free parameter in the COSMO-RS method. This can be set using the `a_effective` argument. Note also that since the σ-potential $\bar{\mu}$ appears on both the right and left side of the equation, the sigma potential for each surface segment is calculated iteratively.

[4] CoryăC. Pye, Tom Ziegler, Erik van Lenthe, and JaapăN. Louwen. An implementation of the conductor-like screening model of solvation withing the Amsterdam density functional package - Part II. COSMO for real solvents. *Can. J. Chem.*, 87:790–797, 2009. doi:10.1139/V09-008.

The surface segment interaction energy is the sum of two additional terms, the misfit energy and the hydrogen bonding energy. The misfit energy, E_{misfit} which measures the energy of interaction between two surface segments can be given as:

$$E_{misfit}(\sigma_i, \sigma_j, \sigma_i^{\perp}, \sigma_j^{\perp}) = \frac{\alpha'}{2}(\sigma_i + \sigma_j)[(\sigma_i + \sigma_j) + f_{corr}(\sigma_i^{\perp} + \sigma_j^{\perp})]$$

Here the charge densities are taken from two different surface elements i and j. This equation also contains two additional free parameters. α' represents the strength of the misfit energy interaction, and can be set with the input argument `alpha_prime`. Likewise f_{corr} represents the strength of the correlation charge density interaction, and can be set with the argument `f_correlation`.

The hydrogen bonding energy E_{hb} utilizes only the local charge densities σ. This energy can be given as:

$$E_{hb}(\sigma_i, \sigma_j) = c_{hb} f_{hb}(T) \max(0, \max[\sigma_i, \sigma_j] - \sigma_{hb}) \min(0, \min[\sigma_i, \sigma_j] + \sigma_{hb})$$

In this equation c_{hb} represents the strength of the hydrogen bonding interaction, while σ_{hb} represents the charge density limit above which interactions are deemed to include hydrogen bonding. These are both free parameters, and can be set with the `c_hydrogen_bonding` and `sigma_hydrogen_bonding` respectively. Scaling of the hydrogen bonding interaction can also be included through the function $f_{hb}(T)$. This can be given as:

$$f_{hb}(T) = \frac{T \ln(1 + \exp(\bar{E}/RT)/200)}{\bar{T} \ln(1 + \exp(\bar{E}/R\bar{T})/200)}$$

Here $\bar{E}$ is a reference energy, set to 20kJ/mol and $\bar{T}$ is a reference temperature, set to 298.15K. This temperature scaling lowers the hydrogen bonding energy at temperatures above 298.15K. As this scaling has no free parameters, it can only be either enabled or disabled. This is done with the argument `hydrogen_bond_temperature`.

Since the σ-potential is calculated by summing over specific surface elements, it is possible to also use the attached atom of each surface segment to determine whether or not to include hydrogen bonding. This can be useful in cases, such as when modeling metal cations, where molecules may have large charge densities from atoms that do not have any hydrogen bonding character. The elements to include as hydrogen bonding donors or acceptors can be specified with the arguments `hydrogen_bond_donors` and `hydrogen_bond_acceptors`, respectively. These both take a list of elements or the flag `All`. The flag `All` indicates that hydrogen bonding is to be included for all surface segments withing the hydrogen bonding range of charge density regardless of attached atom.

Once the σ-potential is calculated, the residual chemical potential μ_X^{res} of a molecule X can simply be calculated by summing the interactions of the solute surface segments with those of the solvent. This is done through the equation:

$$\mu_X^{res} = \frac{RT}{a_{eff}} \sum_{i \in X} s_\nu \bar{\mu}(\sigma_i, \sigma_i^{\perp})$$

The total chemical potential of a solvated molecule is the sum of both the residual and combinatorial chemical potential. This latter chemical potential includes cavitation and entropic terms. The combinatatorial chemical potential μ_X^{comb} can be given as:

$$\mu_X^{comb} = \lambda_{comb} RT \left[\ln(V^X) + \left(1 - \frac{V^X}{V_{av}} - \ln(V^{av})\right) + \left(1 - \frac{A^X}{A_{av}} - \ln(A^{av})\right)\right]$$

Here A^X and V^X are the surface area and volume of the solute species. Likewise A^{av} and V^{av} are the average surface area and volume of the components of the solvent. All areas and volumes are also divided by the reference of 1^2 and 1^3, respectively, to render them dimensionless. The free parameter λ_{comb} sets the relative size of the combinatorial chemical potential. This can be specified with the argument `lambda_comb`.

A number of free parameters are also used in the estimation of the gas phase chemical potential. In COSMO-RS the gas chemical potential of a substance is defined so that the vapor pressure p can be given as:

$$p = p_0 \exp([\mu^{liq} - \mu^{gas}]/RT)$$

Here p_0 is a reference pressure, defined to be 1 bar. The overall equation of the gas phase chemical potential of a molecule μ_X^{gas} can be given as:

$$\mu_X^{gas} = \Delta^X - \sum_k \gamma_k A_k^X - \omega n_{ring}^X + \eta RT$$

This expression contains a number of terms. The first, Δ^X represents the difference in solvation energy between the gas and solvent states. This can be given as:

$$\Delta^X = E^{gas} - E^{COSMO} + \frac{\lambda_{reg}}{2} \sum_i \Phi_i s_\nu (\sigma_i - \sigma_i^*)$$

Here E^{gas} and E^{COSMO} are the total energy of the molecule in the gas and COSMO solvent model, respectively. The COSMO energy includes both the dielectric energy and the polarization of the molecule resulting from the charge of the solvent cavity. The final sum is a consequence of the COSMO dielectric energy being calculated with the raw charges. In COSMO-RS smoothed charges are always used, and so the final sum accounts for the energy associated with smoothing the charge density distribution. Here Φ is the molecular electrostatic potential at each surface element. The free parameter λ_{reg} estimates how much the total COSMO energy is raised by the molecule being polarized by the solvent cavity surface. This can be set with the argument `lambda_reg`.

Going back to the equation for the total gas chemical potential, the second term accounts for the loss of dispersion interactions from the solvent in transferring the molecule to the gas phase. The dispersion energies are simply calculated by scaling the total surface area associated with each element, A_k^X with a scaling factor γ_k. These scaling factors are different for each element. Since the dispersion energy depends only on the solvent cavity, it is the same for any solvent. For that reason it is not included in the solvent chemical potential, but rather in the gas chemical potential. The scaling factors for each element can be set with the argument `dispersion`. This takes a dictionary, where the keys are each element to be set and the value is the scaling factor.

The third term in the gas chemical potential is a special correction for molecules with rings. Here n_{ring} represents the number of atoms in cyclic structures and η is an energy scaling factor. This can be set with the argument `omega_ring`. The final term in the gas chemical potential accounts for the temperature of the gas. Here η is a dimensionless scaling factor. This can be set with the argument `eta_gas`.

When calculating pK_a values, a linear correction can be applied to the value calculated by COSMO-RS to give an estimate of the actual pK_a value[5]. This corrects for both systematic deficiencies in the underlying DFT calculation and the COSMO-RS methodology. Using this linear correction the pK_a can be given as:

$$pK_a = A \times pK_a^{raw} + B$$

Here pK_a^{raw} is the pK_a value directly calculated by COSMO-RS. The factors A and B can be set with the arguments `pka_scale` and `pka_offset`, respectively.

The final parameters in the *CosmoRSParameters* object relate to numerical details in how the COSMO-RS calculation is performed. Since the σ-potential is calculated iteratively, this is done until either the σ-potential reaches a set convergence limit or a maximum number of steps has been reached. The convergence limit can be set with the argument `sigma_potential_tolerance`. Likewise the maximum number of steps can be set with the argument `sigma_potential_max_steps`. In some cases, such as at low temperature, the σ-potential may not converge using the default settings. In these cases either the convergence limit can be raised or the number of steps increased until convergence is reached. When calculating plots of either the σ-profile or the σ-potential the charge density is divided into a number of steps or bins. The argument `bin_size` sets the spacing of these steps. Since the COSMO-RS calculations are done by summing over surface segments, this argument is not used in calculating chemical potentials.

When creating a *CosmoRSParameters* object, any number or combination of parameters may be specified. The default values for all parameters is taken from the *quantumatk_u2022-12* parameter set. The values contained in this parameter set can be shown using the *COSMO-RS Parameters* dialog in the **COSMO-RS Analyzer**.

[5] Andreas Klamt, Frank Eckert, Michael Diedenhofen, and MichaelăE. Beck. First principles calculations of aqueous pKa values for organic and inorganic acids using COSMO-RS reveal an inconsistency in the slope of the pKa scale. *J. Phys. Chem. A.*, 107:9380–9386, 2003. doi:10.1021/jp034688o.

Once a parameter set is created, it can be saved for further use in QuantumATK. Parameter sets can be added to QuantumATK through the *CosmoRSParameterSets* class, which interfaces to a local database of parameter sets. Parameter sets can also be added manually. The method `createDatabaseEntry` creates a representation of the parameter set in a file. The parameter set is then added to the database by placing it in the `.quantumatk/databases/cosmors_parameters/` in your home directory.

CosmoRSSpeciesDatabase

class CosmoRSSpeciesDatabase

categories()

Returns
A list of the chemical categories used in the database.

Return type
list of str

deleteSpecies(*name*)

Delete the the given named entry from the database. This can only be done for user-added entries.

Parameters
name (*str*) – The name of the species to delete.

exportSpecies(*name*)

Return the CosmoRealSpecies for the given named entry.

Parameters
name (*str*) – The name of the species to return.

findSpecies(*category=None*, *formula=None*, *smiles=None*)

Return the list of the names of the available species. Different selection criteria can be used to return subsets of species names.

Parameters

- **category** (*str*) – Return only species that are in the given category.
- **formula** (*str*) – Return only species that have the given chemical formula.
- **smiles** (*str*) – Return only species whose bond graph matches the bond graph given by the SMILES string. Note that this does not distinguish between cis/trans isomers or stereoisomers.

Returns
A list names of species that match the given selection criteria.

Return type
list of str

importSpecies(*name*, *cosmo_data*, *category=None*, *description=None*, *melting_point=None*, *enthalpy_of_fusion=None*, *specific_heat_capacity_change=None*, *antoine_a=None*, *antoine_b=None*, *antoine_c=None*, *boiling_point=None*, *flash_point=None*, *density=None*)

Add a new configuration to the COSMO-RS database.

Parameters

- **name** (*str*) – The name of the data entry.
- **cosmo_data** (*CosmoRS* | *CosmoRealSpecies*) – The COSMO data including solvent and gas phase DFT calculations.
- **category** (*str*) – The classification category of the configuration.

- **description** (*str*) – A text description of the database entry.
- **melting_point** (PhysicalQuantity of type temperature) – The melting point of the pure substance.
- **enthalpy_of_fusion** (PhysicalQuantity of type energy) – The enthalpy or heat of fusion of the pure substance.
- **specific_heat_capacity_change** (PhysicalQuantity of type energy per temperature) – The difference in the molar isobaric specific heat capacity between the liquid and solid phase.
- **antoine_a** (PhysicalQuantity of type pressure) – The A parameter of the Antoine equation. The units indicate the pressure units in the equation.
- **antoine_b** (PhysicalQuantity of type temperature) – The B parameter of the Antoine equation.
- **antoine_c** (PhysicalQuantity of type temperature) – The C parameter of the Antoine equation.
- **boiling_point** (PhysicalQuantity of type temperature) – The boiling point of the pure substance.
- **flash_point** (PhysicalQuantity of type temperature) – Minimum temperature required for the vaporized pure substance to be combustible in air.
- **density** (PhysicalQuantity of type density) – The liquid density of the pure substance.

Usage Examples

Find names of molecules in the COSMO-RS database by category, chemical formula and bond graph.

```
# Load the COSMO database
database = CosmoRSSpeciesDatabase()

# Find all species with the chemical formula C4H8O
species_names = database.findSpecies(formula='C4H8O')
nlprint(species_names)

# Find specifically the molecule tetrahydrofuran
species_names = database.findSpecies(formula='C4H8O', smiles='O1CCCC1')
nlprint(species_names)
```

find_species_example.py

Load water and SO_2 molecules from the database and calculate the solubility of SO_2 in water.

```
# Load the COSMO species
database = CosmoRSSpeciesDatabase()
water = database.exportSpecies('water')
sulfur_dioxide = database.exportSpecies('sulfur dioxide')

# Determine the gas solubility.
gas_solubility = GasSolubility(
    sulfur_dioxide,
    water,
    solvent_density=1*kiloGram/liter,
    temperature=298*Kelvin,
    parameters=CosmoRSParameters(),
)

# Retrieve the Henry constant.
h_cp = gas_solubility.henryConstantCP()[0].convertTo(molar/bar)
```

(continues on next page)

(continued from previous page)

```
nlprint(f'The Henry constant of SO2 in water is {h_cp}')

# Retrieve the Henry volatility.
h_px = gas_solubility.henryVolatilityPX()[0].convertTo(bar)
nlprint(f'The Henry volatility of SO2 in water is {h_px}')
```

water_so2_example.py

Add and then remove an azide (ammonia) molecule.

```
# Create the COSMO-RS object
solvation_energy = SolvationEnergy(
    configuration=azane
)
azane_cosmo_rs = CosmoRS(
    configuration=azane,
    solvation_energy=solvation_energy
)

# Load the database
database = CosmoRSSpeciesDatabase()

# Add the molecule to the database
database.importSpecies(
    'azane',
    azane_cosmo_rs,
    category='Inorganic bases',
    description='Added as example of COSMO-RS molecular database',
    boiling_point=239.81*Kelvin,
    melting_point=195.42*Kelvin,
    density=0.682*kiloGram/liter,
    antoine_a=4.86886*bar,
    antoine_b=1113.928*Kelvin,
    antoine_c=-10.409*Kelvin,
)

# Remove the species from the database
database.deleteSpecies('azane')
```

add_remove_example.py

Notes

The *CosmoRSSpeciesDatabase* object provides a script interface to the molecule database in the **Cosmo-RS Analyzer**. Through this class *CosmoRealSpecies* objects can be exported from the database using the `exportSpecies` method. These *CosmoRealSpecies* objects can then be used directly in a COSMO-RS calculation. *CosmoRealSpecies* or *CosmoRS* objects can also be saved into the database using the `importSpecies` method. As well as the data object, the `importSpecies` method can optionally take a category label, a description or a range of experimental data that may be used in COSMO-RS calculations. These data can also be set when running the COSMO-RS calculation. Configurations that have been added to the database can also be removed by the `deleteSpecies` method. Configuration entries that are shipped with QuantumATK cannot be deleted.

In the database species have a name as a primary key. This is often the common name for the molecule, rather than the

systematic IUPAC name. Specific molecules can be searched for using a combination of classification class, chemical formula and SMILES string in the `findSpecies` method. Classification class and chemical formula match all records with the same data. SMILES strings use graph matching to match all records that have the same bond graph. Note that this does not distinguish between cis and trans isomers. The `findSpecies` method returns the name of all records that match the given criteria.

CosmoRealGas

class CosmoRealGas(*temperature*, *parameters=None*)

Constructor for COSMO-RS gas phase. This can be used to calculate gas interactions in the COSMO-RS model.

Parameters

- **temperature** (*PhysicalQuantity* of type temperature) – The gas temperature.
- **parameters** (*CosmoRSParameters*) – The COSMO real solvent parameters

chemicalPotential(*species*)

Calculate the gas phase chemical potential of the given species.

Parameters
species (*CosmoRealSpecies*) – The species for which the chemical potential is calculated.

Returns
The chemical potential.

Return type
PhysicalQuantity of type energy

parameters()

Returns
The parameters used for the COSMO-RS model.

Return type
CosmoRSParameters

temperature()

Returns
The temperature of the gas.

Return type
PhysicalQuantity of type temperature

uniqueString()

Return a unique string representing the state of the object.

Usage Examples

Calculate the gas-phase pseudochemical potential of water with respect to the ideal screened state.

```
# Load the COSMO species
database = CosmoRSSpeciesDatabase()
water = database.exportSpecies('water')

# Create the gas.
```

(continues on next page)

(continued from previous page)

```
gas = CosmoRealGas(
    298*Kelvin,
    parameters=CosmoRSParameters(),
)

# Calculate chemical potential of a methanol molecule in solvent water.
chemical_potential = gas.chemicalPotential(water)
nlprint(f'The chemical potential of gas-phase water with respect to ideal screened state␣
↪is {chemical_potential}')
```

water_gas_example.py

Notes

The *CosmoRealGas* object calculates the pseudochemical potential of a gaseous species with respect to the ideal screened state surrounded by a perfect conductor. In COSMO-RS the gas phase chemical potenial is defined so that the vapor pressure p of a substance can be given as

$$p = p_0 \exp([\mu^{liq} - \mu^{gas}]/RT)$$

Here μ is the chemical potential of the species and p_0 is a reference pressure, defined to be 1 bar. For more information on the COSMO-RS formalism, including how the gas phase chemical potential is approximated, please refer to *CosmoRSParameters*. Note that the *CosmoRealGas* is instantiated only with a temperature and a parameter set. The pseudochemical potential of a *CosmoRealSpecies* is then determined by calling the `chemicalPotential` method which takes in the *CosmoRealSpecies* as an argument.

CosmoRealSolid

class CosmoRealSolid(*temperature*, *parameters=None*)

Constructor for COSMO-RS solid phase. This can be used to calculate solid interactions in the COSMO-RS model.

Parameters

- **temperature** (*PhysicalQuantity* of type temperature) – The gas temperature.
- **parameters** (*CosmoRSParameters*) – The COSMO-RS parameters

chemicalPotential(*species*)

Calculate the pseudo-chemical potential of the solid state, using the pure liquid state as reference.

Parameters
species (*:class`~.CosmoRealSpecies`*) – The species for which the pseudo-chemical potential is calculated.

Returns
The pseudo-chemical potential.

Return type
PhysicalQuantity of type temperature

freeEnergyOfFusion(*species*)

Calculate the free energy of fusion of the given species.

Parameters
species (*CosmoRealSpecies*) – The species the free energy is calculated for.

Returns
The Gibbs free energy of fusion.

Return type
PhysicalQuantity of type energy

parameters()

Returns
The parameters used for the COSMO-RS model.

Return type
CosmoRSParameters

temperature()

Returns
The temperature of the solid.

Return type
PhysicalQuantity of type temperature

uniqueString()

Return a unique string representing the state of the object.

Usage Examples

Set up a water *CosmoRealSolid*. Example data available at Data link.

```
# Load the COSMO species
database = CosmoRSSpeciesDatabase()
water = database.exportSpecies('water')
water.setMeltingPoint(273.15 * Kelvin)
water.setEnthalpyOfFusion(6 * kiloJoulePerMol)
specific_heat_capacity_change = (4.187 - 2.108) * Joule / (gram*Kelvin)
specific_heat_capacity_change *= water.molarMass()
water.setSpecificHeatCapacityChange(specific_heat_capacity_change)

# Create the solid at 10K below the melting point.
solid = CosmoRealSolid(
    263*Kelvin,
    parameters=CosmoRSParameters(),
)

# Calculate Gibbs free energy of fusion of ice.
dG_fus = solid.freeEnergyOfFusion(water).convertTo(kiloJoulePerMol)
nlprint(f'The free energy of fusion of ice is {dG_fus}')

# Calculate chemical potential of ice.
chemical_potential = solid.chemicalPotential(water).convertTo(kiloJoulePerMol)
nlprint(f'The chemical potential of ice is {chemical_potential}')
```

water_solid_example.py

Notes

The *CosmoRealSolid* object allows calculation of the pseudochemical potential of a solid substance. The solid pseudochemical potential is calculated with reference to the liquid pseudochemical potential such that:

$$\mu^{sol} = \mu^{liq} - \Delta G_{fus}$$

Here μ_{sol} is the solid pseudochemical potential, μ_{liq} is the corresponding liquid chemical potential and ΔG_{fus} is the free energy of fusion of the species. The free energy of fusion cannot be calculated directly by COSMO-RS, and therefore must be approximated. This can be done in a number of ways. In general, the most accurate approximation can be given as:

$$\Delta G_{fus} = \Delta H_{fus}\left(1 - \frac{T}{T_m}\right) - \Delta Cp_{fus}(T_m - T) + \Delta Cp_{fus} T \ln\frac{T_m}{T}$$

Note several pure compound data are required. T_m is the melting pont, ΔH_{fus} the heat of fusion. Likewise, ΔCp_{fus} is the change in molar heat capacity upon melting which corresponds to the difference in molar heat capacity of a compound in its pure liquid and solid state[1]. If ΔCp_{fus} is not available the two last terms may be neglected which gives

$$\Delta G_{fus} = \Delta H_{fus}\left(1 - \frac{T}{T_m}\right)$$

If none of these data is provided the Gibbs free energy of fusion is predicted from a simple linear model fitted at 298K.

$$\Delta G^{i}_{fus}(298K) = 12.2V^{COSMO} - 0.76N_{ring\ atoms} + 0.54\mu_i^{water}$$

The linear coefficients are purely empirical and determined by fitting to experimental data[2]. Note that here μ_i^{water} represents the chemical potential of the given molecule i dissolved in water at 298K. This gives a measure of the polarity of the molecule.

As with *CosmoRealSolvent* and *CosmoRealGas* the temperature of the substance is given as input when the object is created. For meaningful results using *CosmoRealSolid* the given temperature should be below the melting point.

CosmoRealSolvent

class CosmoRealSolvent(*temperature*, *solvent_components*, *parameters=None*)

Constructor for COSMO-RS solvent. This can be used to calculate solvent interactions in the COSMO-RS model.

Parameters

- **temperature** (*PhysicalQuantity* of type temperature) – The solvent temperature.
- **solvent_components** (*MoleculeConfiguration* | *CosmoRealSpecies* | *CosmoRSMixture*) – The solvents chemical components. This can either be a pure compound or a mixture.
- **parameters** (*CosmoRSParameters*) – The COSMO-RS parameters

chemicalPotential(*species*)

Calculate the total chemical potential of the species in the solvent.

Parameters
species (*CosmoRealSpecies*) – The species for which the chemical potential is calculated.
